D1 through D3, iodothyronine deiodinases; N, no change; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone.

Thyroid Function during Fasting or Illness

A number of changes take place in thyroid function during nutritional deprivation or illness. These consist of a central reduction in TSH secretion, decreased plasma T₃ levels, and decreased T₄ and T₃ binding in serum. This constellation of findings is termed the *low T₃ syndrome*, the *euthyroid sick syndrome*, or *nonthyroid illness*. The pattern of changes in circulating thyroid hormones and TSH during fasting and during illness are similar. During fasting, there is a reduction of 50% or more in serum T₃ and an increase in serum rT₃, without initial changes in serum total T₄ or free T₄ (Table 11-9).^{107,145} Although the role of specific deiodinases in causing these changes has not been documented at a tissue level in humans during fasting, several lines of evidence suggest that decreases in peripheral T₄-to-T₃ conversion by D1 and D2 and reduced clearance of rT₃ by D1 do contribute to this process.

Whereas the reduction in D1- and D2-catalyzed deiodination could explain the low T₃ and high rT₃ concentrations, the inactivating enzyme, D3, was found to be present in liver and skeletal muscle of patients dying in an intensive care unit, suggesting that a D3-mediated increased catabolism also occurs as part of this process. The finding of normal T₃ plasma levels in mice with the genetic absence of both D1 and D2 enzymes suggests that thyroid by itself is able to compensate for impaired peripheral conversion to normalize serum T₃. This implies that very powerful mechanisms are in place to maintain serum T₃ levels within the normal range, except when it is not meant to be in that range—that is, during fasting or illness. In these circumstances, by a mechanism probably regulated by the hypothalamus, all compensatory mechanisms are reduced, and serum T₃ drops almost to undetectable levels.⁷⁴ Deiodination by D3 increases the generation of rT₃ from T₄ and converts T₃ to 3,3'-diiodothyronine (see Fig. 11-3), which would exaggerate the changes resulting from the decrease in outer ring deiodination. The finding that D3 null mice can develop the low T₃ syndrome suggests that D3 upregulation is not the only event occurring in this clinical state. It is not yet known whether such an increase in D3 also occurs during caloric restriction. The attenuation of TSH secretion despite a fall in serum T₃ levels during fasting was discussed earlier (see “The Hypothalamic-Pituitary-Thyroid Axis”).

During fasting, basal oxygen consumption and heart rate decline, and nitrogen balance, initially negative, returns toward normal.¹⁴⁶ In some studies, these changes in overall metabolism are partially reversed by replacement of exogenous T₃ as fasting continues. Therefore, the

decrease in T₃ during fasting (and presumably during illness) can be viewed as a beneficial energy- and nitrogen-sparing adaptation. Chronic malnutrition, such as occurs in anorexia nervosa, is also associated with a reduction in serum T₃ and, rarely, in free T₄.¹⁴⁷ TSH concentrations remain in the normal range, although again they are inappropriately low in the context of the reductions in circulating T₃. In contrast, overfeeding, particularly with carbohydrate, increases T₃ production rates and the serum T₃ concentration, reduces serum rT₃, and increases basal thermogenesis.¹⁴⁸

During illness, decreases in T₃ and pulsatile TSH release and increases in rT₃ also occur.¹⁴⁹ If illness progresses, the hypothalamic-pituitary-thyroid axis is even further suppressed with a consequent reduction in the free T₄. The reduction in free T₄ corresponds to the gradual development of a more complex syndrome and worsening of clinical outcome for these patients, and a marked decrease in serum T₄ is associated with a high probability of death. This syndrome is associated with a decrease in TRH mRNA in the human paraventricular nuclei.¹⁵⁰ An increase in T₃ production by D2-catalyzed T₄-to-T₃ conversion in the ependymal cells lining the third ventricle may contribute to the blunted response of TSH to the reduced serum T₃, particularly during infections.¹⁵¹ Cytokines, such as interleukin-6, also increase during illness, coincident with the decrease in circulating T₃, although it is not clear whether this is the cause of the hypothalamic changes.¹⁵² These endogenous changes may be further exaggerated by agents such as dopamine or glucocorticoids, which suppress the TRH-TSH axis, at least transiently.¹⁵³

The changes in thyroid function are a continuum, with the abnormalities becoming progressively more severe in parallel with the patient's clinical condition (see Table 11-9). Mild to moderate changes are observed in patients with illnesses such as mild myocardial infarction, in those undergoing elective surgical procedures, and during infections such as pyelonephritis or pneumonia in otherwise healthy individuals. In these circumstances, the serum free T₃ is reduced by as much as 50%, and the total rT₃ concentration is increased twofold to threefold. The total serum T₄ concentration remains normal, as does TSH. During prolonged critical illness, serum free T₄ and TSH are markedly reduced, and T₃ is reduced in plasma and in tissues to barely detectable levels.¹⁵³ Postmortem studies of patients with prolonged critical illness show that hepatic D1 activity is reduced by about 50%, skeletal muscle D2 is absent, and D3 is present in liver and skeletal muscle.¹⁵⁴ Tissue T₃ is reduced in these individuals in parallel with the decrease in the serum hormone concentration. No differences have been found in the T₃ transporter MCT8 in skeletal muscle or liver, and possible abnormalities in other thyroid hormone transporters have not been evaluated.

The same global pattern of changes observed during acute medical illness has also been described in patients with primary hypothyroidism who are receiving levothyroxine.¹⁵⁵ In such patients, serum T₄, T₃, and TSH concentrations fell by about 50% over the first 3 days, presumably due to a disruption of T₄ binding resulting from decreased TBG, TTR, and albumin and to blockade of T₄-protein interactions caused by endogenous interfering substances. A contributing factor may be the translational modification of TBG caused by the serpin-catalyzed release of a C-terminal fragment of TBG in inflamed tissues (see “Thyroxine-Binding Globulin”).

Therapies have been introduced to ameliorate certain of the illness-related central abnormalities in the hypothalamic-pituitary axis (including decreases in growth hormone

and gonadotropins). One of these, infusions of growth hormone-releasing peptide 2 (GHRP2) combined with TRH, resulted in increases in TSH, T_3 , and T_4 , as well as insulin-like growth factor 1 (IGF1), insulin, and IGF binding proteins 1, 3, and 5.¹⁵⁶ Although the biochemical improvements were significant, the clinical state did not change. Neither T_3 nor T_4 administration improves the outcomes in sick patients, and insulin-mediated improvements in hyperglycemia have not altered the abnormalities in thyroid-related parameters in critically ill patients.¹⁵⁷

Although serum TSH concentrations in severely ill patients are reduced, an increase in TSH above the normal range may appear during recovery, with the elevation in TSH concentration persisting until circulating free T_4 and T_3 levels return to normal.¹⁵⁸ This pattern can be confusing if the elevated TSH concentration is found in association with the still-reduced concentrations of free T_4 . Such patients meet all laboratory criteria for primary hypothyroidism with the exception of the clinical context. Follow-up usually reveals a normalization of TSH and T_4 within 1 to 2 months (see Table 11-9).

Despite the severity of the abnormalities, particularly in serum T_3 , there is still disagreement as to whether therapeutic intervention should be initiated even in the most severely ill patients. This is because most controlled studies have not shown beneficial effects of T_4 or T_3 supplementation in such individuals.¹⁵⁷ The one exception is the possible beneficial effect of T_3 therapy after coronary artery bypass grafting, with one study showing a positive effect and a second showing no beneficial effect.^{159,160}

The Thyroid Axis and Neuropsychiatric Illness

Patients with neuropsychiatric disease can present with any of a number of abnormalities in thyroid function. Patients with bipolar disorders may show slight elevations in serum TSH and reductions in free T_4 , whereas patients with severe depression have slight elevation in serum T_4 and reduced serum TSH. Other acutely psychotic patients may have either high or low serum TSH concentrations and tend to have elevations in free T_4 .¹⁶¹ The etiology of these minor abnormalities is not clear, but such patients may have thyroid function test results resembling those in patients with primary thyroid disease, from whom they must be differentiated.

Effects of Hormones on Thyroid Function

Glucocorticoids

The acute administration of pharmacologic doses of glucocorticoid eliminates pulsatile release of serum TSH in normal patients, presumably by reducing TRH release. With continued administration, there is an escape from this suppression (Table 11-10). Pharmacologic doses of glucocorticoid decrease the serum T_3 concentration in normal and hyperthyroid patients, as well as in hypothyroid patients maintained on levothyroxine. The latter finding and the accompanying increase in rT_3 production suggest that glucocorticoids may increase D3 activity.⁹⁰

Primary adrenal insufficiency may be associated with reduced serum T_4 and elevated serum TSH concentrations, suggesting the coexistence of primary hypothyroidism. However, treatment of the adrenal insufficiency can lead to complete resolution of these abnormalities, suggesting that in some patients they are a consequence of glucocorticoid deficiency rather than primary thyroid disease.¹⁶² Nevertheless, the prevalence of primary hypothyroidism is increased in patients with autoimmune hypoadrenalism,

TABLE 11-10

Effects of Hormones on Thyroid Function

Glucocorticoids

Excess

Decreased TSH, TBG, TTR (high-dose)
Decreased serum T_3/T_4 ratio, increased rT_3/T_4 ratio
Increased rT_3 production (? ↑ D3)
Decreased T_4 and T_3 secretion in Graves' disease

Deficiency

Increased TSH

Estrogen

Increased TBG sialylation and increased half-life in serum
Increased TSH in postmenopausal women
Increased T_4 requirement in hypothyroid patients

Androgen

Decreased TBG
Decreased T_3 turnover in women, reduced T_4 requirement in hypothyroid patients

Growth Hormone

Decreased D3 activity

D3, type 3 deiodinase; rT_3 , reverse T_3 ; T_3 , triiodothyronine; T_4 , thyroxine; TBG, thyroxine-binding globulin; TSH, thyrotropin; TTR, transthyretin.

so the two causes must be differentiated (see Chapter 15). Likewise, patients successfully treated for Cushing's disease can develop thyroid autoimmunity.

Gonadal Steroids

Estrogen increases TBG by mechanisms already mentioned.¹⁶³ Estrogen administration to postmenopausal women causes an increase of 15% to 20% in TSH.¹⁶⁴ Presumably, this increases T_4 secretion, in that total T_4 increases and free T_4 is unchanged. Estrogen also increases the levothyroxine requirement in patients with primary hypothyroidism.⁵⁸ In contrast, administration of androgens to women decreases TBG and decreases T_4 turnover and levothyroxine requirements in patients with primary hypothyroidism.¹⁶⁵

Growth Hormone

Growth hormone increases the serum free T_3 and decreases free T_4 in both levothyroxine-treated and normal individuals, suggesting either suppression of D3 activity or increased T_4 -to- T_3 conversion.

PHYSICAL EVALUATION OF THE THYROID GLAND

Manifestations of thyroid disease are usually caused by excessive or insufficient production of thyroid hormone, local symptoms in the neck (principally goiter, but occasionally pain or compression of adjacent structures), or, in the case of Graves' disease, ophthalmopathy or dermopathy. A functional diagnosis of thyroid disease is based on a carefully taken history, a thorough search for the physical signs of hypothyroidism or thyrotoxicosis, and an appraisal of the results of laboratory tests. Although conditioned by the functional diagnosis, the anatomic diagnosis depends largely on the physical examination of the thyroid gland itself. The typical symptoms of an excess or a deficiency of thyroid hormone are discussed in Chapters 12 and 13.

Examination of the neck is best accomplished with the patient seated in good light with the neck relaxed. The patient should be provided with a cup of water to facilitate swallowing. The physician should first inspect the neck, especially while the patient swallows, with the neck slightly extended. The presence of old surgical scars, distended veins, and redness or fixation of the overlying skin should be noted. The position of the trachea should be noted. If a mass is present, a determination should be made as to whether it moves with swallowing. A midline mass high in the neck that rises further when the patient extends the tongue is typical of a thyroglossal duct remnant or cyst. Movement on swallowing is a characteristic of the thyroid gland because it is ensheathed in the pretracheal fascia; this feature distinguishes a goiter from most other neck masses. However, if the thyroid is so large that it occupies all the available space in the neck, movement on swallowing may be lost. The physician should also inspect the posterior dorsum of the tongue, which is the origin of the thyroglossal duct and the location of lingual thyroid tissue.

Except when thyroid enlargement is extreme, the thyroid examination can be readily performed with the physician facing the seated patient. The physician should use gentle pressure with his or her thumb to locate the thyroid isthmus just caudal to the cricoid cartilage. This provides a convenient starting point for palpation of the lobes of the gland, but an increase in thickness or a firm texture of the isthmus will already suggest the presence of some generalized thyroid enlargement. To examine the right lobe, the right thumb is moved laterally, without release of gentle pressure, to locate the lobe of the thyroid by pressing it against the trachea as the patient swallows sips of water. In this strategy, the palpating thumb laterally displaces the medial border of the sternocleidomastoid muscle, allowing direct access to the entire thyroid lobe. As the patient swallows with the thumb pressing the lobe against the trachea with sufficient tension to displace it slightly over the midline, the trachea will slide up and down under the ball of the thumb. This permits an appreciation of the size and texture of the gland as well as the presence or absence of nodules. A similar strategy with the left thumb is employed for the left lobe. The thyroid may also be examined with the physician standing behind the seated patient and palpating with the fingertips of both hands.

The examiner should note the shape of the gland, its size in relation to normal, and its consistency, which is usually slightly greater than adipose tissue but less than muscle. The normal thyroid lobe has approximately the same size in frontal projection as the terminal phalanx of the patient's thumb. Whereas a diffuse goiter and the hyperplastic gland in a hyperthyroid patient with Graves' disease may be softer than normal, the gland of a patient with Hashimoto's disease is usually firm. Irregularities of the surface, variations in consistency, and tender areas should be noted. If nodules are palpated, their shape, size, position, translucency, and consistency in relation to the surrounding tissue should be determined. It may seem counterintuitive, but a firm nodule is more likely to be a cyst than a malignancy. A search should be made for the pyramidal lobe; this is a thin band of tissue extending upward from the isthmus to the thyroid cartilage to the right or left of the midline. A hypertrophied pyramidal lobe may be mistaken for a pretracheal lymph node that sometimes accompanies thyroid carcinoma or thyroiditis. It is usually palpable in patients with generalized thyroid disease (e.g., Hashimoto's disease, Graves' disease). During palpation, a vascular thrill may be felt; in the absence of

cardiac disease, this is suggestive of hyperthyroidism. Finally, palpation should always include examination of the regional lymph nodes along the jugular vein, posterior to the sternocleidomastoids, and in the supraclavicular region.

Auscultation of the neck may confirm the increased vascularity of an enlarged, hyperactive gland, suggesting Graves' disease. A systolic or continuous bruit is sometimes heard over a hyperplastic gland. Care should be taken to distinguish a thyroid bruit from a murmur transmitted from the base of the heart or from a venous hum that can be obliterated by gentle compression of the external jugular vein or by turning the head. A venous hum is typically found in younger patients with high cardiac output, such as occurs in Graves' disease or with severe anemia.

An arm-raising test is useful when a retrosternal goiter is suspected. The basis for this maneuver is that the size of the thoracic inlet is already reduced by such a goiter. Raising both arms until they touch the sides of the head further narrows the thoracic inlet and causes congestion and venous engorgement of the face and sometimes respiratory distress (*Pemberton's sign*) or even (rarely) syncope.

In addition to examination of the thyroid gland and regional lymph nodes, evidence of compression or displacement of adjacent structures should be sought. Hoarseness may indicate compression of the recurrent laryngeal nerve, usually by a malignant thyroid neoplasm, and this should be confirmed by laryngoscopy. Displacement of the trachea may be evident and is usually associated with a large nodule or nodules; inspiratory stridor may indicate its compression.

It is likely that an ultrasound device will become an ubiquitous instrument in the endocrinologist's office or clinic in the coming years because of its superior sensitivity for the detection of thyroid nodules. This should enhance, not replace, physical examination of the thyroid, the only endocrine gland that is accessible to physical examination.

LABORATORY ASSESSMENT OF THYROID STATUS

In considering the laboratory assessment of known or suspected thyroid disease, the physician should seek to arrive at both a functional and, when appropriate, an anatomic diagnosis. Laboratory determinations will confirm whether there is an excess, normal, or insufficient supply of thyroid hormone to verify the inferences from the clinical history and physical examination. Laboratory tests can be divided into five major categories: (1) those that assess the state of the hypothalamic-pituitary-thyroid axis; (2) estimates of T_4 and T_3 concentrations in the serum; (3) tests that reflect the impact of thyroid hormone on tissues; (4) tests for the presence of autoimmune thyroid disease; and (5) tests that provide information about thyroidal iodine metabolism. The use of iodine and other isotopes for scintiscanning is discussed in Chapter 14.

Tests of the Hypothalamic-Pituitary-Thyroid Axis

Thyroid-Stimulating Hormone

Although they represent an inherently indirect reflection of thyroid hormone supply, tests that assess the state of the hypothalamic-pituitary-thyroid axis play a critical role in the diagnosis of thyroid disease. This is because the rate of

TSH secretion is exquisitely sensitive to the plasma concentrations of free thyroid hormones, thus providing a precise and specific barometer of the thyroid status of the patient (see Figs. 11-8 and 11-9). The rare exceptions to this rule are discussed later. Immunometric assay technology now makes it possible to define the normal range for serum TSH and to ascertain when thyroid function is inadequate or the hormone supply is excessive (see Chapter 6). This assay uses the TSH molecule to link a TSH antibody bound to an inert surface (e.g., particles, the side of a test tube) to a second antibody (directed against a different TSH epitope) that is labeled with a detectable marker such as ^{125}I , an enzyme, or a chemiluminescent reagent. The signal generated is proportional to the concentration of TSH in the serum. This technique is more specific, sensitive, and rapid than radioimmunoassay.

The normal range of the serum TSH concentration by immunometric assay varies slightly in different laboratories but is most commonly 0.4 to 4.2 mU/L. There has been discussion of adopting an even lower upper limit for the normal range, but the value of 4.2 mU/L includes 96% of the disease- and risk-free population.^{166,167} The lower limit of 0.4 is too high for a pregnant patient because of hCG-induced hyperthyroidism, as discussed earlier.¹²⁷ It should be kept in mind that there is a diurnal variation of TSH secretion, with peak values in the early evening and a nadir in the afternoon. A borderline abnormal value should always be repeated within a week or so to be certain that it is representative. A minimally suitable TSH assay should be able to quantitate concentrations of TSH as small as 0.1 mU/L with a coefficient of variation of less than 20%. Potential artifacts of these assays are discussed in Chapter 6.

The free α -subunit common to TSH, FSH, LH, and hCG is usually detectable in serum, with a normal range of 1 to 5 $\mu\text{g/L}$, but the TSH β -subunit is not. When FSH and LH production are increased, as in postmenopausal women, or when TSH production is increased, as in primary hypothyroidism, the free α -subunit level is also increased. The α -subunit concentration may also be increased in patients with glycoprotein-producing tumors of the anterior pituitary (see Chapter 9). Its measurement may be useful in the rare patient with hyperthyroidism and a normal or elevated TSH, to differentiate between neoplastic and non-neoplastic causes of TSH excess.^{168,169}

TSH in Patients with Thyroid Dysfunction

Patients with hyperthyroidism (excess thyroid hormone secretion) or thyrotoxicosis (excess thyroid hormone from any cause), or both, will virtually always have a subnormal level of TSH. The values fall into two general categories: those between the lower limit of normal and 0.1 mU/L, and those lower than 0.1 mU/L. Individuals in the former category are often asymptomatic (*subclinical hyperthyroidism*), whereas those in the latter group usually have symptomatic thyrotoxicosis and a significant elevation in free T_4 .

Patients with hypothalamic or pituitary hypothyroidism often have normal or even slightly elevated serum TSH values. The circulating TSH typically has reduced biologic activity due to abnormal glycosylation, reflecting the impaired access of TRH to the thyrotroph.^{105,106} Patients with primary hypothyroidism have serum TSH concentrations that range from minimally elevated to 1000 mU/L. In general, the degree of TSH elevation correlates with the clinical severity of the hypothyroidism. Patients with serum TSH values in the range of 5 to 15 mU/L have few, if any, symptoms; the serum free T_4 or free T_4 index (FT₄I)

is typically low-normal, whereas the serum free T_3 concentration is normal. Such individuals with modest TSH elevation are said to have *subclinical hypothyroidism* if the serum free T_4 is in the normal range. These findings indicate minor thyroidal failure with a compensatory increase in TSH secretion.

A detailed discussion of the various conditions associated with abnormal serum TSH concentrations is presented later. Elevation in both serum TSH and free T_4 is unusual and indicates either autonomous TSH production, as with a TSH-secreting pituitary tumor; resistance to thyroid hormone; or hyperthyroidism with an artifactual elevation in TSH. Differentiating among these diagnoses may require magnetic resonance imaging (MRI) of the hypothalamic-pituitary region or consultation with the clinical chemistry laboratory to rule out an assay artifact (see Chapter 6).

QUANTITATION OF SERUM THYROID HORMONE CONCENTRATIONS

Total T_4 and T_3

Quantitation of the circulating thyroid hormone concentrations is essential to confirm that the thyroid status abnormality suggested by an abnormal TSH result is accurate and to document its severity. Sensitive and specific radioimmunoassays are available for measuring the total concentrations of T_4 and T_3 and some of their metabolic byproducts (see Chapter 6). Because the thyroid status correlates with the free, rather than the total, hormone concentration, the physician must also obtain some estimate of free hormone (see later discussion). The degree of abnormality in the free T_4 level generally correlates with the severity of the hormone excess or deficiency, whereas the serum TSH concentration is an indication of the impact of this abnormality in that specific patient. The normal range for total T_4 in healthy, euthyroid adults with a normal circulating TBG concentration is 64 to 142 nmol/L (5 to 11 $\mu\text{g/dL}$). Normal serum T_3 concentrations are 1.1 to 2.9 nmol/L (70 to 190 ng/dL). At birth (cord serum), T_3 concentrations are about 50% of those in normal adults, but within a few hours T_3 rises abruptly, peaking within about 24 hours at concentrations in the low thyrotoxic range for adults.

Radioimmunoassays for r T_3 , $T_3\text{SO}_4$, triac, tetrac, and the diiodothyronines are of primary interest in the research setting, because these iodothyronines are derived from the circulating T_4 or T_3 , both of which can be easily quantitated. An exception may be the so-called compound W, an as yet unidentified product of T_4 metabolism in the fetal circulation that appears in maternal sera.⁸⁶ If validated, measurements of compound W could serve as a much-needed index of the effects of maternal antithyroid drug therapy on fetal thyroid function.

Concentrations of Free T_4 and T_3

The most accurate and direct measurements of the concentrations of free T_4 and free T_3 in serum are performed by assay of these hormones in a dialysate or ultrafiltrate of serum. This is not practical for clinical purposes, and alternative strategies have been developed to estimate free thyroid hormone concentrations. In one method, serum is enriched with tracer amounts of the labeled hormone, and the concentration of the isotope in the dialysate or ultrafiltrate is expressed as a fraction of that in undiluted serum. The absolute concentration of free hormone is the product of the total hormone concentration and the fraction that

is dialyzable or ultrafiltrable. About 0.02% of T_4 and 0.3% of T_3 is free or unbound (see Table 11-5). The normal ranges for free T_4 is 9 to 30 pmol/L (0.7 to 2.5 ng/dL), and for free T_3 is 3 to 8 pmol/L (0.2 to 0.5 ng/dL).

Because T_4 is the major secretory product of the thyroid and correlates most closely with the serum TSH, in most situations a free T_4 estimate is all that is required to ascertain the state of thyroid secretion or supply. An array of methods is used to quantitate free T_4 (or T_3) in whole serum using automated methods. Even though many such automated tests imply that they quantitate free T_4 directly, they do not, and in general the results in sera with abnormal binding proteins are not absolute.¹⁷⁰ There are two categories of methods: comparative free T_4 methods and FT₄I methods. Three general approaches are used: (1) two-step labeled hormone methods, (2) one-step labeled analogue methods, and (3) labeled antibody approaches (see Chapter 6). The two-step labeled hormone back-titration methods are less subject to artifacts caused by abnormal binding proteins, changes in albumin, TBG, or increased free fatty acids, compared with the one-step hormone analogue methods.^{171,172} All of the approaches are subject to artifacts from endogenous antibodies to T_4 , abnormal binding proteins, or illness.^{170,173} Therefore, the clinician must be wary if the free T_4 result obtained by any method does not agree with the clinical state and the TSH. In such cases, another method should be used to estimate the free T_4 , the FT₄I should be measured, or the result should be ignored. For pregnant or severely ill patients, the automated methods typically give falsely low results, particularly if one-step procedures are used. A reasonable alternative for pregnancy is to multiply the normal range for the serum T_4 concentration by 1.5 in lieu of an automated free T_4 assay.^{125,174}

The Free T_4 Index

It is particularly useful in estimating the free T_4 in severely ill patients to determine the thyroid hormone-binding ratio (THBR) and multiply that result by the total T_4 (or T_3) to obtain a free hormone index (FT₄I or FT₃I). In this test, a tracer quantity of labeled T_4 (or T_3) is added to serum, which is then exposed to a solid phase matrix coated with T_4 or T_3 antibody or to an inert matrix that binds the iodothyronine irreversibly. The proportion of labeled T_4 or T_3 bound by the solid phase is then quantitated. This value, like the free fraction of T_4 quantitated directly in a dialysate, varies inversely with the concentration of unoccupied TBG sites in the serum. If tracer T_3 is used, its binding to TBG is determined by the ratio of T_4 (not T_3) to TBG. T_4 is present in 50- to 60-fold higher concentrations than T_3 , has a much higher affinity for TBG than does T_3 , and therefore determines the ratio of unoccupied to occupied TBG.

The results of such assays are normalized by comparing them with results obtained simultaneously for standard control sera with normal TBG and serum T_4 concentrations. This is usually done by dividing the result for the unknown sample by that obtained for control sera in the same assay. The quotient is the THBR, which typically has a normal range of 0.85 to 1.10. Because the THBR is proportional to the free fraction of the endogenous thyroid hormones in the serum, it can be multiplied by the total T_4 (or T_3) concentration to estimate the free thyroid hormone concentration, termed the FT₄I or FT₃I. Because the normal THBR is 1.0, the FT₄I has a normal range in units that is identical to that of the total T_4 (or T_3)—for example, 64 to 142 in SI units and 5 to 11 in gravimetric terms. A schematic demonstration of the relationships among total and free T_4 , occupied and unoccupied TBG binding sites, and the THBR is shown in Figure 11-13 for

Figure 11-13 Patterns of changes in total serum thyroxine (T_4) concentration and thyroid hormone-binding ratio (THBR) in euthyroid patients with alterations in the circulating concentrations of thyroxine-binding globulin (TBG). To convert T_4 from nmol/L to μ g/dL (total) or pmol/L (free), divide by 12.87.

Figure 11-14 Patterns of changes in total serum thyroxine (T_4) concentration and thyroid hormone-binding ratio (THBR) in patients with hyperthyroidism or hypothyroidism with normal concentrations of serum thyroxine-binding globulin (TBG).

euthyroid individuals with variations in TBG concentrations and in Figure 11-14 for subjects with a constant TBG and alterations in serum thyroid hormone production rates.

Estrogen, pregnancy, and severe illness are more common causes of changes in total T_4 than are hyperthyroidism and hypothyroidism (Table 11-11). In the euthyroid person, only about one third of the available binding sites on TBG are occupied by T_4 , and the free T_4 fraction is 2×10^{-4} of the total. During pregnancy, the TBG binding capacity, the serum T_4 , and the number of unoccupied TBG binding sites approximately double, leading to an approximately 50% reduction in the free T_4 fraction. This is reflected in a reduced THBR. If the reduced THBR (or free fraction) is multiplied by the increased total T_4 , the FT₄I estimate will be found to be normal, an accurate reflection of the free T_4 concentration. In patients in whom the serum T_4 concentration is reduced owing to a low TBG, the concentration of unoccupied binding sites is reduced to an

TABLE 11-11

Circumstances Associated with Altered Binding of Thyroxine by Thyroxine-Binding Globulin

Increased Binding	Decreased Binding
Pregnancy	Androgens
Neonatal state	Large doses of glucocorticoids
Estrogens and hyperestrogenemic states	Active acromegaly
Tamoxifen	Nephrotic syndrome
Oral contraceptives	Major systemic illness
Acute intermittent porphyria	Genetic factors
Infectious and chronic active hepatitis	Asparaginase
Biliary cirrhosis	
Genetic factors	
Perphenazine	
Human immunodeficiency virus infection	

even greater extent. This reduction leads to an increase in the free T_4 (and T_3) fractions and the THBR, and both the free T_4 and the FT_4I remain in the normal range.

There is one caution when calculating the FT_4I using the product of the total T_4 and the THBR. The THBR is not linearly related to the free fraction of thyroid hormones at the extremes of its range. Therefore, it is important to consider both the calculated FT_4I and the pattern of the deviations of total hormone and THBR from normal to derive the maximum information. When concentrations of TBG are altered, the deviation of the total T_4 measurement from normal is in the opposite direction to that of the THBR (see Fig. 11-13, central panels). On the other hand, when the T_4 level is elevated due to increased T_4 secretion or overreplacement, the concentration of unoccupied TBG binding sites is reduced, and both the free fraction and the total T_4 are altered in the same direction (see Fig. 11-14). In hypothyroidism, these changes are both in the opposite direction, although of lower magnitude. The reduced FT_4I of hypothyroidism is caused predominantly by the decrease in T_4 rather than a decrease in its free fraction.

Simultaneous abnormalities in both TBG and thyroid hormone production may also occur. Hyperthyroidism should be suspected in a pregnant patient if the T_4 concentration is very high and the THBR is not subnormal. Likewise, a serum T_4 concentration in the lower normal range for a nonpregnant individual, accompanied by a significant reduction in the THBR, indicates hypothyroidism. For pregnant patients, the best strategy may be to use the normal range of total T_4 for the assay being used, multiplied by 1.5.

Several caveats should be kept in mind when interpreting the results of these tests. The use of labeled T_3 in some assays can produce difficulties in three situations: in cases of familial dysalbuminemic hyperthyroxinemia; in the presence of endogenous antibodies directed against T_3 ; and in sick patients, as discussed earlier. In cases of familial dysalbuminemic hyperthyroxinemia, the abnormal albumin binds T_4 , but not T_3 , with increased avidity. Therefore, these patients have an elevated total T_4 and a reduced free fraction of T_4 , but not of T_3 .⁵⁶

An alternative approach to assessing the FT_4I is to measure TBG by saturation analysis or radioimmunoassay. Normal concentrations of TBG on radioimmunoassay are about 270 nmol/L (1.0 to 1.5 mg/dL); levels are only slightly higher in women than in men. However, it should be recalled (see earlier discussion) that the elastase released

from leukocytes during infection may reduce the binding affinity of TBG for T_4 (and T_3) but does not change its immunoreactivity or its binding capacity.¹⁷⁵ In such patients, the gravimetric TBG concentration is not paralleled by its binding affinity for T_4 or T_3 . With this proviso, the serum TBG concentration result can be employed in one of two ways. First, normalization of the T_4 /TBG (or T_3 /TBG) ratio yields values that correlate reasonably well with the FT_4I or FT_3I . Second, an FT_4I can be derived from the concentrations of TBG and total T_4 and the association constant for the interaction between the two. In most instances, values calculated in this manner correlate with the FT_4I determined by other techniques, although the T_4 /TBG ratio suggests a subnormal FT_4I in some euthyroid patients who have an elevated TBG.¹⁷²

Causes of Abnormal TSH or Thyroid Hormone Concentrations

Several causes of an abnormal TSH should be considered by the clinician (Table 11-12). The clinical status and free T_4 or FT_4I results allow assignment of the etiology. Assay of the FT_3I is rarely required but is included here for completeness.

Causes of a Suppressed TSH. The most common cause of a reduction in serum TSH is an excess supply of thyroid hormone resulting from either increased endogenous thyroid hormone production or excessive exogenous thyroid hormone. Because the concentration of TSH is inversely proportional to the degree of thyroid hormone excess, patients with clinical symptoms almost invariably have serum TSH concentrations lower than 0.1 mU/L. Such patients almost always have an increase in the serum free T_4 . In rare patients with low iodine intake and clinical thyrotoxicosis, the FT_4I is only high-normal despite a suppressed TSH. An FT_3I is required in those patients to establish a diagnosis of T_3 thyrotoxicosis. If the thyroid hormone supply is only slightly in excess of the requirement for that patient, serum TSH is suppressed, but clinical manifestations are subtle or absent and the FT_4I (and FT_3I) are in the high-normal range. Such minimal changes can occur with "euthyroid" Graves' disease, autonomous thyroid hormone-producing adenomas, multinodular goiters, subacute or painless thyroiditis, and the ingestion of an amount of exogenous thyroid hormone slightly greater than that required for metabolic needs. This condition is termed *subclinical hyperthyroidism*.

The hypothalamic-pituitary axis may remain suppressed for up to 3 months after complete resolution of the thyrotoxic state.¹⁷⁶ The best test for assessing the physiologic state in such patients is the free T_4 or FT_4I . A common scenario for this pattern is during follow-up of patients receiving antithyroid drugs or ^{131}I for Graves' disease. With time, the TSH feedback regulatory loop normalizes and TSH secretion returns and becomes appropriate for the circulating free thyroid hormone concentration.

In patients with severe illnesses, with or without dopamine infusion or excess glucocorticoid, TSH is suppressed, making assessment of thyroid functional status difficult (see earlier discussion). Because the FT_4I may also be reduced in such patients, astute clinical judgment is required to assign thyroid status.

Because hCG can activate the TSHR, the TSH concentration is often suppressed in conditions in which hCG is elevated, such as in the first trimester of pregnancy, with twin pregnancies, during severe *hyperemesis gravidarum*, and in patients with hydatidiform mole or choriocarcinoma.¹²⁷ TSH returns to normal in the second and third

TABLE 11-12

Thyroid Status and Free Thyroid Hormone Levels in Clinical States Associated with Abnormal Serum Thyrotropin (TSH) Concentrations*

	Expected TSH (mU/L)	Clinical Thyroid Status	Free T ₄ Index	Free T ₃ Index
Thyrotropin Reduced				
Hyperthyroidism of any cause	<0.1	↑	↑	↑

Psychiatric illnesses	0.4-10	N	N	N, ↓
Adrenal insufficiency	5-30	N	N	N, ↓
Artifact (endogenous antimouse γ-globulin antibodies)	10-500	N	N	N

*Arrows indicate the nature of the abnormality in the T₄ or T₃ index. Parentheses indicate that such a result is unusual but may occur.

trimesters in the euthyroid patient. A persistently suppressed TSH (<0.1 mU/L) in a pregnant patient after the first trimester suggests that the hyperthyroidism is caused by autonomous thyroid function.

Changes in thyroid test results in patients with psychosis or depression, in the geriatric population, and with the use of long-term glucocorticoids were discussed earlier.

If the serum TSH is suppressed and the serum free T₄ is low, ingestion of liothyronine (triiodothyronine) should be suspected. Desiccated thyroid also has a high T₃/T₄ ratio and, if given in excess, may cause a similar abnormality.¹⁷⁷

Causes of an Elevated TSH. Elevated TSH values almost always imply a reduction in the supply of T₄ or T₃, which may be permanent or transient. Primary hypothyroidism is by far the most common explanation. Other causes include acute illness (e.g., renal insufficiency¹⁷⁸) and the asynchronous return of the hypothalamic-pituitary and thyroid axes to normal as patients recover from critical illness.¹⁷⁹ Iodine deficiency is the most common cause of an elevation in TSH worldwide, but this is not the case in North America. The rare patient with resistance to thyroid hormone may be clinically hyperthyroid, euthyroid, or hypothyroid. The most common laboratory pattern is a serum TSH that is normal in absolute terms but inappropriately high for the elevated free T₄. Individuals with a

more marked "pituitary" than "general" resistance to thyroid hormone (sometimes termed pituitary resistance to thyroid hormone or PRTH) have symptoms suggesting hyperthyroidism, an elevated FT₄I, and a normal or even elevated serum TSH.^{180,181} They must be differentiated from patients with a thyrotroph tumor in whom the persistent secretion of TSH causes hyperthyroidism (see Chapters 9 and 12).¹⁶⁸

Patients with hypothalamic-pituitary dysfunction may have clinical and chemical hypothyroidism but low, normal, or even elevated serum TSH concentrations. The explanation for this paradox is that the biologic effectiveness of the circulating TSH is impaired due to abnormal glycosylation secondary to reduced TRH stimulation of the thyrotrophs. Nonetheless, the abnormal TSH is a suitable antigen in the immunometric assay. In adrenal insufficiency, TSH may be modestly elevated but returns to normal with glucocorticoid replacement.¹⁶² This may reflect glucocorticoid-mediated amelioration of Hashimoto's thyroiditis.

Despite the utility and general efficacy of the serum TSH measurement alone as a screening tool for identifying patients with thyroid dysfunction, a patient should not receive treatment for this dysfunction solely on the basis of an abnormal TSH. The TSH assay is an indirect reflection of thyroid hormone supply and does not, by itself, permit a conclusive diagnosis of a specific disorder of thyroid

hormone production. Accordingly, the TSH abnormality must be confirmed and an alteration in thyroid hormone concentrations verified before treatment is initiated.

Tests That Assess the Metabolic Impact of Thyroid Hormones

Abnormalities in the supply of thyroid hormone to peripheral tissues are associated with alterations in a number of metabolic processes that can be quantitated. Some of these may be useful in rare patients in whom serum TSH is not an accurate barometer of thyroid status, such as those with resistance to thyroid hormone. These tests may be the sole means of evaluating the metabolic response of the peripheral tissues to thyroid hormones in such patients.

Basal Metabolic Rate. Thyroid hormones increase energy expenditure and heat production, as manifested by weight loss, increased caloric requirement, and heat intolerance. Because it is impractical to measure heat production directly, the based metabolic rate (BMR) measures oxygen consumption under specified conditions of fasting, rest, and tranquil surroundings. Under these conditions, the energy equivalent of 1 L of oxygen is 4.83 kcal.

Under basal conditions, energy expenditure in visceral organs (including the liver, kidneys, and heart) accounts for approximately 25% of oxygen consumption; that in the brain for 25%; respiratory activity for 10%; and skeletal muscle activity for the remainder. Because energy expenditure is related to functioning tissue mass, oxygen consumption is related to some index thereof, most often body surface area. Calculated in this way, basal oxygen consumption (resting energy expenditure) is higher in men than in women, and it declines rapidly from infancy to the third decade and more slowly thereafter. Values in patients, calculated as a percentage of established normal mean for gender and age, typically range from -15% to +5%. In severely hypothyroid patients, values may be as low as -40%, and in thyrotoxic patients they may reach +25% to +50%. Abnormal (usually elevated) values are seen during recovery in burn patients and in systemic disorders such as febrile illnesses, pheochromocytoma, myeloproliferative disorders, anxiety, and disorders associated with involuntary muscular activity. Resting energy expenditure correlates very well with the free T_4 and TSH levels in hypothyroid patients given varying doses of exogenous levothyroxine.¹⁸²

Biochemical Markers of Altered Thyroid Status. Occasionally, a diagnosis of thyroid dysfunction is first suspected because of an abnormality in a laboratory result performed during an evaluation for an unrelated medical problem. Classic examples are a markedly elevated creatine kinase MM isoenzyme or low-density lipoprotein (LDL) cholesterol leading to the recognition of hypothyroidism.¹⁸³ Other similar markers are listed in Table 11-13. These tests are not useful in the diagnosis of thyroid disease, but some, such as sex hormone-binding globulin, ferritin, or LDL cholesterol, have been used as end points in clinical studies of the responsiveness of the liver to thyroid hormone in patients with thyroid hormone resistance.

Serum Thyroglobulin

The functional sensitivity of most Tg assays is 1 ng/mL or less.¹⁸⁴ The results can be artifactually altered by serum anti-Tg antibodies (Tg-Ab), and serum should be screened for Tg-Ab with a sensitive immunoassay. In

immunoradiometric assays, interferences lead to underestimations of Tg or false-negative values.

Tg is normally present in the serum, the concentration ranging up to 90 pmol/L (50 ng/mL); mean normal values vary with the assay used but are on the order of 30 pmol/L (20 ng/mL).¹⁸⁵ Concentrations are somewhat higher in women than in men and are several-fold elevated in pregnant women and newborns. Levels are elevated in three types of thyroid disorders: goiter and thyroid hyperfunction, inflammatory or physical injury to the thyroid, and differentiated follicular cell-derived thyroid tumors. Values are elevated in both endemic and sporadic nontoxic goiter, and the degree of elevation correlates with thyroid size. Transient elevations occur in patients with subacute thyroiditis and as a result of trauma to the gland during thyroid surgery or after ^{131}I therapy. Subnormal or undetectable concentrations are found in patients with thyrotoxicosis factitia and aid in differentiating this disorder from other causes of thyrotoxicosis with a low thyroid radioiodine uptake (RAIU).

A major clinical value of measuring the level of serum Tg is in the management, but not in the diagnosis, of differentiated thyroid carcinoma.^{184,186} Serum Tg concentrations are increased in both benign and differentiated malignant follicular cell-derived tumors of the thyroid and do not serve to distinguish between the two. After total thyroid ablation for papillary or follicular thyroid carcinoma, Tg should not be detectable, and its subsequent appearance signifies the presence of persistent disease.¹⁸⁶ The serum Tg level is related to the volume of neoplastic tissue and may be undetectable in patients with small lymph node metastases that can be detected on neck ultrasonography (see Chapter 14). Secretion of Tg is TSH dependent. Therefore, the serum Tg level may rise when suppressive therapy is withdrawn or after injections of recombinant human TSH, which increases the sensitivity of the marker for detection of persistent or recurrent thyroid carcinoma, even when ^{131}I scans are negative (see Chapter 14). Supersensitive assays of Tg with a functional sensitivity of less than 0.1 ng/mL improve the sensitivity

TABLE 11-14

Prevalence of Thyroid Autoantibodies (Ab)

Group	TSHR-Ab (%)	hTg-Ab (%)	hTPO-Ab (%)
General population	0	5-20	8-27
Graves' disease	80-95	50-70	50-80
Autoimmune thyroiditis	10-20	80-90	90-100
Relatives of patients	0	40-50	40-50
Patients with IDDM	0	40	40
Pregnant women	0	14	14

IDDM, insulin-dependent diabetes mellitus; hTg-Ab, human thyroglobulin antibody; hTPO-Ab, human thyroid peroxidase antibody; TSHR-Ab, thyroid-stimulating hormone receptor antibody.

during thyroid hormone treatment but at the expense of a decreased specificity.^{187,188} Whether the use of these modern assays will allow one to avoid TSH stimulation in the follow-up of some thyroid cancer patients needs further studies. In the hypothyroid newborn, serum Tg is undetectable in patients with thyroid agenesis and is usually elevated in those with ectopic thyroid tissue or goiter.

Tests for Thyroid Autoantibodies

Graves' disease and Hashimoto's thyroiditis are well-characterized and interrelated *autoimmune thyroid disorders* with a variety of clinical manifestations. The diagnostic hallmark of the autoimmune thyroid disorders is the presence, in most patients, of circulating antibodies and reactive T cells against one or another thyroid antigen.¹⁸⁹ Three varieties of thyroid autoantibodies are in common use and widely available in clinical diagnostic laboratories (Table 11-14). In this section, antibodies to Tg and TPO are discussed. Antibodies directed against the TSHR, the cause of hyperthyroidism in patients with Graves' disease, are covered in detail in Chapter 12.

Autoantibodies to Thyroid Peroxidase and Thyroglobulin

Modern assay techniques for thyroid autoantibodies have good precision because they depend on direct measurement of the interaction between autoantibody and autoantigen (i.e., the interaction between labeled thyroid antigen and the patient's serum). In general, the more sensitive an assay, the more precise and antigen-specific it is. However, many euthyroid individuals exhibit low levels of autoantibodies; in this situation, the specificity of the more sensitive tests is reduced and the absolute concentration of autoantibody, the greater the clinical specificity (see Table 11-14).¹⁹⁰

So that comparisons of thyroid antibody concentrations can be made from one office visit to the next, among different patients, and among laboratories, assays for thyroid autoantibodies have been standardized, with results expressed as standard units per milliliter. Of course, the actual standard serum preparation cannot be included in every assay. Instead, a serum pool is usually compared and normalized to the original standard. Nevertheless, autoantibodies differ considerably in their affinity and epitope recognition of antigen. As a result, despite this attempt at standardization, assay results from different commercial assays may still vary considerably. Hence,

when monitoring antibody titers (e.g., after the treatment of thyroid cancer), it is important to use the same autoantibody assay consistently.

Do Thyroglobulin and Thyroid Peroxidase Antibodies Have a Pathogenic Role?

Tg-Ab and TPO autoantibodies (TPO-Ab) appear to be a secondary response to thyroid injury and are not thought to cause disease themselves, although they may contribute to its development and chronicity. Both types of antibodies are polyclonal, and although they are of the immunoglobulin G class, they are not restricted to one particular immunoglobulin G subclass. Polyclonality mitigates against a primary role in disease pathogenesis.^{191,192} For example, these thyroid antibodies cannot transfer disease from mother to fetus or between animals even though they can pass across the placenta. Both antibodies may contribute to disease mechanisms, however. For example, TPO-Ab on the surface of B cells may be involved in antigen presentation, thus activating thyroid-specific T cells.¹⁹³ Others may have complement-fixing cytotoxic activity. TPO-Ab, in particular, correlate well with thyroidal damage and lymphocytic infiltration.

Thyroid Autoantibodies in Hashimoto's Thyroiditis and Graves' Disease

The disease most widely associated with Tg-Ab and TPO-Ab is *autoimmune thyroiditis*, or Hashimoto's disease (terms that embrace both goitrous thyroiditis, as first described by Hashimoto, and atrophic thyroid failure, previously referred to as *primary myxedema*). Both Tg-Ab and TPO-Ab are found in almost 100% of such patients, but TPO-Ab has higher affinity and occurs in higher concentrations, so testing for TPO-Ab is the best choice if only a single test is ordered.

Tg-Ab and TPO-Ab are also detectable in 50% to 90% of patients with Graves' disease, indicative of the associated thyroiditis that is evident histologically as a heterogeneous lymphocytic infiltration. Although the presence of such autoantibodies favors an autoimmune cause for the hyperthyroidism over other causes, the tests are neither sensitive nor specific in this setting and are interpretable only as part of the clinical scenario. Testing for TSHR antibodies remains the test of choice in such patients.

Thyroid Autoantibodies in Nonautoimmune Thyroid Disorders

Tg-Ab and TPO-Ab are more common in patients with sporadic goiter, multinodular goiter, or isolated thyroid nodules and cancer than in the general population. This finding usually represents an associated thyroiditis on histologic examination. Low levels of thyroid autoantibodies may occur transiently in patients with subacute (de Quervain's) thyroiditis but correlate poorly with disease course and are probably a nonspecific response to thyroid injury. There is also a higher prevalence of thyroid autoantibodies in other autoimmune diseases, particularly insulin-dependent diabetes mellitus.

The "Normal" Population

Although the prevalence of thyroid autoantibodies depends on the technique used for detection, Tg-Ab and TPO-Ab are common in the general population (see Table 11-14). At all ages, these antibodies are almost five times more common in women than in men.¹⁹⁰ Selected groups at risk include younger women and relatives of patients with an autoimmune thyroid disorder, in whom the incidence is higher.

The low levels of TPO-Ab and Tg-Ab found in many individuals are of uncertain significance in the presence of normal thyroid function; however, they remain a significant risk factor in families with autoimmune thyroid disorders.¹⁹⁴

Radioiodine Uptake

The only direct test of thyroid function employs a radioactive isotope of iodine as a tag for the body's stable form of iodine, ¹²⁷I. Most often, the test involves measurement of the fractional uptake by the thyroid of a tracer (chemically inconsequential) dose of radioiodine. However, several factors make this test less frequently used than in the past, including improvements in indirect methods for assessing thyroid status. The normal values for thyroid RAIU have decreased consequent to the widespread increase in daily dietary iodine intake, and this has also reduced the utility of the test in the diagnosis of thyroid disorders.

¹³¹I (half-life, 8.1 days) and ¹²³I (half-life, 0.55 day) emit gamma radiation, which permits their external detection and quantitation at sites of accumulation, such as the thyroid. These isotopes (abbreviated I* hereafter) are physiologically indistinguishable, not only from one another but also from the naturally occurring ¹²⁷I, permitting their use as valid tracers. The shorter half-life of ¹²³I is preferable because the radiation delivered to the thyroid per amount of administered ¹²³I is only about 1% of that delivered by ¹³¹I.

Physiologic Basis

When tracer quantities of inorganic radioiodine are administered orally or intravenously, the isotope quickly mixes with the endogenous stable iodide in the extracellular fluid and begins to be removed at the two major sites of clearance, the thyroid and the kidneys. As this process continues, the plasma level of tracer iodide I* decreases exponentially. Low levels are reached by 24 hours, and inorganic I* is virtually undetectable in the plasma 72 hours after its administration. The thyroid content of I* increases rapidly during the early hours, then at a decreasing rate until a plateau is approached. The proportion of administered I* ultimately accumulated by the thyroid is a function of the clearance of iodide by the thyroid and kidneys. The relation is simply expressed as follows:

$$\text{RAIU at plateau} = \frac{C_T}{C_T + C_K}$$

where C_T represents the thyroid iodide clearance rate and C_K is the renal iodide clearance rate. The normal thyroid iodide clearance rate is approximately 0.4 L/hour, and the renal rate is 2.0 L/hour, so uptake of I* normally approximates 20% of the administered dose.

Measurements of RAIU are typically made at 24 hours, both as a matter of convenience and because the value at 24 hours is usually near the plateau, but it can be measured at 6 hours with appropriate determination of a normal range. The RAIU usually indicates the rate of thyroid hormone synthesis and, by inference, the rate of thyroid hormone release into the blood.

Radioactive Iodine Uptake

Little difference will be noted if the uptake is measured at any time during the day following that on which the isotope was administered. For calculation of therapeutic radioiodine doses in the treatment of thyrotoxic Graves'

TABLE 11-15

Factors That Influence 24-Hour Thyroid Iodide Uptake

Factors That Increase Uptake

Increased Hormone Synthesis

Hyperthyroidism
Response to glandular hormone depletion
Recovery from thyroid suppression
Recovery from subacute thyroiditis
Antithyroid agents
Excessive hormone losses
Nephrotic syndrome
Chronic diarrheal states
Soybean ingestion

Normal Hormone Synthesis

Iodine deficiency
Dietary insufficiency
Excessive loss (dehalogenase defect, pregnancy)
Hormone biosynthetic defects

Factors That Decrease Uptake

Decreased Hormone Synthesis

Primary hypofunction
Primary hypothyroidism
Antithyroid agents
Hormone biosynthetic defects
Hashimoto's disease
Subacute thyroiditis
Secondary hypofunction
Exogenous thyroid hormones

Not Reflecting Decreased Hormone Synthesis

Increased availability of iodine
Diet or drugs
Cardiac or renal insufficiency
Increased hormone release
Very severe hyperthyroidism (rare)

disease, an early uptake at 3 to 6 hours may produce results comparable to those found at 20 to 28 hours.¹⁹⁵ With the use of this modified early RAIU measurement, diagnosis and treatment of thyrotoxic Graves' disease can be accomplished on the same day. The range of normal values in North America is approximately 5% to 25%. Higher values are found in iodine-deficient regions and in patients with thyroid hyperfunction, but, as with other procedures, patients with mild hyperthyroidism may display values at or just above the upper limit of the normal range (Table 11-15).

The Perchlorate Discharge Test

In normal individuals, more than 90% of thyroidal radioiodine is present as iodotyrosine and iodothyronine within minutes of its entry into the thyroid. It is then no longer in the intracellular iodide pool. In patients with Pendred syndrome or other disorders that inhibit the iodination of tyrosine, such as Hashimoto's thyroiditis, and in those receiving thiourea drugs, this process is delayed, as was shown by the exit (discharge) of more than 10% of thyroidal radioiodine within 2 hours after administration of 500 mg of KClO₄.⁸ Perchlorate inhibits NIS function by competing with iodide for NIS, eliminating the iodide gradient that is required for maintaining the radioiodide in the gland. This illustrates that both iodide transport by NIS at the basal pole of the thyrocyte and its efflux across the apical membrane mediated by pendrin are required for thyroid hormone synthesis.

States Associated with Increased RAIU

Hyperthyroidism. Hyperthyroidism causes increased RAIU unless body iodide stores are increased. Such increases in uptake are always evident except in patients with severe thyrotoxicosis, in whom release of hormone can be so rapid that the thyroid content of I^* has decreased to the normal range by the time the measurement is made. This condition is rare and is usually associated with obvious thyrotoxicosis.

Aberrant Hormone Synthesis. RAIU can be increased in the absence of hyperthyroidism in disorders in which iodine accumulation is normal but the secretion of hormone is impaired, such as abnormal Tg synthesis.¹⁹⁶ The magnitude of the increase in uptake and the time at which the plateau is achieved vary with the nature and severity of the disorder. Differentiation of these states from hyperthyroidism is usually not difficult, because the clinical findings and laboratory evidence of hyperthyroidism are lacking, and indeed hypothyroidism may be present.

Iodine Deficiency. RAIU is increased in acute or chronic iodine deficiency, as demonstrated by measurement of urinary iodine excretion, with urinary iodine values lower than 100 $\mu\text{g/day}$ indicating deficiency. Chronic iodine deficiency is usually the result of inadequate content of iodine in the food and water (endemic iodine deficiency). Patients with cardiac, renal, or hepatic disease may develop iodine deficiency if given diets severely restricted in salt, especially if diuretic agents are administered.

Response to Thyroid Hormone Depletion. Rebound increases in RAIU are seen after withdrawal of antithyroid therapy, after subsidence of transient or subacute thyroiditis, and after recovery from prolonged suppression of thyroid function by exogenous hormone. A striking increase in uptake occurs in patients with iodide-induced myxedema after cessation of iodide administration. The duration of the rebound depends on the time required to replenish thyroid hormone stores.

Excessive Hormone Losses. In nephrotic syndrome, excessive losses of hormone in the urine, occurring in association with urinary loss of binding protein, cause a compensatory increase in hormone synthesis and RAIU. A similar sequence may occur when losses of hormone via the gastrointestinal tract are abnormal, as in chronic diarrheal states or during ingestion of agents, such as soybean protein and cholestyramine, that bind T_4 in the gut.

States Associated with Decreased RAIU

A general increase in iodine intake has made values of the RAIU in hypothyroidism indistinguishable from those at the lower end of the normal range. Therefore, the major indication for measurement of RAIU is to establish whether thyrotoxicosis is due to hyperthyroidism (high RAIU) or thyroiditis (low RAIU).

Exogenous Thyroid Hormone: Thyrotoxicosis Factitia. Except in disorders in which homeostatic control is disrupted or overridden (e.g., Graves' disease, autonomously functioning thyroid nodules), administration of exogenous thyroid hormone suppresses TSH secretion and reduces the RAIU, usually to values lower than 5%.

Low values of the RAIU in a patient who is clinically thyrotoxic may also indicate the presence of *thyrotoxicosis factitia*, the syndrome produced by ingestion of excess

thyroid hormone. The unmeasurably low level of Tg in serum differentiates thyrotoxicosis factitia from other causes of thyrotoxicosis with decreased RAIU.¹⁹⁷

Disorders of Hormone Storage. The RAIU is usually low in the early phase of subacute thyroiditis and in chronic thyroiditis with transient hyperthyroidism. Here, inflammatory follicular disruption leads to loss of the normal storage function of the gland and leakage of hormone into the blood. In the early stage of subacute thyroiditis, leakage of hormone is usually sufficient to suppress TSH secretion and the RAIU. Transient hypothyroidism often occurs late in both diseases, when stores of preformed hormone are depleted; the RAIU may return to normal or increased values at that time.

Exposure to Excessive Iodine. Exposure to excessive iodine is a common cause of a subnormal RAIU. Such decreases are spurious in the clinical sense because they do not indicate decreased absolute iodine uptake or decreased hormone production but can be produced by the introduction of excessive iodine in any form—inorganic, organic, or elemental. Common offenders are organic iodinated dyes used as x-ray contrast media and amiodarone (see Table 11-7). The duration of suppression of the uptake varies among individuals and with the compound administered. In general, dyes used for pyelography or computed tomographic scanning are cleared within a few months, whereas amiodarone may influence the uptake for up to 12 months due to its storage in fat. A single large dose of inorganic iodide can decrease uptake for several days, and chronic ingestion of iodide may depress the uptake for many weeks. Excessive quantities of iodine may also be present in vitamin and mineral preparations, vaginal or rectal suppositories, and iodinated antiseptics such as povidone (see Table 11-7).

The measurement of urinary iodine excretion is an invaluable means of establishing or excluding the existence of excessive body iodide stores; the 24-hour iodine excretion can be roughly extrapolated from the iodide-to-creatinine ratio in a random urine sample. Values in excess of 2 mg/day can account for a low RAIU value, whereas values lower than 1 mg/day suggest that one of the other disorders discussed in this section is the cause of a low RAIU.

CHAPTER

12

Thyrotoxicosis

SUSAN J. MANDEL • P. REED LARSEN • TERRY F. DAVIES

The term *thyrotoxicosis* refers to the classic physiologic manifestations of excessive quantities of the thyroid hormones that are so characteristic of this condition. The term *thyrotoxicosis*, rather than *hyperthyroidism*, should be used for this disorder because it need not be associated with hyperfunction of the thyroid gland. The term *hyperthyroidism* is reserved for disorders that result from sustained overproduction and release of hormone by the thyroid itself, Graves' disease being the most common example (Table 12-1). The other common conditions causing thyrotoxicosis are inflammation of the thyroid gland (called *thyroiditis*), which is usually autoimmune or viral related, and autonomous nodules.

Hyperthyroidism and thyroiditis must be differentiated from thyrotoxicosis caused by exogenous thyroid hormone, whether iatrogenic or self-administered. For most patients with thyrotoxicosis, it is the symptoms or signs caused by an excess of the thyroid hormone, regardless of source, that lead to medical attention. Other patients have surprisingly few symptoms and are referred because of a suppressed level of thyroid-stimulating hormone (TSH).

This chapter begins with a brief review of the symptoms and signs of thyrotoxicosis and their pathophysiologic basis. The appropriate use of the laboratory tests described in Chapter 11 is then presented to show how these can focus the search for a diagnosis.

CLINICAL MANIFESTATIONS OF THYROTOXICOSIS

One very important clinical clue to the cause of a patient's thyrotoxicosis is the duration of the symptoms. Patients with hyperthyroidism typically have had manifestations for many months before presentation, but because the week-to-week increases in thyroid hormones are so small they may become rather extreme before they are noticed by the patient. In addition, patients often attribute these symptoms to other causes—their fatigue to family or work responsibilities, their heat intolerance to the weather, their weight loss to an effective diet, and their dyspnea and palpitations to a lack of regular exercise.

On the other hand, patients with thyrotoxicosis due to thyroiditis can often date the onset of their symptoms precisely, and they usually seek medical attention within a month or so after onset, as might be expected considering the effects of the release of the equivalent of 30 to 60 days' supply of thyroid hormone into the circulation over a few days to weeks.

Therefore, ascertaining the chronology as well as the spectrum of symptoms is a critical goal of the interview process. Another general characteristic is that the symptoms and signs of thyrotoxicosis are more readily recognized in young than in older patients.¹ The term *masked*

TABLE 12-1

Causes of Thyrotoxicosis

Sustained Hormone Overproduction (Hyperthyroidism)

Low TSH, High RAIU

Graves' disease (von Basedow's disease)
Toxic multinodular goiter
Toxic adenoma
Chorionic gonadotropin-induced
Gestational hyperthyroidism
Physiologic hyperthyroidism of pregnancy
Familial gestational hyperthyroidism due to TSH receptor mutations
Trophoblastic tumors
Inherited nonimmune hyperthyroidism associated with TSH receptor or G protein mutations

Low TSH, Low RAIU

Iodide-induced hyperthyroidism (Jod-Basedow effect)
Amiodarone-associated hyperthyroidism due to iodide release

Struma Ovarii

Metastatic functioning thyroid carcinoma

Normal or Elevated TSH

TSH-secreting pituitary tumors
Thyroid hormone resistance with pituitary predominance

Transient Hormone Excess (Thyrotoxicosis)

Low TSH, Low RAIU

Thyroiditis
Autoimmune
Lymphocytic thyroiditis (silent thyroiditis, painless thyroiditis, postpartum thyroiditis)
Acute exacerbation of Hashimoto's disease
Viral or postviral
Subacute (granulomatous, painful, postviral) thyroiditis
Drug-induced or associated thyroiditis
Amiodarone
Lithium, interferon- α , interleukin-2, GM-CSF
Infectious thyroiditis

Exogenous Thyroid Hormone

Iatrogenic overreplacement
Thyrotoxicosis factitia
Ingestion of natural products containing thyroid hormone
"Hamburger" thyrotoxicosis
Natural foodstuffs
Thyromimetic compounds (e.g., tiratricol PLB)
Occupational exposure to thyroid hormone (e.g., pill manufacturing, veterinary occupations)

GM-CSF, granulocyte-macrophage colony-stimulating factor; RAIU, radioactive iodine uptake; TSH, thyroid-stimulating hormone.

or *apathetic* thyrotoxicosis is used to describe the syndrome sometimes seen in elderly persons, which may manifest as congestive heart failure with arrhythmia or as unexplained weight loss without the increased appetite that is typical in the younger patient.

At present, the ready availability of sensitive serum TSH assays, a reliable indicator of excess thyroid hormone in the ambulatory patient (see Chapter 11), has made the more classic and severe manifestations of long-standing thyrotoxicosis less prevalent. In fact, a current area of controversy is how aggressively to treat the condition termed *subclinical* or *mild* hyperthyroidism, a biochemical diagnosis in which a subnormal serum TSH level is accompanied by normal free thyroid hormone concentrations. Nonetheless, the classic presentation is still common, and it serves to illustrate the pleiotropic physiologic effects of excess thyroid hormones.

If not recognized, hyperthyroidism can progress to life-threatening severity despite the fact that it is a benign

condition. The following sections review the pathophysiology of the most important manifestations of excess thyroid hormone.

Cardiovascular System

Alterations in cardiovascular function in the thyrotoxic patient are in part due to increased circulatory demands that result from the hypermetabolism and the need to dissipate the excess heat produced.² At rest, peripheral vascular resistance is decreased and cardiac output is increased as a result of an increase, first, in heart rate, and with more severe disease, in stroke volume. Thyroid hormones in excess also have a direct inotropic effect on cardiac contraction mediated by an increase in the ratio of α - to β -myosin heavy chain expression. Tachycardia is almost always present due to a combination of increased sympathetic and decreased vagal tone.³ Widening of the pulse pressure results from the increase in systolic and decrease in diastolic pressure due to reduced resistance.^{4,5} The decreased resistance is caused by increased nitric oxide production.⁶

The increased systolic force is often felt by the patient as a "palpitation" and is evident on inspection or palpation of the precordium. Because of the diffuse and forceful nature of the apex beat, the heart may seem enlarged, and echocardiography may show an increased ventricular mass. In addition, the pre-ejection period is shortened, and the ratio of pre-ejection period to left ventricular ejection time is decreased.⁵ The heart sounds are enhanced, particularly S_1 , and a scratchy systolic sound along the left sternal border, resembling a pleuropericardial friction rub (*Means-Lerman scratch*), may also be heard. These manifestations abate when a normal metabolic state is restored.

Mitral valve prolapse occurs more frequently in Graves' or Hashimoto's disease than in the normal population.^{7,8} Cardiac arrhythmias are almost invariably supraventricular, especially in younger patients.⁹ Between 2% and 20% of patients with thyrotoxicosis have atrial fibrillation, and about 15% of patients with otherwise unexplained atrial fibrillation are thyrotoxic.² In the Framingham cohort, individuals older than 60 years of age with a suppressed TSH level had a 2.8-fold increased risk of developing atrial fibrillation, compared to those with a normal serum TSH value.¹⁰ This finding was confirmed in the Cardiovascular Health Study.¹¹

The increased cardiovascular cost of a standard workload or metabolic challenge is adequately met if the thyrotoxic patient is not, or has not previously been, in heart failure. That is, cardiac competence is maintained in most patients without underlying heart disease. Mild peripheral edema may occur in the absence of heart failure. Heart failure per se usually occurs in patients with preexisting heart disease, and therefore typically in the elderly, but it may not be possible to determine whether underlying heart disease is present until after thyrotoxicosis is relieved.

Atrial fibrillation decreases the efficiency of the cardiac response to any increased circulatory demand and may play a role in causing cardiac failure.¹² Attempts to convert atrial fibrillation to sinus rhythm are not indicated while thyrotoxicosis is present, and about 60% of patients revert spontaneously to sinus rhythm after treatment, usually within 4 months.¹³ For this reason and because thromboembolism is rare in patients younger than 50 years of age with thyrotoxicosis, routine anticoagulation is not recommended for younger patients who are without a history of underlying heart disease or prior thrombotic disorder.^{14,15} Medical or electrical cardioversion of patients with

thyrotoxicosis-induced atrial fibrillation is often successful even after a year has passed.¹⁶

Protein, Carbohydrate, and Lipid Metabolism

The stimulation of metabolism and heat production in patients with thyrotoxicosis is reflected in an increased basal metabolic rate (BMR), increased appetite, and heat intolerance, but only rarely is the basal body temperature elevated.¹⁷ Despite increased food intake, a state of chronic caloric and nutritional inadequacy often ensues, depending on the degree of increased metabolism. Both synthesis and degradation rates of proteins are increased, the latter to a greater extent than the former, with the result that in severe thyrotoxicosis there is a net decrease in tissue protein, as indicated by loss of weight, muscle wasting, proximal muscle weakness, and even mild hypoalbuminemia. Preexisting diabetes mellitus may be aggravated, one cause being accelerated turnover of insulin. Both lipogenesis and lipolysis are increased in thyrotoxicosis, but the net effect is lipolysis, as reflected by an increase in the plasma concentration of free fatty acids and glycerol and a decrease in the serum cholesterol level; triglyceride levels are usually slightly decreased. The enhanced mobilization and oxidation of free fatty acids in response to fasting or catecholamines is a result of enhancement of lipolytic pathways by thyroid hormones.¹⁷

Sympathetic Nervous System and Catecholamines

Many of the manifestations of thyrotoxicosis and those of sympathetic nervous system activation are similar. However, plasma concentrations of epinephrine and norepinephrine, as well as their urinary excretion and that of their metabolites, is not increased in patients with thyrotoxicosis, and thyroid hormones exert effects separate from, but similar and additive to, those of the catecholamines.¹⁸

The improvement in cardiac function with β -blockade in patients with hyperthyroidism has led to the concept that there is increased sympathetic tone or increased cardiac sensitivity to the sympathetic nervous system in these patients.¹⁹ Support for the latter was provided by experiments using transgenic mice in which overexpression of type 2 iodothyronine deiodinase (D2) in the heart increased myocardial triiodothyronine (T_3) and the cyclic adenosine monophosphate (cAMP) response to norepinephrine in cardiac myocytes due to alterations in G proteins.^{20,21} In addition, adipocytes from thyrotoxic patients have exhibited 3-fold increases in norepinephrine-induced lipolysis, 15-fold increases in response to β_2 -adrenergic receptor agonists, and 3-fold increases in response to forskolin or cAMP.²² Therefore, thyroid hormones increase sensitivity to catecholamines in both cardiomyocytes and adipocytes by a variety of mechanisms.

Nervous System

Alterations in the function of the nervous system in thyrotoxicosis are manifested by nervousness, emotional lability, and hyperkinesia. Fatigue may be caused by both muscle weakness and insomnia, which is commonly present. Emotional lability is common, and in rare cases mental disturbance may be severe; manic depressive, schizoid, or paranoid reactions may emerge. The hyperkinesia

of the thyrotoxic patient is characteristic. During the interview the patient shifts positions frequently, and movements are quick, jerky, exaggerated, and often purposeless. In children, in whom such manifestations tend to be more severe, inability to focus may lead to deterioration of school performance, suggesting attention deficit-hyperactivity disorder. A fine tremor of the hands, tongue, or lightly closed eyelids may appear and mimic that of Parkinsonism. The electroencephalogram reveals an increase in fast-wave activity, and in patients with convulsive disorders, the frequency of seizures is increased.

Muscle

Weakness and fatigability usually are not accompanied by objective evidence of muscle disease, save for the generalized wasting associated with weight loss. The weakness is most prominent in the proximal muscles of the limbs, causing difficulty in climbing stairs or fatigue from minimal exertion, such as using a blowdryer or lifting an infant. Proximal muscle wasting may be out of proportion to the overall loss of weight (*thyrotoxic myopathy*). Myopathy affects men with thyrotoxicosis more commonly than women and may overshadow the other manifestations of the syndrome. In the most severe forms, the myopathy may involve the more distal muscles of the extremities and the muscles of the trunk and face. Although myopathy of ocular muscles is unusual, the disorder may mimic myasthenia gravis or ophthalmic myasthenia.²³ Muscular strength returns to normal when a normal metabolic state is restored, but muscle mass takes longer to recover.

Graves' disease occurs in about 3% to 5% of patients with myasthenia gravis, and about 1% of the patients with Graves' disease develop myasthenia gravis. Antibodies and T cells specific for the TSH and acetylcholine receptors are involved in the pathogenesis of the two diseases.²⁴ Unlike thyrotoxic myopathy, the association of myasthenia gravis with Graves' disease has a distinct female preponderance. The effect of thyrotoxicosis and its alleviation on the course of myasthenia gravis is variable, but in most instances, myasthenia is accentuated during the thyrotoxic state and improves after a normal metabolic state is restored. A form of myasthenia affecting mainly the orbital muscles may also occur more commonly in patients with Graves' disease and needs to be distinguished from Graves' orbitopathy by the prominence of bilateral ptosis of a variable degree.²³

Periodic paralysis of the hypokalemic type may occur together with thyrotoxicosis, and its severity is accentuated by the latter disorder. The coincidence of the two disorders is particularly common in Asian and Latino men.²⁵⁻²⁷

Eyes

Retraction of the upper or lower eyelids, or both, is evident as the presence of a rim of sclera between the lid and the limbus and is a common manifestation in all forms of thyrotoxicosis, regardless of the underlying cause; it is responsible for the typical "stare" of these patients. Also common is lid lag, a phenomenon in which the upper lid lags behind the globe when the patient is asked to shift the gaze slowly downward, or globe lag, which becomes evident when the eye lags behind the upper lid when the patient looks up. These ocular manifestations appear to be the result of increased adrenergic tone. It is important to differentiate these signs, which may occur in any form of thyrotoxicosis, from those of infiltrative autoimmune

orbitopathy, which are associated with Graves' disease and are described later.

Skin and Hair

The most characteristic change in patients with longstanding thyrotoxicosis is the warm, moist feel of the skin that results from cutaneous vasodilation and excessive sweating. The elbows may be smooth and pink, the complexion is rosy, and the patient blushes readily. Palmar erythema may resemble "liver palms," and telangiectasia may be present. The hair is fine and friable, and hair loss may increase. The nails are often soft and friable. A characteristic but uncommon finding is *Plummer's nails*, or onycholysis, typically involving the fourth and fifth fingers. Vitiligo, another autoimmune disease, is more common in patients with autoimmune thyroid disease.

Respiratory System

Dyspnea is common in severe thyrotoxicosis, and several factors may contribute to this condition. Vital capacity is commonly reduced, mainly from weakness of the respiratory muscles. During exercise, ventilation is increased out of proportion to the increase in oxygen uptake, but the diffusing capacity of the lung is normal.

Alimentary System

An increase in appetite is common but usually is not seen in patients with mild disease. In more severe disease, the increased intake of food is inadequate to meet the increased caloric requirements, and weight is lost at a variable rate. More often, the patient reports a gratifying success after previously frustrated attempts at weight control. The frequency of bowel movements is increased, but diarrhea is rare. The increased gastric emptying and intestinal motility in thyrotoxicosis appear to be responsible for slight malabsorption of fat; these functions return to normal after a normal metabolic state has been restored. Celiac and Graves' diseases may coexist, and there is an increased prevalence of pernicious anemia.

Hepatic dysfunction occurs, particularly when thyrotoxicosis is severe; hypoproteinemia and increases in serum alanine aminotransferase (ALT) occur, and bone or liver alkaline phosphatase levels may be elevated.²⁸ Hepatomegaly and jaundice can develop with severe, prolonged disease, and liver failure was a cause of death before the development of successful treatment for patients with Graves' disease. Splanchnic oxygen consumption is increased in proportion to the metabolic rate, but splanchnic blood flow is not proportionately increased. As a result, the arteriovenous oxygen difference across the splanchnic bed is increased, and hypoxia may contribute to hepatic dysfunction.²⁹ A reduction in cardiac output by pulse rate reduction due to β -adrenergic blockade may exacerbate that process, because it does not reduce the hepatic hypermetabolism.

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is generally associated with increased excretion of calcium and phosphorus in urine and stool; with demineralization of bone, as demonstrated by routine bone densitometry; and occasionally with pathologic fractures, especially in elderly women.³⁰⁻³³ In such instances,

the pathologic changes are variable and may include osteitis fibrosa, osteomalacia, or osteoporosis. Urinary excretion of collagen breakdown products is increased in thyrotoxicosis. Kinetic studies indicate an increase in the exchangeable calcium pool and acceleration of both bone resorption and accretion, particularly the former. Thyroid hormone (T_3) has been shown to accelerate activity of the osteoclasts and helps to explain these widespread changes.^{34,35} Indeed, data indicate that TSH itself may have a local action that normally helps balance thyroid hormone action on osteoclasts and enhance osteoblast activity.^{36,37} Such an action by TSH would be absent in hyperthyroidism, allowing accentuation of the thyroid hormone effects.

These changes in hyperthyroidism lead to decreased bone density in many patients. As the thyrotoxicosis is treated, bone density may normalize in many younger patients, but not in all.³⁸ Postmenopausal women may have an accelerated reduction in bone density that requires treatment (see Chapter 27). Much controversy has existed regarding the induction of decreased bone density by TSH-suppression therapy in patients with thyroid cancer. Suffice it to say that postmenopausal, but not premenopausal, women given a TSH-suppressive dosage of thyroid hormones are at risk for osteopenia and require prophylaxis with calcium and vitamin D or more aggressive approaches.^{39,40} The decision to relax TSH suppression in low-risk patients may be influenced by their bone status.

For all the same reasons, hypercalcemia may occur in patients with severe thyrotoxicosis. The total serum calcium concentration is increased in as many as 27% of patients, and the ionized serum calcium is elevated in 47%. The concentrations of heat-labile serum alkaline phosphatase and osteocalcin are also frequently elevated. These findings resemble those of primary hyperparathyroidism, but the concentration of parathyroid hormone in serum is low-normal in most cases.⁴¹ True primary hyperparathyroidism and thyrotoxicosis sometimes coexist. Plasma 25-hydroxycholecalciferol levels are decreased in thyrotoxic patients, and this alteration could contribute to the decreased intestinal absorption of calcium and osteomalacia observed in some patients.

Renal Function: Water and Electrolyte Metabolism

Thyrotoxicosis produces no symptoms referable to the urinary tract save for mild polyuria, which may lead to nocturia. Nevertheless, renal blood flow, glomerular filtration, and tubular reabsorptive and secretory maxima are increased. Total exchangeable potassium is decreased, possibly due to a decrease in lean body mass, but electrolytes are normal except when hypokalemic periodic paralysis occurs.

Hematopoietic System

The red blood cells are usually normal, as judged by the usual indices, but red blood cell mass is increased. The increase in erythropoiesis results from both a direct effect of thyroid hormones on the erythroid marrow and increased production of erythropoietin. A parallel increase in plasma volume also occurs, with the result that the hematocrit is normal.

Approximately 3% of patients with Graves' disease have pernicious anemia, and a further 3% have antibodies to intrinsic factor but normal absorption of vitamin B_{12} . Autoantibodies against gastric parietal cells may also be present

in patients with Graves' disease, and the requirements for vitamin B₁₂ and folic acid appear to be increased. The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased, leading to a relative lymphocytosis. The numbers of monocytes and eosinophils may also be increased. Splenic enlargement occurs in about 10% of the patients, and enlargement of the thymus and lymph nodes is common. The latter may manifest as a mediastinal mass. Thymic hyperplasia is also sometimes seen in patients with thyroid cancer receiving excess exogenous thyroxine for TSH suppression.^{42,43}

Platelet levels and the intrinsic clotting mechanism are normal, but the concentration of factor VIII is often increased, returning to normal after the thyrotoxicosis is treated. Despite this increase, there is an enhanced sensitivity to warfarin because of accelerated clearance of the vitamin K-dependent clotting factors. Therefore, the dosage of warfarin needs to be reduced in thyrotoxic patients.⁴⁴ This must be kept in mind if anticoagulant treatment for atrial fibrillation is being initiated.⁴⁵ Coincidental autoimmune thrombocytopenia may also occur.

Pituitary and Adrenocortical Function

The thyrotoxic state imposes several challenges on pituitary and adrenocortical function. The hepatic inactivation of cortisol is accelerated with increased levels of 5 α /5 β -reductases. As a result of these changes, the disposal of cortisol is accelerated, but its rate of secretion is also increased, so the plasma cortisol concentration remains normal. The concentration of corticosteroid-binding globulin in plasma is also normal. The urinary excretion of free cortisol is normal or slightly increased (see Chapter 15).⁴⁶

Reproductive Function

Thyrotoxicosis in early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated. Thyrotoxicosis after puberty influences reproductive function, especially in women. The intermenstrual interval may be prolonged or shortened; menstrual flow is initially diminished and ultimately ceases. Fertility may be reduced, and if conception takes place, there is an increased risk of miscarriage.^{47,48} In some patients, menstrual cycles are predominantly anovulatory with oligomenorrhea, but ovulation occurs in most, as indicated by a secretory endometrium. In those with anovulatory cycles, a subnormal midcycle surge of luteinizing hormone (LH) may be responsible. In premenopausal women with thyrotoxicosis, basal plasma concentrations of LH and follicle-stimulating hormone (FSH) are reportedly normal but may display enhanced responsiveness to gonadotropin-releasing hormone (GnRH).

Thyrotoxicosis, whether spontaneous or induced by exogenous hormone, is accompanied by an increase in the concentration of sex hormone-binding globulin (SHBG) in plasma.⁴⁹ As a result, the plasma concentrations of total testosterone, dihydrotestosterone, and estradiol are increased, but their unbound fractions are normal or transiently decreased. Increased binding in plasma may be responsible for the decreased metabolic clearance rate of testosterone and dihydrotestosterone. In the case of estradiol, however, the metabolic clearance rate is normal, suggesting that tissue metabolism of the hormone is increased. Conversion rates of androstenedione to testosterone, estrone, and estradiol and of testosterone to

dihydrotestosterone are increased.⁵⁰ The increased rate of conversion of androgens to estrogenic byproducts may be the mechanism for gynecomastia and erectile dysfunction in some 10% of thyrotoxic men and one mechanism for menstrual irregularities in women. Another likely mechanism for menstrual changes is the disruption in amplitude and frequency of LH/FSH pulses caused by thyroid hormone influences on GnRH signaling.

LABORATORY DIAGNOSIS

The effects of thyrotoxicosis on the major organ systems are the same regardless of the underlying etiology, but the frequency and intensity of these effects and the other findings with which they are associated are influenced by the cause of the excess thyroid hormone. To a large extent, the same is true of laboratory test results. However, the patient with thyrotoxic symptoms will almost always have a serum TSH concentration of less than 0.1 mU/L and an elevated concentration of serum-free thyroxine (T₄). In general, when thyrotoxicosis is caused by hyperthyroidism, serum free T₃ is more elevated than the free T₄ is, but this measurement is rarely required for an accurate diagnosis.

If the possibility of exogenous thyroid hormone can be eliminated, the primary differential is between hyperthyroidism and thyroiditis (Fig. 12-1). Often, this differentiation can be made on the basis of the history and physical examination. Laboratory findings, including an increased sedimentation rate and a high serum thyroglobulin level, may favor thyroiditis, but the most critical differentiating test is the radioactive iodine uptake (RAIU), which is elevated or inappropriately high-normal given the suppressed serum TSH level in hyperthyroidism and very low (<5%) in patients with thyroiditis. However, the RAIU may be low in a hyperthyroid patient who has recently received an iodine load, usually iodinated contrast for a computed tomographic (CT) scan or for angiography. A 24-hour urine iodine measurement can confirm this.

If the physical examination or thyroid ultrasonography indicates the presence of a nodular thyroid, scintigraphy can confirm nodular hyperfunction. The association of thyrotoxicosis with an elevated TSH is rare and suggests a TSH-producing pituitary tumor (see Fig. 12-1). The possibility of an artifactually elevated TSH level in a patient with Graves' disease should be ruled out by repetition of the assay by a different method in another laboratory (see Chapter 6). Exceptions to these general guidelines are discussed later, within the appropriate subsection.

GRAVES' DISEASE

Robert Graves' disease, although first described by Parry in 1825,⁵¹ is best known as Graves' disease in the English-speaking world and as von Basedow's disease on the continent of Europe because of the prominence of the disease reports by these eminent physicians. It is the most enigmatic and, in areas of iodine abundance, one of the most common thyroid diseases, representing 50% to 80% of all cases of thyrotoxicosis.

Presentation

Graves' disease is characterized by diffuse goiter and thyrotoxicosis; it may be accompanied by an infiltrative orbitopathy and ophthalmopathy and occasionally by infiltrative dermopathy. In an individual patient, thyroid

**Patient with symptoms and signs suggesting thyrotoxicosis, no amiodarone;
serum TSH <0.2 mU/L, free T₄ or T₃ elevated**

disease and the infiltrative phenomena may occur singly or together, but their courses are largely independent. The thyroid histology is closely related to autoimmune thyroiditis with the presence of lymphocytic infiltrate. In Graves' disease, hyperthyroidism occurs in the presence of some degree of chronic thyroiditis and may ultimately be replaced, in the long term, by thyroid hypofunction. Conversely, hyperthyroidism may occasionally supervene in patients with preexisting Hashimoto's thyroiditis. Both of these diseases may occur within the same family.

Autoimmune Characteristics

Autoimmune thyroid disease is characterized by the occurrence in the serum of antibodies against thyroid peroxidase

(TPO) (still incorrectly called the "microsomal" antigen by many physicians), thyroglobulin (Tg), and the TSH receptor (TSHR). T cell-mediated autoimmunity can also be demonstrated against the three primary thyroid antigens, as judged by a variety of criteria, including the ability of the T cells to elaborate various cytokines and to exhibit a mitogenic response when exposed to thyroid antigens or peptide sequences from the antigens.⁵² Autoimmune thyroid disease is also characterized by lymphocytic infiltration of the thyroid gland—intense in autoimmune thyroiditis and heterogeneous in Graves' disease. In patients and their relatives, there is an increased frequency of other disorders of autoimmune origin, such as insulin-dependent diabetes mellitus, pernicious anemia, myasthenia gravis, Addison's disease, Sjögren's syndrome,

Figure 12-2 Schematic diagram of thyroid cell stimulation and blockade by antibodies to the thyroid-stimulating hormone receptor. Such autoantibodies may act as agonists or antagonists, or they may be neutral, depending on how they interact within the extracellular domain.

lupus erythematosus, rheumatoid arthritis, and idiopathic thrombocytopenic purpura (see Chapter 42).

The circulating autoantibodies specific to hyperthyroid Graves' disease are directed against the TSHR and are called thyrotropin receptor antibodies (TRAbs). They behave as thyroid-stimulating antibodies⁵³ because they compete with TSH for binding to its specific receptor site in the cell membrane and can activate multiple signaling pathways including adenylate cyclase.⁵⁴ Similar but distinct autoantibodies in the sera of some patients with autoimmune thyroiditis also compete with TSH for binding but do not stimulate the thyroid cell very well; they may block the ligand-binding site and act as TSH antagonists or weak agonists. Others are neutral in their influence on TSH binding but may also act as weak agonists (Fig. 12-2).

The thyroid gland itself is the major site of thyroid autoantibody secretion in autoimmune thyroid disease via the B cells that form part of the intrathyroidal infiltrate. Transplantation of Graves' thyroid tissue into T cell- and B cell-deficient mice with severe combined immunodeficiency (SCID mice) results in the appearance of human thyroid autoantibodies, including TRAbs, in the serum.⁵⁵ Additional evidence for a role of the thyroid itself in antibody production comes from animal models of thyroiditis and from the decline in thyroid autoantibody levels after anti-thyroid drug treatment,⁵⁶ thyroidectomy, or radioiodine ablation.⁵⁷ However, some patients shown no loss of autoantibody secretion after thyroidectomy or radioiodine treatment, which suggests extrathyroidal sources of continued production. The role of the TSHR expressed in extrathyroidal tissues in perpetuating this response remains uncertain.

Pathology

In patients with Graves' disease, the thyroid gland is characterized by a nonhomogeneous lymphocytic infiltration with an absence of easily found follicular destruction, although areas of apoptosis can be discerned by specific staining (Fig. 12-3).⁵⁸ Anti-thyroid drug treatment may reduce the degree of infiltration, influencing the observed histology.

Although the intrathyroidal lymphocyte population is mixed, most are T lymphocytes (both Th1 and Th2 types, along with CD25+ regulatory T cells); B-cell germinal centers are much less common than in autoimmune thyroiditis. However, both intraepithelial T cells and plasma

cells can be seen in peripilesis within the thyroid follicles. Follicular epithelial cell size correlates with the intensity of the local infiltrate, suggesting local thyroid cell stimulation by TRAbs. Memory T cells may predominate within the T-cell population, but this finding can vary from patient to patient. Activated B-cell and T-cell markers are more frequent in intrathyroidal lymphocyte cultures than in peripheral blood cultures.

Prevalence

The prevalence of hyperthyroidism varies with the degree of iodine sufficiency in the population under study. The National Health and Nutrition Examination Survey (NHANES III) data⁵⁹ from the United States and a detailed epidemiologic survey in the United Kingdom⁶⁰ demonstrated the female preponderance among thyroid patients and the lower prevalence of hyperthyroidism compared to hypothyroidism. The results indicated a prevalence of 1% to 2% in women and about one tenth as much in men. Overall, the incidence in women was estimated to be 1 case per 1000 per year over a 20-year follow-up. Graves' disease is the most common cause of spontaneous hyperthyroidism in patients younger than 40 years of age, and the hazard rate does not change with age. The overall prevalence of autoimmune thyroid disease (i.e., Graves' disease and autoimmune thyroiditis) approaches or exceeds that of diabetes mellitus; when mild thyroid disease is included, the prevalence may be very much higher.

Pathogenesis

The Major Antigen of Graves' Disease: The Thyrotropin Receptor

The TSHR has seven transmembrane domains and employs multiple G proteins for signal transduction.⁶¹ The human TSHR (hTSHR) is the primary autoantigen of Graves' disease, as shown by the development of hyperthyroidism in mice and hamsters after exposure to normal hTSHR antigen.⁶²⁻⁶⁴ Extrathyroidal TSHR messenger RNA (mRNA) and protein have been reported in many other tissues, including fibrocytes, adipocytes, lymphocytes, osteoclasts and osteoblasts, and pituitary cells. Although the physiologic role of TSHRs in these sites is slowly being revealed, their role in autoimmune thyroid disease remains mostly unclear.

Molecular Structure of the Human Thyrotropin Receptor

Cloning of human TSHR complementary DNA (cDNA) made it possible to begin to define the structure of the hTSHR gene; its chromosomal location (14q31) and its crystallographic structure have now been revealed.⁶⁵ Seven hydrophobic transmembrane spanning regions in the hTSHR indicate that it is a member of the G protein-coupled receptor gene superfamily, and those receptors with large extracellular domains have been designated subgroup B. The TSH holoreceptor consists of a 100-kD, glycosylated, 744-amino-acid sequence and a 20-amino-acid signal peptide. The TSHR holoreceptor is cleaved into two subunits, designated α (or A) and β (or B), which are linked by disulfide bonds to form the physiologic receptor (Fig. 12-4). The 50-kD α -subunit is water soluble and has TSH-binding activity. TSH and TRAbs bind to the leucine-rich repeat (LRR) regions of the α -subunit.^{66,67} The 30-kD β -subunit is water insoluble, contains the membrane-spanning domain with its three extracellular loops and

Figure 12-3 Histopathology of the Graves' thyroid. Sections of thyroid glands from normal tissue (**A**) and from a patient with Graves' disease (**B** and **C**). (Courtesy of Dr. Pamela Unger, Mount Sinai School of Medicine, New York, NY.)

three cytoplasmic loops, and is 70% to 75% homologous with the LH/human chorionic gonadotropin (hCG) receptor. Shedding of the α -subunit has been shown in vitro, and this has been suggested to also occur in vivo. The TSHR forms dimers and multimeric complexes on the thyroid-cell surface, which appears to enhance the stability of the receptor.⁵³

Autoantibodies to the Thyrotropin Receptor

In Graves' disease, TRAbs, discovered by Adams and Purves,^{68,69} bind to the TSHR and activate $G_s\alpha$ and G_q signaling complexes; this ultimately induces thyroid growth, increases vascularity, and causes an increased rate of thyroid hormone production and secretion. As mentioned earlier, TRAbs in patients with Graves' disease are referred to as thyroid-stimulating antibodies. Other varieties of TRAbs may also be present, and all antibodies that bind to the TSHR appear to have the capacity for signal transduction to varying degrees.⁵⁴ Receptor antibodies that act as TSH antagonists are referred to as *blocking* TRAbs, although they may still initiate some signaling. In the same way, *neutral* antibodies may also signal to varying degrees. These different types of TRAbs may co-occur with the stimulating type, and they may predominate in certain patients after treatment with radioiodine, anti-thyroid drugs, or surgery (see

Fig. 12-2). Blocking TRAbs can also be found in 15% of patients with autoimmune thyroiditis, particularly in patients without a goiter (the atrophic variety).⁷⁰ TRAbs are not detectable in the normal population with the use of currently available methods.

Bioactivity of Thyrotropin Receptor Autoantibodies

The self-infusion of sera from patients with Graves' disease caused thyroid stimulation and was the first demonstration of the role of TRAbs in the induction of human hyperthyroidism.⁷¹ Another example of the in vivo effects of TRAbs came from studies in neonates demonstrating transplacental stimulation of the fetal thyroid in mothers with high titers of TRAbs.⁷² TRAbs show light-chain restriction in many patients with Graves' disease, and TRAbs that exhibit TSH agonist bioactivity are in the immunoglobulin G1 (IgG1) subclass; both observations suggest oligoclonality.^{73,74}

Prevalence of Thyrotropin Receptor Autoantibodies in Graves' Disease

The fact that TRAbs are detectable only in patients with autoimmune thyroid disease indicates that the autoantibodies are disease specific, in contrast to the high

Figure 12-4 Structure of the human thyroid-stimulating hormone receptor (TSHR). The TSHR has seven transmembrane domains, a large extracellular domain, and a small intracellular domain. The receptor is cleaved, probably after activation, into α (or A) and β (or B) subunits. The α -subunit is thought to be shed from the cell surface. C, carboxyterminus; N, aminotermius; PM, plasma membrane; TM, transmembrane domain. (Adapted from Nunez MR, Sanders J, Jeffreys J, et al. Analysis of the thyrotropin receptor-thyrotropin interaction by comparative modeling. *Thyroid*. 2004;14:991-1011.)

prevalence of Tg antibodies (Tg-Ab) and TPO antibodies (TPO-Ab) in the population. Furthermore, TRAbs are unique human autoantibodies and do not occur in natural animal disease. A total of 90% to 100% of untreated hyperthyroid patients with Graves' disease have detectable TRAbs with thyroid-stimulating activity when measured by a sensitive assay.⁷⁵⁻⁷⁷ The levels of TRAbs are decreased by treatment of the disease and, when they persist, may predict recurrence.⁷⁸⁻⁸⁰ With time, TSHR-blocking autoantibodies may become the more prevalent type after treatment of Graves' disease causing hypothyroidism.

Intrathyroidal T Cells

T cells in patients with autoimmune thyroid disease are reactive to thyroid antigens and to peptides derived from these antigens^{81,82} and are oligoclonal. About 10% of activated T cells infiltrating the thyroid gland in patients with autoimmune thyroid disease proliferate in response to thyroid-cell antigens. Intrathyroidal T cells from patients with Graves' disease exhibit characteristics of both helper T cell subset 1 (Th1), which are recognized by their secretion of interleukin-2 (IL-2) and interferon- γ , and helper T cell subset 2 (Th2), which are recognized by their secretion of IL-4.⁸³ The presence of Treg cells and Th17 cells in situ in Graves' thyroid tissue awaits characterization.

Regulation of the Immune Response in Autoimmune Thyroid Disease

Although thyroid hormone excess itself may give rise to changes in T-cell numbers and function, the immune system continues to exert its overall peripheral control. This is achieved by secretion of T-cell cytokines, by the suppressive influence of "anergized" T cells, and by the presence of regulatory cells that are a subset of CD4+ T cells (D25+Fox3p+) and have now been extensively

characterized.⁸⁴ Such regulatory cells can suppress experimental thyroiditis in a variety of models,^{67,85} although their characterization in hyperthyroid patients with Graves' disease has not shown major disruption.⁸⁶ Studies of Th17, a new subset of T cells thought to be important in the initiation of autoimmune disease, are awaited.

In addition to these potential regulatory influences, another important mechanism of control is central tolerance caused by positive and negative selection of T cells and B cells in the thymus, where thyroid antigens, including the TSHR, are expressed.^{87,88} Here, the role of the *AIRE* gene has been clarified as important in self-antigen presentation, including presentation of thyroid antigens.⁸⁹ Failure of such mechanisms may lead to the development of pathology but must be distinguished from those risk factors that allow the initiation of disease, which are discussed separately.

Mechanisms in the Development of Autoimmune Thyroid Disease

The Consequences of an Insult

Initiation of autoimmune thyroid disease is thought to occur with an insult that leads to an immune response (Fig. 12-5). This may take the form of a direct insult to the thyroid gland by a viral infection or another external influence (e.g., trauma) leading to activation of T cells,^{90,91} currently presumed to be of the Th17 variety. Alternatively, it may be initiated elsewhere in the body. In the latter case, the arrival of activated T cells in the thyroid gland starts the process. Such an arrival may be nonspecific, because the same T cells may arrive in many glands, but the patient has a particular susceptibility to autoimmune thyroid disease. Initiation of disease may be mediated by bystander

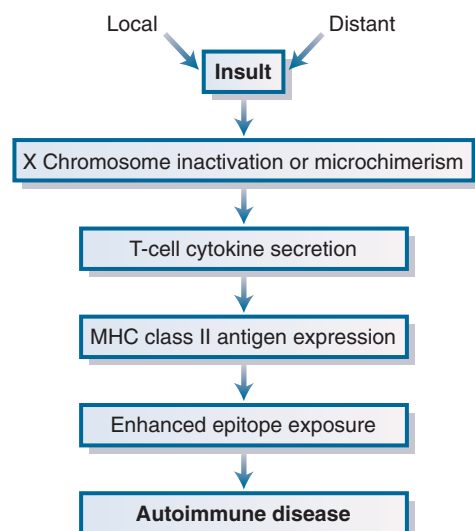

Figure 12-5 An overview of the most likely mechanisms involved in the cause and precipitation of Graves' disease. MHC, major histocompatibility complex.

activation, molecular mimicry, or cryptic antigen presentation, as described in the following sections, but the importance of these different mechanisms in Graves' disease remains uncertain.

Mechanism #1—Bystander Activation

Evidence has mounted that bystander activation of local resident antigen-specific and nonspecific T cells may initiate autoimmunity.^{92,93} The presence of activated T cells within the thyroid gland after an insult may induce, via cytokine secretion, the activation of local thyroid-specific and non-thyroid-specific T cells, as demonstrated in animal models of thyroiditis.⁹⁴ This series of events can occur only in a susceptible individual with the right immune repertoire. Bystander activation could arise from any T cells within the thyroid gland, which could be activated by many different infections and antigens unrelated to the thyroid gland itself. The attractiveness of this model is that many different types of infection could lead to the same clinical disease phenotype. There is much evidence for residual thyroid-resident T cells and dendritic cells in the glands of patients with Graves' disease that could have been activated by this mechanism at the time of disease onset.⁹⁵

Mechanism #2—Molecular Mimicry (Specificity Crossover)

In addition to the effects of the direct release of cytokines from T cells activated elsewhere via the bystander effect, intrathyroidal T cells may become activated in another nonspecific way. Structural or conformational similarity (i.e., sequence, shape, or both) between different antigens can lead to specificity crossover (or molecular mimicry).⁹⁶ Antigenic similarity between bacteria or viruses and human proteins is common, and in one study 4% of monoclonal antibodies raised against a variety of viruses cross-reacted with antigens in tissues.⁹⁷ Furthermore, mice infected with reovirus type 1 developed an autoimmune polyendocrinopathy with autoantibodies directed against normal pancreas, pituitary, thyroid, and gastric mucosa, suggesting molecular mimicry between a reoviral antigen and a common tissue antigen.⁹⁸ Molecular mimicry has also been reported between *Yersinia enterocolitica* and the TSHR based

on the observed cross-reaction between sera from patients with *Yersinia* infection and sera from patients with Graves' disease.^{99,100} Similar evidence has been presented on the basis of structural similarities between borellia or retroviral sequences and the TSHR.¹⁰¹

Mechanism #3—Thyroid Cell Involvement by Aberrant Expression of Class II HLA Antigens

Normal thyroid epithelial cells do not express human leukocyte antigen (HLA) class II antigens, but they are markedly expressed in thyroid glands from patients with autoimmune thyroid disease (Fig. 12-6).¹⁰² A local insult, whether trauma or infection of the thyroid gland, can cause an inflammatory infiltrate and the production of interferons or other cytokines in the thyroid gland that are able to induce HLA class II antigen expression. HLA class II antigens are used to present antigen to the immune system (discussed earlier), and overexpression on the thyroid cell would lead to enhanced presentation of thyroid autoantigens and activation of local autoreactive thyroid-specific T cells in a susceptible individual. Support for this concept comes from the *in vivo* induction of such molecules on mouse thyrocytes by interferon- α that also induced autoimmune thyroiditis¹⁰³ and from the demonstration of the necessity for major histocompatibility complex (MHC) molecules on TSHR-expressing fibroblasts used in the induction of Graves' disease in mice.⁶² A number of viruses may also induce thyroid-cell expression of such antigens independent of immune-cell cytokine secretion; these include reovirus types 1 and 3 and cytomegalovirus.

Mechanism #4—Cryptic Antigens

T-cell tolerance depends on visualization of self-antigens by the immune system in sufficient amounts to initiate continuous T-cell deletion, anergy induction, and regulatory T-cell activation. However, some antigens and antigenic epitopes are not seen in sufficient concentrations to cause the removal of T cells that react to them. These molecules contain what are sometimes called cryptic epitopes.¹⁰⁴ T cells specific for these cryptic epitopes may be

Figure 12-6 Photomicrograph of Graves' thyroid tissue stained for human leukocyte antigen (HLA) class II (DR) antigen expression using the immunoperoxidase technique. Notice the brown thyroid epithelial cells indicating the presence of DR antigen. Notice also the relative lack of lymphocytic infiltration in this region.

present in the immune repertoire, and they may induce autoaggressive T cells if such an epitope is uncovered or increased in concentration by a local insult. HLA class II antigen expression in a situation in which it normally does not occur (e.g., on the thyroid epithelial cell) would then allow the presentation of these normally cryptic thyroid antigens to local autoreactive T cells if they are present. To date, however, such potential cryptic thyroid antigens have not been characterized.

Potential Risk Factors for Graves' Disease

Risk Factor #1—Genetic Susceptibility

The development and course of Graves' disease are greatly influenced by heredity.¹⁰⁵ The role of hereditary factors is evidenced by the increased incidence of other autoimmune disorders in families of these patients, such as Graves' disease, Hashimoto's disease, insulin-dependent diabetes (type 1), or pernicious anemia. Additionally, autoantibodies against endocrine tissues, gastric parietal cells, and intrinsic factor in some families suggest a hereditary influence. Siblings have a high risk of being affected, as shown by a sibling recurrence risk (λ s) of 11.6.¹⁰⁶ In addition, monozygotic twins have a higher concordance rate for Graves' disease than do dizygotic twins,¹⁰⁷ despite the rearrangement of B-cell and T-cell V genes that cause the immune repertoires of identical twins to differ (see Chapter 42), thus implicating non-V genes in susceptibility. Nevertheless, the propensity for development of thyroid autoantibodies appears to be an autosomal dominant trait linked to the cytotoxic T-lymphocyte antigen 4 (CTLA4) gene that codes for a modulator of the second signal to T cells.¹⁰⁸

Because a number of genetic loci may contribute to Graves' disease susceptibility, it is referred to as a polygenic or complex disorder.¹⁰⁹ To date, these genes and gene regions account for only a small part of the calculated genetic susceptibility, so much more remains to be understood. There is a much-investigated association with the HLA gene region (e.g., increased frequency of the HLA DR3 and DQA10501 haplotypes in Caucasians), but this region provides less than 5% of the genetic susceptibility and yields a risk ratio of only twofold to fourfold (Table 12-2).^{110,111} Additional nonspecific genetic susceptibility, after the HLA and CTLA4 contributions, includes the genes for lymphoid tyrosine phosphatase (PTPN22), the signaling molecule CD40, the IL-2 receptor- α , and the orphan Fc

receptor L3, which may all be involved in providing a background autoimmunity susceptibility.

The search for thyroid-specific genetic susceptibility has revealed small influences exerted by polymorphisms in the Tg gene and the TSHR gene but no major thyroid antigen-specific contribution. More remains to be learned about how thyroid disease specificity is engineered into the genetic susceptibility to Graves' disease.

Risk Factor #2—Infection

Much has been written about the possible role of infection in the development of autoimmunity acting via bystander effects or molecular mimicry.^{112,113} There is no evidence that a specific infection initiates Graves' disease.⁹⁰ An identifiable agent should be present in most patients, and transfer of the agent to susceptible recipients should transfer the disease. As discussed earlier, it has been long suggested that Graves' disease is associated with infectious agents (e.g., *Y. enterocolitica*), but no studies meet the necessary criteria to prove this. Infections of the thyroid gland itself (e.g., subacute thyroiditis, congenital rubella, hepatitis C) may be associated with thyroid autoimmune phenomena.^{90,114} Nevertheless, a causative role of infectious agents has not been definitively demonstrated in Graves' disease, despite the observation that thyroid disease can be induced in experimental animals by certain viral infections.¹¹⁵ Reports of retroviral sequences in the thyroid glands of patients with Graves' disease have failed to be reproduced. Clinical infection with human T-cell lymphotropic virus 1 (HTLV-1) has been reported to be associated with the development of autoimmune thyroid disease but most likely as a result of immune-cell changes rather than thyroid infection.¹¹⁶

Risk Factor #3—Stress

Commonly, Graves' disease appears to become evident after severe emotional stress (e.g., actual or threatened separation from a loved one) or after an acute fright (e.g., an automobile accident). There are many clinical experiences and reports associating major stress with the onset of Graves' disease, including data on the high incidence of thyrotoxicosis among refugees from Nazi prison camps, which may have been more directly related to iodine status. Some data suggest that stress induces an overall state of immune suppression by nonspecific mechanisms,^{117,118} perhaps secondary to the effects of cortisol and the action of corticotropin-releasing hormone at the level of the immune cell. Compared with control groups, more patients with Graves' disease give a history of major stress in the 12 months before disease onset.

After acute immune suppression by stress, there is presumably an overcompensation by the immune system when the suppression is released. This could precipitate autoimmune thyroid disease, similar to the development of thyroiditis or Graves' disease after release from the immunosuppression of pregnancy.¹¹⁹ The rebound phenomenon would result in greater immune activity than normal and would initiate disease only if the individual were genetically susceptible.

Risk Factor #4—Gender

Graves' disease is more common in women than in men (7:1 to 10:1), and it tends to become more prevalent after puberty. The female preponderance and the fact that the disorder is uncommon before puberty suggest that female sex steroids may be responsible for this difference. Indeed, androgens may actually suppress autoimmune thyroiditis.^{120,121} In contrast, estrogen has been shown to influence the immune system, particularly the B-cell repertoire, and

TABLE 12-2

Figure 12-7 Computed tomographic scans of orbits in two patients with Graves' orbitopathy. **A**, Notice the obviously grossly swollen medial rectus extraocular muscles in both orbits and the resulting proptosis. **B**, The patient shows considerable proptosis with only minimal muscle enlargement, suggesting the presence of a large amount of retroorbital fat. (Courtesy of Dr. Peter Som, New York, NY.)

has often been suggested as the reason for female susceptibility. However, Graves' disease continues to occur after the menopause and is seen in many men. When the disease develops in men, it tends to occur at a later age, to be more severe, and to be accompanied more often by ophthalmopathy. Such observations suggest that the X chromosome, rather than sex steroids, may be the responsible element in female susceptibility. Women have two X chromosomes and, therefore, receive twice the gene dose. Genetic studies identified a locus on the X chromosome linked to Graves' disease, but this has not been confirmed in larger studies.¹²² The phenomenon of X-chromosome inactivation has also been invoked in autoimmune disease.¹²³ Female cells may inactivate different X chromosomes to different degrees in different tissues, leading to potentially different immune responses. Evidence for the importance of X-chromosome inactivation has been repeatedly described in Graves' disease.¹²⁴⁻¹²⁶

Risk Factor #5—Pregnancy

Severe Graves' disease is uncommon during pregnancy, because hyperthyroidism is associated with reduced fertility. For those women with milder disease who successfully conceive, hyperthyroidism endows an increased risk of pregnancy loss and complications in established pregnancy,^{127,128} as exemplified by the influence of high thyroid hormone levels in normal pregnancy in patients with thyroid hormone resistance.¹²⁹ Such data indicate that excess thyroid hormone has a direct toxic effect on the fetus. However, pregnancy is a time of immunosuppression, so that the disease tends to improve as pregnancy progresses. Both T-cell and B-cell functions are diminished as pregnancy progresses, under the influence of local placental factors and regulatory T cells (see later discussion).¹³⁰ Rebound from this immunosuppression after delivery may contribute to the development of postpartum thyroid disease.¹³¹ As many as 30% of young female patients give a history of pregnancy in the 12 months before the onset of Graves' disease,¹³² indicating that postpartum Graves' disease is a surprisingly common presentation and that pregnancy is a major risk factor for development of the disease in susceptible women (see later discussion). Consistent with this observation is the higher rate of Graves' disease relapse occurring after delivery in women who were previously in remission.¹³³

Risk Factor #6—Iodine and Drugs

Iodine, iodine-containing drugs (e.g., amiodarone), and iodine-containing contrast media may precipitate Graves' disease or its recurrence in a susceptible individual.^{134,135} Iodine is most likely to precipitate thyrotoxicosis in an iodine-deficient population, simply by allowing TRAbs to effectively stimulate the formation of more thyroid hormone. Whether there is any other precipitating event is unclear. Iodine may also damage thyroid cells directly, releasing thyroid antigens to the immune system.

Risk Factor #7—Irradiation

There is no evidence that radiation exposure itself is a risk factor for Graves' disease, although Graves' disease is well known to be precipitated in some patients treated with radioactive iodine for multinodular goiter.^{136,137} There is also evidence that thyroid autoantibodies are more prevalent in a radiation-exposed population, and claims of increased autoimmune thyroiditis in such populations have been made.¹³⁸⁻¹⁴⁰ In addition, radioactive iodine treatment may cause the onset or worsening of clinical ophthalmopathy, but often this is transient (see later discussion).¹⁴¹

Pathogenesis of Graves' Orbitopathy and Dermopathy

The pathogenesis of the orbitopathy and dermopathy is now better understood than ever before. The extraocular muscle and adipose tissue are swollen by the accumulation in the extracellular matrix of glycosaminoglycans that are secreted by fibroblasts under the influence of cytokines such as interferon- γ from local lymphocytes (Fig. 12-7; see also Fig. 12-6).¹⁴² This accumulation of glycosaminoglycans disrupts and impairs the function of muscle. As the disease runs its course and inflammation decreases, the damaged muscles become fibrosed. Histologic examination of the extraocular muscles shows disrupted muscle fibrils and a patchy lymphocytic infiltrate, predominantly of T cells, and some muscle cells exhibit HLA class II antigen as seen within the thyroid gland. Such T cells react in vitro with retroorbital tissue.^{143,144} Transplantation of extraocular muscle into mice deficient in B cells and T cells (SCID/SCID mice) causes TRAbs to appear in the murine serum, showing

accumulation of TSHR-reactive cells within the muscle samples.¹⁴⁵ Evidence of TSHR expression in retroorbital and pretibial tissues such as fibrocytes and adipocytes has strengthened the notion that it is the TSHR itself that is responsible for the immune response.¹⁴² Retroorbital fibrocytes may be derived from circulating marrow fibrocytes, and they express more TSHR than is seen at other sites, which also supports the TSHRs as the primary antigen of Graves' orbitopathy.¹⁴⁶ Studies on the role of the insulin-like growth factor 1 (IGF1) receptor as a retroorbital antigen and the role of serum IGF1 and IGF1 receptor antibodies may shed further light on the propensity for the eyes and skin to be involved in Graves' disease by acting synergistically with TSHR antibodies.^{147,148}

In keeping with the hypothesis that the TSHR is the primary antigen, patients with the most severe orbitopathy have the highest titers of TRAbs, and the level of TRAbs often correlates with the severity of the eye disease. There is currently no convincing evidence that specific antibodies against orbital tissue contents play a primary pathogenic role. More likely, antigen-specific T cells have the major role in initiating the disorder, perhaps augmented by TSHR antibodies providing additional signaling at the target cells. However, non-eye-specific antibodies may serve as markers of extraocular muscle inflammation, including the recently described antibodies to the IGF1 receptor.¹⁴⁹

Risk Factors for Graves' Orbitopathy and Dermopathy

Although there have been many claims, there is still no reproducible evidence that a separate and distinct genetic risk can be ascribed to severe ophthalmic Graves' disease; this suggests that it is mainly environmental factors that lead to the enhanced retroorbital inflammation in some patients.¹⁵⁰ All of the same risk factors (e.g., infection, stress, gender and gonadal steroids, pregnancy, drugs, irradiation) apply to the onset of both thyroid and eye involvement in Graves' disease.

There are, however, three additional distinct risk factors that deserve attention. The first is smoking, which has increased the risk for ophthalmic involvement in many studies, perhaps by causing anoxia or simply by direct inflammation.¹⁵¹ The second is radioiodine, which in controlled clinical trials accentuates ophthalmic Graves' disease.¹⁴¹ However, this worsening is related to the severity of the baseline ophthalmopathy, which may be mild and transient, and it may be ameliorated with corticosteroid treatment lasting 3 to 4 months. Many physicians are reluctant to prescribe radioiodine to patients with moderate or severe eye disease unless they are receiving corticosteroids. Third, the role of trauma in the initiation of thyroid and retroorbital inflammation is well recognized.^{88,91,150}

Natural History and Course of Graves' Disease

The course of the thyrotoxic component of Graves' disease is variable. In some patients, thyrotoxicosis persists, although it may vary in severity. In others, the course is cyclic, exhibiting remissions of varying frequency, intensity, and duration. This cyclic feature has an important bearing on treatment. With the passage of months or years, thyrotoxicosis tends to give way to euthyroidism. Approximately one third of patients become hypothyroid within 20 years after treatment with anti-thyroid agents.¹⁵²

The orbitopathy may or may not commence together with the thyrotoxic component. Thyrotoxic patients may initially be free from eye disease but become affected by it months or years later or not at all. Conversely, orbitopathy may be the first manifestation of future Graves' disease, with hyperthyroidism developing later. In euthyroid patients with orbitopathy, evidence of a thyroid abnormality may be manifested only by the presence of TRAbs and other thyroid autoantibodies. Some of these patients become hypothyroid within a few years, some become hyperthyroid, and a few remain euthyroid. However, many such euthyroid patients do have evidence of chronic thyroiditis. The course of thyroid function in many of these patients is therefore unpredictable.

Histopathology

Thyroid Gland

The older designation for Graves' disease, *diffuse toxic goiter*, reflected the fact that the gland is both enlarged and uniformly affected. The gland may vary in consistency, from softer than normal to firm and rubbery, depending on the degree of thyroiditis. The outer surface is usually smooth but may be somewhat lobular; less commonly, the gland is grossly nodular before treatment. The cut surface is red and glistening. Microscopically, the follicles are small and lined with hyperplastic columnar epithelium and contain scant colloid that displays much marginal scalloping and vacuolization (see Fig. 12-3). Nuclei are vesicular and basally located and exhibit occasional mitoses. Papillary projections of the hyperplastic epithelium extend into the lumina of the follicles. Vascularity is increased, and there is a varying heterogeneous infiltration by lymphocytes and plasma cells that collect in aggregates and may form infrequent germinal centers. In such regions, thyroid epithelial cells express HLA class II antigens, a phenomenon not seen in normal thyroid glands, and are large, perhaps due to local stimulation by TRAbs.

When the patient is given iodine or anti-thyroid drugs, the thyroid gland may undergo involution if TRAbs decrease. Then hyperplasia and vascularity regress, papillary projections recede, and follicles enlarge and become filled with colloid once again.

Eyes

In patients with infiltrative orbitopathy, the volume of orbital contents is enlarged because of increases in retrobulbar connective tissue and adipose tissue and in the total extraocular muscle mass (see Fig. 12-7). Some of the increase in muscle mass is due to edema resulting from accumulation in the ground substance of hyaluronic acid and chondroitin sulfates, which are hydrophilic; this is thought to be the result of cytokine action. The extraocular muscles are swollen, and some fibers exhibit loss of striation, fragmentation, and lymphocytic infiltration. The lacrimal glands may also be involved. Ultimately, the tissues fibrose (Fig. 12-8).

Skin

The most uncommon element of the Graves' triad, dermopathy (Fig. 12-9) is usually a late manifestation, and 99% of patients with infiltrative dermopathy have Graves' orbitopathy. The content of hyaluronic acid and chondroitin sulfates in the dermis is increased, probably secondary to cytokine activation of fibroblasts. This causes compression of the dermal lymphatics and nonpitting edema: the collagen fibers are separated and fragmented, and

Figure 12-8 Section of extraocular muscle from a biopsy taken from a patient with severe Graves' orbitopathy. Notice the patch of lymphocytic infiltration within the muscle fibers. (Courtesy of Dr. D. Kendler, University of British Columbia, Vancouver, Canada.)

early lesions contain a lymphocytic infiltrate. As discussed earlier, TSHR expression can be demonstrated in fibroblasts and adipocytes,¹⁴² and TRAbs are very high in such patients. Nodule and plaque formation may occur in chronic lesions.

Figure 12-9 Chronic pretibial myxedema in a patient with Graves' disease and orbitopathy. The lesions are firm and nonpitting, with a clear edge to feel. (Courtesy of Dr. Andrew Werner, New York, NY.)

Pathophysiology

In Graves' disease, normal pituitary regulatory mechanisms are overridden by the action of TRAbs of the stimulating variety. The resulting hyperfunction of the thyroid gland leads to suppression of TSH secretion that is reflected in undetectable serum TSH. In this context, the term "functional autonomy" is often misused when the intent is to imply that thyroid function is independent of TSH stimulation. True functional autonomy occurs when the thyroid gland is capable of functioning at a normal or an increased pace in the absence of both TSH and any other circulating thyroid stimulator (e.g., in congenital hyperthyroidism secondary to constitutively activated TSHRs). In Graves' disease, the thyroid gland is controlled by an abnormal stimulator, the TRAbs; in molar pregnancy, hCG is responsible. When the abnormal stimulator is withdrawn (i.e., when the disease enters remission), hyperfunction subsides, and the nonautonomous nature of thyroid function becomes evident in the re-emergence of normal TSH secretion and control of thyroid function.

The molar ratio of T_3 to T_4 in Tg is about twice normal, reflecting chronic hyperstimulation of the gland. The major product of glandular secretion is still T_4 , but the ratio of T_3 to T_4 in the thyroid secretion is increased in proportion to the overproduction of T_3 . In some instances, especially where there is iodine deficiency, T_3 appears to be the major secretory product, so that the serum T_3 level is increased while serum T_4 concentration is within the normal range (T_3 thyrotoxicosis). The proportion of total plasma T_4 and T_3 in the free (or unbound) state is increased because of a decrease in the concentration of thyroxine-binding globulin (TBG) and an increase in the concentration of T_4 .

Clinical Picture

The Thyroid Gland

Graves' disease is most common in the third and fourth decades of life; it is rare before age 10 years but still occurs in the elderly, sometimes in an "apathetic" form. The features include diffuse goiter, thyrotoxicosis, infiltrative orbitopathy, and, occasionally, infiltrative dermopathy. Because the orbitopathy and dermopathy can occur independently of other manifestations, they are discussed separately. In other respects, the symptoms and signs of thyrotoxicosis are the same in Graves' disease as in other causes of hyperthyroidism.

In most patients, the thyroid gland is enlarged. However, hyperthyroidism in Graves' disease occurs in a gland of normal size in a minority of patients, and goiter is absent in 20% of elderly patients. The size of the thyroid gland is most often two or three times normal but may be massively enlarged. The consistency varies from soft to firm and rubbery. The enlargement is usually symmetric. The surface is generally smooth but may feel lobular. In severe cases, a thrill can be felt, usually over the upper or lower poles, where the superior and inferior thyroid arteries, respectively, enter the gland. A thrill is always accompanied by an audible bruit. However, the bruit, which occurs in systole, may be difficult to auscultate if the patient is very tachycardic. The bruit should not be confused with a venous hum or murmur arising from the base of the heart. To differentiate a true bruit from a transmitted cardiac flow murmur, the auscultated bruit should be louder over the thyroid than in the upper left sternal area. In addition,

Figure 12-10 Characteristic signs of Graves' orbitopathy (**A**) subsequently corrected by orbital decompression surgery (**B**). Note the thyroid stare, the asymmetry, the proptosis, and the periorbital edema prior to correction. (Courtesy of Dr. Jack Rootman, University of British Columbia, Vancouver, Canada.)

mitral valve prolapse is more common than in the normal population and may account for a cardiac murmur.¹⁵³

Manifestations of Infiltrative Orbitopathy and Dermopathy

Graves' ophthalmopathy is so named because most cases occur in patients with active or past Graves' disease. However, this entity is also termed *thyroid eye disease* or *thyroid-associated orbitopathy*, reflecting its association with any autoimmune thyroid disease.¹⁵⁴ Infiltrative orbitopathy may follow an independent course from the thyrotoxic manifestations and is often uninfluenced by their treatment. The natural history is characterized by rapid onset and deterioration followed by gradual improvement.

Infiltrative orbitopathy is evident in about 25% of patients with Graves' disease. However, ultrasonography¹⁵⁵ CT, or magnetic resonance imaging (MRI) of the orbits reveals changes, such as swelling of extraocular muscles and increased retroorbital fat, in a large majority of the patients, including those in whom the clinical changes are minimal or absent.

Signs and Symptoms. Spasm and retraction of the eyelids lead to widening of the palpebral fissures so that the sclera are exposed above the superior margin of the limbus (Fig. 12-10). Lid retraction may be asymmetric. When the patient looks downward, the upper lid lags behind the globe, exposing more sclera. When the patient gazes upward, often with difficulty, the globe lags behind the lid (lid lag and globe lag). The movements of the lids are jerky and spasmodic, and the lightly closed lids may show a tremor. Simple lid retraction and globe and lid lag are often a manifestation of the thyrotoxicosis per se and frequently abate after the thyrotoxicosis is relieved. On the other hand, significant swelling and inflammation of the muscles and orbital contents (so-called infiltrative orbitopathy) may occur.

The disease symptoms and signs of infiltrative ophthalmopathy appear in varying combinations. Early symptoms

and signs include a sense of irritation in the eyes, resembling that caused by a foreign body, and excessive tearing that is often made worse by exposure to air or wind, especially if exophthalmos is present. The conjunctivae may be injected. Exophthalmos is frequently asymmetric and may cause a feeling of pressure behind the globes. If exophthalmos is pronounced, the eyes may not close during sleep, a condition termed lagophthalmos. Exophthalmos may be masked by periorbital edema, which is a common accompaniment and source of complaint. Patients frequently describe blurred vision and easy tiring of the eyes. Double vision may occur in combination with the foregoing symptoms or alone. In severe cases, color vision, and then visual acuity, may be decreased or lost, and the corneas may ulcerate or become infected.

The manifestations of extreme orbitopathy can be catastrophic and can include subluxation of the globe. Blindness may result from ulceration or infection of the cornea secondary to incomplete apposition of the lids or to optic nerve ischemia due to reduced blood flow caused by increased intraocular and intraorbital pressure. In the most severe cases, which should now be unusual, ophthalmoscopic examination reveals venous congestion and papilledema, which may be accompanied by visual field defects.

Objective Assessment of Eye Disease. The American Thyroid Association and the European Group on Graves' Orbitopathy (EUGOGO) recommend that the eye changes of Graves' disease be assessed with the use of an overall activity score, shown in Table 12-3.¹⁵⁶

Infiltrative Dermopathy. Dermopathy now occurs in fewer than 5% of patients with Graves' disease, and it is almost always accompanied by infiltrative orbitopathy, usually of a severe degree. These lesions cause hyperpigmented, nonpitting induration of the skin of the legs, commonly over the pretibial area (pretibial myxedema) and the dorsa of the feet, sometimes in the form of individual nodules and plaques or becoming confluent with a

TABLE 12-3

Clinical Assessment of the Patient with Graves' Ophthalmopathy
Activity Measures*

Spontaneous retrobulbar pain
Pain on attempted up or down gaze
Redness of the eyelids
Redness of the conjunctiva
Swelling of the eyelids
Inflammation of the caruncle and/or plica
Conjunctival edema

Severity Measures

Lid aperture: distance between lid margins in millimeters with the patient looking in the primary position, sitting relaxed, and with distant fixation
Swelling of the eyelids (absent/equivocal, moderate, severe)
Redness of the eyelids (absent/present)
Redness of the conjunctivae (absent/present)
Conjunctival edema (absent, present)
Inflammation of the caruncle or plica (absent, present)
Exophthalmos: measured in millimeters using the same Hertel exophthalmometer and the same intercanthal distance for an individual patient
Subjective diplopia score[†]
Eye muscle involvement (ductions in degrees)
Corneal involvement (absent/punctate keratopathy/ulcer)
Optic nerve involvement: best-corrected visual acuity, color vision, optic disk, relative afferent pupillary defect (absent/present), plus visual fields if optic nerve compression is suspected

*Based on the seven classic features of inflammation in Graves' ophthalmopathy. The clinical activity score (CAS) is the total number of items present; a CAS ≥ 3 indicates active ophthalmopathy.

[†]Subjective diplopia score: 0 = no diplopia; 1 = intermittent (i.e., diplopia in primary position of gaze, when tired, or when first awakening); 2 = inconstant (i.e., diplopia at extremes of gaze); 3 = constant (i.e., continuous diplopia in primary or reading position).

smooth, characteristic edge or shoulder (see Fig. 12-9). Rarely, lesions develop on the face, elbows, or dorsa of the hands. The cause of the characteristic pretibial location of the dermatopathy is unclear but most likely depends on trauma to the exposed areas. Indeed, surgical trauma to

such tissues aggravates the disease dramatically.⁹¹ Clubbing of the digits is occasionally associated with long-standing thyrotoxicosis (thyroid acropathy), which is now uncommon with early treatment (Fig. 12-11).

Laboratory Tests

In moderate or severe Graves' disease, laboratory findings are consistent with the pathophysiology previously discussed. The serum TSH level, when measured by a sensitive immunoassay, is almost totally suppressed, and serum T_4 and T_3 levels are elevated (see Chapter 11 and Fig. 12-1). The free T_4 and T_3 levels are increased more than are the total T_4 and T_3 levels. The serum T_3 concentration may be proportionally more elevated than the serum T_4 level. The increase in thyroid iodide uptake and clearance rates is often, but not always, reflected in the increased RAIU, which is usually measured at 24 hours. The RAIU may be inappropriately normal in a patient with milder disease given the suppressed serum TSH level. However, in patients with severe accompanying illness, conversion of T_4 to T_3 is impaired, permitting return to normal of the free T_3 concentration but usually not the free T_4 (i.e., T_4 thyrotoxicosis). Occasionally, usually in iodine deficiency, the discrepancy between T_4 and T_3 levels is exaggerated, the serum T_4 concentration being normal and only the serum T_3 concentration being elevated (T_3 thyrotoxicosis).

Because there are other causes of suppressed serum TSH, such as depression and hypothalamic-pituitary disease (see Table 11-12 in Chapter 11), and to exclude the possibility that an increase in serum T_4 concentration is the result of an increase in hormone binding in the blood, the free T_4 concentration should also be measured.

Determining the RAIU is not useful in the diagnosis when the clinical presentation is compatible with straightforward Graves' disease, but it is appropriate in excluding thyrotoxicosis not caused by hyperthyroidism. Very low values of RAIU in association with thyrotoxicosis signal the presence of (1) thyroiditis (painless, subacute, acute or drug-induced); (2) factitious thyrotoxicosis; (3) ectopic thyroid tissue; or (4) iodine contamination by recent administration of iodinated radiographic contrast, such as for a CT examination or amiodarone administration (see Fig. 12-1).

Figure 12-11 Rare thyroid acropathy in a patient with Graves' disease. The hypermetabolic state leads to axial bone destruction, presumably secondary to enhanced osteoclast activity. Acropathy should not be confused with clubbing, which is usually painless. (Courtesy of Dr. Andrew Werner, New York, NY.)

Mild (Subclinical) Graves' Disease

In subtle or mild cases of thyrotoxicosis, laboratory tests are most important, particularly if values are only slightly abnormal. A TSH concentration lower than 0.1 mU/L (normal range, 0.4 to 4.0 mU/L) may be associated with symptoms of an excessive thyroid hormone supply. A value between 0.1 and 0.4 mU/L suggests a supranormal exposure to thyroid hormones but not a condition likely to be associated with severe clinical manifestations. Treatment of such mild (subclinical) thyrotoxicosis is discussed later in this chapter.

Measuring Thyrotropin Receptor Autoantibodies

Two types of tests are usually employed for the detection of TRABs, and both are available commercially. The first test assesses the capacity of patient serum or IgG to inhibit the binding of labeled TSH to solubilized TSHRs or to compete with a monoclonal antibody to the TSH-binding site on the TSH receptor. These protein-binding inhibition assays are of low cost and good precision, and the frequency of positive results in patients with active and untreated disease has increased as the sensitivity of the assay has improved and is now greater than 90%.

The second type of test is a bioassay that assesses the capacity of the patient's serum or IgG to stimulate adenylate cyclase in thyroid epithelial cells or mammalian cells expressing recombinant TSHR. Tests of this type, which measure the biologic action of the antibodies, are much more expensive, have relatively poor precision, and are positive in 80% to 90% of patients with active untreated Graves' disease. Because of the proliferation of acronyms describing these antibodies, we encourage designation of the specific assay used.

Standardization. As with all autoantibody tests, it is important to use an internationally accepted standard to allow comparison of results from different laboratories. A TRAB standard from the Medical Research Council (MRC) is often employed and reported in MRC units. Alternatively, results have been reported in terms of equivalent TSH units. However, the hTRABs from different patients may not give parallel results with the MRC standards or TSH standards when measured in different dilutions. This means that the conversion of hTRAB data into MRC units or TSH units can be erroneous.

Indications for Measuring Thyrotropin Receptor Autoantibodies. Quantitation of TRABs may be a useful indicator of the degree of disease activity in an individual patient and can confirm the clinical diagnosis of Graves' disease in a scientific manner. A bioassay is not needed in a hyperthyroid patient, because the patient is already demonstrating antibody bioactivity. Demonstration of TRABs may also be of diagnostic value in the euthyroid patient with exophthalmos, especially if it is unilateral. High levels of TRABs in a pregnant woman with Graves' disease increase the likelihood that fetal or neonatal thyrotoxicosis will be present in her offspring, and in this situation a bioassay late in pregnancy is preferred.

Another use of TRAB testing is in the prognosis of patients with Graves' disease who are treated with antithyroid agents. A persisting high level of TRABs is a useful predictor of relapse on cessation of the drug.^{79,157} In patients with low or negative titers, the test is much less helpful. The presence of iodine deficiency may interrupt the development of hyperthyroidism despite the presence of TRABs.¹⁵⁸

Differential Diagnosis

The patient with major manifestations of Graves' disease (namely thyrotoxicosis, goiter with an accompanying bruit or thrill, and infiltrative orbitopathy) does not pose a diagnostic problem. In some patients, however, one of the major manifestations dominates the clinical picture or is present alone, and the disorder may mimic another disease. All of these issues can be resolved by appropriate laboratory testing.

Thyroid Differential

The diffuse goiter of Graves' disease in a patient with severe hyperthyroidism may rarely be confused with that of other thyroid diseases. In subacute thyroiditis, asymmetry of the gland, tenderness on palpation, and systemic evidence of inflammation assist in the diagnosis. If Graves' disease is in a latent or inactive phase and thyrotoxicosis is absent and in patients with extremely mild hyperthyroidism, the goiter may require differentiation from Hashimoto's thyroiditis or simple nontoxic goiter as possible diagnoses. The goiter of Hashimoto's disease is somewhat lobulated and feels firmer and rubbery compared with that of Graves' disease. Serum levels of thyroid antibodies are generally higher in Hashimoto's disease but may not be helpful in distinguishing individual patients. The very low RAIU distinguishes thyrotoxicosis caused by painless or subacute thyroiditis from Graves' disease in the absence of iodine excess (see Fig. 12-1).

Eye Disease Differential

The orbitopathy of Graves' disease, if bilateral and associated with thyrotoxicosis past or present, does not require differentiation from exophthalmos of any other origin, such as is seen in morbid obesity. However, unilateral exophthalmos, even when associated with thyrotoxicosis, should alert the physician to the possibility of a local cause. Rare diseases that may produce unilateral or bilateral exophthalmos include orbital neoplasms, carotid-cavernous sinus fistulas, cavernous sinus thrombosis, infiltrative disorders affecting the orbit, and pseudotumor of the orbit. Mild bilateral exophthalmos, without infiltrative signs, is seen commonly in morbid obesity and is occasionally present on a familial basis; it also sometimes occurs in patients with Cushing's syndrome, cirrhosis, uremia, chronic obstructive pulmonary disease, or superior vena cava syndrome.

Ophthalmoplegia as the sole manifestation of the orbitopathy of Graves' disease requires exclusion of diabetes mellitus and other disorders affecting the brainstem and its connections. The demonstration of swelling of the extraocular muscles by orbital ultrasonography, CT, or MRI is diagnostic of Graves' orbitopathy, as is the detection of TRABs in serum or the demonstration of a suppressed TSH level.

Treatment

It is not possible to treat the basic pathogenetic factors in Graves' disease in a risk-free way. Existing therapies for the thyrotoxic and ophthalmic manifestations all have significant side effects. The lack of general agreement as to which therapy is the best is due to the fact that none is ideal.¹⁵⁹ Because the therapeutic problems posed by thyrotoxicosis and orbitopathy differ, and because they run independent courses, their treatments are discussed separately.

Treatment of thyrotoxicosis is designed to impose restraint on hormone secretion by means of chemical

agents that inhibit hormone synthesis or release or by reducing the quantity of thyroid tissue. There are three effective therapeutic options, and physician and patient preference often dictate the choice. Radioiodine is a popular therapy in the United States, whereas in Europe and Japan the preference is for anti-thyroid drug therapy or surgery.¹⁶⁰

Anti-Thyroid Agents

Thionamides. The major agents for treating thyrotoxicosis are drugs of the thionamide class, most commonly methimazole, propylthiouracil, and carbimazole (10 mg of carbimazole is metabolized to approximately 6 mg of methimazole).¹⁶¹ These agents inhibit the oxidation and organic binding of thyroid iodide and therefore produce intrathyroidal iodine deficiency that further increases the ratio of T_3 to T_4 in the thyroid secretion, as reflected in the high T_3/T_4 ratio in the serum. In addition, large doses of propylthiouracil (600 mg), but not methimazole, impair the conversion of T_4 to T_3 by type 1 deiodinase (D1) in the thyroid and peripheral tissues.¹⁶² The propylthiouracil-sensitive D1 is the major source of peripheral T_3 production in the hyperthyroid patient.¹⁶³ Because of this additional action, large doses of propylthiouracil may provide rapid alleviation of severe thyrotoxicosis.¹⁶⁴

The half-life in plasma of methimazole is about 6 hours, whereas that of propylthiouracil is about 1.5 hours, and both drugs are accumulated by the thyroid gland.¹⁶¹ A single dose of methimazole may exert an anti-thyroid effect for longer than 24 hours. This provides a rational basis for the single-daily-dose regimen of methimazole for mild or moderate thyrotoxicosis. Both of these drugs cross the placenta and can inhibit thyroid function in the fetus, but both drugs have been used highly effectively in pregnant patients (see later discussion).

Immunosuppressive Action of Thionamides. Thionamide drugs may also directly influence the immune response in patients with autoimmune thyroid disease.⁵⁶ This action occurs within the thyroid gland, where the drugs are concentrated. The action on the thyroid cells themselves decreases thyroid antigen expression and decreases prostaglandin and cytokine release from thyroid cells. Thionamides also inhibit the generation of oxygen radicals in T cells, B cells, and particularly antigen-presenting cells and hence may cause a further decline in antigen presentation. It has also been shown that methimazole induces the expression of Fas ligand on thyroid epithelial cell, thereby inducing apoptosis of infiltrating lymphocytes such as T cells that express FasL and decreasing the lymphocytic infiltration.^{165,166} The clinical importance of immunosuppression and induction of apoptosis compared with inhibition of thyroid hormone formation is unclear. However, the decrease in immune infiltration seen in patients taking such drugs and the fall in autoantibody levels after initiation of such therapy is powerful evidence of their effect.

Use of Thionamides. Based on its half-life, methimazole can be prescribed on a once-daily basis. However, the initial dose of methimazole commonly employed in moderate thyrotoxicosis is 20 to 30 mg/day (or the equivalent of carbimazole) until the patient is euthyroid, followed by a maintenance dose of 5 to 10 mg/day. For significantly hyperthyroid patients, a randomized, controlled trial reported that normalization of free T_4 at 3 months occurred more frequently among patients taking higher-dose methimazole (30 mg/day) than among those taking lower doses (15 mg/day).¹⁶⁷

Because of propylthiouracil's well-known rare but serious side effect of hepatic failure, sometimes requiring liver

transplantation, in June 2009 the U.S. Food and Drug Administration (FDA) issued an advisory that propylthiouracil should not be used as a first-line agent for hyperthyroidism in adults or children. Its use is still recommended in the first trimester of pregnancy and in life-threatening thyrotoxicosis or thyroid storm to take advantage of its ability to inhibit peripheral conversion of T_4 to T_3 , and also for those who are intolerant of methimazole.¹⁶⁸ If prescribed, its shorter duration of action requires an equivalent initial propylthiouracil dose of 100-200 mg every 8 hours, depending on the severity of hyperthyroidism, with reduction to a maintenance dose of 50 to 100 mg given two to three times daily as hyperthyroidism ameliorates. When large amounts are required, propylthiouracil should be administered at 4- to 6-hour intervals, although this agent is available only in a 50-mg tablet.

The therapeutic response to effective anti-thyroid therapy invariably occurs after a latent period, because the agents inhibit the synthesis but not the release of hormone; reduction in the supply of hormone to the tissues does not occur until glandular hormone stores are depleted. Although propylthiouracil differs from methimazole in having the additional effect of inhibiting the peripheral conversion of T_4 to T_3 , there appears to be little difference in duration of the latent period for these agents when either is employed alone in the usual dosage. This is because the extrathyroidal effect of propylthiouracil on conversion of T_4 to T_3 is more apparent at dosages greater than 600 mg/day. This effect may be an advantage in the acute treatment of severe hyperthyroidism.^{162,169} In general, improvement within the first 2 weeks includes decreased nervousness and palpitations, increased strength, and weight gain. Usually, the metabolic state becomes normal within about 6 weeks. At that time, the dosage can often be reduced substantially to maintain a normal metabolic state.

During treatment, the size of the thyroid gland decreases in one third to one half of the patients. In the remainder, it may remain unchanged or even enlarge. In the latter situation, the change signals either an intensification of the disease process, which often requires that the dosage of drug be increased, or the onset of hypothyroidism and increased TSH secretion as a result of excessive treatment. It is important to differentiate between these causes. Clinical criteria are not the main guidelines by which adequacy of treatment can be judged. Adequacy of therapy is assessed by measurement of free T_4 in the first several months, when the serum TSH level usually remains suppressed, and then subsequently by TSH assessment. Mild thyrotoxicosis may persist despite a serum T_4 concentration in the normal range because the serum T_3 concentration remains elevated, typically because of intrathyroidal iodine deficiency¹⁷⁰ and the increased T_3/T_4 ratio in Graves' Tg.¹⁷¹ The latter phenomenon may also account for maintenance of a normal metabolic state in the setting of a subnormal serum T_4 level. Importantly, the serum TSH concentration may remain subnormal for many months, perhaps secondary to accelerated conversion of T_4 to T_3 in the pituitary thyrotrophs. An enlarging thyroid gland in a treated patient with Graves' disease may also indicate the presence of a neoplasm and should be investigated appropriately.

Anti-thyroid agents can cause hypothyroidism if given in excessive amounts over long periods. When this occurs, the patient often complains of gain in weight, sluggishness, and fatigue, and signs of mild hypothyroidism may be present. As suggested earlier, one major sign of incipient hypothyroidism is enlargement of the thyroid gland secondary to increased TSH. The hypothyroidism can be

reversed by reducing the dosage of the anti-thyroid drug or by administering supplemental thyroid hormone.

Block-and-Replace Regimens. The logic behind prescribing a full dose of a thionamide drug and adding T₄ supplements to prevent the patient from becoming hypothyroid is twofold. First, in a few patients, the euthyroid state is difficult to maintain with thionamide therapy alone, and a block-and-replace regimen can be helpful and requires fewer office visits. Second, the immunosuppressive action of the thionamides may be helpful in attenuating the natural history of the autoimmune thyroid diseases directly.

Although an initial report found the relapse rate after the block-and-replace approach to be much reduced,¹⁷² subsequent studies found no such difference.^{173,174} One explanation for such disparities may be the iodine status of the various patient groups. In addition, this regimen is associated with a higher rate of side effects.¹⁷⁵

Predicting the Response to Drug Withdrawal. A central question in the treatment of Graves' disease with anti-thyroid drugs is how to determine the appropriate duration of anti-thyroid drug treatment. As discussed earlier, anti-thyroid therapy may alter the course of the underlying autoimmune process, but remission after withdrawal of treatment will persist only if the disorder has entered an inactive phase. This latter transition and the natural decline in levels of TRABs are more likely to occur the longer the course of treatment. This reasoning is the basis for the traditional practice of continuing anti-thyroid treatment for at least 12 months.

Remission rates are reported to be lower in men, older patients, smokers, and those with more active Graves' disease (including those with higher titers of TRABs and larger goiters).¹⁷⁶ Factors preventing a recurrence also include (1) a change from stimulating TRABs to blocking antibodies, which occurs rarely; (2) progression of concomitant autoimmune thyroiditis; and (3) iodine deficiency itself, which may prevent the recurrence of Graves' disease. The persistence of high levels of circulating TRABs during treatment of Graves' disease portends recurrence after withdrawal of anti-thyroid drugs. Whether this is helpful in the management of the individual patient remains controversial,¹⁷⁷ and some have been unable to confirm the predictive value of TRAB measurement in areas of iodine deficiency.

However, most patients do not have persisting high levels of TRAB, and predicting their outcome is even more difficult. Genetic typing, for example using HLA, is still not helpful for such predictions in the individual patient. However, the results of combining HLA with Tg haplotyping are beginning to look impressive in a small number of patients.¹⁷⁸

Anti-thyroid drug therapy usually should be continued for 12 to 18 months and then withdrawn if the serum TSH level returns to normal. Therapeutic duration longer than 18 months does not increase remission rates, according to a meta-analysis.¹⁷⁵ The average rate of remission, as defined by a normal serum TSH level after withdrawal of anti-thyroid therapy, is 30% to 50%; in other words, about 50% of patients relapse or are unable to stop therapy.^{161,179}

About 75% of relapses occur during the first 3 months after withdrawal of therapy, and most of the remainder occur during the subsequent 6 months. Suppression of the TSH concentration below normal levels is the first signal of relapse, even in the presence of a normal serum T₄ level. Nevertheless, about one third of patients experience a lasting remission. This fact alone indicates that anti-thyroid

TABLE 12-4

Incidence of Major Toxic Reactions to Anti-Thyroid Drugs in Adults

Side Effect	Frequency (%)	Comments
Polyarthrititis	1-2	—
ANCA+ vasculitis	Rare	Mostly PTU
Agranulocytosis	0.1-0.5	May be more common with PTU
Hepatitis	0.1-0.2	PTU only
Cholestasis	Rare	Methimazole only

agents have a significant role as the sole therapy in the initial treatment of thyrotoxicosis.

Adverse Reactions. Adverse reactions occur in only a small number of patients taking thionamide drugs, although some can be very severe if left uncared for (Table 12-4). Among the more serious side effects, the one that elicits the most concern is agranulocytosis, which occurs in 0.1% to 0.3% of patients, usually within the first few weeks or months of treatment. Older patients and those taking higher anti-thyroid doses are at higher risk.

Agranulocytosis is accompanied by fever and sore throat.¹⁶¹ When therapy with a thionamide is begun, the patient should be instructed to discontinue the drug and notify the physician immediately should these symptoms develop. This precaution is more important than frequent measurement of white blood cell counts, because agranulocytosis can develop within a day or two. Because of the high frequency of lymphopenia in hyperthyroidism itself, a complete blood count with differential is recommended before anti-thyroid drug therapy is started. If the absolute neutrophil count falls to less than 1500 cells/μL, the drug should be withdrawn. Similarly, if agranulocytosis occurs, the drug should be discontinued immediately and the patient treated with antibiotics as appropriate. Granulocyte colony-stimulating factor may speed the recovery that invariably takes place. Lymphocytes of patients who have developed agranulocytosis while taking propylthiouracil undergo blast transformation when exposed in vitro to propylthiouracil or methimazole; consequently, these patients should not be given a thionamide drug again.

Granulocytopenia occurs during anti-thyroid therapy and is sometimes a forerunner of agranulocytosis, but it can also be a manifestation of thyrotoxicosis itself. Granulocytopenia that develops during the first few weeks of therapy may be difficult to interpret. In this circumstance, serial measurements of the leukocyte count should be made. If they display a downward trend, the anti-thyroid drugs should be discontinued. If serial measurements of the white blood cell count remain constant or return to normal, treatment need not be interrupted.

Propylthiouracil has in rare instances been associated with fulminant hepatic necrosis, and it is the third most common cause of drug-related liver failure, accounting for 10% of all drug-related liver transplantations. Cessation of the treatment results in recovery in most cases. This propylthiouracil-associated liver failure may occur at any time during therapy, so routine monitoring of liver function may not be helpful.¹⁸⁰ Methimazole is associated with cholestasis rather than hepatic necrosis, and the risk is increased with higher doses administered in older patients.¹⁸¹ There are no reported cases of liver transplantation attributed to methimazole toxicity.

Mild side effects occur in up to 20% of patients and include skin reactions, arthralgias, gastrointestinal symptoms, an abnormal sense of taste, and, occasionally, sialadenitis. Other effects include thrombocytopenia, enlargement of lymph nodes, a lupus-like syndrome including the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis,¹⁸² and toxic psychoses. The mechanisms underlying these reactions are not known, although some reactions disappear with continuance of treatment.

It is recommended that patients be informed in writing about the possible side effects and stop the medication and inform their physician if they develop pruritic rash, jaundice, acholic stools or dark urine, arthralgias, abdominal pain, nausea, fever, or pharyngitis. In addition, all patients should have a baseline complete blood count with differential white blood count and liver function tests including transaminases, bilirubin, and alkaline phosphatase. We believe that suspicion of any serious manifestation should be an indication for abandonment of anti-thyroid therapy and recourse to surgery or treatment with iodine ¹³¹I.

Iodide Transport Inhibitors. Both thiocyanate and perchlorate inhibit thyroid iodide transport. Theoretical and practical disadvantages, such as frequent side effects, preclude their use except in special circumstances.

Iodine and Iodine-Containing Agents. Iodine may be administered directly or contained in contrast media used therapeutically. However, iodine is now rarely used as a sole therapy. The mechanism of action of iodine in relieving thyrotoxicosis differs from that of the thionamides. Although quantities of iodine in excess of several milligrams can acutely inhibit organic binding (acute Wolff-Chaikoff effect), this transient phenomenon probably does not contribute to the therapeutic effect. Instead, the major action of iodine is to inhibit hormone release. Administration of iodine increases glandular stores of organic iodine, but the beneficial effect of iodine is evident more quickly than the effects of even large doses of agents that inhibit hormone synthesis. In patients with Graves' disease, iodine acutely retards the rate of secretion of T_4 , an effect that is rapidly lost when iodine is withdrawn.

These features of iodine action provide both disadvantages and advantages. The enrichment of glandular organic iodine stores that occurs when this agent is given alone may retard the clinical response to subsequently administered thionamide, and the decrease in RAIU produced by iodine prevents the use of radioiodine as treatment for several weeks. Furthermore, if iodine is withdrawn, resumption of accelerated release of hormone from an enriched glandular hormone pool may exacerbate the disorder.

Another reason for not using iodine alone is that the therapeutic response on occasion is incomplete or absent. Even if iodine treatment is initially effective, it may lose its effect with time. This phenomenon, which has been termed *iodine escape*, should not be confused with the escape from the acute Wolff-Chaikoff effect (see Chapter 11).¹⁸³ Nevertheless, the rapid slowing of hormone release with iodine treatment makes it more effective than the thionamide drugs when prompt relief of thyrotoxicosis is mandatory.

Aside from its use in preparation for thyroid surgery, iodine is useful mainly in patients with actual or impending thyrotoxic crisis, severe thyrocardiac disease, or acute surgical emergencies. If iodide is used in these circumstances,

it should be administered with large doses of a thionamide. The dose of iodine required for control of thyrotoxicosis is approximately 6 mg/day, a quantity much less than that usually given. Six milligrams of iodine is present in one eighth of a drop of saturated solution of potassium iodide (SSKI) or approximately 1 drop of Lugol's solution; many physicians, however, prescribe 5 to 10 drops of one of these agents three times daily. Although it is advisable to administer amounts larger than the suggested minimal effective dose, huge quantities of iodine are more likely to produce adverse reactions, including iodide myxedema. We recommend the use of a maximum of 2 to 3 drops of SSKI twice daily.

For patients who are so ill that medications cannot be taken by mouth, anti-thyroid agents may be triturated and administered by stomach tube; iodine may be given by the same route, or it can be absorbed through the oral mucosa. If use of a stomach tube is contraindicated, thionamide drugs cannot be administered, because no parenteral preparations are available. In such cases, the disadvantages attendant on administration of iodine may be accepted if the clinical situation is sufficiently serious. Iodine appears to be particularly effective after administration of a therapeutic dose of ¹³¹I for the rapid alleviation of thyrotoxicosis.

Reactions to Iodine. Adverse reactions to iodine are unusual and usually are not serious but may include rash (which may be acneiform), drug fever, sialadenitis, conjunctivitis and rhinitis, vasculitis, and a leukemoid eosinophilic granulocytosis. Sialadenitis may respond to reduction of dosage and the addition of lemon/lime candies to increase salivary flow; if any of the other reactions occur, iodine should be stopped.

Other Anti-Thyroid Agents

Cholecystographic Agents. In doses of 1 g daily, the iodine-containing cholecystographic contrast agent sodium ipodate (or iopanoate) causes a prompt decrease in serum T_4 and serum T_3 concentrations in patients with hyperthyroidism.¹⁸⁴ These effects result from both the release of iodine and the ability of the agent to inhibit peripheral T_3 production from T_4 —a combination that can be useful in the seriously ill patient. As with iodine itself, however, withdrawal of the drug carries the risk of an exacerbation. Supplies of this and related agents are no longer available in the United States.

Lithium. Lithium carbonate also inhibits thyroid hormone secretion but, unlike iodine, it does not interfere with the accumulation of radioiodine. Lithium, 300 to 450 mg every 8 hours, is employed only to provide temporary control of thyrotoxicosis in patients who are allergic to both thionamide and iodide. This is because the blocking effect is often lost with time. The goal is to maintain a serum lithium concentration of 1 mEq/L.¹⁸⁵ Another short-term use for lithium has been as an adjunct to radioiodine therapy, because the drug slows the release of iodine from the thyroid.

Dexamethasone. Dexamethasone, 2 mg every 6 hours, inhibits the peripheral conversion of T_4 to T_3 and has well-known immunosuppressive effects.¹⁸⁶ The inhibitory effect of dexamethasone on conversion of T_4 to T_3 is additive to that of propylthiouracil, suggesting a different mechanism of action. Concurrent administration of propylthiouracil, SSKI, and dexamethasone to a patient with severe, life-threatening thyrotoxicosis effects a rapid reduction in serum T_3 concentration, often to the normal range within 24 to 48 hours.¹⁵⁷

β -Blocking Agents. Drugs that block the response to catecholamines at the receptor site (e.g., propranolol) ameliorate some of the manifestations of thyrotoxicosis and are often used as adjuncts in management. Tremulousness, palpitations, excessive sweating, eyelid retraction, and heart rate decrease; effects are rapidly manifested and appear to be mediated largely through modulation of the increased sensitivity to the sympathetic nervous system induced by excess thyroid hormone (described earlier).^{20,22} Propranolol, but not other β -adrenergic blockers, may also weakly block the conversion of T_4 to T_3 via a mechanism independent of its effect on catecholamine signaling.

Adrenergic antagonists are most useful in the interval before the response to thionamide or radioiodine therapy occurs. They are of limited usefulness in patients with mild to moderate disease but are useful in those with thyrotoxic symptoms and in those with impending or actual thyrotoxic crisis (see “**Thyroid Storm**”). Adrenergic antagonists are especially useful when tachycardia is contributing to cardiac insufficiency. However, the fact that β -adrenergic blockade can reduce cardiac output without altering oxygen consumption can have adverse effects in some organs, such as the liver, where the arteriovenous oxygen difference is already elevated in the hyperthyroid state.²⁹ Moreover, thyroid hormone also has a direct stimulatory effect on the myocardium independent of the adrenergic nervous system.

Propranolol is the most widely used agent because it is relatively free from adverse effects and has a short half-life, allowing for easy control. It can be given orally in a dose of 20 to 40 mg every 6 or 8 hours. For intravenous use, a shorter-acting agent may be preferable (see “**Thyroid Storm**”). Propranolol may be contraindicated in patients with asthma or chronic obstructive pulmonary disease because it aggravates bronchospasm. Because of its myocardial depressant action, it is also contraindicated in patients with heart block and in patients with congestive failure, unless severe tachycardia is a contributory factor. β -Blocking agents such as atenolol or metoprolol are longer-acting drugs that allow a once-daily regimen when treatment is likely to be prolonged.

Surgery

Because of the occasional recurrence of hyperthyroidism after subtotal thyroidectomy, the current surgical procedure of choice for treatment of Graves' disease is a near-total thyroidectomy.

Complications of Surgery. The hazards of thyroidectomy are inversely related to the experience and skill of the surgical team^{187,188}; in experienced hands, the frequency of complications such as permanent hypoparathyroidism and damage to the recurrent laryngeal nerve is low (Table 12-5). Unless circumstances are otherwise compelling, thyroidectomy should not be performed by surgeons who do the operation only occasionally. Bleeding into the operative site, the most serious postoperative complication, can rapidly produce death by asphyxia and requires immediate evacuation of the blood and ligation of the bleeding vessel. Even with subtotal surgery, the recurrent laryngeal nerve can be damaged. If such damage is unilateral, it causes dysphonia that usually improves in a few weeks but may leave the patient slightly hoarse, especially an older patient.

Hypoparathyroidism can be either transient or permanent. Transient hypoparathyroidism results from inadvertent removal of some parathyroids and impairment of blood supply to those that remain. Depending on the

TABLE 12-5

Complications of Surgery in 322 Patients with Graves' Hyperthyroidism in Experienced Hands (1986-1995)

Complication	%
Recurrent hyperthyroidism	2.0
Vocal cord paralysis	
Transient	2.5
Permanent	0.3
Prolonged postoperative hypocalcemia (>7 days)	3.7
Permanent hypoparathyroidism	0.6

Adapted from Werga-Kjellman P, Zedenius J, Tallstedt L, et al. Surgical treatment of hyperthyroidism: a ten-year experience. *Thyroid*. 2001;11:187-192.

severity of these insults, symptoms and signs of hypocalcemia appear, usually within 1 to 7 days after surgery. Severe hypoparathyroidism should be treated with intravenous calcium gluconate. Milder cases can be treated with oral calcium carbonate and calcitriol in doses of 0.25-0.50, one to three times daily.

However, the hypocalcemia that occurs immediately after surgery for thyrotoxicosis may not be caused by transient hypoparathyroidism, because it occurs more frequently in patients with Graves' disease than in those with other thyroid disorders. Instead, it may be caused by “hungry bones,” resulting from the demineralization of bone that occurs in hyperthyroidism. This begins to be reversed after cure of the hyperthyroid state and may contribute to the modest elevation in alkaline phosphatase during recovery unless the patient has been rendered euthyroid for some time before surgery. The treatment of hypoparathyroidism is discussed in Chapter 28, but many surgeons who fear that they have caused damage to the parathyroid glands during a total thyroidectomy may reimplant the apparent parathyroid tissue into local muscles.

Preparation for Surgery. Preoperative use of anti-thyroid agents has greatly decreased the morbidity and mortality rates of surgery for Graves' disease, because these drugs deplete glandular hormone stores and restore the metabolic state to normal. However, these agents do not improve the hyperplasia and hypervascularity of the gland in the short term unless TRAb levels fall. Iodine, however, is reported to cause a decrease in height of the follicular cells, enlargement of follicles with retention of colloid, and reduction of hypervascularity. Hence, the aim of preoperative management is to restore the metabolic state to normal with anti-thyroid agents and then to induce involution of the gland with iodine.^{189,190}

Patients who are to undergo thyroidectomy are first given anti-thyroid therapy in the manner described earlier. Often, relatively large doses are given to hasten the clinical response and because surgical candidates frequently have severe disease or large goiters. In addition, iodide (SSKI, 2 to 3 drops twice daily) should be initiated at least 7 to 10 days before surgery, as iodide decreases thyroid blood flow and vascularity and, hence, intraoperative blood loss during thyroidectomy.¹⁹¹ During this period, a preexisting bruit or thrill may decrease in intensity or disappear entirely, and the gland may become firm.

Several cautions should be observed. No date for surgery should be set until a normal metabolic state has been restored. Much too often, the operation is planned well in advance and the patient is given a standardized regimen

independent of clinical progress. Therapy with iodide should not be started until a normal metabolic state has been restored; iodine should not be relied on to complete an incomplete response to anti-thyroid therapy, because iodide enriches glandular hormone stores if the anti-thyroid drug is not entirely effective. Anti-thyroid agents should not be withdrawn when iodine therapy is begun.

β -Blockade Alone before Thyroid Surgery. Propranolol may be a useful adjunct in controlling signs and symptoms (see earlier discussion) while the patient is being prepared for surgery. However, propranolol has been used alone in preoperative preparation of patients in whom surgery is to be undertaken.¹⁹² Although this mode of therapy is probably safe and effective in many patients with mild disease, thyroid crises can still occur when patients receive propranolol alone. However, there is no compelling indication for the use of propranolol alone. Restoration of the patient to a eumetabolic state, as outlined earlier, is appropriate before subjecting the patient to the stress of surgery.

Radioiodine Therapy

Radioiodine produces thyroid ablation without the complications of surgery. There has been concern that this form of therapy might produce thyroid carcinoma, leukemia, or an increase in thyroid cell mutation rates. However, during the half-century in which radioiodine has been in use, no increased prevalence of thyroid or other carcinoma in treated adults has been noted.¹⁹³ The prevalence of leukemia is also no greater in adults treated with radioiodine, and the frequency of genetic damage in the offspring of patients with prior radioiodine therapy does not appear to be increased. As long as hypothyroidism is treated appropriately, there is no increase in mortality.¹⁹⁴

In view of the lack of evidence of serious toxicity from radioiodine in doses typically employed for treatment of hyperthyroidism in adults, the age limit for use of radioiodine has been lowered progressively by some physicians, from the initial lower limit of 40 years to age 10 or less.¹⁹⁵ However, in childhood, anti-thyroid drugs continue to be the first treatment of choice, and the use of radioiodine in women of reproductive age remains unpopular. Radioiodine use is contraindicated during pregnancy, and fetuses exposed to ¹³¹I after 10 weeks of gestation may be born athyreotic.¹⁹⁶ In addition, ¹³¹I should not be administered for at least 8 weeks after cessation of lactation because it is concentrated in breast milk.

Preparation before Radioiodine Therapy. The use of anti-thyroid drugs before radioiodine treatment is widely used to theoretically decrease a post-treatment increase in thyroid hormone release. This is considered especially dangerous in older patients with ischemic heart disease, in whom cardiac deaths have been reported. Anti-thyroid drugs may also prevent the increase in thyroid autoantibodies that occurs after radioiodine therapy and may affect ophthalmopathy.¹⁹⁷ Normally, such drugs are withdrawn 3 to 7 days before treatment; if needed, they can be reintroduced 7 days after treatment.

Radioiodine Dosing. Attempts have been made to standardize the radiation delivered to the thyroid gland by varying the dose of radioiodine according to the size of the gland, the uptake of ¹³¹I, and its subsequent rate of release (dosimetry). However, such calculations do not provide uniform results, probably because of variations in individual sensitivity, determined perhaps by stimulating TRAbs. A dose of 20 mCi achieves thyroid ablation in

almost all patients and results in hypothyroidism in 75% to 90% of treated patients.¹⁹⁸ Some physicians have settled on an arbitrary dose calculated to result in the delivery of 300 MBq (approximately 8 mCi) of ¹³¹I to the thyroid gland 24 hours after administration.¹⁹⁹ Others aim to deliver 50 to 100 Gy (5000 to 10,000 rad) to the gland. No data support an advantage of dosimetry over a fixed-dose regimen.²⁰⁰

Drug-induced radioresistance has been the subject of much discussion, particularly in relation to propylthiouracil, but it is not a major issue.^{198,201} A meta-analysis reported that methimazole therapy may also be associated with a similar decreased efficacy of radioiodine therapy.²⁰²

¹³¹I administration is contraindicated during pregnancy. A pregnancy test should be carried out in women of child-bearing age before ¹³¹I therapy is initiated if there is any possibility of pregnancy.²⁰³

Treatment after Radioiodine Therapy. Treatment with anti-thyroid drugs after radioiodine therapy should be avoided for approximately 1 week because they also reduce the success of treatment, particularly if nonablative doses are used, via their acceleration of ¹³¹I release.²⁰⁴ Although exacerbation of thyrotoxicosis after radioiodine therapy is rare,²⁰⁵ methimazole use should be considered for patients with severe hyperthyroidism and other comorbidities. Clearly, it is important to monitor serum FT₄ and T₃ levels in at-risk patients and to consider β -adrenergic blockade, whether or not anti-thyroid drugs are used before or after RAI treatment. Patients are seen at 4-week intervals after ¹³¹I administration and monitored by measurements of serum T₄ and TSH levels; hypothyroidism is treated if it appears.

Women who are planning to become pregnant are advised to wait for an arbitrary period of 4 to 6 months after ¹³¹I therapy to allow for resolution of any transient effects of gonadal irradiation and for stabilization of thyroid function.

If, after 6 months, hyperthyroidism is still present and the patient is symptomatic, the treatment is repeated, usually with about 1.5 times the initial dose of ¹³¹I or an ablative amount.

Complications of Radioiodine Therapy

#1—Thyroid Cancer from Low-Level Exposure. There is no increase in thyroid cancer or any other cancer after diagnostic or therapeutic use of radioiodine in hyperthyroid adults,²⁰⁶ in accord with earlier reports.¹⁹³ However, concerns remain about a potentially increased prevalence of thyroid carcinoma in patients treated with low amounts of radiation in childhood or adolescence, as exemplified by the increased prevalence of thyroid cancer among children exposed to the radiation during the Chernobyl incident.^{207,208} In the Chernobyl case, exposure for most of the children who developed thyroid carcinoma was to relatively low doses of radiation rather than the thyrodestructive doses prescribed in hyperthyroidism.²⁰⁹ Nevertheless, many physicians think that the use of radioactivity in children should be avoided whenever possible.

#2—Mortality after Radioiodine. Patients treated with radioiodine for hyperthyroidism had increased mortality compared with age- and period-specific mortality rates in the background population.¹⁹⁴ This effect was not seen in patients rendered hypothyroid. The findings support the idea of treating hyperthyroidism with doses of radioiodine that are sufficient to induce overt hypothyroidism. An association was seen in this study with mortality from ischemic heart disease in patients with subclinical

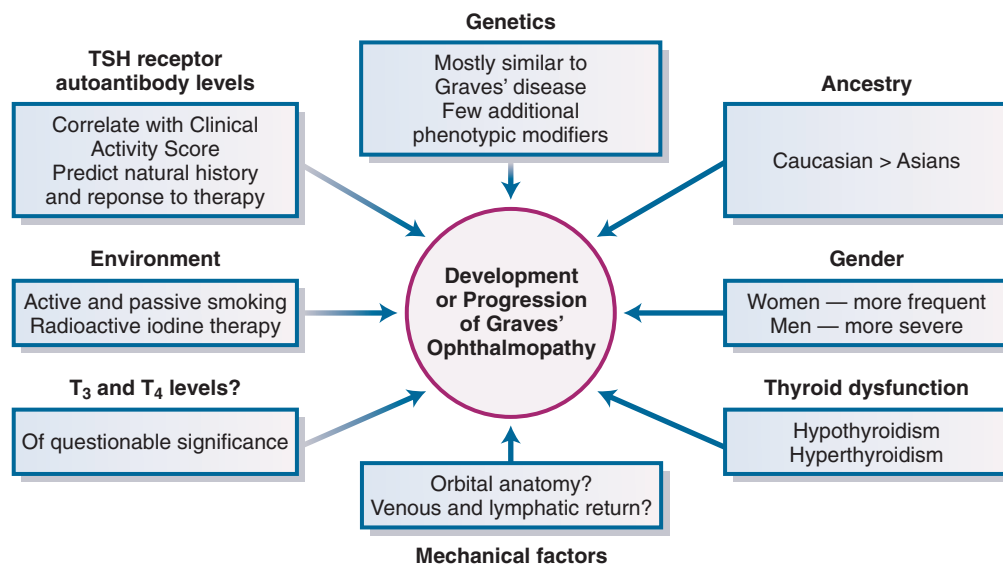

Figure 12-12 Probability of the development or worsening of orbitopathy in patients with Graves' disease. T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone. (From Stan MN, Bahn RS. Risk factors for development or deterioration of Graves' ophthalmopathy. *Thyroid*. 2010;20:777-783.)²¹⁶

hypothyroidism, suggesting that T₄ replacement should be considered if this biochemical abnormality develops after radioiodine therapy.

#3—Hypothyroidism after Radioiodine. In theory, the therapeutic goal of ¹³¹I administration is to induce euthyroidism so that Graves' disease cannot recur. However, the incidence of hypothyroidism is significant during the first year or two after treatment with radioiodine, regardless of how the dose is calculated. The rate continues to increase by approximately 5% per year thereafter, and this actual incidence does depend on the dose of radioiodine prescribed by dosimetry or based on a standard dose.^{200,210} If the dose delivered is sufficient for ablation, permanent hypothyroidism will ensue in more than 80% of patients by 6 months. Many physicians prefer the certainty of induced hypothyroidism rather than the "wait and see" approach.

#4—Radiation Thyroiditis. The early euthyroidism and later hypothyroidism are both consequences of radiation-induced destruction of thyroid parenchyma. With larger doses of radioactive iodine, a tender radiation thyroiditis may develop within the first week after treatment, as evidenced by epithelial swelling and necrosis, disruption of follicular architecture, edema, and infiltration with mononuclear cells. Resolution of the acute phase is followed by fibrosis, vascular narrowing, and further lymphocytic infiltration. These changes account for the early response to radioiodine, whether favorable or excessive.

Radiation thyroiditis may lead to an exacerbation of thyrotoxicosis 10 to 14 days after administration of radioiodine; this occasionally has serious consequences, including precipitation of a thyrotoxic crisis and aggravation of severe thyrotoxicosis or cardiac insufficiency. In patients with thyrocardiac disease, therefore, anti-thyroid drugs should always be given for several months before radioiodine, to deplete glandular hormone stores, and an β -adrenergic blocking regimen should be initiated to limit any potential arrhythmias, if this is appropriate. Anti-thyroid drugs prevent an outpouring of hormone if severe radiation thyroiditis should occur. The anti-thyroid agent

should be withdrawn 3 to 7 days before administration of the radioiodine; if the clinical condition warrants, the agent can be started again 1 week later.

#5—Orbitopathy and Radioiodine. As discussed earlier, Graves' orbitopathy is probably the result of a cross-over specificity between retroorbital and thyroid antigens, including the TSHR itself. Therefore, any worsening of the autoimmune thyroid response might worsen the orbital immune response. After radioiodine therapy, the levels of circulating TRAbs are strikingly elevated,^{57,211} perhaps secondary to impairment of immune restraint caused by the intrathyroidal irradiation that renders regulatory cells more sensitive. This change is in keeping with exacerbation of pretibial myxedema after radioiodine administration.²¹² Similarly, carefully conducted studies indicate that significant eye disease worsens in about 10% of patients with Graves' orbitopathy who are treated with radioiodine (Fig. 12-12),^{213,214} although this may not apply in mild disease.²¹⁵ Deterioration, if any, is usually mild and temporary but on occasion can involve a dramatic worsening.

Some physicians advocate the use of glucocorticoids at the time of radioiodine treatment to prevent such effects.^{141,217} One regimen involves prednisone, 0.4 to 0.5 mg/kg given 1 month before ¹³¹I treatment, with a gradual tapering over 3 to 4 months. However, maneuvers such as careful control of thyroid function before and after therapy and cessation of smoking by the patient may also help minimize ocular changes. We do not advocate the use of radioiodine in patients with severe Graves' ophthalmopathy unless steroid therapy is provided.

#6—Other Side Effects of Radioiodine. Additional hazards may attend the use of radioiodine, particularly in large doses. The parathyroid glands are exposed to radiation in patients treated with radioiodine. Although parathyroid reserve may be diminished in some patients, development of overt hypoparathyroidism is rare. The effect of radioiodine on other tissues that concentrate iodide (e.g., salivary glands, gastric glands, breasts) has often had attention but is not likely to be a problem with the relatively low doses prescribed for Graves' disease compared with the treatment of thyroid cancer.

Choice of Therapy

The choice of therapy for thyrotoxicosis is influenced by the experience of the treating clinician, emotional attitudes, economic considerations, and family and personal issues. Our choice of therapy takes into account the natural history of the disease, the advantages and disadvantages of the available therapies, and the features of the patient's population group. Apart from direct request by the patient, surgery is recommended only when the shortcomings of other modes of therapy are of particular importance, such as in patients with allergy to anti-thyroid drugs, a coincident cold nodule, a very large goiter, or need for a rapid return to normal. Occasionally, in young adults, it is necessary to remove a diffuse toxic goiter because of obstructive symptoms or cosmetic disfigurement. Nevertheless, in the United States, only a small percentage of patients with Graves' disease are now recommended for surgery. The choice, therefore, is among anti-thyroid drugs, radioiodine therapy, or a mixture of both.

In one common approach to therapy in adults, the physician initiates treatment with anti-thyroid drugs in all patients to produce a euthyroid state before reaching a final decision regarding a definitive therapeutic strategy. This allows the patient to return to a euthyroid status as rapidly as possible and provides an estimate of the anti-thyroid drug dose requirement. The magnitude of the drug requirement and the size of the thyroid gland are two of a number of factors considered in the evaluation of the patient with regard to the likelihood of a remission. The options for treatment are explained to the patient during these first months of contact, and individual recommendations are then formulated. This approach allows the establishment of a workable physician-patient relationship, which is especially important in addressing anxieties about the use of radioiodine. Such concerns lead many patients, especially those younger than 50 years of age, to elect a prolonged trial of anti-thyroid drugs before definitive therapy with ¹³¹I.

Anti-thyroid drug therapy may be especially preferable in patients predicted to have a higher rate of remission. Patients with a large thyroid gland, a maintenance thionamide dose requirement of more than 10 mg of methimazole (or carbimazole equivalent), or high titers of TRAb are likely to require prolonged anti-thyroid treatment and should be advised that the chance of spontaneous remission is less than 30%. A therapeutic trial is usually pursued for 12 months if long-term thionamide therapy is selected. One can, in theory, treat forever unless side effects occur.

When a decision in favor of radioiodine is made, ¹³¹I may be prescribed at a dose designed to result in the retention of about 300 MBq (8 mCi) ¹³¹I in the thyroid gland at 24 hours, or an ablative dose (20 mCi) may be prescribed. Radioiodine therapy may be used in young women desiring pregnancy, but they should wait 4 to 6 months after ¹³¹I administration to become pregnant. Because of the possibility of exacerbation of Graves' disease following pregnancy and the transplacental passage of anti-thyroid drugs, it is preferable to ablate the thyroid before conception and to adjust levothyroxine dosages during pregnancy.

Hypothyroidism in the Recently Hyperthyroid Patient

The early onset of hypothyroidism may cause distinct symptoms in the previously thyrotoxic patient after ¹³¹I or surgical treatment or even after high doses of thionamide drugs. Such patients may develop severe muscle cramps, often in large muscle groups such as the trapezius

or latissimus dorsi or the proximal muscles of the extremities. Such symptoms can develop even when the serum hormone levels are only low-normal or slightly decreased and before the serum TSH concentration has risen. It is possible to mistake a symptom such as back or hip pain for an unrelated illness, and the patient should be warned in advance. It is also not unusual for patients to complain of hypothyroid symptoms when thyroid function test results return to the normal range. Such patients appear to have trouble adjusting to normal thyroid hormone levels after being exposed to excessive amounts for long periods. Weight gain is a frequent complaint after recovery from chronic thyrotoxicosis, and patients should be cautioned regarding their diet.²¹⁸

Treatment of Infiltrative Orbitopathy or Infiltrative Dermopathy

Infiltrative orbitopathy varies in severity from the common mild form to a severe form that threatens vision. The latter type is rare and remains difficult to treat, especially if not seen early after disease onset. The natural course of the disorder, which is variable and characterized by exacerbations and remissions, makes conclusions about the efficacy of any treatment difficult.²¹⁹⁻²²¹ A further source of confusion is the variable terminology used to describe the manifestations of orbitopathy and the lack of rigid criteria for defining their severity. Use of a clinical activity score is strongly recommended for everyday clinical practice (see Table 12-3).

Effect of Treatment of the Thyroid Gland on Orbitopathy. The first question that arises is whether different treatments for thyrotoxicosis affect the course of the eye disease differently. Most researchers have found that subtotal or total thyroidectomy and thionamide drug therapy do not influence ophthalmopathy unless they lead to the development of hypothyroidism.^{222,223} However, some experienced investigators have found that total thyroidectomy with thyroid ablation of any remnant favors a better long-term outcome for this disorder.²²⁴ However, hypothyroidism has an adverse effect on the disorder and should be treated fully when it occurs. As discussed earlier, controlled studies suggest that radioiodine treatment can lead to a slight but significant worsening of orbitopathy, and it may be best to avoid radioiodine in patients with severe eye disease. Alternatively, concurrent glucocorticoid therapy may prevent deterioration of orbitopathy after radioiodine therapy, but glucocorticoid therapy may itself cause significant side effects.²²⁵

Symptomatic Treatment. Treatment modalities can be largely symptomatic (useful mainly in the mild form of orbitopathy), or they can attempt to arrest or reverse the progression of the disorder. With milder forms, little treatment is required. The patient who experiences photophobia and sensitivity to wind or cold air can benefit by wearing dark glasses, which also afford protection from foreign bodies. Elevation of the head of the bed at night and instillation of lubricants, such as 1% methylcellulose, may be helpful if the eyelids do not appose completely during sleep. Artificial tears may be used during the day. Because the ophthalmic manifestations tend to be self-limited and progression to a more severe form is uncommon, such measures usually suffice to tide the patient over until the disorder regresses spontaneously.

Glucocorticoids. The appearance of increasing proptosis with inability to appose the eyelids or of severe infiltrative

manifestations such as chemosis warrants the use of more vigorous therapeutic measures. Such changes, even when severe, may respond favorably and rapidly to glucocorticoids. Some physicians use large doses of prednisone (100 mg/day). If improvement occurs, the dose is decreased to the lowest level at which improvement is maintained. The latter dose is still likely to be large, but it is hoped that a halt to the progression or actual regression of the disease will occur before untoward effects make withdrawal of the drug necessary. Other physicians find that much smaller doses of prednisone (20 to 30 mg/day) can be highly effective with rapid reduction to a longer-term maintenance dose (10 to 15 mg/day).

Intravenous methylprednisolone pulse therapy (such as 500 mg initially, then 250 mg weekly for 6 weeks) has been shown to have fewer side effects than high doses of oral prednisone and to have a more rapid onset of effectiveness.^{226,227} However, liver damage has been reported when used doses are excessive (>10 g total), and this approach has not been widely used in the United States.

It is important to protect the patient's bones during corticosteroid treatment, especially with a postmenopausal woman, and this can be achieved with a bisphosphonate drug such as alendronate, 70 mg once a week, in combination with calcium/vitamin D supplements.

External Radiation. The value of external radiation to the retroorbits has been established in some, but not all, clinical trials.²²⁸⁻²³¹ This treatment is steroid-sparing rather than steroid-replacing therapy, and it is said by some to work best in combination with steroids, especially early in the onset of the disorder.¹⁴¹ Whether it is even more effective than prednisone therapy is unclear. Side effects of retroorbital irradiation have included the development of retinal angiogenesis, and the presence of diabetes mellitus is a clear contraindication to this approach. The safe administration of highly collimated supervoltage radiation to the retroorbital space requires experienced personnel and should, in our opinion, be reserved for the early treatment of severe disease. Although periorbital edema may be helped, exophthalmos and ophthalmoparesis are usually minimally affected. There is a clear need for a reliable disease marker to monitor the effects of such treatment.

Orbital Decompression. If glucocorticoid therapy or external radiation (or both) does not halt progression of the disease, or if loss of vision is threatened by ulceration or infection of the cornea or by changes in the retina or optic nerve, orbital decompression can be performed by a variety of techniques.^{232,233} In some patients, desire for a nearly complete cosmetic correction may be such that decompression surgery is the only satisfactory route. This procedure usually involves removal of either the lateral wall or the roof of the orbit or resection of the lateral wall of the ethmoid sinus and the roof of the maxillary sinus. However, the operation often causes or worsens diplopia, and even in the best of hands corrective muscle surgery is necessary later. However, overall results are usually good in 95% of patients, and a reduction of up to 5 mm in proptosis can be achieved. Whenever possible, such surgery should be delayed until the disease becomes less active for fear of further inflammatory activity after the surgery.

Newer Treatments for Graves' Orbitopathy. The search for an immunosuppressive approach to Graves' orbitopathy has been long and tortuous. Without knowing the precise immunopathology, such an approach cannot be disease specific. However, use of an anti-B cell monoclonal

antibody (rituximab) has produced some impressive early results after single-dose treatments.^{234,235} Side effects of this therapy may occur, including the transient induction of retroorbital swelling, which in some patients may threaten vision. Carefully controlled trials will decide whether this approach is suitable for general clinical use.

An Approach to the Treatment of Orbitopathy. We recommend a trial of oral or intravenous glucocorticoid therapy for patients with severe or progressive orbitopathy. If a positive effect is not seen within a few weeks, a course of external irradiation may be attempted in suitable patients if edema predominates. However, oral glucocorticoid therapy may provide an opportune time to treat with radioiodine or to remove the goiter.

Along with these major forms of treatment, local measures should be employed. Ulceration and infection of the cornea should be treated with antibiotics, lubricants, and protective shields. An attempt to appose the eyelids by means of sutures (tarsorrhaphy) should be performed only by an experienced ophthalmologist, because sutures can tear loose and cause scarring.

The management of severe orbitopathy should never be undertaken by the endocrinologist or by the ophthalmologist acting alone. Close, coordinated observation of the effects of medical therapy and the progress of the disease is necessary to determine whether and when surgery is appropriate. Surgery almost invariably halts the progress of the disease and preserves vision if it is performed in time. This decision is influenced by the ability of the available surgical team, because the degree of success of such procedures is proportional to experience.

Treatment of Infiltrative Dermopathy. Treatment of infiltrative dermopathy is necessary as soon as the condition is recognized. The application of a topical, high-potency glucocorticoid preparation with an occlusive dressing may cause regression or disappearance of the lesion.^{236,237} Long-standing untreated dermopathy is more resistant to treatment.

Thyroid Storm (Accelerated Hyperthyroidism)

Thyroid storm or *accelerated hyperthyroidism* is an extreme accentuation of thyrotoxicosis. It is an uncommon but serious complication, usually occurring in association with Graves' disease but sometimes with toxic multinodular goiter in the elderly patient.

Presentation

Thyroid storm is usually of abrupt onset and occurs in patients in whom preexisting thyrotoxicosis has been treated incompletely or not at all. The condition is usually precipitated by infection, trauma, surgical emergencies, or planned operations or, less commonly, by radiation thyroiditis, diabetic ketoacidosis, toxemia of pregnancy, or parturition. The mechanisms by which such factors worsen thyrotoxicosis may be related to cytokine release and acute immunologic disturbance caused by the precipitating condition. The serum thyroid hormone levels in crisis are not appreciably greater than those in severe uncomplicated thyrotoxicosis, but the patient can no longer adapt to the metabolic stress. The clinical picture is one of severe hypermetabolism. Fever is almost invariable and may be severe; sweating is profuse. Marked tachycardia of sinus or ectopic origin and arrhythmias may be accompanied by

*Scoring system: A score of 45 or greater is highly suggestive of thyroid storm; 25-44 is suggestive of impending storm, and <25 is unlikely to represent thyroid storm.

Adapted from Burch HB, Wartofsky L. Life-threatening thyrotoxicosis: thyroid storm. *Endocrinol Metab Clin North Am*. 1993;22:263-277.

pulmonary edema or congestive heart failure. Tremulousness and restlessness are present; delirium or frank psychosis may supervene. Nausea, vomiting, and abdominal pain may occur early in the course. As the disorder progresses, apathy, stupor, and coma may supervene, and hypotension can develop. If unrecognized, the condition can be fatal. This clinical picture in a patient with a history of preexisting thyrotoxicosis or with goiter or exophthalmos (or both) is sufficient to establish the diagnosis, and emergency treatment should not await laboratory confirmation. A clinical score (Table 12-6) may be used to help confirm the diagnosis.²³⁸

Even with this approach, there are no foolproof criteria by which severe thyrotoxicosis complicated by some other serious disease can be distinguished from thyrotoxic crisis induced by that disease. In any event, the differentiation between these alternatives is of no great significance, because treatment is the same in either case.

Treatment of Thyroid Storm

Treatment aims to correct both the severe thyrotoxicosis and the precipitating illness and to provide general support. There are no clinical trials of treatment for accelerated thyrotoxicosis, and opinions vary to some degree on the details, in particular the doses of anti-thyroid drugs that should be used. However, all agree that the patient thought to have thyroid storm should be monitored in a medical intensive care unit during the initial phases of therapy. The therapy itself is designed to inhibit hormone synthesis and release, to antagonize the increased sensitivity to adrenergic stimulation mediated by severe thyrotoxicosis, and to combat the hyperpyrexia.

Large doses of an anti-thyroid agent (up to 400 mg of propylthiouracil every 4 to 6 hours) are given by mouth, by stomach tube, or, if necessary, per rectum. Propylthiouracil is preferable to methimazole because it has the additional action of inhibiting the peripheral as well as the thyroidal generation of T_3 from T_4 by D1, which is the major source of the T_3 .^{162,163,169,239} Administration of propylthiouracil initiates therapy for the postcrisis period and prevents enrichment of glandular hormone stores by iodide, whose administration is of more immediate importance. The latter, administered either as SSKI (3 drops twice daily) or the equivalent as Lugol's solution (10 drops twice daily) (see earlier discussion), acutely retards the release of preformed hormone from the thyroid gland.

Theoretically, propylthiouracil should be administered before iodine to inhibit the synthesis of additional thyroid hormone from the administered iodine. However, because iodide and blocks its own organification through the Wolff-Chaikoff effect, its administration should not be delayed (until the availability of a thionamide) or omitted in the severely toxic patient in the absence of known allergy to iodide per se.

Large doses of dexamethasone (8 mg orally once daily) or hydrocortisone (100 mg every 8 hours) should be given to support the response to stress and to inhibit both the release of hormone from the gland (in conjunction with iodide) and possibly the peripheral generation of T_3 from T_4 (synergizing with propylthiouracil). The combined use of propylthiouracil, iodide, and glucocorticoids can restore the concentration of T_3 to normal within 24 to 48 hours.^{240,241} In the absence of cardiac insufficiency or asthma, a β -adrenergic blocking agent should be given to ameliorate the hyperadrenergic state. Most experience has been with propranolol given at a dose of 40 to 80 mg orally every 6 hours, but a very-short-acting β -adrenergic blocker such as labetalol or esmolol may be safer than propranolol in this situation. High-output congestive heart failure can develop in patients with severe thyrotoxicosis, and a β -adrenergic antagonist may further reduce cardiac output. If β -adrenergic blocking agents are contraindicated, a calcium channel blocker (diltiazem) may be used to slow the heart rate.

Supportive measures include correction of dehydration and hypernatremia, if present, and administration of glucose. Hyperpyrexia should be treated vigorously, and the administration of a wide-spectrum antibiotic is appropriate after blood and urine cultures have been taken. In mild cases, acetaminophen may help, but a cold blanket or ice packs may be required. Salicylates should be avoided because they compete with T_3 and T_4 for binding to TBG and transthyretin (TTR) and therefore increase the free hormone levels.²⁴² In addition, high doses of salicylates increase the metabolic rate. If heart failure or pulmonary congestion is present, appropriate use of diuretics is

TABLE 12-7

Complications of Hyperthyroidism in Pregnancy

Increased and recurrent pregnancy loss
Preterm delivery
Preeclampsia
Fetal growth restriction
Fetal thyroid hyperfunction or hypofunction caused by TRAbs
Fetal goiter from excessive anti-thyroid drug treatment
Neonatal thyrotoxicosis
Increased perinatal and maternal mortality
Potential for decreased IQ of offspring because of excessive use of anti-thyroid drugs

TRAbs, thyrotropin receptor antibodies.

indicated. In patients with atrial fibrillation, the rapid ventricular response requires appropriate blockade of atrioventricular node conduction.

When treatment is successful, improvement is usually manifested within 1 or 2 days and recovery occurs within 1 week. At that time, the dexamethasone can be tapered and plans for long-term management made.

Graves' Disease during Pregnancy and the Postpartum Period

Although it is seen regularly in clinical practice, a truly overactive thyroid gland is uncommon in established pregnancy, affecting approximately 0.2% of pregnant women. This rate is low because fertility is reduced in thyrotoxicosis. Autoimmune responses tend to be suppressed during pregnancy, and Graves' disease, an autoimmune disorder, is the most common cause of thyrotoxicosis in young women.^{130,243} Furthermore, while thyrotoxicosis has a variety of negative influences on fertility itself, it is also associated with increased pregnancy loss and serious medical complications for both the mother and the infant if it should persist^{48,244,245} (Table 12-7). More commonly, a woman who is already under treatment for hyperthyroidism becomes pregnant. Whatever the sequence, pregnancy complicates the diagnosis and treatment of hyperthyroidism in Graves' disease and influences its severity and course.

Influence of Pregnancy on the Immune System

The development of pregnancy and growth of the placenta have profound influences on the immune system, as discussed earlier (see **Risk Factor #5**). The overall suppression of autoimmune responses that occurs is designed to allow the fetus, with its 50% paternal antigens, to survive immune assault.^{243,246} The mechanisms invoked in pregnancy are multiple and include peripheral tolerance mechanisms that deplete fetal reactive cells and inhibition of pathways capable of causing damage after immune activation (Table 12-8). These changes promote maternal-fetal tolerance, but the role of regulatory T cells (which increase in number in pregnancy) and their suppression of maternal responses to the fetus appears to be predominant and long lived.²⁴⁷ It has been shown that a major shift in such T-cell control reduces the effectiveness of all inflammatory T cells.

Fetal Microchimerism

In normal pregnancy, cells pass from mother to child and from child to mother. The presence of fetal microchimerism in parous women has been shown to persist for longer than 20 years,²⁴⁸ indicating complete tolerance for the fetal cells. This is an exaggerated and long-lasting form of

the immunosuppression of pregnancy described earlier. Whether such cells can ever stimulate an immune response as tolerance fades has been the subject of much speculation, fueled by the apparent accumulation of fetal cells at sites of inflammation including the thyroid, but the concept remains unproven.²⁴⁹ However, fetal microchimerism has been associated with Graves' disease-susceptible HLA haplotypes,²⁵⁰ and a failure of fetal tolerance remains a likely contributing mechanism to postpartum thyroid disease.²⁵¹

Thyroid Antibodies in Pregnant Patients with Graves' Disease

The hallmark of the immune effects initiated by the placenta is the fall in secretion of thyroid autoantibodies (TPO-Ab, Tg-Ab, and TRAbs) that is seen in almost all patients as pregnancy progresses.²⁵² This is now considered to be secondary to enhanced regulatory T-cell activity,²⁵³ and it is followed by a rapid increase in autoantibody levels after the immunosuppression is lost in the postpartum period. Assays for TRAbs in the serum of pregnant women with Graves' disease may be of clinical value in selected cases, because a failure of this immunosuppression may indicate potential fetal problems.^{72,254-256}

Because maternal antibodies cross the placenta, there is a correlation between the maternal level of stimulatory TRAbs and the development of fetal thyrotoxicosis. Fetal and neonatal thyrotoxicosis occurs in only 1% of infants of mothers with Graves' disease, and high levels of TRAbs, usually greater than three times the upper normal limit, are correlated with fetal thyroid stimulation.¹²⁸ Pregnant women who are at risk for failure to suppress thyroid autoantibodies include those with more severe hyperthyroidism and those with significant Graves' orbitopathy or infiltrative dermopathy. In addition, prior ablative treatment of the mother with either surgery or radioiodine may not always be accompanied by a reduction in TRAbs. In such cases, the fetus of a treated patient with Graves' disease may still be at risk for development of fetal or neonatal thyrotoxicosis, and the mother may need anti-thyroid drug treatment. The fetus may require monitoring by umbilical cord blood testing and ultrasonography.²⁵⁷

Differential Diagnosis

When mild thyrotoxicosis is present during early pregnancy, it may be a gestational thyrotoxicosis (GTT) that occurs secondary to hCG stimulation of the thyroid gland (see later discussion).²⁵⁸⁻²⁶⁰ When it is more severe, it is usually due to Graves' disease, because toxic multinodular goiters and hot nodules are uncommon in this age group.

TABLE 12-8

Mechanisms of Immunosuppression in Pregnancy Leading to Immune Privilege

Maternal Peripheral Immune System

Regulatory T cells suppress fetal-reactive immune cells.
Sex steroids affect the immune system and negatively regulate B cells.

Maternal-Fetal Interface (Trophoblast-Immune Cell Interaction)

Apoptosis is induced in activated T cells by Fas expression on trophoblast cells.
T-cell proliferation is inhibited by local cytokines and chemokines.
Natural killer cells are inhibited by expression of human leukocyte antigen G (HLA-G).
Complement system is inactivated.

Diagnosis

Pregnancy and hyperthyroidism are both accompanied by thyroid stimulation, a hyperdynamic circulation, and hypermetabolism. Amenorrhea may occur in thyrotoxicosis not associated with pregnancy. In pregnancy, serum TBG levels are increased by estrogen-induced changes in glycosylation that lengthen the half-life. Therefore, in both conditions, the total serum T_4 and T_3 levels are elevated so that the upper limit of the normal range during gestation is about 1.5 times the upper nonpregnant reference limit.¹²⁸ However, serum free T_4 levels, as measured by both analog and equilibrium dialysis methodologies, may actually decrease as pregnancy progresses, and the normal third-trimester reference range for a given assay is significantly less than its nonpregnant reference range.¹²⁸ Serum TSH levels also decrease during normal pregnancy, reaching a nadir between the 8th and 14th gestational week because of stimulation of the thyroid gland by hCG during this interval (GTT), as discussed earlier.

The lower limits for serum TSH levels (95% confidence interval) are 0.06, 0.3, and 0.3 mIU/L, respectively, for the first, second, and third trimesters.²⁶¹ Biochemically, the diagnosis of thyrotoxicosis is confirmed if the serum TSH level is lower than the trimester-specific lower limit and the total or free T_4 level is higher than the normative range for pregnancy (see Fig. 11-12 in Chapter 11). Detection of TRAbs can confirm the diagnosis of Graves' disease, which may or may not be obvious from the clinical history and examination.

Treatment during Pregnancy

Mild hyperthyroidism in pregnancy does not lead to a significant increase in risk for mother or fetus, whereas severe thyrotoxicosis can lead to many complications and endanger both lives. However, the management of hyperthyroidism during pregnancy can be an even greater problem than its diagnosis. Graves' disease can worsen in the first trimester, but the subsequent trimesters have an attenuating influence on the hyperthyroid state because of the immunosuppression associated with pregnancy. Pregnancy is also one of the few clinical situations in which an assay of the biologic activity of the TRAbs is helpful in predicting its potential effect on the newborn.

Anti-Thyroid Drugs. Medical therapy is the method of choice in pregnancy. Because of the usual improvement in the disease, the dosage of anti-thyroid drug required to control the disease in the later phases of pregnancy is usually much less than that which would be required in the same patient were she not pregnant. Overtreatment of the hyperthyroid pregnant woman remains a common but avoidable clinical problem with potentially severe consequences for the fetus, and mild undertreatment should be preferred to hypothyroidism.^{257,262-264} It is imperative for the clinician to understand the therapeutic targets for titrating anti-thyroid drug dosages during pregnancy.²⁶⁵

Certain aspects of placental physiology are relevant to the use of anti-thyroid drugs. Propylthiouracil and methimazole cross the placenta readily and equally well, and they are concentrated in the fetal thyroid. In excess quantity, these agents can cause goitrous hypothyroidism in the fetus.²⁶⁶ Maternal T_4 crosses the placenta (as evidenced by infants born with significant circulating serum T_4 concentrations despite congenital hypothyroidism), and this is the major source of fetal thyroid hormone before functional development of the hypothalamic-pituitary axis in the fetus is complete (at about 20 weeks' gestation).

Transplacental passage of maternal TRAbs in the latter half of pregnancy can result in fetal thyroid stimulation. Therefore, the fetal thyroid is subject to the same factors that influence maternal thyroid hormone production.

Until recently, the anti-thyroid drug of choice throughout pregnancy in the United States was propylthiouracil because of the rare embryopathy (including aplasia cutis and choanal atresia) thought to be associated with methimazole.^{262,267-269} However, because of the rare but serious side effect of hepatic failure, in June 2009 the FDA issued an advisory that propylthiouracil should be reserved for the first trimester of pregnancy, while organogenesis is occurring.¹⁶⁸ Subsequently, methimazole should be prescribed. One must keep in mind that the therapeutic anti-thyroid potency ratio of methimazole to propylthiouracil is at least 15:1. A patient who requires only 50 mg of propylthiouracil in the first trimester may not even require a thionamide during the remainder of pregnancy.

The therapeutic target for a pregnant Graves' patient is a healthy infant, meaning one with subclinical hyperthyroidism analogous to the normal gestational physiology of the first trimester.²⁶⁵ This is associated with the lowest impact on fetal thyroid function and the highest rate of normal neonatal thyroid hormone levels.²⁷⁰ The maternal serum free T_4 level should be maintained at or just above the upper normal *nonpregnant* range, and no attempt should be made to normalize the serum TSH concentration. However, it is the clinical status of the patient that is the most important indication for treatment or increases in dosage. A modest tachycardia is a physiologic response to the increased metabolic demands of pregnancy, and pulse rates of 90 to 100 are well tolerated without evidence of myocardial decompensation during delivery. The natural amelioration of Graves' disease in the third trimester should be kept in mind. Repeated attempts should be made to reduce or discontinue the thionamide as the delivery date approaches to avoid TSH-induced goiter in the newborn, which could cause asphyxia (see Fig. 11-11 in Chapter 11). A block-and-replace strategy is therefore not appropriate for thionamide therapy in the pregnant patient. The serum TSH concentration should be monitored monthly, more to avoid inadvertent overtreatment rather than as the target for normalization.

All pregnant patients with significant Graves' disease should be managed in close cooperation with obstetricians who are experienced with modern techniques for monitoring the fetus for intrauterine thyroid dysfunction. These techniques include fetal heart rate monitoring and ultrasonographic assessment of fetal growth rate. With advanced ultrasonography, it is usually possible to examine the fetus for the presence of goiter. Convincing evidence of fetal hyperthyroidism may be an indication to consider another approach. In a compliant patient, a dose requirement in excess of 300 mg/day of propylthiouracil is a reasonable threshold for considering subtotal thyroidectomy, preferably in the second trimester. However, transplacental passage of TRAbs may also cause fetal enlargement, although 50 to 100 mg of propylthiouracil is usually sufficient to treat this condition because it is transferred transplacentally.²⁷¹

Iodide and β -Blockers. Obviously, therapeutic radioiodine is contraindicated in pregnancy, although no harm has been found after diagnostic doses of ^{123}I .²⁰³ Iodide itself should also not be used as therapy for longer than 2 to 3 weeks in the pregnant woman, because it readily crosses the placenta and can induce a large goiter that could cause airway obstruction in the newborn (see Fig. 11-11 in

Chapter 11). Large amounts of iodide are contraindicated in the last month of pregnancy but can be used at earlier times in emergent situations. Whether propranolol or other β -blockers should be used in the pregnant woman with hyperthyroidism has been a matter of debate. In the experience of some, it can cause intrauterine growth retardation, delayed lung development, and neonatal hypoglycemia or depression,²⁷² but large studies have suggested that it can be employed with safety for short periods or at very low doses.²⁷³ Low doses of iodine have been used in pregnancy but only when all other approaches are contraindicated.²⁷⁴

Surgery. Surgery during the first and third trimesters is not desirable because of the possible induction of early pregnancy loss or later premature labor, respectively. Surgery may be successful during the second trimester, but it is best to avoid major surgery during pregnancy if possible. Nevertheless, if anti-thyroid drug requirements are very high or cannot be used, surgery may be indicated. Iodide can be given for 7 to 10 days to aid in patient preparation for those with large and highly vascular thyroid glands.

Consequences of Overtreatment. The influence of maternal hypothyroidism on fetal brain development and the subsequently reduced IQ of the children of hypothyroid mothers is discussed elsewhere (see Chapter 13).²⁷⁵ Overuse of anti-thyroid drugs in pregnancy could potentially lead to the same consequences. There is considerable evidence that many pregnant patients with Graves' disease are overtreated as far as the fetus is concerned, as evidenced by transiently elevated serum TSH levels on newborn screening tests.²⁷⁶ This is another reason why one should accept a slightly hyperthyroid rather than a slightly hypothyroid maternal status.

Graves' Disease in the Postpartum Period

Postpartum thyroiditis with transient thyrotoxicosis due to thyroid-cell destruction may occur in 5% to 10% of patients during the first 4 to 12 months after delivery.²⁷⁷ Rapid return of hyperthyroidism is less common.

Changes in the Immune Response in the Postpartum Period. As discussed earlier, pregnancy induces a variety of immune changes that are responses to the paternal foreign antigens so that the fetus is not rejected. These changes include enhanced regulatory T-cell influences and a T-cell shift from Th1 to Th2. They result in an overall decrease in all autoimmune responses, as evidenced by marked decreases in thyroid autoantibodies. After delivery, these immune changes are slowly lost, and a return to normal is observed, but only after a period of exacerbated autoimmune reactivity in which large increases in T-cell and autoantibody activity occur. It is at this time—3 to 12 months postpartum—that new-onset or recurrent thyroid thyrotoxicosis is seen. Such thyroid dysfunction may be transient or permanent.

Presentation of Postpartum Graves' Disease. A high percentage of women in the 20- to 35-year age group give a history of pregnancy in the 12 months before the onset of Graves' disease.^{132,278} Pregnancy and the postpartum state also apparently influence the course of preexisting Graves' disease. Patients who are in clinical remission during pregnancy are prone to postpartum relapse. Seventy-eight percent of 41 pregnancies in 35 patients in remission were followed by development of thyrotoxicosis during the postpartum period. The patients with Graves' disease and

postpartum thyrotoxicosis were classified into three categories. Some had persistent recurrent hyperthyroidism with an elevated RAIU (classic Graves' disease). Some had a transient disorder associated with a normal or an elevated RAIU (transient Graves' disease). Some patients, especially those with the highest titers of TPO-Ab, experienced a transient thyrotoxicosis with a decreased RAIU (the thyrotoxic phase of postpartum thyroiditis). This phase, in turn, may be followed by a hypothyroid phase.¹¹⁹

The Desire for Pregnancy. A special problem related to hyperthyroidism and pregnancy is presented by the patient who wishes to conceive in the near future and is in early remission after a course of anti-thyroid drug treatment or is being treated with anti-thyroid agents for active Graves' disease. In the first scenario, anti-thyroid drugs can be reintroduced, if required, during pregnancy to treat recurrence of symptomatic thyrotoxicosis. In the second situation, definitive therapy (radioiodine or surgery) should be considered to forestall the complexities of managing hyperthyroidism during pregnancy. As with the treatment of Graves' disease in general, such decisions must involve education of the patient so that the risks and benefits of the various alternatives are clearly appreciated.

Nursing and Anti-Thyroid Drugs. Older studies suggested that relatively more methimazole than propylthiouracil appeared in breast milk of women receiving these drugs, but more recent evidence showed little difference between them.^{266,279} However, women who take anti-thyroid drugs are advised not to nurse their infants because of the difficulty in monitoring thyroid function in infants. No serious drug side effects have been reported in neonates whose mothers were taking anti-thyroid drugs, although periodic tests of neonatal thyroid function may be appropriate in women taking very high doses.²⁸⁰

INHERITED NONIMMUNE HYPERTHYROIDISM

Toxic diffuse thyroid hyperplasia without the pathologic characteristics of autoimmune disease has been reported in families and appears to be inherited as an autosomal dominant condition.^{53,281,282} Polymorphic genomic mutations in the TSHR gene have been reported to cause constitutively activated TSHRs differing from family to family. Recessive mutations on both chromosomes have also been described as causing hyperthyroidism while the parents remained euthyroid. These gain-of-function mutations, mostly in the transmembrane regions of the TSHR, are similar to those somatic mutations seen in toxic adenomas but are in the germline.²⁸³ Treatment is by radioiodine ablation or thyroidectomy, depending on the age of the patient.

TOXIC MULTINODULAR GOITER

Toxic multinodular goiter is a disorder in which hyperthyroidism arises in a multinodular goiter, usually one of long standing. It is the result of one of several pathogenetic factors.²⁸⁴

Pathogenesis

The pathogenesis of toxic multinodular goiter cannot be considered apart from that of its invariable forerunner, nontoxic multinodular goiter, from which it emerges

slowly and insidiously. Two hallmarks of the disorder, structural and functional heterogeneity and functional autonomy, evolve over time. The increase in the extent of autonomous function causes the disease to move from the nontoxic to the toxic phase, but the mechanisms of this change in all cases are uncertain. The somatic mutations in the TSHR gene demonstrated in toxic adenomas have been demonstrated in some cases of toxic multinodular goiter and appear to differ from nodule to nodule.²⁸⁵ However, only about 60% of toxic nodules have TSHR mutations, and only a very few have G-protein mutations. Hence, there are many nodules with autonomy of undetermined cause.²⁸⁶

Radioiodine scintiscans show localization of isotope in one or more discrete nodules, whereas iodine accumulation in the remainder of the gland is usually suppressed. No further suppression is produced by exogenous thyroid hormone, but TSH stimulates iodine uptake in the previously inactive areas, indicating that the suppression is due to lack of TSH. Histopathologically, the functioning areas resemble adenomas in that they are reasonably well demarcated from surrounding tissue. They usually consist of large follicles, sometimes with hyperplastic epithelium, but here, too, architecture correlates poorly with functional state. The remaining tissue appears to be inactive, and zones of degeneration are present in both functioning and nonfunctioning areas. Therefore, from the pathophysiologic standpoint, these thyroids harbor multiple solitary hyperfunctioning and hypofunctioning adenomas interspersed by suppressed normal thyroid tissue.

Clinical Presentation

The overproduction of thyroid hormone in toxic multinodular goiter is usually less than that in Graves' disease. First, the clinical manifestations of thyrotoxicosis are rarely flagrant. Second, the serum T_4 and T_3 concentrations may be only marginally increased, and a suppressed TSH may be the major abnormality. Finally, the total RAIU is only slightly increased or within the normal range. The mildness of the hyperthyroidism is consistent with either of its presumed pathogenetic origins.

Toxic multinodular goiter is a common complication of nontoxic multinodular goiter, but its precise incidence is unknown. Toxic multinodular goiter usually occurs after the age of 50 in patients who have had nontoxic multinodular goiter for many years; such patients often live in regions of iodine deficiency.²⁸⁷ Like its forerunner, toxic multinodular goiter is many times more common in women than in men. Sometimes, hyperthyroidism develops abruptly, usually after exposure to increased quantities of iodine, which permits autonomous foci to increase hormone secretion to excessive levels and which may simply exacerbate already established mild hyperthyroidism (see "[Iodine-Induced Hyperthyroidism](#)"). In addition, Graves' disease may manifest or develop in a multinodular gland, as confirmed by the presence of TRAbs of the stimulating variety. Toxic multinodular goiter is almost never accompanied by infiltrative ophthalmopathy; when the two do coexist, it represents the emergence of Graves' disease.

Cardiovascular manifestations tend to predominate, possibly because of the age of the patients, and include atrial fibrillation or tachycardia with or without heart failure. Weakness and muscle wasting are common—the so-called apathetic or masked thyrotoxicosis. The nervous manifestations are less prominent than in younger patients with thyrotoxicosis, but emotional lability may be pronounced. Because of the physical characteristics of the

thyroid gland and its frequent retrosternal extension, obstructive symptoms are more common than in Graves' disease. On palpation, the characteristics of the goiter are the same as those of the more common nontoxic multinodular goiter. In as many as 20% of elderly patients with thyrotoxicosis, the thyroid gland is firm and irregular but not distinctly enlarged. Ultrasound examination will confirm the diagnosis as toxic multinodular goiter rather than a single toxic adenoma or Graves' disease.

Laboratory Tests and Differential Diagnosis

All patients with a multinodular goiter should be screened annually by measurement of serum TSH. If TSH is suppressed, the free T_4 (or if TSH is normal, the free T_3) should be determined. Serum TSH levels intermediate between 0.1 and 0.4 mU/L are not usually associated with significant symptoms. Such patients have thyroid autonomy but are not thyrotoxic (see "[Subclinical Hyperthyroidism](#)"). For patients with established thyrotoxicosis, an RAIU scintiscan study will help in gauging the dose of ^{131}I to be administered and will identify the autonomously functioning nodules. The latter can then be treated with ^{131}I .

Treatment

Radioiodine may be the treatment of choice for patients with toxic multinodular goiter despite disagreement about the size and number of doses required to achieve a therapeutic response.^{284,288} We attempt to deposit about 12 to 14 mCi into the gland at 24 hours, based on a pretreatment RAIU. In the United States, iodine intake is higher than in many regions in Europe, so that 24-hour RAIU values of 20% to 30% are not unusual. Such patients require 50 mCi or more to restore a euthyroid state and may even require a second treatment.

Because a number of patients with this disorder have underlying heart disease, the administration of radioiodine should be preceded by a course of anti-thyroid therapy with methimazole until a eumetabolic state is achieved. Medication is then discontinued for at least for 4 to 7 days before radioiodine is administered. One week later, the anti-thyroid drug is reinstituted, so that the thyrotoxicosis will be controlled until radioiodine takes effect, which typically requires 3 to 4 months. A decrease in size of the hyperfunctioning nodules is a positive sign. After that occurs, the anti-thyroid drug can be tapered, but if the TSH level remains lower than 0.1 mU/L after 6 months, a second dose may be considered.

Surgical therapy is often recommended after adequate preoperative preparation in patients with obstructive manifestations. In these patients, a CT or MRI study is recommended to define the extent of the goiter and the adequacy of the tracheal walls. Respiratory function studies may also be helpful in assessing the need for surgery. Patients with fixed, especially partially retrosternal, goiter should be considered for therapy because of the risk of more complete obstruction should hemorrhage into a nodule occur. However, if surgery is contraindicated, even significant obstructive symptoms can be relieved by adequate radioiodine therapy.²⁸⁹

TOXIC ADENOMA

A third, less common form of hyperthyroidism is caused by one or more autonomous adenomas of the thyroid gland. As used here, the term *toxic adenoma* refers to a

tumor in a thyroid that is otherwise intrinsically normal. The disorder is usually caused by a single adenoma that is either palpable or seen on ultrasound as a solitary nodule; hence, it is sometimes referred to as *hyperfunctioning solitary nodule* or *toxic nodule*. Occasionally, two or three adenomas of similar character are present.

Pathogenesis

Toxic adenomas are true follicular adenomas (for histopathologic characteristics, see Chapter 14). The basic pathogenesis in many cases is one of several somatic point mutations in the TSHR gene, commonly in the third transmembrane loop. These single-nucleotide substitutions cause amino acid changes that lead to constitutive activation of the TSHR in the absence of TSH.²⁹⁰ The TSHR appears to be “tripped” from an “off” state to an “on” state. Similarly, loss-of-function rather than gain-of-function mutations may occur in the TSHR gene and cause hypothyroidism (see later discussion). A small number of autonomous adenomas have mutations in G-protein genes that lead to a similar state of constitutive activation.²⁸⁶

Clinical Presentation

The toxic adenoma often manifests as a nodule in a patient with a suppressed TSH; on ultrasonography, it appears as a single hypoechogenic nodule. A radioiodine thyroid scan shows a localized area of increased radioiodine accumulation (Fig. 12-13). This condition occurs in a younger age group than does toxic multinodular goiter, typically in patients in their 30s or 40s.

Frequently there is a history of a long-standing, slowly growing lump in the neck. It is unusual for adenomas to produce thyrotoxicosis until they have achieved a diameter

Figure 12-13 Radioiodine (^{123}I) thyroid scan shows a hyperfunctioning hot nodule corresponding to physical examination findings with a faint outline of the remaining suppressed gland. In this unusual case, Graves' disease developed a few months later after an oral contrast agent load. (From Soule J, Mayfield R. Graves' disease after ^{131}I therapy for toxic nodule. *Thyroid*. 2001;11:91-92.)

greater than 3 cm.²⁸⁴ Up to that point, patients have subclinical hyperthyroidism. The adenoma can undergo central necrosis and hemorrhage, spontaneously relieving the thyrotoxicosis, and the remainder of the thyroid may resume its function. Calcification in the area of hemorrhage may take place and may be evident on sonographic examination. Such calcification is usually macroscopic and irregular and does not resemble the finely stippled calcification that is suggestive of papillary cancers. The peripheral clinical manifestations of a toxic adenoma are usually milder than those of Graves' disease and are notable for the absence of infiltrative orbitopathy and myopathy, although cardiovascular manifestations may occur.

Laboratory Tests

The results of laboratory tests depend on the stage and function of the adenoma. At first, serum thyroid hormone concentrations are normal except for borderline suppression of the serum TSH. This finding, together with ultrasound examination to exclude multiple nodules, confirms the diagnosis. Later, a thyroid scan may show localization of radioisotope in the palpated nodule, but this does not occur until TSH secretion is suppressed. If the nodule continues to grow, frank hyperthyroidism develops, accompanied by elevation of serum thyroid hormone levels. Occasionally, the serum free T_4 concentration is normal and only the serum T_3 level is increased (T_3 thyrotoxicosis). Incidental thyroid carcinoma may rarely coexist within a gland exhibiting a hyperfunctioning adenoma, although autonomous malignant nodules causing functional hyperthyroidism are very rare.

Treatment

Hyperfunctioning adenomas may eventually cause clinical hyperthyroidism, but many do so slowly, and others not at all.²⁸⁴ Therefore, treatment of asymptomatic patients with functional adenomas is decided on an individual basis. Clinically euthyroid subjects who wish to avoid both surgery and radioiodine therapy may be monitored with annual TSH measurements. However, suppression of TSH below normal, particularly to less than 0.1 mU/L, indicates hyperthyroidism, and therapy may be warranted. Two definitive therapies are available: radioiodine and surgery.

Radioiodine

In terms of the specificity of treatment, functioning thyroid nodules are good candidates for radioiodine therapy. In theory, the radiation should be directed almost exclusively to the diseased tissue, because TSH is suppressed and the normal thyroid tissue surrounding the nodule does not take up radioiodine. However, this suppression may be incomplete, and a significant fraction of patients receiving ^{131}I develop thyroid failure. For the patient older than 18 years of age with a nodule 5 cm in diameter or smaller, ^{131}I is an appropriate treatment if the risk of eventual hypothyroidism is acceptable to the patient. For such lesions, doses of radioiodine are given sufficient to result in the presence of 300 to 370 MBq (8 to 10 mCi) in the nodule at 24 hours based on the uptake.²⁸⁴ Because of the potential for hypothyroidism, prolonged follow-up is mandatory.

Surgery

Toxic nodules are readily treated by surgical excision. A hemithyroidectomy may avoid the long-term development of hypothyroidism, and with modern surgical

procedures it can be performed on an outpatient basis or even with the use of local anesthesia. Surgical excision may be preferable in patients who are younger than 18 years of age because it avoids the long-term consequences of irradiation, including effects on perinodular tissue. Because toxic adenoma is not diffusely hypervascular, preoperative preparation with iodine is not required. In the patient with overt thyrotoxicosis, however, a normal metabolic state should be restored with the use of an anti-thyroid drug before surgery.

SUBCLINICAL HYPERTHYROIDISM

Definition

As mentioned in Chapter 11, the availability of sensitive assays for TSH has allowed recognition of a syndrome, *subclinical hyperthyroidism*, in which there are no signs or symptoms of thyrotoxicosis but the serum TSH is subnormal despite normal serum free thyroid hormone concentrations. Although the term is somewhat of a misnomer because it is defined by biochemical characteristics, all endocrinologists have a concept of what it means. Nonetheless, the classification of a patient as having subclinical hyperthyroidism may simply reflect the fact that the detection of physiologic evidence of excess thyroid hormone on a chronic basis is less sensitive than measurements of TSH. The situation is further complicated by the fact that the hypothalamic-pituitary axis is sensitive to both serum free T_4 and T_3 , whereas the peripheral tissues (e.g., heart) primarily sense the free T_3 (see Chapter 11).^{291,292}

Given the wide normal range for free thyroid hormone concentrations, it is easy to assume that an individual with a low-normal free T_4 set point for TSH secretion would have a reduced TSH level if that set-point concentration were exceeded by 50% but still remained within the normal range. In fact, in patients with primary hypothyroidism and normal TSH, small additional quantities of levothyroxine decrease TSH below normal without producing a supra-normal free T_4 .²⁹¹ On the other hand, in the now classic studies in the Framingham population of patients older than 60 years of age, the cumulative incidence of atrial fibrillation over 10 years was 28% in patients with a serum TSH concentration of 0.1 mU/L or less but only 11% in those with serum TSH concentrations between 0.1 and 0.4 mU/L—just slightly higher than the incidence in the normal population.^{10,11} Other studies have shown similar results.^{293,294}

Bone density is another end point for such studies, because it is well known that thyroid hormone causes a net resorption of cortical bone. Several studies have demonstrated lower bone density in patients with *subclinical thyrotoxicosis*, although others have not.⁴⁰ These results illustrate the conundrum of the term “subclinical,” because, by definition, such patients should not have any clinical abnormalities associated with thyrotoxicosis.²⁹⁵

This is a subject of considerable interest, because the condition is much more common than overt thyrotoxicosis (e.g., 0.7% of the population in NHANES III) and has broad implications with respect to the cost of diagnosis, treatment, and follow-up.⁵⁹ In general, normalization of thyroid function in postmenopausal women with subclinical hyperthyroidism seems to improve bone density and certain aspects of cardiac function.²⁹⁶⁻²⁹⁸ These data would generally favor treatment in the older population, but there are no large, long-term, randomized studies to allow evidence-based conclusions as to the risk/benefit ratio.

TABLE 12-9

Indications for Treatment of Persistent Subclinical Hyperthyroidism

Postmenopausal osteoporosis
Rheumatic valvular disease with left atrial enlargement or atrial fibrillation
Recent-onset atrial fibrillation or recurrent cardiac arrhythmias
Congestive heart failure
Angina pectoris
Infertility or menstrual disorders
Nonspecific symptoms such as fatigue, nervousness, depression, or gastrointestinal disorders, especially in patients older than 60 years of age (consider therapeutic trial)

Diagnosis

The diagnosis of subclinical hyperthyroidism requires tests revealing several subnormal TSH concentration results spaced months apart in the presence of normal free T_3 and T_4 concentrations. Several studies have shown that suppressed TSH can normalize spontaneously over several years, particularly in patients without nodular goiter.^{299,300} As with overt thyrotoxicosis, there are two sources of excess thyroid hormones: endogenous and exogenous. In a study of more than 25,000 individuals attending health fairs in Colorado, 58% of those with a TSH level lower than 0.3 mU/L were receiving thyroid hormones.³⁰¹ If thyroid hormones are not being administered intentionally for treatment of persistent thyroid carcinoma, thyroid hormone excess is easily treated by more careful monitoring of the levothyroxine dosage using serum TSH concentrations. Endogenous subclinical thyrotoxicosis has the same causes as in overt thyrotoxicosis (see earlier discussion). In the population older than 60 years of age, multinodular goiter is a more likely cause of hyperthyroidism than it is in younger individuals.

Treatment

There are insufficient data to conclude that individuals with serum TSH concentrations greater than 0.1 mU/L due to hyperthyroidism will benefit from treatment.³⁰² In considering the decision for or against treatment of persistently subnormal TSH concentrations (i.e., <0.1 mU/L with normal free thyroid hormone concentrations), an evaluation should be made for conditions that may benefit from treatment (Table 12-9) as well as to determine the cause of the hyperthyroidism. In elderly persons, postmenopausal osteoporosis and various cardiac diseases are the primary indications for which treatment should be considered. Infertility and menstrual disorders are important in young women.

Identifying the cause of the hyperthyroidism allows assessment of the potential risks of treatment. At one extreme, the treatment of mild Graves' disease with radioiodine usually causes hypothyroidism, whereas this typically does not occur in patients with multinodular toxic goiter. Therefore, in an asymptomatic patient with mild Graves' disease, watchful waiting for a possible spontaneous remission for several years may be the best course of action.³⁰⁰ On the other hand, patients with subclinical hyperthyroidism due to toxic nodular goiter or a solitary hyperfunctioning adenoma can often be treated with a single dose of radioactive iodine with a relatively low risk of subsequent hypothyroidism. Therefore, the threshold for treatment of such patients is lower. As always, the

rationale for treatment and its risks and benefits should be carefully discussed with the patient, and one should be guided by common sense and not by the principle of simply treating an abnormal test result.³⁰³⁻³⁰⁵

IODIDE-INDUCED HYPERTHYROIDISM

Administration of supplemental iodine to subjects with endemic iodine deficiency goiter can result in iodine-induced Graves' disease. This response, termed *iodide-induced hyperthyroidism* or the *Jod-Basedow* effect (*Jod* is derived from the German word for "iodine"), occurs in only a small fraction of individuals at risk. The term *Jod-Basedow* specifically refers to iodine-induced von Basedow's (Graves') disease but is often used to refer to iodine-induced hyperthyroidism of any type.

There are two major patterns of the underlying thyroid disorder.³⁰⁶ In the first, which is common in older individuals, a nodular goiter with areas of autonomous function is present, and TRAbs are not detectable in the blood. The second pattern occurs in younger individuals with diffuse goiter, in whom stimulating TRAbs are often present. These findings indicate that *Jod-Basedow* occurs in thyroid glands in which thyroid function is independent of TSH stimulation. The occurrence of *Jod-Basedow* is not a contraindication to treatment of endemic iodine deficiency. Apart from the many other benefits that accrue from iodine treatment and prophylaxis, over the long run the frequency of spontaneous hyperthyroidism due to toxic nodular goiter is diminished.²⁸⁷

Iodide-induced hyperthyroidism is an important disorder in areas of the world in which dietary iodine intake is high.³⁰⁷ In regions in which iodine intake is marginal but overt iodine deficiency is absent, moderate increments in iodine intake may induce hyperthyroidism in patients with autonomous thyroid nodules. Consequently, the physician must be alert to the possibility of inducing hyperthyroidism when administering iodine in expectorants, x-ray contrast media, medications containing iodine (e.g., amiodarone), povidone iodine, or any other form to patients with nodular goiter.^{308,309} Because nodular goiter is generally a disease of the elderly, induction of the *Jod-Basedow* phenomenon can have serious consequences, because enrichment of the thyroid with iodine forestalls administration of ¹³¹I and delays the response to anti-thyroid agents. Prevention of an acute exacerbation may be achieved by pretreatment of at-risk subjects with methimazole starting before exposure and for several weeks afterward.^{310,311}

Although the *Jod-Basedow* phenomenon can occur only when the thyroid is partially autonomous, patients with iodine-induced hyperthyroidism have been reported in whom thyroid function was normal and normally suppressible after iodine was withdrawn and a euthyroid state restored. The mechanism by which iodine induces thyrotoxicosis in such instances is unknown. The treatment in these cases can be difficult. Even after discontinuation of exogenous iodide, the uptake of ¹³¹I by the thyroid gland may remain low, not adequate for conventional doses of radioiodine. The elevated thyroid hormone content secondary to the iodide level also makes thionamide drugs less effective. It may be necessary to treat such individuals for prolonged periods (6 to 9 months) before administering radioiodine. On the other hand, if uptake is detectable, larger doses of radioiodine may be given to destroy thyroid tissue, or the use of recombinant TSH may be entertained.

Amiodarone

The drug most commonly associated with iodine-induced thyrotoxicosis is amiodarone. This iodine-rich drug has become increasingly popular because of its effectiveness in combating severe cardiac arrhythmias. However, its use has been limited by toxicity due to its high fat solubility and high iodine content inducing thyroid disease and by pulmonary fibrosis and liver disease.

Amiodarone has complex effects on the thyroid, although the majority of patients (about 80%) remain euthyroid.³¹² Structurally, the drug resembles T₄ (see Fig. 11-6 in Chapter 11) and contains 37% iodine by weight. Of the 75 mg of iodine present in a 200-mg tablet, about 6 mg of iodide is released per day. In contrast, the typical daily iodine supply in North America is about 150 to 200 µg. Amiodarone has a half-life of 50 to 60 days and therefore remains available for a long period even after drug withdrawal. In addition to providing huge amounts of iodide, amiodarone inhibits the D1 and probably D2 deiodinases and may compete with T₃ for binding to the thyroid hormone receptor. Amiodarone also has a direct cytotoxic effect on thyroid cells via induction of apoptosis.³¹³ In addition, the iodine load, the drug, or its metabolites may precipitate autoimmune thyroid disease in susceptible individuals.

A new drug, dronedarone, is a benzofuran derivative related to amiodarone. In dronedarone, the iodine moieties have been removed to reduce the toxic effects on the thyroid and other organs; and a methylsulfonamide group has been added to reduce solubility in fats. Dronedarone continues to display amiodarone-like class III anti-arrhythmic activity in vitro and in clinical trials.³¹⁴ Whether it will supercede amiodarone in clinical practice remains to be seen.

Clinical Presentation

In all patients receiving amiodarone, its effects, particularly the inhibition of the deiodinases, cause a compensatory increase in TSH secretion. This increases serum free T₄ by 30% to 50%, with the serum T₃ and TSH concentrations remaining normal after equilibrium is established.^{315,316} This pattern is identical to that observed in mouse models with low D1 activity due to *Dio1* gene inactivation or genetic D1 deficiency and should not be confused with that of thyrotoxicosis in which TSH is suppressed.^{317,318} The pathologic effects on the thyroid may result in iodide-induced hypothyroidism (the most common thyroid complication in iodine-sufficient regions; see Chapter 13), or in hyperthyroidism in susceptible individuals due to the *Jod-Basedow* effect and development of Graves' disease in iodine-deficient regions, or in the direct cytotoxic effect of thyroiditis-type damage to the thyroid gland induced by iodine. The iodine-induced hyperthyroidism and thyroiditis-like syndromes have also been referred to as type I and type II amiodarone-induced thyrotoxicosis, respectively.^{260,319}

Amiodarone-induced thyrotoxicosis may develop at the outset of exposure or not until after several years of treatment. It commonly manifests as an exacerbation of the underlying cardiac pathology that was the initial indication for its use. This serious complication can sometimes be anticipated by early recognition of a progressive decrease in serum TSH levels. Monitoring of serum TSH throughout amiodarone treatment on a regular basis, such as every 6 months, should be undertaken by the supervising cardiologist or internist. This is especially important in areas of borderline or deficient iodine supply.

Diagnosis

All patients with amiodarone-induced thyrotoxicosis have a suppressed TSH level, with the degree of suppression proportional to the clinical severity. Serum free T_4 is elevated, but the elevation in serum free T_3 is less than that observed in typical thyrotoxic states due to the blockade of T_4 -to- T_3 conversion by the drug. Distinction between the two causes of thyrotoxicosis may not be possible, although many strategies have been suggested. In North America, the cause of thyrotoxicosis is almost always thyroiditis because of the lack of iodine deficiency; a more evenly divided mix of the two causes occurs in Europe.^{312,320,321} Doppler-flow ultrasonography showing hypervascularity accompanied by an enlarged gland favors iodine-induced hyperthyroidism, whereas a normal-sized gland and “normal” or reduced vascularity favor thyroiditis, although results can be equivocal.^{312,320} RAIU values are almost always low except in areas of low iodine intake.

Treatment

If possible, amiodarone should be discontinued, but this is not absolutely necessary. In patients with thyroiditis, a spontaneous resolution may occur, but in most patients a combination of methimazole or carbimazole (20 to 40 mg/day) and prednisolone/prednisone 20 to 40 mg/day is given to cover both diagnostic possibilities.³²² The latter may be tapered after 3 months to determine whether a remission has occurred. In patients with iodine-induced hyperthyroidism, perchlorate (500 mg twice daily for 1 to 2 weeks) may accelerate the resolution of the condition, although this agent has potentially significant renal and bone marrow toxicities precluding long-term use.^{312,323}

For those patients who remain unstable or whose cardiac condition is likely to require lifelong amiodarone therapy, surgery is appropriate. The current consensus is that amiodarone can be restarted in patients who have recovered from thyroiditis, and most patients remain euthyroid if this is done.^{260,324}

HYPERTHYROIDISM DUE TO THYROTROPIN SECRETION

Excess thyrotropin is an exceedingly rare cause of hyperthyroidism. However, pituitary thyrotroph tumors cause this condition and may manifest as a Graves'-like syndrome with diffuse goiter and substantial thyrotoxicosis. Laboratory studies demonstrating an inappropriately detectable or somewhat elevated TSH in the presence of thyrotoxic symptoms alert the clinician to this as the most likely possibility once assay artifacts are eliminated. This condition, discussed in depth in Chapter 9, must be differentiated from the rare *familial resistance to thyroid hormone (RTH)*.³²⁵⁻³²⁷

Thyroid Hormone Resistance

In some patients with familial RTH due to mutations in the β -isoform of the thyroid hormone receptor, the hypothalamic-pituitary feedback mechanism is more resistant to the effects of thyroid hormone than are peripheral tissues such as the heart, which expresses the thyroid receptor α -isoform.³²⁵⁻³²⁷ These patients may present with a hyperthyroid appearance with tachycardia, nervousness, and goiter associated with an elevated concentration of free T_4 . However, because the thyroid hormone hyperproduction is TSH driven, serum TSH concentrations are

detectable (>0.1 mU/L) or even elevated inappropriately for the high serum thyroid hormone levels. In general, the manifestations are due not to excessive but, rather, to inadequate thyroid hormone action, and these individuals may require treatment with thyroid hormone (or thyroid hormone analogs) or β -adrenergic receptor-blocking agents, or both, rather than anti-thyroid drugs (see Chapter 13 for a more extensive discussion of RTH). The critical historical point in such patients is a family history, because RTH is inherited in an autosomal dominant pattern.

CHORIONIC GONADOTROPIN-INDUCED HYPERTHYROIDISM

Human chorionic gonadotropin is a glycoprotein heterodimer composed of an α -subunit (identical to that of TSH, LH, and FSH) and a specific β -subunit that has similarity to TSH. This glycoprotein binds and stimulates the human TSHR,³²⁸ with an in vitro potency of about 0.7 μ U of human TSH equivalent for every 1 U of hCG. In high concentrations, it causes hyperthyroidism characterized by a diffuse goiter, elevated free T_4 , and suppressed TSH. This is readily recognized in the late first trimester of normal pregnancy, a time at which a physiologic mild transient gestational thyrotoxicosis or hyperthyroidism occurs (see Chapter 11).

Transient Gestational Thyrotoxicosis

The syndrome of transient gestational thyrotoxicosis is an exaggeration of the physiologic increase in thyroid stimulation that occurs during the first trimester of pregnancy. It is associated with high levels of hCG (100,000 to 200,000 U/L), similar to those found in twin pregnancies, and is often accompanied by hyperemesis.^{329,330} In most patients, the condition is self-limited, but in rare circumstances, low doses of methimazole (≤ 10 mg/day) may be required for a few weeks until the hCG falls spontaneously. It may be difficult to separate this syndrome from early Graves' disease, and a TRAb test may be helpful.

Two patients have been reported with an inherited variant of gestational thyrotoxicosis in which a mutation in the TSHR gene resulted in a receptor protein with an increase in its responsiveness to hCG.³³¹ Such patients develop hyperthyroidism with each pregnancy due to physiologic serum hCG concentrations.

Hyperthyroidism Associated with Trophoblastic Tumors

Thyroid hyperfunction may accompany hydatidiform mole, choriocarcinoma, or metastatic embryonal carcinoma of the testis.²⁶⁰ Such neoplasms, particularly hydatidiform mole, elaborate differentially glycosylated hCG molecules that also exhibit crossover specificity for binding to the TSHR and can induce variable degrees of thyroid overactivity.³³² Some patients have clinically overt thyrotoxicosis; however, clinical manifestations usually are not prominent, and goiter is absent or minimal despite laboratory evidence of a hyperthyroid state. The levels of free T_4 or free T_3 or both are increased, and TSH values are suppressed. The reason for the discordance between the clinical and the laboratory indices is not known, but it may be related to the relatively short duration of thyroid hormone excess. The possibility of a molar pregnancy should be considered in a young woman with hyperthyroidism and amenorrhea, because the appropriate therapy is evacuation of the uterus.

TRANSIENT THYROTOXICOSIS

Overview

As mentioned at the outset of this chapter, transient thyrotoxicosis must be differentiated from the sustained hyperthyroidism of Graves' disease and other causes of hyperthyroidism. Transient thyrotoxicosis is caused by thyroid-cell breakdown, and the hyperthyroid symptoms are of abrupt onset and short duration. This process may be followed by recovery of thyroid function or the development of transient or permanent thyroid failure. The discussion in this chapter focuses on thyroiditis as the most common cause of transient thyrotoxicosis. This disorder is covered more completely in Chapter 13, because Hashimoto's disease most commonly causes hypothyroidism after the initial phase of transient hyperthyroidism.

Transient thyrotoxicosis has a confusing nomenclature that can be clarified as follows:

- In the autoimmune forms (*Hashimoto's thyroiditis*), there are typically no local symptoms of thyroid inflammation. This has led to the equivalent terms *silent* or *painless thyroiditis*, *lymphocytic thyroiditis*, and *Hashitoxicosis*. This condition may also manifest with thyroid tenderness.
- In the form of postviral thyroiditis (also termed *subacute*, *de Quervain's*, or *granulomatous thyroiditis*), thyroid tenderness may be the most prominent symptom. Thyrotoxicosis is rare and typically self-limited, although this form may rarely also be painless.
- Acute thyroiditis resulting from bacterial or fungal infection is only rarely accompanied by thyrotoxicosis, and the local symptoms predominate (see Chapter 13).
- Thyroiditis may also be drug induced, the principal offenders being amiodarone and lithium. Some of the new, small-molecule kinase inhibitors (e.g., sunitinib) may also cause this form of thyroiditis, resulting eventually in hypothyroidism.³³³

Transient Thyrotoxicosis Due to Autoimmune (Hashimoto's) Thyroiditis

As described earlier, Hashimoto's disease causes two different thyrotoxicosis-associated transient syndromes. The more common one is the painless form, in which the symptoms of thyrotoxicosis, usually mild, predominate; the more uncommon form has a painful type of presentation, probably secondary to a more acute onset. Histopathology in such patients with thyroiditis shows diffuse or local lymphocytic infiltration, varying degrees of fibrosis, and disruption of the follicular architecture (Fig. 12-14).

Thyrotoxicosis from Painless Autoimmune Thyroiditis. This presentation may occur in the postpartum period or spontaneously. Postpartum thyroiditis is the most common example, and its pathophysiology, postpartum enhancement of thyroid-directed autoimmunity (Hashimoto's disease), is analogous to the postpartum exacerbation of Graves' disease (see earlier discussion). The incidence of postpartum thyroiditis varies, but it may occur in as many as 10% of women, in more than 30% of those with positive TPO-Ab, and in even a larger fraction of patients with type 1 diabetes mellitus.²⁴⁵ In women found to be TPO antibody-positive prenatally, postpartum assessment of thyroid function is recommended at 3, 6, and 12 months. As expected, there is a strong association with the HLA DR3

Figure 12-14 Lymphocytic thyroiditis in a patient with transient thyrotoxicosis (painless thyroiditis) secondary to autoimmune (Hashimoto's) thyroiditis. Notice the diffuse lymphocytic invasion of the tissue, including the follicular epithelium, and the loss of follicles. Multinucleated giant cells may also be seen in the follicular lumen. (Courtesy of Dr. Vania Nosé, Brigham and Women's Hospital, Boston, MA.)

and DR5 haplotypes, which are associated with autoimmune thyroid disease.³³⁴

Thyrotoxicosis from spontaneous autoimmune thyroiditis has all the same characteristics as postpartum thyroiditis and is seen in patients early in their development of classic Hashimoto's disease and before the onset of hypothyroidism.

Thyrotoxicosis from Painful Autoimmune Thyroiditis. Some patients with thyrotoxicosis due to painful autoimmune thyroiditis present with local thyroid tenderness, but this is uncommon. Such tender episodes, which can be unilateral, may recur until the thyroid gland is completely destroyed by the disease process. Only rarely does the pain persist, sometimes requiring surgical intervention.

Clinical Presentation of Transient Autoimmune Thyrotoxicosis

More than 75% of patients are women who present with acute onset of symptoms of thyrotoxicosis, usually nervousness, palpitations, and irritability; they can often pinpoint the time of recent onset. In the postpartum syndrome, symptoms manifest 3 to 6 months after delivery but may be mild and overlooked amid the myriad of events involved in the care of the newborn. After 1 to 2 months, the thyrotoxic symptoms fade, but they are often replaced by those suggesting hypothyroidism (Fig. 12-15).

In a significant number of postpartum patients, the thyrotoxic phase is too mild to be noticed, and the patient presents somewhat later after delivery with hypothyroid symptoms. The physical examination shows mild signs of thyrotoxicosis, tachycardia being the most prominent, without the specific eye signs or dermopathy associated with Graves' disease. The thyroid gland is normal in size but may be firm if the Hashimoto's disease is chronic.

Diagnosis

Thyrotoxicosis is usually mild, and this is reflected in the degree of suppression of the serum TSH level and the elevation of the serum free T₄. Significant elevation of the TPO-Ab is typical. Systemic manifestations of

Figure 12-15 The typical course in patients with autoimmune thyroiditis who present with transient thyrotoxicosis. The duration of each phase may vary, and some patients do not experience a discernible hyperthyroid or hypothyroid phase. TSH, thyroid-stimulating hormone. (From Woolf PD. Transient painless thyroiditis with hyperthyroidism: a variant of lymphocytic thyroiditis? *Endocr Rev.* 1980;1:411-420. ©1980, The Endocrine Society.)

inflammation are lacking, and the erythrocyte sedimentation rate is normal or almost normal, but ultrasonography may indicate the heterogeneity of an inflamed gland. If true hyperthyroidism cannot be eliminated as a diagnosis on clinical grounds, the RAIU should be measured unless the patient is nursing. The classic decreased RAIU is due partly to feedback suppression of TSH secretion but also to thyroid follicular-cell destruction. The tendency of the disorder to pass through a hypothyroid phase is not surprising in view of the extensive depletion of Tg, which is processed to thyroxine and not replaced by the dysfunctional cells.

Natural History

The duration of the thyrotoxic phase, which is typically not severe enough to require treatment, averages 1 to 2 months. About one half of the patients return to a euthyroid phase and remain well in the short term. In the remaining half, a hypothyroid phase may follow and may last for 2 to 9 months. In most patients, there is eventual restoration of euthyroidism, but some develop permanent hypothyroidism years later.³³⁵ About one third retain a goiter, usually with persistence of thyroid autoantibodies in the serum. The opposite sequela, recurrence of thyrotoxicosis, may also appear months or years after restoration of a euthyroid state, particularly after pregnancy.

Treatment

The thyrotoxic phase may require alleviation of the peripheral manifestations through the use of β -blockers. Prednisone (20 to 40 mg/day) may decrease the duration of the thyrotoxic phase, but it is typically not needed except when the painful form of the disease is present. If the hypothyroid phase is mild and brief, it also may not require treatment. If treatment with levothyroxine is required, it should be withdrawn slowly approximately 6 months later, because the hypothyroidism is often not permanent.

Subacute Thyroiditis

Subacute thyroiditis (also termed *granulomatous*, *giant cell*, or *de Quervain's thyroiditis*) is thought to be caused directly or indirectly by a viral infection of the thyroid gland and often follows an upper respiratory illness. A tendency to appear in the spring in the Northern latitudes has been noted, and again there is a female predominance. The

mumps virus has been implicated in some cases, and Coxsackie, influenza, echo, and adenoviruses may also be etiologic agents. Positive TPO-Ab are present transiently during the active phase of the disease, although some patients retain evidence of thyroid autoimmunity for many years. A small number of patients eventually develop autoimmune thyroid disease. Subacute thyroiditis is uncommon, but mild cases may be mistakenly diagnosed as pharyngitis.

Pathology

The histopathologic changes are different from those observed in Hashimoto's disease. The lesions are patchy in distribution and vary in their stage of development from area to area. Affected follicles are infiltrated predominantly with mononuclear cells and show disruption of epithelium, partial or complete loss of colloid, and fragmentation and duplication of the basement membrane (Fig. 12-16).

To this extent, the histopathologic appearance may resemble that of Hashimoto's disease. A characteristic feature is the well-developed follicular lesion that consists of a central core of colloid surrounded by the multinucleated giant cells, hence the designation *giant cell thyroiditis*. Colloid may be found in the interstitium or within the giant cells. The follicular changes progress to form granulomas. Interfollicular fibrosis and an interstitial inflammatory reaction are present to varying degrees. After the disease subsides, an essentially normal histologic appearance is restored.

Pathophysiology

Apoptosis of follicular epithelium and loss of follicular integrity are the primary events in the pathophysiology of giant cell thyroiditis. Tg, T_4 , and iodinated Tg fragments are released into the circulation, often in quantities sufficient to elevate not just the serum Tg but also the serum free T_4 , producing clinical thyrotoxicosis and suppressing TSH secretion. As a result, the RAIU decreases to low levels, and hormone synthesis ceases. Later in the disease, after stores of preformed hormone are depleted, serum T_4 and T_3 concentrations decline, sometimes into the hypothyroid range, and the serum TSH level rises, often to elevated values, exactly as occurs in silent thyroiditis (Fig. 12-17).

Figure 12-16 Subacute (viral or postviral) thyroiditis. Diffuse neutrophilic invasion with active destruction of follicles and a multinucleated giant cell. Fibrosis and near-complete loss of follicles have occurred. (Courtesy of Dr. Vania Nose, Brigham and Women's Hospital, Boston, MA.)

Figure 12-17 Thyroid function in a patient during the course of subacute (viral or postviral) thyroiditis. During the thyrotoxic phase (days 10 to 20), the serum thyroglobulin (TG) concentration was greatly elevated, the free thyroxine index (FTI) was high, and the thyroid-stimulating hormone (TSH) was suppressed; the erythrocyte sedimentation rate was 86 mm/hour, and the thyroidal radioactive iodine uptake (RAIU) was 2%. The Tg level and the FTI declined in parallel. During the phase of hypothyroidism (days 30 to 63), when the FTI was below normal, a modest transient increase in serum Tg occurred in parallel with the increase in serum TSH. All parameters of thyroid function were normal by day 150, 5 months after the onset of symptoms. (From DeGroot LJ, Larsen PR, Hennemann G. *Acute and subacute thyroiditis*. In: DeGroot LJ, Larsen PR, Hennemann G: *The Thyroid and Its Diseases*, 6th ed. New York, NY: Churchill Livingstone; 1996:705.)

As the disease becomes inactive, the RAIU may be greater than normal for a time as hormone stores are repleted. Ultimately, after hormone secretion resumes, serum T_4 and T_3 concentrations rise, and the serum TSH concentration decreases to normal values.

Clinical Picture

The characteristic feature is the gradual or sudden appearance of pain in the region of the thyroid gland with or without fever. The pain, which is aggravated by turning the head or swallowing, characteristically radiates to the ear, jaw, or occiput and may mimic disorders arising in these areas. The absence of pain does not exclude the diagnosis, because biopsy-proven painless subacute thyroiditis does occur, but it must be distinguished from acute autoimmune thyroiditis. Hoarseness and dysphagia may be present, and patients may complain of palpitation, nervousness, and lassitude. The latter symptoms can be extreme, considering the local nature of the disease, and may suggest a systemic component. Although acute manifestations are present in severe cases, symptoms in milder disease may be present and overlooked for months.

On palpation, at least part of the thyroid is slightly to moderately enlarged, firm, often nodular, and usually exquisitely tender. One lobe is frequently being more severely affected than the other, and the symptoms may be truly unilateral. The overlying skin may be warm and erythematous. Occasionally, the locus of maximal involvement migrates over the course of a few weeks to other parts of the gland. The disease usually subsides within a few months, leaving no residual deficiency of thyroid function in 90% of patients. In rare patients, the disease smolders, with repeated exacerbations over many months, and hypothyroidism is sometimes the final result.

Diagnosis

The laboratory findings vary with the phase of the disease. During the active phase, the erythrocyte sedimentation rate is increased, often to a remarkable extent

(>100 mm/hour). Indeed, a diagnosis of active subacute thyroiditis is hardly tenable when the sedimentation rate is normal. The white blood cell count is normal or, at most, moderately increased. The serum Tg level is characteristically high, in keeping with the degree of thyroid destruction.

Subacute thyroiditis must be differentiated from acute hemorrhagic degeneration in a preexisting thyroid nodule, Hashimoto's disease with painful recurrence (discussed earlier), acute pyogenic or fungal thyroiditis, and the rare thyroid malignancy with painful nodules. Acute painful exacerbations of Hashimoto's disease may be difficult to distinguish from subacute thyroiditis. Lack of elevation of the erythrocyte sedimentation rate and high titers of thyroid autoantibodies strongly suggest the former condition. Acute pyogenic thyroiditis is distinguished by the presence of a septic focus elsewhere, by a greater inflammatory reaction in the tissues adjacent to the thyroid, and by much greater leukocytic and febrile responses (see Chapter 13). The RAIU and thyroid function are usually preserved in acute pyogenic thyroiditis. Rarely, widespread infiltrating cancer of the thyroid can manifest with a clinical and laboratory picture almost indistinguishable from that of subacute thyroiditis.³³⁶ Ultrasonography and fine-needle aspiration should be performed if this is a consideration.

Treatment

In mild cases, aspirin, nonsteroidal anti-inflammatory drugs, or cyclooxygenase 2 (COX2) inhibitors may control the symptoms. With more severe pain, glucocorticoids (e.g., prednisone up to 40 mg/day) are the only solution for the extreme discomfort. This treatment may be required for several months and should then be withdrawn gradually. If the TSH is not suppressed, TSH-suppressive therapy with levothyroxine may decrease the size of the gland, relieving the pressure on the thyroid capsule. TSH is needed for thyroid-cell regeneration, so such therapy should be decreased as the symptoms subside.

Drug-Associated Thyroiditis

Thyroiditis is an uncommon complication of pharmacotherapy. Amiodarone is an important exception and was discussed earlier in this chapter. Most cases of thyroiditis associated with various therapeutic agents appear to be caused by drug-induced exacerbation of underlying autoimmune disease. This is understandable with those agents that are specifically administered to modify the immune system, including IL-2, interferon- α , and granulocyte/macrophage colony-stimulating factor (GM-CSF), any of which can precipitate silent thyroiditis.^{114,337} This complication has also been described with lithium, and the GnRH agonist leuprolide, but the pathophysiology is obscure.³³⁸⁻³⁴⁰

Thyroiditis has been found in association with the use of a multitargeting kinase inhibitor, sunitinib, in patients with gastrointestinal stromal tumors or renal cell carcinoma. This may manifest as subacute thyroiditis, with a suppressed TSH level being the major manifestation in the early phase, followed by progression to destruction of the gland through an unclear mechanism. Although imatinib has been associated with an increase in levothyroxine requirements in hypothyroid patients (analogous to the effects of phenytoin, carbamazepine, and rifampin), those changes are independent of thyroid function.³⁴¹

OTHER CAUSES OF THYROTOXICOSIS WITH A LOW RADIOIODINE UPTAKE

In addition to silent and subacute thyroiditis, several other entities should be considered if a patient with thyrotoxicosis has a thyroid gland that is either not palpable or not enlarged and has biochemical findings of thyrotoxicosis accompanied by a low RAIU.

Thyrotoxicosis Factitia

Thyrotoxicosis that arises from the ingestion, usually chronic, of excessive quantities of thyroid hormone occurs typically in individuals with underlying psychiatric disease, especially in paramedical personnel who have access to thyroid hormone or in patients for whom thyroid hormone medication has been prescribed in the past. Usually, the patient is aware of taking thyroid hormone but may adamantly deny it. In other instances, large doses of thyroid hormone or other thyroactive material may be given without the knowledge of the patient, usually as part of a regimen for weight reduction. Some "natural" products for weight reduction stated not to contain thyroid hormone nonetheless do. Symptoms are typical of thyrotoxicosis and may be severe.

In the absence of preexisting disease of the thyroid, the diagnosis is made from the combination of typical thyrotoxic manifestations together with thyroid atrophy and hypofunction. Infiltrative ophthalmopathy never occurs, but lid lag, stare, and other "thyrotoxic" eye signs may be present. TSH levels are suppressed. Serum T_4 concentrations are increased unless the patient is taking T_3 , in which case they are subnormal. Serum T_3 concentrations are increased in either case. Hypofunction of the thyroid gland is evidenced by the subnormal values of RAIU. The presence of low, rather than elevated, values of serum Tg is a clear indication that the thyrotoxicosis results from exogenous hormone rather than thyroid hyperfunction.

This disorder may be confused with other varieties of thyrotoxicosis associated with a subnormal RAIU and absence of goiter, including silent thyroiditis, ectopic

thyroid tissue, and hyperfunctioning metastatic follicular carcinoma. Evidence for the last two disorders can be obtained by demonstration of the ectopic focus or foci through external radioiodine scanning or by the presence of normal to elevated serum Tg concentrations. Differentiation from silent thyroiditis may be difficult. The presence of TPO-Ab points to painless chronic autoimmune thyroiditis, whereas a firm thyroid and brief history suggest the painless variant of subacute thyroiditis. Treatment of thyrotoxicosis factitia consists of withdrawal of the offending medication. Psychiatric consultation is often required.

Hamburger Thyrotoxicosis

An unusual form of exogenous thyrotoxicosis occurred in the midwestern portion of the United States in 1984 and 1985. The source was the inclusion of large quantities of bovine thyroid in ground beef preparations.³⁴² When the slaughtering practices were changed, this condition disappeared. Such a possibility, although remote, should be considered, especially if one is confronted with epidemic exogenous thyrotoxicosis.

Thyrotoxicosis Due to Extrathyroidal Tissue

Struma Ovarii. Thyroid tissue is present in 5% to 10% of teratomas, and occasionally such foci are hyperfunctional.^{343,344} About 5% to 10% of these tumors are bilateral. Whereas thyrotoxicosis is unusual, it may occur in as many as 8% to 10% of patients. Rarely, males with germ-cell tumors may develop hCG-induced hyperthyroidism.³⁴⁵

Clinical Presentation. Patients present with variable degrees of thyrotoxicosis but without goiter and usually have lower abdominal symptomatology such as a pain or a mass. Rarely, ascites is present. Laboratory studies show reduced TSH and increased free T_4 of a variable degree, but the RAIU is low. The Tg may be elevated, particularly if the teratoma is malignant and has metastasized to the peritoneum. Abdominal CT or MRI shows a multilocular ovarian mass or masses. Rarely, a struma ovarii is accompanied by Graves' disease.³⁴⁶

Treatment. The patient should be rendered euthyroid if thyrotoxicosis is significant, after which the involved ovary or ovaries should be removed. Therapeutic radioiodine will be required for metastatic disease after ablation of the normal thyroid gland.^{347,348}

Thyrotoxicosis Due to Metastatic Thyroid Carcinoma

In general, thyroid carcinomas are made up of poorly functioning tissue. On occasion, follicular thyroid carcinomas have sufficient function when combined with the total mass of the metastases to result in an elevation in serum free T_4 or T_3 . Typically, such a course is a complication of a previously diagnosed lesion (see Chapter 14).³⁴⁹ The symptoms of thyrotoxicosis are variable, and the metastatic disease is usually obvious from radiologic studies. On occasion, the presentation may be confusing if the patient is receiving TSH-suppressive therapy, and diagnosis will require its discontinuation; TSH will remain suppressed and the serum free T_4 will be elevated. Treatment of this condition is typical for that of thyroid carcinoma and is described in Chapter 14. In patients with thyrotoxicosis due to metastatic tumor, serum Tg is quite elevated, indicating that the thyrotoxicosis is caused by thyroidal tissue that is not located in the neck. An RAIU during the thyrotoxic phase will show no neck uptake due to TSH suppression even if the thyroid is still present.

Hypothyroidism and Thyroiditis

GREGORY A. BRENT • TERRY F. DAVIES

HYPOTHYROIDISM

Reduced production of thyroid hormone is the central feature of the clinical state termed *hypothyroidism*.^{1,2} Permanent loss or destruction of the thyroid, through processes such as autoimmune destruction or irradiation injury, is described as *primary hypothyroidism* (Table 13-1). Hypothyroidism due to transient or progressive impairment of hormone biosynthesis is typically associated with compensatory thyroid enlargement. Central or secondary hypothyroidism, caused by insufficient stimulation of a normal gland, is the result of hypothalamic or pituitary disease or defects in the thyroid-stimulating hormone (TSH) molecule. Transient or temporary hypothyroidism can be observed as a phase of subacute thyroiditis. Primary hypothyroidism is the etiology in approximately 99% of cases of hypothyroidism. Central hypothyroidism is discussed in Chapters 7 and 9.

Reduced action of thyroid hormone at the tissue level in the face of normal or increased thyroid hormone production from the thyroid gland can also be associated with clinical hypothyroidism. Conditions associated with reduced thyroid hormone action are rare and include abnormalities of thyroid hormone metabolism and defects in nuclear signaling. Consumptive hypothyroidism, identified in an increasing number of clinical settings, is the

result of accelerated inactivation of thyroid hormone by the type 3 iodothyronine deiodinase (D3). Defects of activation of the prohormone, thyroxine (T_4), to the active form, triiodothyronine (T_3), have also been identified. Polymorphisms in genes regulating thyroid hormone production and activation may influence thyroid hormone action in some tissues.³ Resistance to thyroid hormone (RTH), the result of defects in the thyroid hormone nuclear receptor or nuclear cofactors, is associated with elevated circulating levels of thyroid hormone (see later discussion). Some tissues, depending on the level of expression of the mutant receptor and other forms of local compensation, have evidence of reduced thyroid hormone action.

Estimates of the incidence of hypothyroidism vary depending on the population studied.^{4,5} In the United States, 0.3% of the population have overt hypothyroidism, defined as an elevated serum TSH concentration and reduced free thyroxine concentration (fT_4), and 4.3% have what has been described as subclinical or mild hypothyroidism.⁵ Although a number of clinical manifestations have been associated with this early or mild phase of hypothyroidism, the term *subclinical* is used here to describe this group, as in most clinical studies. Subclinical hypothyroidism is defined as an elevated serum TSH level with a normal serum fT_4 concentration.⁶ Subclinical hypothyroidism can progress to overt hypothyroidism,⁷ and it can be associated

TABLE 13-1

Causes of Hypothyroidism**Primary Hypothyroidism****Acquired**

Hashimoto's thyroiditis
 Iodine deficiency (endemic goiter)
 Drugs blocking synthesis or release of T₄ (e.g., lithium, ethionamide, sulfonamides, iodide)
 Goitrogens in foodstuffs or as endemic substances or pollutants
 Cytokines (interferon- γ , interleukin-2)
 Thyroid infiltration (amyloidosis, hemochromatosis, sarcoidosis, Riedel's struma, cystinosis, scleroderma)
 Postablative thyroiditis due to ¹³¹I surgery or therapeutic irradiation for nonthyroidal malignancy

Congenital

Iodide transport or utilization defect (NIS or pendrin mutations)
 Iodotyrosine dehalogenase deficiency
 Organification disorders (TPO deficiency or dysfunction)
 Defects in thyroglobulin synthesis or processing
 Thyroid agenesis or dysplasia
 TSH receptor defects
 Thyroidal G_s protein abnormalities (pseudohypoparathyroidism type 1a)
 Idiopathic TSH unresponsiveness

Transient (Post-Thyroiditis) Hypothyroidism

Following subacute, painless, or postpartum thyroiditis

Consumptive Hypothyroidism

Rapid destruction of thyroid hormone due to D3 expression in large hemangiomas or hemangioendotheliomas

Defects of Thyroxine-to-Triiodothyronine Conversion

Selenocysteine insertion sequence-binding protein 2 (SBP2) defect

Drug-Induced Thyroid Destruction

Tyrosine kinase inhibitor (e.g., sunitinib)

Central Hypothyroidism**Acquired**

Pituitary origin (secondary)
 Hypothalamic disorders (tertiary)
 Bexarotene (retinoid X receptor agonist)
 Dopamine and/or severe illness

Congenital

TSH deficiency or structural abnormality
 TSH receptor defect

Resistance to Thyroid Hormone

Generalized
 "Pituitary" dominant

D3, type 3 deiodinase; G_s, stimulatory G protein; NIS, sodium-iodide symporter; TPO, thyroid peroxidase; TSH, thyroid-stimulating hormone.

with manifestations that, in some patients, can be improved with treatment.⁶⁻⁹ The incidence of hypothyroidism is higher among women, the elderly, and in some racial and ethnic groups.⁵ Neonatal screening programs identify hypothyroidism (almost all primary cases) in almost 1 of every 3500 newborns.¹⁰

CLINICAL PRESENTATION

Hypothyroidism can affect all organ systems. These manifestations are largely independent of the underlying disorder but are a function of the degree of hormone deficiency. The following sections discuss the pathophysiology of each

organ system at various levels of thyroid hormone deficiency, from mild to severe. The term *myxedema*, formerly used as a synonym for hypothyroidism, refers to the appearance of the skin and subcutaneous tissues in the patient who is in a severely hypothyroid state (Fig. 13-1). Hypothyroidism of this severity is rarely seen today, and the term should be reserved for description of the physical signs.

Skin and Appendages

Hypothyroidism causes an accumulation of hyaluronic acid that alters the composition of the ground substance in the dermis and other tissues.¹¹ This material is hygroscopic, producing the mucinous edema that is responsible for the thickened features and puffy appearance (myxedema) observed in patients with full-blown hypothyroidism. Myxedematous tissue is characteristically boggy and nonpitting and is apparent around the eyes, on the dorsa of the hands and feet, and in the supraclavicular fossae (see Fig. 13-1). It causes enlargement of the tongue and thickening of the pharyngeal and laryngeal mucous membranes.

A histologically similar deposit may occur in patients with Graves' disease, usually over the pretibial area (infiltrative dermatopathy or pretibial myxedema). In addition to having a puffy appearance, the skin is pale and cool as a result of cutaneous vasoconstriction. Anemia may contribute to the pallor; hypercarotenemia gives the skin a yellow tint but does not cause scleral icterus (see Fig. 13-1). The secretions of the sweat glands and sebaceous glands are reduced, leading to dryness and coarseness of the skin, which in extreme cases may resemble that observed in patients with ichthyosis.

Wounds of the skin tend to heal slowly. Easy bruising occurs because of an increase in capillary fragility. Head and body hair is dry and brittle, lacks luster, and tends to fall out. Hair may be lost from the temporal aspects of the eyebrows, although this feature is not specific for hypothyroidism (see Fig. 13-1B). Growth of hair is retarded, so that haircuts and shaves are required less often. The nails are brittle and grow slowly. Topical T₃ has been shown to accelerate wound healing and stimulate hair growth in a euthyroid mouse model, demonstrating a role for thyroid hormone in these processes.¹²

Histopathologic examination of the skin reveals hyperkeratosis with plugging of hair follicles and sweat glands. The dermis is edematous, and the connective tissue fibers are separated by an increased amount of metachromatically staining, periodic acid-Schiff (PAS)-positive mucinous material. This material consists of protein complexed with two mucopolysaccharides: hyaluronic acid and chondroitin sulfate B. The hygroscopic glycosaminoglycans are mobilized early during treatment with thyroid hormone, leading to an increase in urinary excretion of nitrogen and hexosamine as well as tissue water.¹¹

Patients with hypothyroidism due to Hashimoto's thyroiditis may also have skin lesions with loss of pigmentation characteristic of the autoimmune skin condition called *vitiligo*. This is not a manifestation of reduced thyroid hormone action but reflects the common association of autoimmune endocrine disease and this skin condition, which is recognized as a component of autoimmune polyendocrine syndromes.¹³

Cardiovascular System

The cardiac output at rest is decreased because of reduction in both stroke volume and heart rate, reflecting loss of the

Figure 13-1 **A** and **B**, Typical appearance of patients with moderately severe primary hypothyroidism or myxedema. Notice the dry skin and sallowness; absence of scleral pigmentation differentiates the carotenemia from jaundice. Both individuals demonstrate periorbital myxedema. The patient in **B** illustrates the loss of the lateral aspect of the eyebrow, sometimes termed *Queen Anne's sign*. That finding is not unusual in the age group that is commonly affected by severe hypothyroidism and should not be considered to be a specific sign of the condition.

inotropic and chronotropic effects of thyroid hormones. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These hemodynamic alterations cause narrowing of pulse pressure, prolongation of circulation time, and decrease in blood flow to the tissues.¹⁴⁻¹⁷ The reduction in cutaneous circulation is responsible for the coolness and pallor of the skin and the sensitivity to cold. In most tissues, the decrease in blood flow is proportional to the decrease in oxygen consumption, so the arteriovenous oxygen difference remains normal. The hemodynamic alterations at rest resemble those of congestive heart failure. However, in hypothyroidism, cardiac output increases and peripheral vascular resistance decreases normally in response to exercise, unless the hypothyroid state is severe and of long standing.

In severe primary hypothyroidism, the cardiac silhouette is enlarged (Fig. 13-2), and the heart sounds are diminished in intensity.¹⁸ These findings are largely the result of the effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans, but the myocardium may also be dilated. Pericardial effusion is rarely of sufficient magnitude to cause tamponade.

Angina pectoris may first appear or worsen during treatment of the hypothyroid state with thyroid hormone, although most patients with hypothyroidism and coronary artery disease have no change, or improvement, in anginal symptoms with T_4 treatment.¹⁹ Electrocardiographic changes include sinus bradycardia, prolongation of the PR interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Pericardial effusion is probably responsible for the low amplitude in severe hypothyroidism. Systolic time intervals are altered; the preejection period is prolonged, and the ratio of preejection period to left

ventricular ejection time is increased. Echocardiographic studies have revealed resting left ventricular diastolic dysfunction in overt hypothyroidism and, in some studies, subclinical hypothyroidism.¹⁷ These findings normalize when the hypothyroidism is treated.

Serum levels of homocysteine, creatine kinase, aspartate aminotransferase, and lactate dehydrogenase may be increased in hypothyroidism.^{14,20} Typically, the isoenzyme patterns suggest that the source of the increased creatine kinase and lactate dehydrogenase is skeletal muscle, not cardiac muscle. All levels return to normal with therapy. Sequential cardiac biopsies in a hypothyroid patient with heart failure showed that messenger RNA (mRNA) levels from genes regulated by thyroid hormone that are important for the strength of myocardial contraction were normalized after T_4 treatment.²¹

The combination of large heart, hemodynamic and electrocardiographic alterations, and the described serum enzyme changes has been termed *myxedema heart*. In the absence of coexisting organic heart disease, treatment with thyroid hormone corrects the hemodynamic, electrocardiographic, and serum enzyme alterations of myxedema heart and restores heart size to normal (see Fig. 13-2).

Hypothyroidism is consistently associated with elevations of total and low-density lipoprotein (LDL) cholesterol, which improve with T_4 replacement.²² In a study of a cohort from the Framingham population with short-term hypothyroidism, serum TSH in women was positively correlated with total cholesterol and LDL, but the elevation was from the less atherogenic large LDL particles.²³ The higher the original serum TSH concentration and elevation of serum LDL, the greater the magnitude of reduction in LDL cholesterol after T_4 therapy. A subset of younger (<50 years) male hypothyroid patients have elevated

Figure 13-2 **A** and **B**, Chest roentgenograms in a patient with myxedema heart disease. The patient had signs of severe congestive heart failure and was given thyroid hormone alone. Within 4 months, the heart had returned to normal size (**B**), and there was no evidence of underlying heart disease.

concentrations of serum triglycerides and C-reactive protein that improve with T_4 treatment.²⁴ Most studies have shown that serum high-density lipoprotein (HDL) levels are not influenced by thyroid status.

Hypothyroidism has been shown to be a risk factor for atherosclerosis and cardiovascular disease in several studies, although others have not shown this association. A prospective study from Japan showed an increased risk of ischemic heart disease in men, but not in women, with subclinical hypothyroidism.²⁵ The Whickham study showed no increase in cardiovascular mortality among patients with subclinical hypothyroidism who were followed up for more than 20 years.⁴ A prospective study in the United States that monitored men and women age 65 or older for more than 10 years showed no influence of hypothyroidism (overt or subclinical) on cardiovascular outcome or mortality.²⁶ Cardiovascular outcome studies suggest that improvement from treatment of hypothyroidism, especially subclinical hypothyroidism, occurs primarily among those patients who are in middle age and not in older individuals (>65 years of age).²²

Respiratory System

Pleural effusions usually are evident only on radiologic examination, but in rare instances they may cause dyspnea. Lung volumes are usually normal, but maximal breathing capacity and diffusing capacity are reduced. In severe hypothyroidism, myxedematous involvement of respiratory muscles and depression of both the hypoxic and the hypercapnic ventilatory drives can cause alveolar hypoventilation and carbon dioxide retention, which in turn can contribute to the development of myxedema coma. Obstructive sleep apnea is common but is reversible with restoration of a euthyroid state.

Alimentary System

Although most patients experience a modest gain in weight, appetite is usually reduced. The weight gain that occurs is caused partly by retention of fluid by the hydrophilic glycoprotein deposits in the tissues and does not exceed 10% of body weight. Peristaltic activity is decreased

and, together with the decreased food intake, is responsible for the frequent complaint of constipation. The latter may lead to fecal impaction (myxedema megacolon). Gaseous distention of the abdomen (myxedema ileus), if accompanied by colicky pain and vomiting, can mimic mechanical ileus.²⁷

Elevations in the serum level of carcinoembryonic antigen, which may occur on the basis of hypothyroidism alone, add to the impression that an obstruction is present. Ascites in the absence of another cause is unusual in hypothyroidism, but it can occur, usually in association with pleural and pericardial effusions. Like pericardial and pleural effusions, the ascitic fluid is rich in protein and glycosaminoglycans.

Achlorhydria after maximal histamine stimulation may be present in patients with primary hypothyroidism. Circulating antibodies against gastric parietal cells have been found in about one third of patients with primary hypothyroidism and may be secondary to atrophy of the gastric mucosa. Hypothyroid patients with positive parietal cell antibodies have a higher T_4 requirement compared with antibody-negative patients.²⁸ Among Swedish patients with celiac disease, there was a 4.4-fold increased risk for hypothyroidism, compared to the general population.²⁹ Overt pernicious anemia is reported in about 12% of patients with primary hypothyroidism. The coexistence of pernicious anemia and other autoimmune diseases with primary hypothyroidism reflects the fact that autoimmunity plays the central role in the pathogenesis of these diseases (see Chapter 42).

Hypothyroidism has complex effects on intestinal absorption. Although the rates of absorption for many substances are decreased, the total amount absorbed may be normal or even increased because the decreased bowel motility allows more time for absorption. Malabsorption is occasionally overt.

Liver function test results are usually normal, but levels of aminotransaminases may be elevated, probably because of impaired clearance.³⁰ The gallbladder contracts sluggishly and may be distended. In a population study of patients without diagnosed thyroid disease, men, but not women, with an elevated TSH had a 3.8-fold increased risk of cholelithiasis.³¹

Atrophy of the gastric and intestinal mucosa and myxedematous infiltration of the bowel wall may be demonstrated on histologic examination. The colon may be greatly distended, and the volume of fluid in the peritoneal cavity is usually increased. The liver and pancreas are normal.

Central and Peripheral Nervous Systems

Thyroid hormone is essential for the development of the central nervous system.^{10,32} Deficiency in fetal life or at birth leads to impaired neurologic development, including hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vascularity.^{10,29} If the deficiency is not corrected in early postnatal life, the damage is irreversible. Deficiency of thyroid hormone beginning in adult life causes less severe manifestations that usually respond to treatment with the hormone. Cerebral blood flow is reduced, but cerebral oxygen consumption is usually normal; this finding is in accord with the conclusion that the oxygen consumption of isolated brain tissue in vitro, unlike that of most other tissues, is not stimulated by administration of thyroid hormones. In severe cases, decreased cerebral blood flow may lead to cerebral hypoxia.

All intellectual functions, including speech, are slowed in thyroid hormone deficiency.³³ Loss of initiative is present, and memory defects are common; lethargy and somnolence are prominent, and dementia in elderly patients may be mistaken for senile dementia. Positron emission tomography (PET) brain scans of hypothyroid patients before and after T₄ therapy demonstrate reversible reduced glucose uptake in specific brain areas, such as the limbic system, which also correlates with behavioral and psychiatric symptoms.³⁴ Psychiatric disorders are common and are usually of the paranoid or depressive type and may induce agitation (myxedema madness).³³ Headaches are frequent. Cerebral hypoxia due to circulatory alterations may predispose to confusional attacks and syncope, which may be prolonged and can lead to stupor or coma. Other factors predisposing to coma in hypothyroidism include exposure to severe cold, infection, trauma, hypoventilation with carbon dioxide retention, and depressant drugs.

Epileptic seizures have been reported and tend to occur in myxedema coma. Night blindness is caused by deficient synthesis of the pigment required for dark adaptation. Hearing loss of the perceptive type is frequent due to myxedema of the eighth cranial nerve and serous otitis media. Perceptive deafness may also occur in association with a defect in the organic binding of thyroidal iodide (Pendred's syndrome) (see Chapter 11), but in these instances it is not a result of hypothyroidism per se.

Thick, slurred speech and hoarseness are caused by myxedematous infiltration of the tongue and larynx, respectively. Body movements are slow and clumsy, and cerebellar ataxia may occur. Numbness and tingling of the extremities are frequent; in the fingers, these symptoms may be caused by compression from glycosaminoglycan deposits in and around the median nerve in the carpal tunnel (carpal tunnel syndrome).³⁵ The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic "hung-up reflexes"; this phenomenon is caused by a decrease in the rate of muscle contraction and relaxation rather than a delay in nerve conduction.

The presence of extensor plantar responses or diminished vibration sense should alert the physician to the possibility of coexisting pernicious anemia with combined systemic disease. Electroencephalographic changes include

slow alpha-wave activity and general loss of amplitude. The concentration of protein in the cerebrospinal fluid is often increased, but cerebrospinal pressure is normal.

Histopathologic examination of the brain in patients with untreated hypothyroidism reveals that the nervous system is edematous with mucinous deposits in and around nerve fibers. In patients with cerebellar ataxia, neural myxedematous infiltrates of glycogen and mucinous material are present in the cerebellum. There may be foci of degeneration and an increase in glial tissue. The cerebral vessels may show atherosclerosis, but this is much more common if the patient has had coexistent hypertension.

Hypothyroidism has been associated with several neurologic conditions, although a strong etiologic link has not been established. Epidemiologic studies have shown an association between Alzheimer's disease and hypothyroidism.³⁶ It is difficult to convincingly demonstrate this association, because the incidence of thyroid disease in the elderly population is high and, like that of dementia, increases with age. A mechanistic link is suggested by the observation of amyloid deposition in Down syndrome, a condition that is associated with an increased incidence of Hashimoto's disease, and the fact that thyroid hormone regulates amyloid gene processing in a number of cellular and animal models. However, subclinical hyperthyroidism has also been associated with Alzheimer's disease.³⁷ There is an increase in the cerebrospinal fluid concentration of reverse T₃ in Alzheimer's disease patients who have normal circulating thyroid hormone levels, suggesting the potential for altered thyroid hormone metabolism in the brain.³⁸ However, the impact of normalizing T₃ levels in the brain is not known. A corticosteroid-responsive encephalopathy is associated with chronic Hashimoto's thyroiditis but may be linked to autoimmunity rather than a process mediated specifically by low thyroid hormone levels or thyroid autoantibodies.³⁹

Muscular System

Stiffness and aching of muscles are common and are worsened by cold temperatures. Delayed muscle contraction and relaxation cause the slowness of movement and delayed tendon jerks. Muscle mass may be reduced or enlarged due to interstitial myxedema. Muscle mass may be slightly increased, and the muscles tend to be firm. Rarely, a profound increase in muscle mass with slowness of muscular activity may be the predominant manifestation (*Kocher-Debré-Sémélaigne syndrome* or *Hoffmann syndrome*). Myoclonus may be present. The electromyogram may be normal, or it may exhibit disordered discharge, hyperirritability, and polyphasic action potentials.

On histopathologic examination, the muscles appear pale and swollen. The muscle fibers may show swelling, loss of normal striations, and separation by mucinous deposits. Type I muscle fibers tend to predominate.

Skeletal System: Calcium and Phosphorus Metabolism

Thyroid hormone is essential for normal growth and maturation of the skeleton. Growth failure in thyroid deficiency is caused by impaired general protein synthesis, reduced growth hormone, and especially reduced insulin-like growth factor 1 (Fig. 13-3).⁴⁰ The thyroid hormone receptor isoforms α and β have specific roles in bone maturation. Before puberty, thyroid hormone plays a major role in the maturation of bone. Deficiency of thyroid hormone in early life leads to both a delay in development and an abnormal,

Figure 13-3 The consequences of untreated congenital hypothyroidism are demonstrated in this 17-year-old girl. Her condition was diagnosed at birth but, through a series of misunderstandings, was not treated with thyroid hormone. Notice her size, the poorly developed nasal bridge, the wide-set eyes, and the ears, which are larger than are appropriate for head size. Her tongue is enlarged, and her extremities are inappropriately short in relation to her trunk. (Courtesy of Dr. Ronald B. Stein.)

stippled appearance of the epiphyseal centers of ossification (epiphyseal dysgenesis) (Fig. 13-4). Impairment of linear growth leads to dwarfism in which the limbs are disproportionately short in relation to the trunk but cartilage growth is unaffected (see Fig. 13-3). Children with prolonged hypothyroidism, even after adequate treatment, do not reach predicted height based on midparental height calculations.⁴¹

Urinary excretion of calcium is decreased, as is the glomerular filtration rate, whereas fecal excretion of calcium and urinary and fecal excretion of phosphorus are variable. Calcium balance is also variable, and any changes are slight. The exchangeable pool of calcium and its rate of turnover are reduced, reflecting decreased bone formation and resorption. Because levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present; levels of 1,25(OH)₂D (dihydroxyvitamin D) are also increased.

Levels of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. The alkaline phosphatase level is usually below normal in infantile and juvenile hypothyroidism. Bone density may be increased. The radiologic appearance of the skeleton in cretinism and juvenile hypothyroidism are discussed later.

Renal Function: Water and Electrolyte Metabolism

Renal blood flow, glomerular filtration rate, and tubular reabsorptive and secretory maxima are reduced. Blood urea nitrogen and serum creatinine levels are normal, but uric acid levels may be increased. Urine flow is reduced, and delay in the excretion of a water load may result in reversal of the normal diurnal pattern of urine excretion. The delay in water excretion appears to be due to decreased volume delivery to the distal diluting segment of the nephron as a result of the diminished renal perfusion; evidence supporting inappropriate secretion of vasopressin (syndrome of inappropriate antidiuretic hormone secretion) is less compelling.⁴² These changes are reversed by treatment with

Figure 13-4 X-ray films of the skull and hand of the 17-year-old patient illustrated in Figure 13-3. **A**, Skull film showing that the posterior and anterior fontanelles are open and that the sutures are not fused. The deciduous and permanent teeth are present. **B**, Radiograph of the wrist and hand showing the delayed appearance of the epiphyseal centers of the bones of the hand and the absence of the distal radial epiphysis. The estimated bone age is 9 months. (Courtesy of Dr. Ronald B. Stein.)

thyroid hormone. The ability to concentrate urine may be slightly impaired. Mild proteinuria may occur.

The impaired renal excretion of water and the retention of water by the hydrophilic deposits in the tissues result in an increase in total body water, even though plasma volume is reduced. This increase accounts for the hyponatremia in some patients, because the level of exchangeable sodium is increased. The amount of exchangeable potassium is usually normal in relation to lean body mass. Serum magnesium concentration may be increased, but exchangeable magnesium levels and urinary magnesium excretion are decreased.

Hematopoietic System

In response to the diminished oxygen requirements and decreased production of erythropoietin, the red blood cell mass is decreased; this is evident in the mild normocytic, normochromic anemia that often occurs. Less commonly, the anemia is macrocytic, sometimes from deficiency of vitamin B₁₂. Reference has already been made to the high incidence of pernicious anemia (and of achlorhydria and vitamin B₁₂ deficiency without overt anemia) in primary hypothyroidism (see Chapter 42). Conversely, overt and subclinical hypothyroidism is present in 12% and 15% of patients, respectively, with pernicious anemia. Folate deficiency from malabsorption or dietary inadequacy may also cause macrocytic anemia. The frequent menorrhagia and the defective absorption of iron resulting from achlorhydria may contribute to a microcytic, hypochromic anemia.

The total and differential white blood cell counts are usually normal, and platelets are adequate, although platelet adhesiveness may be impaired. If pernicious anemia or significant folate deficiency is present, the characteristic changes in peripheral blood and bone marrow will be found. The intrinsic clotting mechanism may be defective because of decreased concentrations in plasma of factors VIII and IX, and this, together with an increase in capillary fragility and the decrease in platelet adhesiveness, may account for the bleeding tendency that sometimes occurs.^{27,43}

Pituitary and Adrenocortical Function

In long-standing primary hypothyroidism, hyperplasia of the thyrotropes may cause the pituitary gland to be enlarged. This feature can be detected radiologically as an increase in the volume of the pituitary fossa.⁴⁴ Rarely, the pituitary enlargement compromises the function of other pituitary cells and causes pituitary insufficiency or visual field defects. Patients with severe hypothyroidism may have increased serum prolactin levels, stimulated by the elevation in thyrotropin-releasing hormone (TRH) and proportional to the level of serum TSH elevation, and galactorrhea may develop in some patients. Treatment with thyroid hormone normalizes the serum prolactin and TSH levels and causes disappearance of galactorrhea, if present.

In rodents, thyroid hormone directly regulates growth hormone synthesis. Growth hormone is not directly regulated by thyroid hormone in humans, but thyroid status influences the growth hormone axis.⁴⁵ Hypothyroid children have delayed growth, and the response of growth hormone to provocative stimuli may be subnormal.

As a result of the decreased rate of turnover of cortisol due to decreased hepatic 11 β -hydroxysteroid dehydrogenase type 1 (HSD11B1), the 24-hour urinary excretion of cortisol and 17-hydroxycorticosteroids is decreased, but

the plasma cortisol level is usually normal (see Chapter 15). The response of urinary 17-hydroxycorticosteroid to exogenous adrenocorticotrophic hormone is usually normal but may be decreased. The response of plasma cortisol to insulin-induced hypoglycemia may be impaired.

In severe, long-standing primary hypothyroidism, pituitary and adrenal function may be secondarily decreased, and adrenal insufficiency may be precipitated by stress or by rapid replacement therapy with thyroid hormone.⁴⁵ The rate of turnover of aldosterone is decreased, but the plasma level is normal. Plasma renin activity is decreased, and sensitivity to angiotensin II is increased, which may contribute to the association of hypertension with hypothyroidism (see Chapter 16).⁴⁶

Reproductive Function

In both sexes, thyroid hormones influence sexual development and reproductive function.⁴⁷ Infantile hypothyroidism, if untreated, leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles. Paradoxically, primary hypothyroidism may also rarely cause precocious sexual development and galactorrhea, presumably due to "spillover" of elevated TSH stimulating the luteinizing hormone (LH) receptor⁴⁸ and elevated TRH initiating excess prolactin release.

In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. These changes may be due to deficient secretion of LH or pulse frequency and amplitude, or both. Rarely, in primary hypothyroidism, secondary depression of pituitary function may lead to ovarian atrophy and amenorrhea. Fertility is reduced, and there is an increase in spontaneous abortion and preterm delivery, although many pregnancies are successful.⁴⁹ Pregnancy complications are associated with both overt and subclinical hypothyroidism, although the impact has varied among different studies.⁵⁰ A randomized prospective study of levothyroxine treatment in pregnant women with thyroid peroxidase (TPO) antibody positivity and normal-range TSH showed that the increased incidences of preterm delivery and spontaneous abortion were reversed by treatment, although this finding remains to be confirmed.⁵¹ Primary ovarian failure can also be seen in patients with Hashimoto's thyroiditis as part of an autoimmune polyendocrine syndrome.¹³ Hypothyroidism in men may cause diminished libido, erectile dysfunction, and oligospermia. A significant fraction of men with hypothyroidism or hyperthyroidism have moderate to severe erectile dysfunction that improves with treatment of the thyroid disease.⁵²

Values for plasma gonadotropins are usually in the normal range in primary hypothyroidism. Among postmenopausal women, levels are usually somewhat lower than in euthyroid women of the same age but are nevertheless within the menopausal range. This provides a valuable means of differentiating primary from secondary hypothyroidism.

The metabolism of both androgens and estrogens is altered in hypothyroidism. Secretion of androgens is decreased, and the metabolism of testosterone is shifted toward etiocholanolone rather than androsterone. With respect to estradiol and estrone, hypothyroidism favors metabolism of these steroids via 16 α -hydroxylation rather than 2-oxygenation, with the result that formation of estriol is increased and that of 2-hydroxyestrone and

its derivative, 2-methoxyestrone, is decreased. The sex hormone-binding globulin in plasma is decreased, with the result that plasma concentrations of both testosterone and estradiol are decreased, but the unbound fractions are increased. The alterations in steroid metabolism are corrected by restoration of the euthyroid state.⁵³

Catecholamines

The plasma cyclic adenosine monophosphate (cAMP) response to epinephrine is decreased in hypothyroidism, suggesting a state of decreased adrenergic responsiveness. The fact that the responses of plasma cAMP to glucagon and parathyroid hormone are also decreased suggests that thyroid hormones have a general modulating influence on cAMP generation.⁵⁴ The reduced adrenergic responsiveness associated with hypothyroidism has been linked to all steps of catecholamine signaling, including receptor and postreceptor actions, resulting in an impaired cAMP response. Direct measurement of norepinephrine in abdominal fat of hypothyroid patients shows reduced levels, and there is reduced production of glycerol in response to adrenergic agonist stimulation.⁵⁵ Augmentation of α_2 -receptor signaling has also been proposed as a factor reducing catecholamine responsiveness.

Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

The decrease in energy metabolism and heat production is reflected in the low basal metabolic rate, decreased appetite, cold intolerance, and slightly low basal body temperature.⁵⁶ Both the synthesis and the degradation of protein are decreased, the latter especially so, with the result that nitrogen balance is usually slightly positive. The decrease in protein synthesis is reflected in retardation of both skeletal and soft tissue growth.

Permeability of capillaries to protein is increased, accounting for the high levels of protein in effusions and in cerebrospinal fluid. In addition, the albumin pool is increased because of the greater decrease in albumin degradation compared with albumin synthesis. A greater than normal fraction of exchangeable albumin is in the extravascular space. The total concentration of serum proteins may be increased.

Hypothyroidism is associated with a reduction in the disposition of glucose to skeletal muscle and adipose tissue.⁵⁷ Thyroid hormone has been shown to stimulate expression of the insulin-sensitive glucose transporter (GLUT4), and the levels of this transporter are reduced in hypothyroidism. However, hypothyroidism is also associated with reduced gluconeogenesis, and the net effect of these influences is usually a minimal effect of hypothyroidism on serum glucose levels. Thyroid hormone downregulates expression of prohormone processing enzymes, which, therefore, have increased activity in hypothyroidism. Degradation of insulin is slowed, and the sensitivity to exogenous insulin may be increased. In a patient with preexisting diabetes mellitus who develops hypothyroidism, insulin requirements may be reduced. A further influence on glucose uptake may occur at the tissue level. Polymorphisms in the 5'-deiodinase type 2 (D2) gene, which may affect local T_3 production, have shown to be associated with impaired glucose disposal.⁵⁸

Both the synthesis and the degradation of lipid are depressed in hypothyroidism. However, degradation is reduced to a greater extent, with a net effect of accumulation of LDL and triglycerides.⁵⁶ The decrease in the lipid

degradation rate may reflect the decrease in postheparin lipolytic activity as well as reduced LDL receptors. Plasma free fatty acid levels are decreased, and the mobilization of free fatty acids in response to fasting, catecholamines, and growth hormone is impaired. Impaired lipolysis of white fat in hypothyroid patients at baseline and in response to catecholamine reflects impaired free fatty acid mobilization.^{54,55} All of these abnormalities are relieved by treatment.

A correlation was shown between total cholesterol and serum TSH levels in hypothyroid individuals identified from among 25,862 participants in a health fair, including those not aware of being hypothyroid and those on T_4 replacement.⁵⁹ An elevation in serum LDL-cholesterol has been associated, in most studies, with overt and subclinical hypothyroidism.²² According to most studies, serum HDL and triglycerides levels are not influenced by hypothyroidism.^{22,56} The reduction in LDL with T_4 therapy is generally related to the original magnitude of LDL and TSH elevation: the higher the initial levels, the greater the observed reduction in LDL.²² A typical reduction in LDL is 5% to 10% of the original level.

The role of adipocytokines such as leptin, adiponectin, and resistin in metabolic regulation has been increasingly recognized, as well as their potential for interaction with thyroid hormone.⁵⁶ Rodent studies have shown that leptin regulates central adaptation between the starved and fed state, and that falling leptin levels, associated with starvation, lead to a suppression of the thyroid axis. Hypothyroidism in rodents is associated with reduced leptin and increased resistin levels. Leptin infusion into the cerebral ventricles reverses some of the metabolic changes seen with hypothyroidism, improving glucose disposal and reducing skeletal muscle fat.⁶⁰ However, human studies have not shown consistent changes in adipocytokines in hypothyroidism.⁶¹

CURRENT CLINICAL PICTURE

In adults, the onset of hypothyroidism is usually so insidious that the typical manifestations may take months or years to appear and may go unnoticed by family and friends. The gradual development of the hypothyroid state is the result of slow progression of thyroid hypofunction and of the clinical manifestations after thyroid failure is complete. This course is in contrast with the more rapid development of the hypothyroid state when replacement therapy is discontinued in a patient with treated primary hypothyroidism or when the thyroid gland of a normal subject is surgically removed. In such patients, manifestations of frank hypothyroidism are usually present by 6 weeks, and myxedema appears by 3 months.

Hypothyroidism continues to be diagnosed at earlier stages. Based on the most recent data, subclinical or early hypothyroidism is seen approximately 14 times more commonly than overt hypothyroidism. Scales for assessment of clinical symptoms that suggest hypothyroidism have been developed, reflecting the more typical earlier identification (Fig. 13-5).⁶² Early symptoms are variable and relatively nonspecific. The reason for the increased prevalence of hypothyroid patients presenting with minimal symptoms is largely the availability of sensitive and specific laboratory tests that allow recognition of the primary form of the disease long before severe symptoms have developed. Therefore, there should be a low threshold to test patients for suspected primary hypothyroidism with a serum TSH determination. Patients with significant biochemical

Figure 13-5 Frequency of hypothyroid symptoms and signs (%) in 50 patients with overt hypothyroidism and in 80 euthyroid controls. Two symptoms (pulse rate and cold intolerance, marked by asterisks) showed positive and negative predictive values of less than 70% and therefore were excluded from the new score. (From Zulewski H, Müller B, Exer P, et al. Estimation of tissue hypothyroidism by a new clinical score: evaluation of patients with various grades of hypothyroidism and controls. *J Clin Endocrinol Metab.* 1997;82:771-776.)

abnormalities of hypothyroidism may not score high on indices of symptoms and signs.⁶²

With respect to physical signs of hypothyroidism, the presence of coarse skin, periorbital puffiness that obscures the curve of the malar bone (see Fig. 13-1), cold skin, and delayed ankle reflex relaxation phase are all signs that should lead to appropriate diagnostic tests.

Acute hypothyroidism in the previously hyperthyroid patient after radioiodine therapy is characterized by painful cramping of large muscle groups (see Chapter 12).

Hypothyroidism in Infants and Children

Severe hypothyroidism is seldom apparent at birth, hence the requirement for systematic screening for congenital hypothyroidism.¹⁰ Congenital hypothyroidism can be caused by complete thyroid agenesis, ectopic thyroid, or incomplete thyroid development. Mutations in genes important for thyroid development have been identified in a number of patients and in some cases may explain associated abnormalities in development of other structures (e.g., heart) because of their spatial association during development. The age at which symptoms appear depends on the degree of impairment of thyroid function (see Figs. 13-3 and 13-4). Severe hypothyroidism in infancy is termed *cretinism*. As the age at onset increases, the clinical picture of cretinism merges imperceptibly with that of juvenile hypothyroidism. Retardation of mental development and growth, the hallmark of cretinism, becomes manifest only in later infancy, and the mental retardation is largely irreversible. Consequently, early recognition is crucial and has been achieved by universal population screening in the developed world through measurement of the serum T₄ or TSH concentration routinely in blood spots taken from neonates.

During the first few months of life, symptoms and signs of hypothyroidism include feeding problems, failure to thrive, constipation, a hoarse cry, somnolence, and jaundice. In succeeding months, especially in severe cases, protuberance of the abdomen, dry skin, poor growth of hair and nails, and delayed eruption of the deciduous teeth become evident. Retardation of mental and physical development is manifested by delay in reaching the normal milestones of development, such as holding up the head, sitting, walking, and talking.

Thyroid hormone plays a major role in bone development, and thyroid hormone receptors are expressed in osteoclasts and osteoblasts.⁴⁰ The primary targets of thyroid hormone have been identified in the epiphyseal plates. Impairment of linear growth in congenital hypothyroidism results in dwarfism, with the limbs disproportionately short in relation to the trunk (see Fig. 13-3). Delayed closure of the fontanelles causes the head to be large in relation to the body. The naso-orbital configuration remains infantile. Maldevelopment of the femoral epiphyses results in a waddling gait. The teeth are malformed and susceptible to caries. The characteristic appearance includes a broad, flat nose; widely set eyes; periorbital puffiness; large protruding tongue; sparse hair; rough skin; short neck; and protuberant abdomen with an umbilical hernia. Mental deficiency is usually severe.

Radiologic examination of the skeleton is diagnostic. The skull shows a poorly developed base; delayed closure of the fontanelles; widely set orbits; and a short, flat nasal bone. The pituitary fossa may be enlarged. Shedding of deciduous teeth and eruption of permanent teeth are delayed (see Fig. 13-4).

The radiologic picture of epiphyseal dysgenesis is pathognomonic of hypothyroidism in infancy and childhood and may involve any center of endochondral ossification, depending on the age at onset of the hypothyroid state; it is usually best seen in the femoral and humeral heads and the navicular bone of the foot. The centers of ossification appear late, so bone age is retarded in relation to chronologic age, and when they eventually appear, instead of a single center, multiple small centers are scattered through a misshapen epiphysis (see Fig. 13-4). These small centers of ossification eventually coalesce and form a single center with an irregular outline and a stippled appearance (stippled epiphysis). Epiphyseal dysgenesis is evident only in centers that normally ossify at a time after the onset of the hypothyroidism. After a normal metabolic state is restored by treatment, centers destined to ossify at a later age develop normally.

Hypothyroidism that begins in childhood is usually Hashimoto's disease and can be transient in this age group. Subclinical hypothyroidism is also seen in children and adolescents, and in one study those affected were more likely to be obese and to have a family history of thyroid disease.⁶³ The clinical manifestations of hypothyroidism in

TABLE 13-2

Laboratory Evaluation of Patients with Suspected Hypothyroidism or Thyroid Enlargement*

Free T ₄ Value	TPO-Ab	Diagnosis
TSH > 10 mU/L		
Low	+	Primary hypothyroidism due to autoimmune thyroid disease
Low-normal	+	Primary "subclinical" hypothyroidism (autoimmune)
Low or low-normal	—	Recovery from systemic illness External irradiation, drug-induced, congenital hypothyroidism Iodine deficiency Seronegative autoimmune thyroid disease Rare thyroid disorders (e.g., amyloidosis, sarcoidosis) Recovery from subacute granulomatous thyroiditis
Normal	+, —	Consider TSH or T ₄ assay artifacts
Elevated	—	Thyroid hormone resistance Blockade of T ₄ to T ₃ conversion (amiodarone) or a congenital 5'-deiodinase deficiency Consider assay artifacts
TSH 5-10 mU/L		
Low, low-normal	+	Early primary autoimmune hypothyroidism
Low, low-normal	—	Milder forms of non-autoimmune hypothyroidism (see above) Central hypothyroidism with impaired TSH bioactivity
Elevated	—	Consider thyroid hormone resistance T ₄ -to-T ₃ conversion blockade (e.g., amiodarone)
TSH 0.5-5 mU/L		
Low, low-normal	—	Central hypothyroidism Salicylate or phenytoin therapy Desiccated thyroid or T ₃ replacement
TSH < 0.5 μU/L		
Low, low-normal	—	"Post-hyperthyroid" hypothyroidism (¹³¹ I or surgery) Central hypothyroidism T ₃ or desiccated thyroid excess Post excess levothyroxine withdrawal

*Initial tests: serum TSH, serum free T₄, TPO-Ab, or Tg-Ab.

T₃, triiodothyronine; T₄, thyroxine; Tg-Ab, anti-thyroglobulin antibody; TPO-Ab, thyroid peroxidase autoantibody; TSH, thyroid-stimulating hormone; +, present; —, not present.

children are intermediate between those of infantile and adult hypothyroidism, in that the developmental retardation is not as severe as that of cretinism and the manifestations of full-blown adult myxedema are rarely seen. Growth and sexual development are affected predominantly. If the hypothyroidism is left untreated, linear growth is severely retarded, and sexual maturation and the onset of puberty are delayed.^{40,41} On radiologic examination, epiphyseal dysgenesis may be present, and epiphyseal union is always delayed, resulting in a bone age that is younger relative to the chronologic age.

LABORATORY EVALUATION

Primary and Central Hypothyroidism

A decrease in secretion of the thyroid hormones is common to all varieties of hypothyroidism, except for disorders of thyroid hormone metabolism or action such as *consumptive hypothyroidism* and *RTH* (see later discussion). In patients with primary thyroid disease, the cause of hypothyroidism in more than 99% of the patients, there is a significant increase in basal serum TSH concentration. A strategy for evaluating the patient with suspected hypothyroidism involves a TSH determination (Table 13-2). If the suspicion of hypothyroidism is strong, if a goiter is present, or if

central hypothyroidism is part of the differential diagnosis, an fT₄ assay should be included (see Chapter 11). If hypothyroidism is thought to be unlikely but must be excluded, only a TSH determination is required, because primary hypothyroidism is almost always the cause. If TSH is elevated, an fT₄ assay can be added to the same determination (Fig. 13-6). As hypothyroidism progresses, the serum TSH increases further, the serum fT₄ falls, and finally, at the most severe stage, serum T₃ concentrations may become subnormal (see Table 13-2). The persistence of a normal serum T₃ is, in part, due to preferential synthesis and secretion of T₃ by residual functioning thyroid tissue under the influence of the increased plasma TSH. In addition, the efficiency of conversion of T₄ to T₃ by D2 is increased as the serum T₄ level falls.⁶⁴ Consequently, the serum T₃ concentration may remain within the normal range.

The principal differential diagnosis is between primary and central hypothyroidism (see Chapter 9). The serum TSH concentration is the critical laboratory determination that, in general, allows recognition of the cause of the disease when the serum fT₄ is reduced. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH) in whom a low fT₄ level may be associated with a reduced TSH level for several months after treatment of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of thyroid peroxidase antibodies (TPO-Ab) raises a possible diagnosis of transient

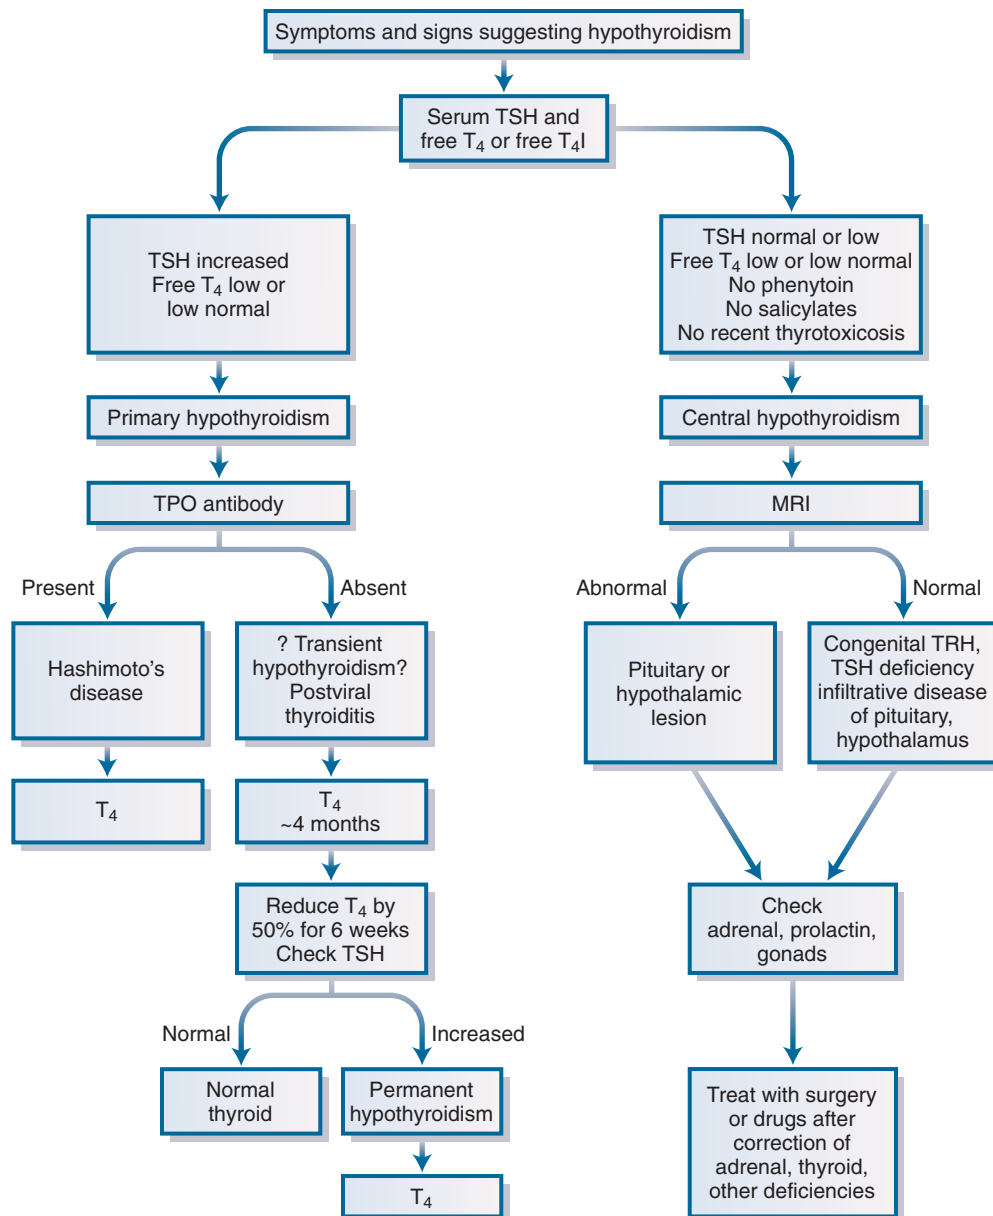

Figure 13-6 Strategy for the laboratory evaluation of patients with suspected hypothyroidism. The principal differential diagnosis is between primary and central hypothyroidism (see Chapter 9). The serum thyrotropin (TSH) concentration is the critical laboratory determination that, in general, allows recognition of the cause of the disease. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH), in whom a low free thyroxine (T_4) level may be associated with a reduced TSH level for several months after relief of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of thyroid peroxidase (TPO) antibodies raises a possible diagnosis of transient hypothyroidism after an undiagnosed episode of subacute or postviral thyroiditis. In such patients, a trial of levothyroxine in reduced dosage after 4 months may reveal recovery of thyroid function, thus avoiding permanent levothyroxine replacement. MRI, magnetic resonance imaging; TRH, thyrotropin-releasing hormone.

hypothyroidism after an undiagnosed episode of subacute or postviral thyroiditis.

The differentiation of hypothyroidism due to intrinsic thyroid failure from hypothyroidism due to diminished TSH secretion resulting from hypothalamic or pituitary disease (central or secondary hypothyroidism) is the most critical decision point in this pathway (see Fig. 13-6). A low thyroid hormone level with a normal or low TSH level should lead to an evaluation for the possibility of failure of other endocrine systems that require trophic pituitary hormones for normal function (see Table 13-1 and Chapters 8 and 9). The only exception is the early stages of *posthyperthyroid* hypothyroidism, in which TSH levels may

remain suppressed for several months even though hypothyroidism, as revealed by a low ft_4 level, has been induced by ^{131}I therapy, surgery, or anti-thyroid drugs (see Table 13-2). In some patients with central hypothyroidism, the basal serum TSH concentration (and the response to TRH) may even be somewhat elevated, but the TSH has reduced biologic potency even though it is immunologically reactive.⁶⁵

In patients with an elevated TSH level and a reduced ft_4 level, the presence or absence of TPO-Ab should be ascertained (see Fig. 13-6). The presence of TPO-Ab usually points to autoimmune thyroid disease (Hashimoto's disease) as the cause of the hypothyroidism. On the other

hand, the absence of TPO-Ab requires a search for less common causes of hypothyroidism, such as transient hypothyroidism, infiltrative thyroid disorders, and external irradiation, as discussed later (see Table 13-1). Nevertheless, approximately 10% of patients with Hashimoto's disease do not have detectable TPO-Ab.

Measurement of radioactive iodine uptake (RAIU) is rarely required in the evaluation of hypothyroidism. Tests that employ radioiodine to assess the function of the thyroid gland display a variable pattern, depending on the underlying thyroid disorder. The diagnostic value of a low RAIU is limited because of the relatively high dietary iodine intake in North America, which reduces uptake of the tracer dose of radioiodine, and variation in iodine intake from day to day in the same individual. National surveys of dietary iodine intake showed a progressive reduction in iodine intake over the last several decades,⁶⁶ but the intake has now stabilized.⁶⁷ The RAIU may be normal or even increased if hypothyroidism results primarily from a biochemical defect in thyroid hormone synthesis rather than thyroid cell destruction, leading to compensatory thyroid enlargement. Specific functional patterns in relation to the causes of hypothyroidism are discussed later. Nonetheless, measurement of RAIU is almost never required in the diagnostic evaluation of the hypothyroid patient.

Differential Diagnosis

The clinical picture of fully developed hypothyroidism is quite characteristic, but the abnormalities can be overlooked, even by experienced clinicians, if the diagnosis is not considered. Despite the availability of inexpensive and specific tests, it is still surprising how often what is retrospectively obvious, severe, primary hypothyroidism is not recognized. A high index of suspicion is required to avoid this oversight.

For the milder forms of hypothyroidism, the clinical presentation overlaps to a significant extent with other conditions. The fact that these disorders often occur in older patients is partly responsible for the diagnostic uncertainty.⁶⁴ In some cases, slowing of mental and physical activity, dry skin, and loss of hair may mimic similar findings in hypothyroidism. Furthermore, older people often become hypothermic with cold exposure.

In patients with chronic renal insufficiency, anorexia, torpor, periorbital puffiness, sallow complexion, and anemia (e.g., see Fig. 13-1) may suggest hypothyroidism and may call for specific testing. Distinguishing nephrotic states from hypothyroidism by clinical examination alone can be even more difficult. In this disorder, waxy pallor, edema, hypercholesterolemia, and hypometabolism may suggest hypothyroidism. In addition, the total serum T_4 concentration may be decreased if significant thyroxine-binding globulin is lost in the urine, but the ft_4 and TSH are normal.

In those patients with pernicious anemia, psychiatric abnormalities, pallor, and numbness and tingling of the extremities may mimic similar findings in hypothyroidism. Although there is a clinical and immunologic overlap between primary hypothyroidism and pernicious anemia, this association is not invariable (see Chapter 42). The presence of hypothyroidism is often suspected in patients who are severely ill, especially in the elderly.^{22,68} In such patients, the total T_4 concentration may be decreased, often markedly so, but the ft_4 is typically normal unless the patient is severely ill (see Chapter 11). These features, together with the absence of an elevation of serum TSH, usually serve to differentiate the ill euthyroid patient from one with

primary hypothyroidism. However, the serum TSH can be transiently increased (up to 20 mU/L) during recovery from severe illness.

Hypothyroidism may develop because of some extrinsic factor or acquired condition or because of a congenital defect that impairs thyroid hormone biosynthesis (see Table 13-1). Inadequate synthesis of hormone leads to hypersecretion of TSH, which in turn produces both goiter and stimulation of all steps in hormone biosynthesis capable of response. In some instances, the compensatory TSH response overcomes the impairment in hormone biosynthesis, and the patient is euthyroid with a goiter. The latter condition (simple or nontoxic goiter) is discussed in Chapter 14. Less commonly, hypothyroidism is associated with an atrophic gland or, in the case of a congenital abnormality, one that never developed properly. Hypothyroidism can also occur after surgical lobectomy, especially in areas of iodine insufficiency or with underlying thyroid TPO-Ab.⁶⁹

CLASSIFICATION

Acquired Causes

Hashimoto's Thyroiditis

Hashimoto's disease is the most common cause of hypothyroidism in areas of the world in which dietary iodine is sufficient. Until it was possible to demonstrate circulating thyroid antigen-specific T cells and thyroid autoantibodies, a diagnosis of Hashimoto's disease could be confirmed only by biopsy of the thyroid. Even now, the terminology used to classify the *autoimmune thyroid diseases* does not reflect current understanding of the pathophysiology of these disorders and suggests that Hashimoto's disease and Graves' disease are distinct entities, which they are certainly not. In pathologic terms, the word *thyroiditis* has implied both the presence of a mononuclear cell infiltrate and destruction of thyroid follicles. However, these are arbitrary criteria. The term *chronic thyroiditis* is more appropriately defined simply as evidence of "intrathyroidal lymphocytic infiltration" without the necessity of follicular damage—which may, however, develop later. By this definition, patients with either Graves' disease or Hashimoto's disease have thyroiditis, and this allows a simple classification for autoimmune thyroid disease into destructive and nondestructive pathologies.⁷⁰ However, most classification systems still use the term *autoimmune thyroiditis* as synonymous with either transient or chronic inflammation, associated with follicular destruction.^{1,2}

Blockade by autoantibodies to the TSH receptor that act as TSH antagonists may be the cause of some cases of the atrophic form of Hashimoto's disease (in the past referred to as "primary myxedema"), but classic Hashimoto's thyroiditis is associated with goiter formation from the marked lymphocytic infiltration.⁷¹ Both Graves' disease and Hashimoto's disease can occur within the same families, and they may share human leukocyte antigen (HLA) and other genetic susceptibility haplotypes.^{71,72} Furthermore, thyroid failure occurs in some patients with Graves' disease, and hyperthyroidism and even orbitopathy may develop in some patients with Hashimoto's disease. Both types of patients can have autoantibodies to thyroglobulin (Tg), TPO, and the TSH receptor. Therefore, the two diseases must be closely related, and autoimmune thyroid disease can be viewed as a spectrum from hyperthyroidism to hypothyroidism.

The Apoptosis Hypothesis

Figure 13-7 Possible involvement of Fas-Fas L in the apoptosis of Hashimoto's thyroiditis. Presence of Fas molecules is indicated by red color; blue color indicates Fas ligand (Fas L). In Graves' disease, the thyroid follicles thrive because the thyroid cells do not express many functional Fas molecules and therefore are resistant to the Fas L, both on the thyroid cells themselves and on the Th₂ T cells. Further apoptotic resistance may be driven by Th₂ cytokines, such as interleukin-4 (IL-4) and IL-10. However, the Th₂ cells express Fas and may themselves be deleted by the Fas L constitutively expressed on the thyroid cells. The result is thyroid cell survival with T-cell destruction. In contrast, in Hashimoto's disease, the thyroid cell expresses many functional Fas molecules, perhaps induced by interferon- γ (IF γ) from the Th₁ type T cells associated with this disease. The expression of thyroid-cell Fas may lead to self (homophilic) apoptosis via thyroid-cell Fas L, or apoptosis may result from attack by the Fas L-armed Th₁ cells. The result is thyroid follicle destruction and T-cell proliferation. Bcl-X_L, Mitochondrial protein involved in Fas-L signal transduction; cFlip, a protease-deficient caspase homolog that acts as an apoptosis inhibitor.

Hashimoto's disease is common and may be increasing in frequency. The mean incidence in women is approximately 3.5 cases per 1000 people per year, and in men it is 0.8 per 1000.^{4,5} No age group is exempt, although the prevalence increases with age in both women and men. Hashimoto's disease is by far the most common cause of goitrous hypothyroidism in areas of iodine sufficiency.

Pathophysiology. Hormone synthesis is impaired due to apoptotic destruction of the thyroid cells. The sick cells exhibit a defect in organic binding of thyroid iodide, as evidenced by a positive perchlorate discharge test (see Chapter 11). In addition, release of iodoproteins, mostly Tg, is enhanced by cell lysis. Approximately 90% of the thyroid gland may be destroyed before clinical hypothyroidism develops. The presence of lymphocytic infiltration of the thyroid (the basis for the older term, *lymphocytic thyroiditis*), circulating thyroid autoantibodies, and clinical or immunologic overlap with other diseases with autoimmune components indicate that Hashimoto's disease is an autoimmune thyroid disorder.

The current understanding of autoimmune mechanisms is discussed in Chapter 12. However, autoimmune thyroiditis is characterized by thyroid cell apoptosis leading to destruction of follicles, rather than the thyroid stimulation and thyroid cell hyperplasia seen in Graves' disease. Although both TPO-Ab and autoantibodies to thyroglobulin (Tg-Ab) are complement fixing and cytotoxic, the thyroid gland is infiltrated by both B cells and T cells; the latter are armed with Fas ligand and capable of destroying thyroid cells expressing Fas via apoptosis (Fig. 13-7).^{73,74} In

addition, other cell death pathways may be involved.⁷⁵ Fas expression on thyroid cells may be secondary to elaboration of a variety of cytokines from T cells that undergo blast transformation when exposed to thyroid antigens (thyrotropin receptor, TPO, and Tg), suggesting that cell-mediated autoimmune mechanisms are pathogenetically involved.⁷⁶

These manifestations of autoimmunity in Hashimoto's disease and other autoimmune thyroid disorders reflect a hereditary susceptibility to thyroid disease that allows the survival and persistence of B cells and T cells directed against thyroid antigens.⁷⁷ The fact that infusion of interleukin-2 (IL-2) and lymphokine-activated killer cells causes progression or development of hypothyroidism in patients with detectable TPO-Ab is additional evidence of the autoimmune nature of this disease.⁷⁷ Animal models and increasing use of interferon- α in chronic liver disease have demonstrated a role for cytokines in initiating thyroid destruction in the setting of lymphocytic infiltration of the thyroid.^{78,79}

Histopathology. The thyroid gland is pale and firm and has a rubbery texture (Fig. 13-8A). Histopathologic changes vary in type and extent but usually consist of diffuse lymphocytic infiltration with germinal center formation and obliteration of thyroid follicles by widespread apoptosis (see Fig. 13-8B). In most cases, there is destruction of epithelial cells and degeneration and fragmentation of the follicular basement membrane. The remaining epithelial cells may be larger and show oxyphilic changes in the cytoplasm; these so-called Askanazy cells are virtually pathognomonic for Hashimoto's disease. In some cases,

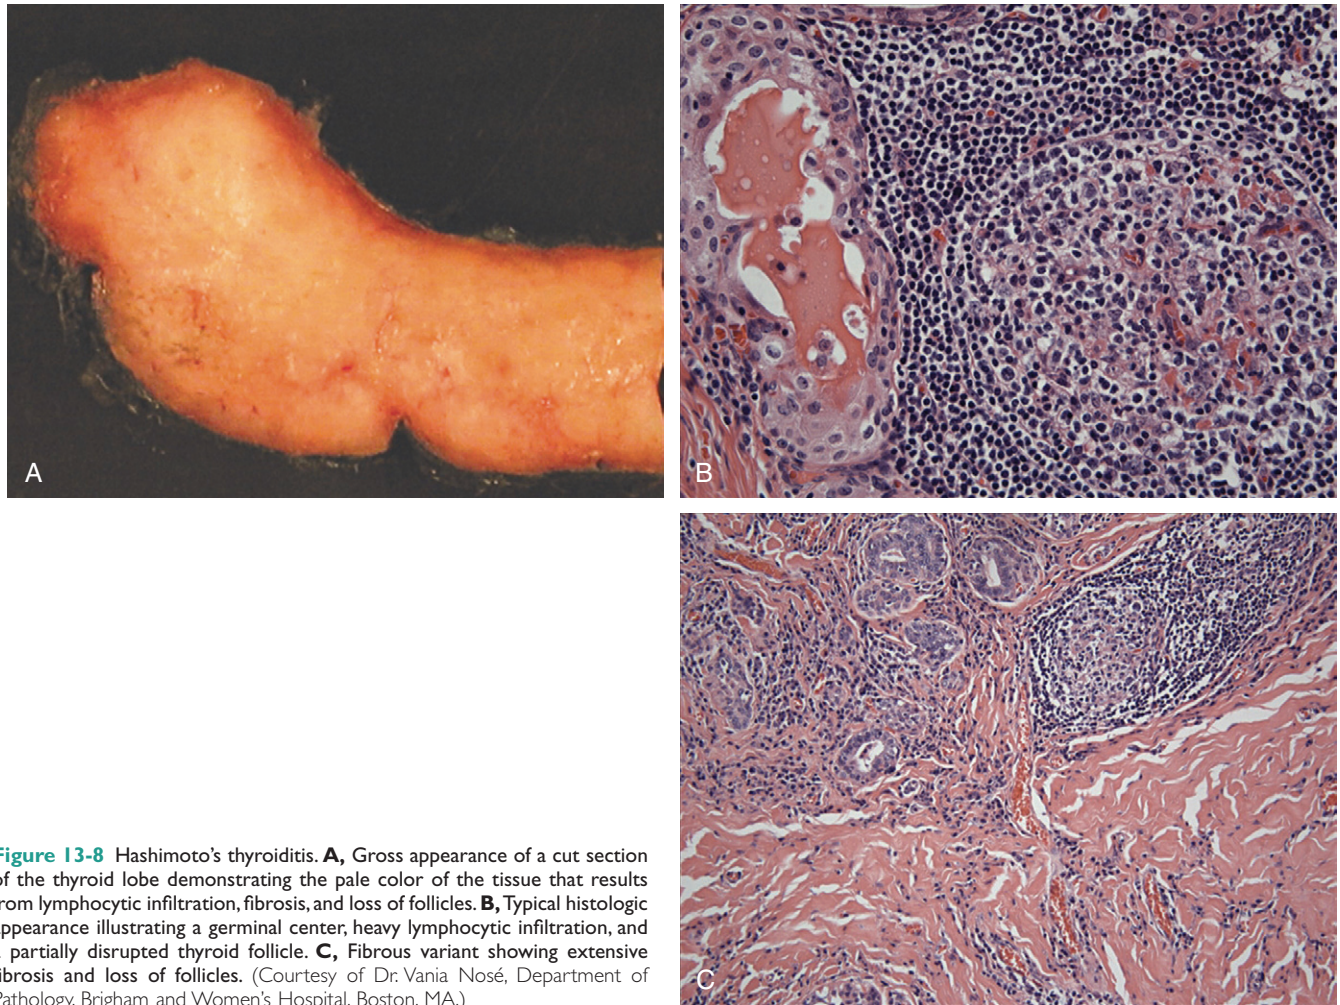

Figure 13-8 Hashimoto's thyroiditis. **A**, Gross appearance of a cut section of the thyroid lobe demonstrating the pale color of the tissue that results from lymphocytic infiltration, fibrosis, and loss of follicles. **B**, Typical histologic appearance illustrating a germinal center, heavy lymphocytic infiltration, and a partially disrupted thyroid follicle. **C**, Fibrous variant showing extensive fibrosis and loss of follicles. (Courtesy of Dr. Vania Nosé, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)

colloid is sparse. Fibrosis is usually present in the more long-standing tissues but not to the extent seen in the variant referred to as Riedel's thyroiditis (see Fig. 13-8C).

In the past, the diagnosis of Hashimoto's disease required the presence of Askanazy cells or lymphoid follicles, but now the primary observation should be follicular destruction, often with mononuclear cell invasion of the follicular spaces. The degree of lymphocytic infiltration usually correlates with the levels of circulating thyroid autoantibodies. In Graves' disease, the heterogeneous lymphocytic infiltration and associated antibodies may favor the development of hypothyroidism in the long term.

Risk Factors

Genetic Susceptibility. We have already referred to the familial predisposition to autoimmune disease in patients with autoimmune thyroid disease. As with Graves' disease, there is a significant but weak association between Hashimoto's disease and HLA DR3 and DR5 haplotypes and certain DQ alleles best correlated with an arginine residue at position 74 of the HLA-DR binding pocket.^{71,72} Unlike the situation in diabetes mellitus, formal linkage of specific histocompatibility antigens with autoimmune thyroid disease has been difficult to demonstrate.

The fact that thyroid cells can express HLA-DR antigens, at least as a secondary phenomenon, indicates the potential role of these cells in perpetuating the immune response and may be related to the propensity of autoimmune disease for certain HLA-DR subgroups. Hashimoto's disease almost certainly is associated with a polygenetic susceptibility, HLA being only one of the genes involved. Efforts are under way to identify non-HLA susceptibility genes in families with autoimmune thyroid disease, and a number of such genes have been shown to have weak associations with this disease.⁸⁰ Of particular interest has been polymorphisms in the *CTLA4* gene, which codes for a regulatory protein inhibiting T-cell reactivity; such polymorphisms have been consistently linked to the propensity to secrete thyroid autoantibodies and are an important risk factor for the disease itself.⁷¹ To date, the only thyroid-specific gene association with Hashimoto's thyroiditis has been that for Tg.⁸¹

Nongenetic Risk Factors. Many of the factors that have been identified as increasing the risk for Graves' disease—pregnancy, drugs, age and gender, infection, and irradiation—apply equally to autoimmune thyroiditis. These are detailed in Chapter 12 and are briefly considered here.

Pregnancy. The recognition of transient postpartum thyroiditis as an important clinical entity has also provided an example of the immune manipulation of thyroid disease with a predictable onset and recovery (see Chapter 12). Maternal microchimerism may be an important component of this risk analysis.⁸² The disease is essentially postpartum Hashimoto's disease except for its transient nature. Data suggest that 8% to 10% of women experience thyroiditis in the postpartum period with a variety of consequences (see later discussion).⁸³ Pregnancy is, therefore, an important risk factor, with transient postpartum thyroiditis developing in some patients and thyroid failure developing permanently or in the early years after pregnancy in a significant proportion.

Iodine and Drugs. Iodine and iodine-containing drugs (e.g., amiodarone) precipitate autoimmune thyroiditis in susceptible populations.^{84,85} This form should be distinguished from direct blockade and destruction of the thyroid gland by iodine. The mechanism is unknown, but much evidence accumulated in animal models suggests that increased iodination of Tg enhances its immunoreactivity.⁸⁶

Cytokines. Treatment of patients with IL-2 or interferon- α may precipitate the appearance of autoimmune thyroid disease in the form of Hashimoto's thyroiditis or Graves' disease.⁷⁸ Destructive thyrotoxicosis may appear suddenly and needs to be distinguished from persistent Graves' disease, which may also develop in such patients. Autoimmune thyroid disease is more common in patients with preexisting TPO-Ab.

Irradiation. Radiation exposure has been shown to induce thyroid autoantibodies and autoimmune thyroid disease in a number of studies. These exposures have arisen from the atomic bomb detonation in Japan,⁸⁷ the Chernobyl disaster,⁸⁸ and therapeutic irradiation for Hodgkin's disease.⁸⁹ Hodgkin's disease survivors have a 17-fold relative risk of developing hypothyroidism.⁸⁹ A long-term follow-up of Japanese atomic bomb survivors after more than 55 years showed a persistent increased risk of thyroid nodules but not thyroid autoantibodies.⁹⁰ It is postulated that the specific effect of radiation on thyroid autoantibody expression may diminish with longer-term follow-up, because the incidence of autoimmune thyroid disease in the general population increases with age.

Age. Because autoimmune thyroid failure continues to occur throughout adult life, the prevalence of the disease increases markedly with age.^{4-6,68} This is similar to other markers of autoimmunity and may reflect an increasing loss of tolerance to self.

Infection. There is no direct evidence that infection causes classic autoimmune thyroiditis in humans, although there is suggestive evidence that the hepatitis C virus may enter thyroid cells and precipitate thyroid disease in susceptible patients.⁷⁸ A number of viral infections in animals also can precipitate thyroid autoimmunity.⁹¹ In addition, persisting signs of thyroid autoimmune disease have been found during long-term follow-up of patients with subacute thyroiditis thought to be a reaction to a viral infection (see later discussion). Infection remains a likely cause of the local or distant insult that is considered to be needed to precipitate autoimmune disease in susceptible individuals (see Chapter 12).

Clinical Picture. Goiter, the hallmark of classic Hashimoto's disease, usually develops gradually and may be found during routine examination or by ultrasonography. On occasion, the thyroid gland enlarges rapidly and, when accompanied by pain and tenderness, may mimic de

Quervain's or subacute thyroiditis (see Chapter 12). Some patients, particularly those with the fibrous variant, are hypothyroid when first seen. The goiter is usually moderate in size and firm in consistency and moves freely on swallowing. The surface is either smooth or bumpy, but well-defined nodules are unusual. Both lobes are enlarged, but the gland may be asymmetric. The pyramidal lobe may also be enlarged, and adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves, may be compressed. Enlargement of regional lymph nodes is unusual.

Other patients with hypothyroidism present without a goiter (atrophic hypothyroidism, discussed later), and this is thought to represent the end result of autoimmune destruction of the thyroid. Progression of goitrous Hashimoto's disease to the atrophied state is not commonly seen in the individual patient. The atrophic thyroid most likely reflects rapid large-scale apoptosis early in the onset of Hashimoto's disease combined with TSH receptor antibodies of the blocking variety. The general histopathologic picture tends to remain rather static except for an increase in fibrous tissue. A study of thyroid volume by ultrasonography in patients with newly diagnosed autoimmune hypothyroidism found that there was a continuum of thyroid size, with atrophy and goiter representing extremes of the distribution rather than distinct entities.⁹²

Clinically, the untreated goiter remains unchanged or enlarges gradually over many years. The manifestations of hypothyroidism may develop over several years in patients who are initially euthyroid. Thyroid lymphoma occurs almost exclusively in patients with underlying Hashimoto's disease and should be suspected if there is rapid, usually painful, enlargement of the thyroid gland.⁹³ The presence of coexistent Hashimoto's disease may be a favorable prognostic factor in patients with papillary carcinoma.⁹⁴

Occasionally, hyperthyroidism due to Graves' disease develops in patients with Hashimoto's disease. In other patients with early autoimmune thyroiditis, transitory thyrotoxicosis (painless or silent thyroiditis with thyrotoxicosis) occurs as the result of thyroid cell destruction. In such cases, evidence of ongoing thyroid hyperfunction is lacking because the thyroid RAIU is depressed. As described earlier, a phase of transient hypothyroidism begins 3 to 6 months after delivery in 30% of pregnant women with autoimmune thyroiditis, as evidenced by the presence of TPO-Ab.⁸³ The history may suggest earlier, mild thyrotoxicosis (see the discussion of syndromes associated with transient hyperthyroidism in Chapter 12).

Laboratory Tests. Results of the common tests of thyroid function depend on stage of disease (see Table 13-2). Rarely, the tests suggest thyroid hyperfunction with a suppressed TSH but without overproduction of hormone. The RAIU may be increased in these rare patients, but serum T₄ and T₃ levels remain normal. At this stage, the patient may be eumetabolic. As the TSH level rises, the glandular response at first compensates for the impairment of hormone biosynthesis. With time, the ability of the thyroid to respond to TSH diminishes, and the RAIU and serum T₄ level decline to subnormal values. The serum T₃ concentration remains normal, probably reflecting maximal stimulation of the failing thyroid by the increased serum TSH. The early phases of the foregoing sequence, when the serum TSH is increased but T₄ and T₃ are still normal, is termed *subclinical hypothyroidism* (see Table 13-2).

The diagnosis of Hashimoto's disease is confirmed by the presence of thyroid autoantibodies in the serum,

usually in high levels. TPO-Ab are more common and are present in higher concentrations than Tg-Ab, probably because circulating serum Tg absorbs the anti-Tg molecules. Sometimes part of a gland with autoimmune thyroiditis may look and feel like a firm thyroid nodule, and ultrasonography or even aspiration biopsy should be performed to resolve the issue.

Differential Diagnosis. Differentiation of Hashimoto's disease from other uncomplicated disorders of the thyroid is facilitated by the demonstration that high levels of thyroid autoantibodies occur more commonly in Hashimoto's disease than in other thyroid disorders. The frequent coexistence of hypothyroidism and Hashimoto's disease serves to distinguish this disease from nontoxic goiter and thyroid neoplasia.

Differentiation of euthyroid Hashimoto's disease from a multinodular goiter is often difficult without sonography, whereas diffuse nontoxic goiter tends to be softer than in Hashimoto's disease. Ultrasound examination may reveal the heterogeneous echotexture characteristic of Hashimoto's disease. In adolescents, differentiation of Hashimoto's disease from diffuse nontoxic goiter is more difficult, because in this age group Hashimoto's disease may not be accompanied by such high levels of thyroid autoantibodies. The presence of well-defined nodules usually distinguishes nontoxic multinodular goiter from Hashimoto's disease.

Differentiation between euthyroid Hashimoto's disease and thyroid carcinoma can sometimes be made on clinical grounds and ultrasonography. Thyroid carcinoma is usually nodular and firm or hard, and the gland may be fixed to adjacent structures. Compression of the recurrent laryngeal nerve with hoarseness is virtually pathognomonic of thyroid neoplasia but occurs late in the disease progression. A history of a recent enlargement of the goiter is more common in thyroid malignancies (carcinoma or lymphoma) than in Hashimoto's disease. Enlargement of regional lymph nodes also suggests thyroid malignancy. In thyroid carcinoma, ultrasound examination or radioiodine scanning of the thyroid may reveal only the isolated lesion. In Hashimoto's disease, activity is usually heterogeneous.

Treatment. In many patients, no treatment is required because the goiter is small and the disease is asymptomatic, with the TSH level remaining in the normal range. In other patients, treatment with thyroid hormone is directed at alleviating goiter, hypothyroidism, or both.

Levothyroxine treatment is indicated in patients who have a goiter that presses on adjacent structures or is unsightly, and it is most effective with goiters of recent onset. In long-standing goiter, treatment with thyroid hormone is usually ineffective, possibly because of fibrosis.

Glucocorticoids can cause regression of the goiter and decrease autoantibody levels, but these agents are not recommended in most patients because of untoward side effects and the return of activity after treatment is withdrawn.

Full-replacement doses of thyroid hormone should be given when hypothyroidism is present. Surgery is justified if pressure symptoms or unsightly enlargement persists after a trial of suppressive therapy. Administration of levothyroxine should be continued after surgery, because hypothyroidism is inevitable. The importance of maintaining the serum TSH level within the normal range is discussed later.

Iodine Deficiency (Endemic Goiter)

The term *endemic goiter* denotes any goiter that occurs in a region where goiter is prevalent.^{84,95} As mentioned, endemic goiter almost always occurs in areas of environmental iodine deficiency. Although this condition is estimated to affect more than 200 million people throughout the world and is of major public health significance, it is most common in mountainous areas, such as the Alps, Himalayas, and Andes, or in the Great Lakes and Mississippi Valley regions of the United States, owing to the depletion of iodine consequent to the persistent glacial run-off in these regions.

The causative role of iodine deficiency in the genesis of endemic goiter is supported by several lines of evidence: the inverse correlation between the iodine content of soil and water and the incidence of goiter, the kinetics of iodine metabolism in patients with the disorder, and a decrease in incidence after iodine prophylaxis. The last finding accounts for the general absence of endemic goiter in the population residing in the Great Plains region of the United States.

The occurrence of endemic goiter can vary, even within an area of known iodine deficiency; the role of dietary minerals or naturally occurring goitrogens and of pollution of water supplies has been suggested in instances of this type.⁸⁴ For example, in the Cauca Valley of Colombia, waterborne goitrogens have been implicated, and in many areas of endemic iodine deficiency, consumption of cassava meal, which gives rise to thiocyanate, aggravates the iodine-deficient state by inhibiting thyroid iodide transport. Familial clustering of goiters within iodine-insufficient areas, usually with an autosomal dominant inheritance, suggests an important genetic component.⁹⁶

Most abnormalities in iodine metabolism in patients with endemic goiter are consistent with the expected effects of iodine deficiency (see Chapter 11). Thyroid iodide clearance rates and RAIU are increased in proportion to the decrease in urinary excretion of stable iodine. The absolute iodine uptake is normal or low. In areas of moderate iodine deficiency, the serum T₄ concentration is usually in the lower range of normal; in areas of severe deficiency, values are decreased. Nevertheless, most patients in these areas do not appear to be in a hypothyroid state because of an increase in the synthesis of T₃ at the expense of T₄ and because of an increase in the activity of thyroidal D1 and D2.⁶⁴ TSH levels are typically in the upper range of normal.

The incidence and severity of endemic goiter and the metabolic state of the goitrous patient depend mainly on the degree of iodine deficiency. In the absence of hypothyroidism, the effects of the goiter are mainly cosmetic. However, if the goiter becomes nodular, hemorrhage into a nodule may cause acute pain and swelling, mimicking subacute thyroiditis or neoplasia. The goiter may also compress adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves. The borderline nature of the iodine supply in many countries of Western Europe is exemplified by the development in Belgium of compensatory maternal and fetal goiter during pregnancy in response to the increased requirement for thyroid hormone during gestation.⁹⁷

The incidence of endemic goiter has been greatly reduced in many areas by the introduction of iodized salt.⁸⁴ In the United States, table salt is enriched with potassium iodide to a concentration of 0.01%, which, if the intake of salt is average, would provide an iodine intake of approximately 150 to 300 µg/day, the desired amount in an adult (see Table 11-1 in Chapter 11). The use of iodine-containing

flour in bread products and iodized salt in commercially produced food has been markedly reduced.⁹⁸ Iodine content of bread and infant formula is variable within a given product and often does not match the measured content.⁹⁸ As mentioned, iodine intake in the United States has been decreasing in recent decades, probably because of reduced use of iodine in commercial food products, although iodine intake has now stabilized.⁶⁷ A significant fraction of pregnant women in Boston, based on urinary iodine excretion, have iodine intake below the recommended level for pregnancy.⁹⁹ Most prescription prenatal vitamins do not contain iodine.¹⁰⁰ An annual injection of iodized oil is another effective means of administering iodine, and endemic goiter can be treated by the addition of iodine to communal drinking water.

Administration of iodine has little, if any, effect on a long-standing endemic goiter, but it causes the early endemic hyperplastic goiter of iodine deficiency to regress.¹⁰¹ Similarly, thyroid hormone usually has no effect on long-standing goiter or on established mental or skeletal changes, but it should be given in full-replacement doses if there is evidence of hypothyroidism. This is of paramount importance in pregnant women. Surgical treatment is indicated if the adjacent structures are compressed or if the goiter is either very large or enlarging rapidly.

Endemic Cretinism

Endemic cretinism is a developmental disorder that occurs in regions of severe endemic goiter.⁸⁴ Both parents of an endemic cretin are usually goitrous, and, in addition to the features of sporadic cretinism described earlier, endemic cretins often have deaf-mutism, spasticity, motor dysfunction, and abnormalities in the basal ganglia demonstrable by magnetic resonance imaging.

Three types of cretins can be discerned: hypothyroid cretins, neurologic cretins, and cretins with combined features of the two. The pathogenesis of neurologic cretinism is obscure but may be the result of severe thyroid hormone deficiency during a critical early phase of central nervous system development in utero.³² Some cretins are goitrous, but in others the thyroid is atrophic, possibly as a consequence of exhaustion atrophy from continuous overstimulation or lack of iodine.

Iodide Excess

Goiter and hypothyroidism, either alone or in combination, are sometimes induced by chronic administration of large doses of iodine in organic or inorganic form (see Table 11-7 in Chapter 11).^{84,85,102} Iodide-induced goiter was formerly seen in patients with chronic respiratory disease who were given potassium iodide as an expectorant. The development of iodide goiter has also been reported after a single administration of radiographic contrast medium, from which iodide is released slowly over a long period, and it may also occur during amiodarone administration. Iodide goiter without hypothyroidism may occur endemically, such as on the island of Hokkaido, Japan, where seaweed products are consumed in large quantities.

From an analysis of reported cases and from the fact that only a small percentage of patients who receive iodides chronically develop goiter, it appears that the disorder evolves on a background of underlying thyroid dysfunction. Categories of susceptible individuals include patients with Hashimoto's disease; patients with Graves' disease, especially after its treatment with radioiodine; and patients with cystic fibrosis. Among these groups, many individuals display a positive iodide-perchlorate discharge test, indicating a defect in the thyroidal organic iodine-binding

mechanism (see Chapter 11). However, intrinsic thyroid disease need not be present, because a propensity to develop iodide goiter and hypothyroidism has also been demonstrated in patients who have undergone hemithyroidectomy for a solitary thyroid nodule, in whom the remaining lobe was histologically normal.⁶⁹ In these patients, as in those with Hashimoto's disease or Graves' disease studied prospectively, individuals with the highest basal serum TSH concentrations, even within the normal range, were those who developed iodide goiter. Iodinated contrast material, amiodarone, and povidone-iodine are common sources.¹⁰¹

Goiter and hypothyroidism commonly occur in newborn infants born to women given large quantities of iodine during pregnancy, and death from neonatal asphyxia has been reported (see Fig. 11-11 in Chapter 11). In such cases, the mother is usually free from goiter. Pregnant women should not receive large doses of iodine (≥ 1 mg/day) over prolonged periods (>10 days), especially near term. Maternal amiodarone therapy causes thyroidal dysfunction in up to 20% of newborns.⁸⁴ It is not known whether iodide goiter in newborns results from an inherent hypersensitivity of the fetal thyroid or from the fact that the placenta concentrates iodide several-fold, or both.

As discussed in Chapter 11, large doses of iodine cause an acute inhibition of organic binding that abates in the normal individual despite continued iodine administration (acute Wolff-Chaikoff effect and escape).¹⁰³ Iodide goiter appears to result from a more pronounced inhibition of organic binding and failure of the escape phenomenon. Decreased hormone synthesis and the consequent increase in TSH result in enhanced iodide transport. Because inhibition of organic binding is a function of the intrathyroidal concentration of iodide, a vicious circle, augmented by this increase in serum TSH, is set in motion.

The disorder usually appears as a goiter with or without hypothyroidism, although in rare instances iodine may produce hypothyroidism unaccompanied by goiter. Usually, the thyroid gland is firm and diffusely enlarged, often greatly so. Histopathologic examination reveals intense hyperplasia. The ft_4 concentration is low, the TSH concentration is increased, and the 24-hour urinary iodine excretion and serum inorganic iodide concentration are increased. The disorder regresses after iodine is withdrawn. Thyroid hormone may also be given to relieve severe symptoms.

Drugs That Block Thyroid Hormone Synthesis or Release, Causing Goiter Formation

Ingestion of compounds that block thyroid hormone synthesis or release may cause goiter with or without hypothyroidism. Apart from the agents used in the treatment of hyperthyroidism, anti-thyroid agents may be encountered as drugs for the treatment of disorders unrelated to the thyroid gland or as natural agents in foodstuffs.⁸³

Goiter with or without hypothyroidism can occur in patients given lithium, usually for bipolar manic-depressive psychosis.⁸³ Like iodide, lithium inhibits thyroid hormone release, and in high concentrations it can inhibit organic binding reactions. In the latter respect, iodide and lithium act synergistically, at least acutely. The mechanisms underlying the several effects of lithium are uncertain; what differentiates patients who develop goiter during lithium therapy from those who do not is also unclear. Underlying autoimmune thyroiditis may be at least one factor, because many patients with this combination have autoimmune thyroid disease.

Other drugs that occasionally produce goitrous hypothyroidism include para-aminosalicylic acid, phenylbutazone,

aminogluthethimide, and ethionamide. Like the thionamides, these drugs interfere with both the organic binding of iodine and, perhaps in later steps, hormone biosynthesis. Although soybean flour is not an anti-thyroid agent, soybean products in feeding formulas formerly resulted in goiter in infants by enhancing fecal loss of hormone, which, together with the low iodine content of soybean products, produced a state of iodine deficiency. Feeding formulas containing soybean products are now enriched with iodine.

Cigarette smoking increases the risk of hypothyroidism in patients with underlying autoimmune thyroid disease. Although the mechanism is unclear, certain components of cigarette smoke, including thiocyanate, hydroxypyridine, and benzopyrene derivatives, may be responsible. These components of smoke may also interfere with thyroid hormone action.¹⁰⁴

Both the goiter and the hypothyroidism usually subside after the anti-thyroid agent is withdrawn. If continued administration of pharmacologic goitrogens is required, replacement therapy with thyroid hormone causes the goiter to regress.

Goitrogens in Foodstuffs or as Endemic Substances or Pollutants

Anti-thyroid agents also occur naturally in foods. These are widely distributed in the Cruciferae and Brassicaceae families, particularly in the genus *Brassica*, including cabbages, turnips, kale, kohlrabi, rutabaga, mustard, and various plants that are not eaten by humans but serve as animal fodder. It is likely that some thiocyanate is present in such plants (particularly cabbage). Cassava meal, a dietary staple in many regions of the world, contains linamarin, a cyanogenic glycoside, the preparation of which leads to the formation of thiocyanate. Ingestion of cassava can accentuate goiter formation in areas of endemic iodine deficiency. Except for thiocyanate, dietary goitrogens influence thyroid iodine metabolism in the same manner as do the thionamides, which they resemble chemically; their role in the induction of disease in humans is uncertain. Waterborne, sulfur-containing goitrogens of mineral origin are believed to contribute to the development of endemic goiter in certain areas of Colombia.

A number of synthetic chemical pollutants have been implicated as a cause of goitrous hypothyroidism, including polychlorinated biphenyls and resorcinol derivatives.^{105,106} Perchlorate has also been noted in high concentrations in geographic regions in which explosives and rocket fuel were made.¹⁰⁷ Perchlorate has been detected in water, food, and breast milk, although the amount does not appear to be sufficient to disrupt thyroid function.¹⁰³ In an area of Chile with a high level of natural perchlorate contamination in the water, thyroid function in pregnant women was not different from that in a region with no perchlorate, although iodine intake was quite high in that area.¹⁰⁸

Cytokines

Patients with chronic hepatitis C or various malignancies may be given interferon- α or IL-2.⁷⁸ Such patients may experience hypothyroidism, which is usually transient but may persist. These agents activate the immune system and can induce a clinical picture suggesting an exacerbation of underlying autoimmune disease such as occurs during postpartum thyroiditis (see Chapter 12). Graves' disease with hyperthyroidism may also develop, and ablative therapy may be required to treat this condition. Patients with preexisting evidence of autoimmune thyroid disease

who have positive TPO-Ab are probably at higher risk for this complication and should be monitored carefully during and after a course of treatment with either of these cytokines.

Congenital Causes of Goiter

Inherited defects in hormone biosynthesis are rare causes of goitrous hypothyroidism and account for only about 10% to 15% of the 1 in 3500 newborns with congenital hypothyroidism.¹⁰ In most instances, the defect appears to be transmitted as an autosomal recessive trait. Individuals with goitrous hypothyroidism are believed to be homozygous for the abnormal gene, whereas euthyroid relatives with slightly enlarged thyroids are presumably heterozygous. In the latter group, appropriate functional testing may disclose a mild abnormality of the same biosynthetic step that is defective in the homozygous individual. In contrast with nontoxic goiter, which is more common in females than in males, these defects, as a group, affect females only slightly more commonly than males.

Although goiter may be present at birth, it usually does not appear until several years later. Therefore, the absence of goiter in a child with functioning thyroid tissue does not exclude the presence of hypothyroidism. The goiter is initially diffusely hyperplastic, often intensely so, suggesting papillary carcinoma, but it eventually becomes nodular. In general, the more severe the biosynthetic defect, the earlier the goiter appears, the larger it is, and the greater the likelihood of early development of hypothyroidism or even cretinism. Five specific defects in the pathways of hormone synthesis have been identified.

Iodide Transport Defect. An iodide transport defect, resulting from impaired iodide transport by the sodium-iodide symporter (NIS) protein mechanism, is rare and is reflected in defective iodide transport in the thyroid, salivary gland, and gastric mucosa.¹⁰⁹ Some mutations in such patients produce reduced activity, and others completely inactivate NIS by preventing the protein from being transported and inserted into the membrane. With the milder NIS mutations, administration of iodide raises the plasma and intrathyroidal iodide concentration, permitting the synthesis of normal quantities of hormone.

Defects in Expression or Function of Thyroid Peroxidase. TPO is a protein that is required for normal synthesis of iodothyronines. Quantitative or qualitative abnormalities of TPO were identified in 1 of every 66,000 infants in the Netherlands.¹¹⁰ The most common of the 16 mutations identified in 35 families was a GGCC insertion in exon 8, leading to a premature stop codon.

Pendred's Syndrome. The most common presentation in patients with Pendred's syndrome is a defect in iodine organification accompanied by sensory nerve deafness.¹¹¹ The abnormality is in the *PDS* gene encoding pendrin, which is involved in the apical secretion of iodide into the follicular lumen (see Fig. 11-2 in Chapter 11). Thyroid function is only mildly impaired in this disorder.

Defects in Thyroglobulin Synthesis. Defects in the synthesis of Tg due to genetic causes are rare, having been identified only in a small number of families with congenital hypothyroidism.¹¹² Some defects lead to premature termination of translation, whereas another causes deficiency in endoplasmic reticulum processing of the Tg molecule. The complex regulation and huge size of this gene makes screening for mutations a difficult task, and considerable

work is still required to unravel the extent of the defects in this gene.

Iodotyrosine Dehalogenase Defect. The pathogenesis of goiter and hypothyroidism in the iodotyrosine dehalogenase defect is complex. The major abnormality is an impairment of both intrathyroidal and peripheral deiodination of iodotyrosines, presumably because of the dysfunction of the iodotyrosine *Dehal1b* gene (see Chapter 11).¹¹³ As a consequence of intense thyroid stimulation and lack of intrathyroidal recycling of iodide derived from dehalogenation, iodide is rapidly accumulated by the thyroid gland and is rapidly released; monoiodotyrosine (MIT) and diiodotyrosine (DIT) are elevated in plasma and, together with their deaminated derivatives, in the urine. Hypothyroidism is presumed to result from the loss of large quantities of MIT and DIT in the urine and from secondary iodine deficiency. The goiter and hypothyroidism are relieved by administration of high doses of iodine.

Thyroid Infiltration Causing Hypothyroidism and Goiter

A number of infiltrative or fibrosing conditions can cause hypothyroidism. Some are often associated with goiter, such as Riedel's struma (see later discussion).¹¹⁴ Others, such as amyloidosis,¹¹⁵ hemochromatosis,¹¹⁶ or scleroderma,¹¹⁷ may not be. Although the other manifestations of these conditions are usually obvious and hypothyroidism is only a complication, the presence of significant hypothyroidism without evidence of autoimmune thyroiditis should lead to a consideration of these rare causes of this condition.

Postablative Hypothyroidism

Postablative hypothyroidism is a common cause of thyroid failure in adults. One type occurs after total thyroidectomy usually performed for thyroid carcinoma. Although functioning remnants may be present, as indicated by foci of radioiodine accumulation, hypothyroidism invariably develops. Another etiologic mechanism is subtotal resection of the diffuse goiter of Graves' disease or multinodular goiter. Its frequency depends on the amount of tissue remaining, but continued autoimmune destruction of the thyroid remnant in patients with Graves' disease may be a factor, because some studies suggest a correlation between the presence of circulating thyroid autoantibodies in thyrotoxicosis and the development of hypothyroidism after surgery.¹¹⁸ Hypothyroidism can be manifested during the first year after surgery, but, as with postradioiodine hypothyroidism, the incidence increases with time to approach 100%. In some patients, mild hypothyroidism appears during the early postoperative period and then remits, as also occurs after radioiodine treatment.

Hypothyroidism after destruction of thyroid tissue with radioiodine is common and is the one established disadvantage of this form of treatment for hyperthyroidism in adults. Its frequency is determined in large part by the dose of radioiodine and radioiodine uptake, but it is also influenced by other factors, including age, thyroid gland size, magnitude of thyroid hormone elevations, and use of anti-thyroid drugs.¹¹⁹ The incidence of postradioiodine hypothyroidism increases with time, approaching 100%. Although the fT_4 is low in patients with postablative hypothyroidism, serum TSH levels may be anomalously low for several months after surgical or ^{131}I -induced hypothyroidism if TSH synthesis has been suppressed for a long period before treatment.

Primary atrophic thyroid failure may also develop in patients with Hodgkin's disease after treatment with mantle irradiation or after high-dose neck irradiation for other forms of lymphoma or carcinoma.^{88,89} Surgical, radioiodine, or external-beam therapy may also lead to a state of subclinical hypothyroidism (see Table 13-2).

Congenital Causes

Thyroid Agenesis or Dysplasia

Developmental defects of the thyroid are often responsible for the hypothyroidism that occurs in 1 of every 3500 newborns.¹⁰ These defects may take the form of complete absence of thyroid tissue or failure of the thyroid to descend properly during embryologic development. Thyroid tissue may then be found anywhere along its normal route of descent, from the foramen cecum at the junction of the anterior two thirds and posterior third of the tongue (lingual thyroid) to the normal site or below. Absence of thyroid tissue or its ectopic location can be ascertained by scintiscanning.

As indicated, a number of proteins are known to be crucial for normal thyroid gland development.¹⁰ These include the thyroid-specific transcription factor PAX8 and thyroid transcription factors 1 and 2 (TTF1 and TTF2). It might be anticipated that defects in one or more of these proteins could explain abnormalities in thyroidal development. These have been identified in several patients with PAX8 mutations, and a mutation in the human TTF2 gene was associated with thyroid agenesis, cleft palate, and choanal atresia. Despite a specific search, no mutations have been found in the TTF1 gene in infants with congenital hypothyroidism.

Thyroid Aplasia Due to Thyrotropin Receptor Unresponsiveness

Several families exist in which thyroid hypoplasia, high TSH concentrations, and a low fT_4 level are associated with loss-of-function mutations in the TSH receptor.¹²⁰ The thyroid glands were in the normal location but did not trap pertechnetate (TCO_4^-). Somewhat surprisingly, Tg levels were still detectable. The molecular details of these patients are still under study.

A second type of abnormality that could cause TSH unresponsiveness is a mutation in the G_s protein that occurs in pseudohypoparathyroidism type 1A. These patients have inactivating mutations in the α -subunit of the G_s protein and, consequently, mild hypothyroidism.¹²¹ Other patients have been reported to have elevated TSH levels and hypothyroidism in which the molecular nature of the defect has not yet been defined.¹²²

Transient Hypothyroidism

Transient hypothyroidism is defined as a period of reduced fT_4 with suppressed, normal, or elevated TSH levels that is eventually followed by a euthyroid state. This form of hypothyroidism usually occurs in the clinical context of a patient with subacute (postviral), lymphocytic (painless), or postpartum thyroiditis. These conditions are reviewed in detail in Chapter 12.

The patient reports mild to moderate symptoms of hypothyroidism of short duration, and serum TSH concentrations are typically elevated, although not greatly so. The patient often has a preceding episode of symptoms consistent with mild or moderate thyrotoxicosis. If these symptoms cannot be elucidated from the history, it may be difficult to distinguish such patients from those with a permanent form of hypothyroidism. In the early phases of

post-thyroiditis hypothyroidism, TSH concentrations may still be suppressed even though the fT_4 is low because of the delayed recovery of pituitary TSH synthesis, such as in patients with Graves' disease or with toxic nodules who have undergone surgery and who have experienced rapid relief of hyperthyroidism (see Table 13-2). In the latter situation, the TSH response to hypothyroidism may be suppressed for many months; in post-thyroiditis hypothyroidism, this period is rarely longer than 3 to 4 weeks.

A significant fraction (approximately 33%) of women with autoimmune thyroiditis but normal thyroid function have episodes of hypothyroidism during the postpartum period.⁸¹ In some, the preceding hyperthyroidism was relatively asymptomatic, which can make an accurate clinical diagnosis difficult. Patients who have had an episode of typical subacute postviral thyroiditis with pain, tenderness, and hyperthyroidism are not difficult to recognize.

Diagnostic evaluation should include a determination of TSH, fT_4 , and TPO-Ab. Negative or low antibodies argue strongly for a nonautoimmune cause. This is significant, in that it may be possible for the patient to be treated only temporarily for hypothyroidism. In such patients, a trial of a lower levothyroxine dosage after 3 to 6 months may reveal that thyroid function has recovered (see Fig. 13-6). This may also occur in patients with hypothyroidism that follows acute autoimmune thyroiditis (e.g., in the postpartum period), but it is somewhat less likely to occur because of the underlying progressive nature of the autoimmune thyroiditis.

In patients with hypothyroidism due to postviral thyroiditis, the thyroid gland is usually relatively small and atrophic. In patients with hypothyroidism that follows an episode of subacute thyroiditis, the gland is usually slightly enlarged and somewhat firm, reflecting the underlying scarring and infiltration associated with that condition.

Consumptive Hypothyroidism

Consumptive hypothyroidism is the term given to an unusual cause of hypothyroidism that has been identified in infants with visceral hemangiomas or related tumors.^{123,124} The first patient reported with this syndrome presented with abdominal distention caused by a large hepatic hemangioma and respiratory compromise secondary to upward displacement of the diaphragm. However, clinical signs suggested hypothyroidism, which was confirmed by finding a markedly elevated TSH level and undetectable T_4 and T_3 levels. The infant's response to an initial intravenous infusion of liothyronine (T_3) was transient, leading to the decision to use parenteral thyroid hormone replacement to relieve the clinical hypothyroidism. The accelerated degradation of thyroid hormone was apparent from the fact that it required 96 μ g of liothyronine plus 50 μ g of levothyroxine to normalize the TSH level. The equivalent dosage as levothyroxine alone is roughly nine times that ordinarily required for treatment of infants with congenital hypothyroidism. The infant succumbed to complications of the hemangioma, and a postmortem tumor biopsy showed D3 activity in the tumor at levels eightfold higher than those normally present in term placenta. The serum reverse T_3 was extremely elevated (400 ng/dL), and the serum Tg was greater than 1000 ng/mL, indicating the presence of a highly stimulated thyroid gland.

Retrospective search revealed two other patients with similar pathophysiology in whom the cause of the hypothyroidism had not been recognized. Significant D3 expression has now been identified in all proliferating cutaneous hemangiomas studied to date. The cutaneous hemangiomas of infancy, although they express D3, are not

associated with hypothyroidism owing to their small size. Because a significant fraction of hemangiomas remit with glucocorticoid and interferon- α therapy, it is important to treat such patients with adequate doses of thyroid hormone, to prevent the permanent neurologic complications associated with untreated hypothyroidism during the critical phase of neurologic development. A similar syndrome has been identified in adults, including an epithelioid hemangioendothelioma and an individual with a fibrous tumor.¹²⁴

Defects in Activation of Thyroxine to Triiodothyronine

The enzymes that convert the precursor T_4 to the active form, T_3 , are the 5'-deiodinases, D1 and D2, both of which contain selenocysteine in their active site.⁶⁴ A stem loop structure in the 3'-untranslated region of the mRNA, termed the *SECIS element*, directs insertion of selenocysteine at the UGA codon, rather than allowing it to function as a stop codon. Defects in a SECIS-binding protein (SECISBP2) were found in two families with elevated fT_4 , reduced T_3 , and elevated TSH levels.¹²⁵ Affected individuals have growth retardation, compared with unaffected family members.

Polymorphisms in genes associated with thyroid hormone metabolism have been associated with patterns of thyroid function studies as well as obesity. The D2 polymorphism that substitutes an alanine for a threonine at codon 92 (Thr92Ala) has been associated with obesity, reduced glucose disposal, and lower D2 activity in skeletal muscle.¹²⁶ This polymorphism also has a higher frequency in groups with a high incidence of obesity and type 2 diabetes (i.e., Mexican Americans and Pima Indians).¹²⁶

Hypothyroidism Due to Drug-Induced Thyroid Destruction

Thyroid inflammation or activation of autoimmune thyroid destruction has been associated with a number of drugs.⁸³ However, the tyrosine kinase inhibitors (e.g., sunitinib) are associated with a high incidence of hypothyroidism due to thyroid destruction.¹²⁷ Sunitinib is used to treat renal cell carcinoma and gastrointestinal stromal tumors; it inhibits multiple cellular pathways including KIT, PDGF, VEGF, and RET. An abnormal TSH was found in 62% of patients taking sunitinib after 37 weeks of follow-up.¹²⁸ Patients studied by ultrasonography demonstrated no thyroid tissue. Although 40% of hypothyroid patients initially had a suppressed TSH, suggesting thyroiditis, the long-term course was most consistent with sunitinib-induced follicular-cell apoptosis. These findings indicate that it is important to monitor thyroid function in patients taking tyrosine kinase inhibitors. These agents have now been shown to slow disease progression in advanced thyroid cancers that are unresponsive to radioiodine.¹²⁹

Central Hypothyroidism

Central hypothyroidism is the result of TSH deficiency caused by acquired or congenital hypothalamic or pituitary gland disorders. TSH deficiency caused by pituitary dysfunction is called *secondary* hypothyroidism, and that of hypothalamic origin is called *tertiary* hypothyroidism; however, this distinction is not necessary in the initial separation of primary from central hypothyroidism.

In many cases, hyposecretion of TSH is accompanied by decreased secretion of other pituitary hormones, with the result that evidence of somatotroph, gonadotroph, and corticotroph failure is also present. Hyposecretion of TSH as the sole demonstrable abnormality (monotropic deficiency) is less common but does occur in both acquired

and congenital forms. Hypothyroidism due to pituitary insufficiency varies in severity from instances in which it is mild and overshadowed by features of gonadal and adrenocortical failure to those in which the features of the hypothyroid state are predominant. Because a small but significant fraction of thyroid gland function (10% to 15%) is independent of TSH, hypothyroidism due to central causes is less severe than primary hypothyroidism.

The causes of central hypothyroidism are both acquired and congenital. The general subject is discussed in Chapters 8 and 9, and those causes with relatively specific thyroid-related deficiencies are mentioned here for completeness. In addition to pituitary tumors, hypothalamic disorders, and the like, an unusual cause of secondary hypothyroidism occurs in individuals given bexarotene (a retinoid X receptor [RXR] agonist) for T-cell lymphoma.¹³⁰ This drug suppresses the activity of the human TSH β -subunit promoter in vitro. Serum T_4 concentrations are reduced by about 50%, and patients experience clinical benefit from thyroid hormone replacement. Dopamine, dobutamine, high-dose glucocorticoids, and severe illness may suppress TSH release transiently, leading to a pattern of thyroid hormone abnormalities suggesting central hypothyroidism.¹³⁰ As discussed in Chapter 11, this severe state of hypothalamic-pituitary-thyroid suppression is a manifestation of stage 3 illness (see Table 11-9 in Chapter 11). Although these agents might be expected to have similar effects when given for long periods, they do not; nor does somatostatin have a similar effect when given for acromegaly, although it does block the response of TSH to TRH and it has been administered to patients with thyrotropin-secreting pituitary adenomas.¹³¹

Congenital defects in stimulation or synthesis of TSH or in its structure have been identified as rare causes of congenital hypothyroidism.¹⁰ These include defects in several of the homeobox genes, including *POU1F1* (formerly termed *Pit-1*), *PRO1*, and *HESX1*. The last gene encodes a factor that is necessary for development of the hypothalamus, pituitary, and olfactory portions of the brain. Defects in *POU1F1* and *PRO1* cause hereditary hypothyroidism, usually accompanied by deficiencies in growth hormone and prolactin.¹³² One patient has been identified with a familial defect in the TRH receptor gene.¹³³ All of these conditions are associated with the typical pattern of central hypothyroidism, a reduced ft_4 and TSH.

Structural defects in TSH have also been described. These include a mutation in the CAGYC peptide sequence of the β -subunit, which is thought to be necessary for its association with the α -subunit,¹³⁴ and defects that produce premature termination of the TSH β -subunit gene.¹³⁵ Some of these abnormalities may be associated with elevations in TSH, suggesting the diagnosis of primary hypothyroidism, but the TSH molecule is immunologically, but not biologically, intact.

Resistance to Thyroid Hormone

The clinical manifestations of RTH depend on the nature of the mutation.^{136,137} Most patients with RTH have a mutation in the gene encoding the thyroid hormone receptor β -subunit (TR β) that interferes with the capacity of that receptor to respond normally to T_3 , usually by reducing its T_3 -binding affinity (see Fig. 11-7 in Chapter 11). Alternatively, patients with RTH may have hyperthyroidism if the resistance is more severe in the hypothalamic-pituitary axis than in the remainder of the tissues. In clinical terms, patients in the former group are said to have *generalized RTH*, whereas those in the latter group are said to have *pituitary RTH*. The mutations in the TR β gene (called *THRB*)

that cause RTH cluster in three areas of the thyroid hormone receptor have been recognized to have important contacts with the hydrophobic ligand-binding domain cavity of the receptor, as recognized from its crystal structure. The mutations do not interfere with the function of the DNA-binding domain or its region of heterodimerization with RXR.

RTH is probably produced by heterodimerization of the mutant TR β with RXR or homodimerization with a normal TR β or TR α . These mutant TR β -containing dimers compete with wild-type dimers for binding to the thyroid hormone response elements (TREs) of thyroid hormone-dependent genes.¹³⁶ Because these complexes bind corepressor molecules that cannot be released in the absence of T_3 binding, genes containing these TREs are more repressed than they would be normally at the prevailing concentrations of circulating thyroid hormones. Receptors that contain mutations in the activation domain may have a combination of both decreased affinity for T_3 and impaired activating potential.

The mutant TR β complex can interfere with the function of the wild-type TRs, producing a pattern termed *dominant negative inhibition* with an autosomal dominant pattern of inheritance. At least 400 families have been identified with this condition, and there are probably many more unreported cases. The gene frequency estimate is about 1 in every 50,000 persons, and study of the function of the mutant receptors in this disorder has provided valuable insights into the mechanism of thyroid hormone action.^{136,137}

Patients with RTH usually are recognized because of thyroid enlargement, which is present in about two thirds of these individuals. Patients usually report a mixture of symptoms of hyperthyroidism and hypothyroidism. With respect to the heart, palpitations and tachycardia are more common than a reduced heart rate; however, patients may also demonstrate growth retardation and retarded skeletal maturation.¹³⁸ This has been attributed to the primary dependence of thyroid hormone effects in the heart on TR α rather than TR β ; in contrast, the hypothalamic-pituitary axis is primarily regulated through TR β .

Abnormalities in neuropsychological development exist, with an increased prevalence of attention deficit-hyperactivity disorder, which is found in approximately 10% of people with RTH.¹³⁹ Other neuropsychological abnormalities have also been described.¹⁴⁰ Deafness in patients with RTH reflects the important role of TR β and thyroid hormone in the normal development of auditory function. The mixture of symptoms, some suggesting hypothyroidism and others suggesting hyperthyroidism, may differ in individuals within the same family, despite the identical mutation, further confusing the clinical picture.

Because patients may present with symptoms suggesting hyperthyroidism, it is important to keep this diagnosis in mind in a patient with tachycardia, goiter, and elevated thyroid hormones. RTH is discussed here because a reduced response to thyroid hormone is the biochemical basis for the condition. However, the laboratory results may be the first clear evidence that a patient, otherwise thought to have hyperthyroidism, has RTH. These tests show the unusual combination of an increased ft_4 accompanied by normal or slightly increased TSH levels (see Table 13-2). Therefore, the principal differential diagnosis is between a TSH-secreting pituitary tumor causing hyperthyroidism and RTH.^{140,141}

Factors that may assist in the differential diagnosis include absence of a family history in patients with

TSH-producing tumors, normal thyroid hormone levels in family members of individuals with TSH-induced hyperthyroidism due to pituitary tumor, and the presence of an elevated glycoprotein α -subunit in patients with pituitary tumor but not in those with RTH.

A definitive diagnosis requires sequencing of the *THRB* gene demonstrating the abnormality. Mutations in this gene are found in about 90% of individuals with a clinical diagnosis. In a few patients this is not the case, suggesting that there may be mutations in coactivator proteins or in one of the RXR receptors, leading to a similar presentation.¹⁴²

Treatment is difficult because thyroid hormone analogues that are designed to suppress TSH and thereby relieve the hyperthyroxinemia may lead to worsening of the cardiovascular manifestations of the condition.¹⁴³ Therapy with 3,5,3'-triiodothyroacetic acid (TRIAc) has been used in several patients.¹⁴⁴ The development of analogues of thyroid hormone with TR β (as opposed to mixed or TR α) preferential effects and analogues that selectively bind mutant TRs may eventually prove useful in treatment.¹⁴⁵

TREATMENT

Hypothyroidism, either primary or central, is gratifying to treat because of the ease and completeness with which it responds to thyroid hormone. Treatment is almost always with levothyroxine, and the proper use of this medication has been reviewed extensively.¹⁴⁶⁻¹⁴⁸ A primary advantage of levothyroxine therapy is that the peripheral deiodination mechanisms can continue to produce the amount of T₃ required in tissues under the normal physiologic control.⁶⁴ If one accepts the principle that replicating the natural state is the goal of hormone replacement, it is logical to provide the prohormone and allow the peripheral tissues to activate it by physiologically regulated mechanisms.

Pharmacologic and Physiologic Considerations

Levothyroxine has a 7-day half-life. About 80% of the hormone is absorbed relatively slowly and equilibrates rapidly in its distribution volume, so large postabsorptive perturbations in fT₄ levels are avoided. Because of its long half-life, omission of a single day's tablet has no significant effect, and the patient may safely take an omitted tablet on the following day. In fact, the levothyroxine dosage can be calculated almost as satisfactorily on a weekly as on a daily basis. Although T₄ is well absorbed and does not require fasting, regular ingestion of levothyroxine on an empty stomach results in the least variation in serum TSH concentration.¹⁴⁹

The U.S. Food and Drug Administration (FDA) has issued standards for single-dose bioequivalence studies in normal volunteers to assess and compare T₄ products in the United States.¹⁵⁰ The area under the curve (AUC) confidence interval must fall within 80% to 125% of the comparison product for a preparation to be considered equivalent. The desirability of a pharmacotherapeutic measurement such as TSH as an end point has been suggested by many professional organizations.¹⁵⁰ Recent regulations have narrowed the guidelines for measured T₄ content, from between 90% and 110% to between 95% and 105% of the stated tablet dose, with that content maintained for the entire shelf-life.¹⁵¹ The availability in many countries

of a multiplicity of tablet strengths with content ranging from 25 to 300 μ g allows precise titration of the daily levothyroxine dosage for most patients with a single daily tablet, improving compliance significantly.

The typical dose of levothyroxine, approximately 1.6 to 1.8 μ g per kilogram of ideal body weight per day (0.7 to 0.8 μ g/pound), usually results in the prescription of 75 to 112 μ g/day for women and 125 to 200 μ g/day for men. Replacement doses need not be adjusted upward in obese patients and should be based on lean body mass.¹⁵² This dosage is about 20% greater than the T₄ production rate because of incomplete absorption of the levothyroxine. In patients with primary hypothyroidism, these amounts usually result in serum TSH concentrations that are within the normal range. Because of the 7-day half-life, approximately 6 weeks is required before there is complete equilibration of the fT₄ and the biologic effects of levothyroxine. Accordingly, with rare exceptions (e.g., pregnancy), assessments of the adequacy of a given dose or of the effects of a change in dosage should not be made until this interval has passed.

By and large, levothyroxine products are clinically equivalent, although problems do occur.¹⁵³ The variation in tablet content permitted by the FDA can result in slight variations in serum TSH in patients with primary hypothyroidism, even when the same brand is used. Using levothyroxine from a single manufacturer reduces variability that may be relevant for patients in whom close titration is required, such as the elderly, pregnant women, and thyroid cancer patients.¹⁵⁴ Although the serum TSH level is an indirect reflection of the levothyroxine effect in patients with primary hypothyroidism, it is superior to any other readily available method of assessing the adequacy of therapy. Return of the serum TSH level to normal is therefore the goal of levothyroxine therapy in patients with primary hypothyroidism. Some patients require slightly higher or lower doses than are generally used, owing to individual variations in absorption, and a number of conditions or associated medications may change levothyroxine requirements in patients with established hypothyroidism (see later discussion).

In decades past, desiccated thyroid was successfully employed for the treatment of hypothyroidism, and it still accounts for a small fraction of the prescriptions written for thyroid replacement in the United States. Although this approach was successful, desiccated thyroid preparations contain thyroid hormone derived from animal thyroid glands that have significantly higher ratios of T₃ to T₄ than the 1:11 value in normal human thyroid gland.¹⁵⁵ Accordingly, these unnatural preparations may lead to supraphysiologic levels of T₃ in the immediate postabsorptive period (2 to 4 hours) due to the rapid release of T₃ from Tg, its immediate and almost complete absorption, and the 1-day period required for T₃ to equilibrate with its 40-L volume of distribution (see Table 11-5 in Chapter 11).¹⁵⁶

Mixtures of liothyronine and levothyroxine (*liotrix*) contain in a 1-grain (64-mg) equivalent tablet (Thyrolar-1 in the United States) the amounts of T₃ (approximately 12.5 μ g) and T₄ (approximately 50 μ g) present in the most popular desiccated thyroid tablet.¹⁵⁷ The levothyroxine equivalency of a 1-grain desiccated thyroid tablet or its liotrix equivalent can be estimated as follows. The 12.5 μ g of liothyronine (T₃) is completely absorbed from desiccated thyroid or from liotrix tablets.¹⁵⁶ Levothyroxine is approximately 80% absorbed,¹⁵⁸ and about 36% of the 40 μ g of levothyroxine absorbed is converted to T₃, with the molecular weight of T₃ (651) being 84% that of T₄ (777). Accordingly, a 1-grain tablet should provide about 25 μ g of T₃,

which would be approximately equivalent to that obtained from 100 µg of levothyroxine. This equivalency ratio can be used as an initial guide when switching patients from desiccated thyroid or liotrix to levothyroxine. Although levothyroxine is absorbed in the stomach and small intestine, normal gastric acid secretion is required for complete absorption.¹⁵⁹ Patients with impaired acid secretion on levothyroxine therapy require a 22% to 34% higher dose of levothyroxine to maintain the desired serum TSH. In those patients in whom acid secretion was normalized therapeutically, the levothyroxine dose returned to baseline.¹⁵⁹

As indicated earlier, the use of levothyroxine for thyroid hormone replacement is a compromise with the normal pathway of T_3 production, in which about 80% of T_3 is derived from T_4 5'-monodeiodination and approximately 20% (about 6 µg) is secreted directly from the thyroid gland.⁶⁴ Studies in thyroidectomized rats, for example, show that it is not possible to normalize T_3 simultaneously in all tissues by an intravenous infusion of T_4 .¹⁶⁰ However, it should be recalled from the earlier discussion of T_4 deiodination that the ratio of T_3/T_4 in the human thyroid gland is about 0.09, but in the rat thyroid gland it is 0.17.⁶⁴ Therefore, about 40% of the rat's daily T_3 production is derived from the thyroid, compared with about 20% in humans.⁶⁴ Accordingly, the demonstration that T_4 alone cannot provide normal levels of T_3 in all tissues in the rat is of interest but is not strictly applicable to thyroid hormone replacement in humans. Nonetheless, the ratio of T_3 to T_4 in the serum of a patient receiving levothyroxine as the only source of T_3 must be about 20% lower than that in a normal individual.

Similarly, the quantity of levothyroxine required to normalize TSH in an athyreotic patient results in a slightly higher serum fT_4 concentration than is present in normal individuals. This was shown in a comparison of thyroid function in before and after thyroidectomy in the same patient.¹⁶¹ Although serum T_3 was the same level before and after thyroidectomy, a higher serum T_4 concentration was necessary when the patient was on T_4 replacement to maintain the same serum T_3 level.¹⁶¹ Although this may, to some extent, compensate for the lack of T_3 secretion, the fact that T_4 has an independent mechanism for TSH suppression, owing to the intracellular generation of T_3 in the hypothalamic-pituitary-thyroid axis, means that a portion of the feedback regulation is independent of the plasma T_3 concentration.

Although the concept of combined T_4/T_3 therapy has been recognized for many years, a positive study published in 1999 generated a great deal of interest in this approach.¹⁶² Patients received 12.5 µg of T_3 as a substitution for 50 µg of their levothyroxine preparation and scored, on average, somewhat higher on tests of mood than when they were taking levothyroxine alone. The dosage of thyroid hormone used in these studies was excessive, as judged by the fact that 20% of the group had serum TSH values below normal on either regimen, and the test period was only a few months. Since this report, a large number of studies using a wide range of replacement strategies and relative T_4/T_3 content have been performed in different populations, and none has shown an advantage for combination therapy over T_4 alone.¹⁶³

On the other hand, another study showed that the fT_4 index correlated as closely as TSH levels with the resting energy expenditure in a group of patients in whom small supplements or decrements in their ideal replacement levothyroxine dosage were made.¹⁶⁴ The correlation with serum T_3 was not statistically significant, suggesting that in

humans, perhaps because of differences in peripheral metabolism of T_4 compared with rodents, the fT_4 index may be as accurate as the TSH value as an index of satisfactory thyroid hormone replacement. The practical difficulty with the design of tablets providing combinations of T_3 and T_4 is that the approximate dose of 6 µg of T_3 provided would need to be released in a sustained fashion over 24 hours, which is quite different from the rapid absorption of T_3 (with a peak at 2 to 4 hours) when given in its conventional form. Therefore, it appears that the current approach to thyroid replacement using levothyroxine alone, although not a perfect replication of the normal physiology, is satisfactory for most patients. A sustained-release T_3 preparation has been developed and produces more stable levels of serum T_3 .¹⁶⁵ The clinical consequence of this more "physiologic" replacement profile is not known.

Institution of Replacement Therapy

The initial dose of levothyroxine prescribed depends on the degree of hypothyroidism and the age and general health of the patient. Patients who are young or middle age and otherwise healthy with no associated cardiovascular or other abnormalities and mild to moderate hypothyroidism (TSH concentrations, 5 to 50 mU/L) can be given an initial complete replacement dose of about 1.7 µg per kilogram of ideal body weight. The resulting increase in serum T_4 concentration to normal requires 5 to 6 weeks, and the biologic effects of T_3 are sufficiently delayed so that these patients do not experience adverse effects. At the other extreme, an elderly patient who has heart disease, particularly angina pectoris, without reversible coronary lesions should be given a small initial dose of levothyroxine (25 µg/day), and the dosage should be increased in 12.5-µg increments at 2- to 3-month intervals with careful clinical and laboratory evaluation.

The goal in the patient with primary hypothyroidism is to return serum TSH concentrations to normal, reflecting normalization of that patient's thyroid hormone supply. This usually results in a midnormal to high-normal serum fT_4 concentration. The serum TSH should be evaluated 6 weeks after a theoretically complete replacement dose has been instituted, followed by minor adjustments to optimize the individual dose.¹⁶⁶ In patients with central hypothyroidism, serum TSH is not a reliable index of adequate replacement and the serum fT_4 should be restored to a concentration in the upper half of the normal range. T_4 dosing based on body weight and a serum fT_4 in the upper reference range was found to improve markers of thyroid hormone action and was superior to replacement with a combination of T_4/T_3 .¹⁶⁷ Patients with central hypothyroidism should also be evaluated and treated for glucocorticoid deficiency, if necessary, before institution of thyroid replacement (see Chapter 9).

Although the adverse effects of the rapid institution of therapy are unusual, pseudotumor cerebri has been reported in profoundly hypothyroid juveniles (8 and 12 years of age) who were given even modest initial levothyroxine replacement.¹⁶⁸ This complication appears 1 to 10 months after initiation of treatment and responds to treatment with acetazolamide and dexamethasone.

The interval between initiation of treatment and the first evidence of improvement depends on the strength of dose given and the degree of the deficit. An early clinical response in moderate to severe hypothyroidism is a diuresis of 2 to 4 kg. The serum sodium level increases even sooner if hyponatremia was present initially. Thereafter, pulse rate and pulse pressure increase, appetite improves,

and constipation may disappear. Later, psychomotor activity increases and the delay in the deep tendon reflex disappears. Hoarseness abates slowly, and changes in skin and hair do not disappear for several months. In individuals started on a complete replacement dose, the serum fT_4 level should normalize after 6 weeks; a somewhat longer period may be necessary for serum TSH levels to return to normal, perhaps up to 3 months.

In some cases, it is clinically appropriate to alleviate hypothyroidism rapidly. For example, patients with severe hypothyroidism withstand acute infections or other serious illnesses poorly, and myxedema coma (discussed later) may develop as a complication. In such circumstances, rapid near-repletion of the peripheral hormone pool in the average adult can be accomplished by a single intravenous dose of 500 μ g levothyroxine. Alternatively, because of its rapid onset of action, liothyronine (25 μ g orally every 12 hours) may be administered if the patient can take medication by mouth. With both approaches, an initial biologic effect is achieved within 24 hours. Parenteral therapy with levothyroxine is then continued with a dose that is 80% of the appropriate oral dose but not in excess of 1.4 μ g/kg of ideal body weight. Because of the possibility that rapid increases in metabolic rate will overtax the existing pituitary-adrenocortical reserve, supplemental glucocorticoid (intravenous hydrocortisone, 5 mg/hour) should also be given to patients with severe hypothyroidism who are receiving high initial doses of thyroid hormones. Finally, in view of the tendency of hypothyroid patients to retain free water, intravenous fluids containing only dextrose should not be given.

When replacement therapy is withdrawn for short periods (4 to 6 weeks) for the purpose of evaluating therapy for thyroid cancer, rapid reinstitution of levothyroxine using a loading dose of three times the daily replacement dose for 3 days can usually be given, unless other complicating medical illnesses are present.

When hypothyroidism results from administration of iodine-containing or anti-thyroid drugs, withdrawal of the offending agent usually relieves both the hypothyroidism and the accompanying goiter, although it is appropriate to provide interim replacement until the gland recovers its function. This is especially true for amiodarone, which can remain in tissues for up to 1 year.

Therapy in Infants and Children

In infants with congenital hypothyroidism, the determining factor for eventual intellectual attainment is the age at which adequate treatment with thyroid hormone is begun.^{10,169} The therapy in infants with congenital hypothyroidism should consist initially of raising the serum T_4 level to more than 130 nmol/L (10 μ g/dL) as rapidly as possible and maintaining it at that level for the first 3 to 4 years of life. This is usually accomplished by administering an initial levothyroxine dose of 50 μ g/day, which is higher than the adult dose on a weight basis and in keeping with the higher metabolic clearance of the hormone in the infant. The serum TSH concentration may not return to normal even with this high dose because of residual reset of the pituitary feedback mechanism. After 2 years of age, a TSH level in the normal range is an index of optimal therapy, as it is in adults.¹⁷⁰

Monitoring Replacement Therapy

Monitoring the adequacy of, and compliance with, thyroid hormone therapy in patients with primary hypothyroidism

is easily done by measuring serum TSH. This value should be within the normal range when determined by an assay that is sufficiently sensitive to measure, with confidence, the lower limit of the normal range. The normal serum TSH concentration varies between 0.5 and 4.0 mU/L in most second- and third-generation assays, and results within this range are associated with elimination of all clinical and biochemical manifestations of primary hypothyroidism, except in patients with RTH. Based on analysis of the National Health and Nutrition Examination Surveys III (NHANES III) reference group,⁵ a reference TSH range with an upper limit of 2.5 mU/L has been suggested. However, this adjustment would identify a large number of individuals as having abnormal thyroid function without providing a clear indication of the clinical significance of TSH levels in this range.¹⁷¹ A more recent analysis, based on age-specific references ranges, indicated that older adults without thyroid autoantibodies have an increased upper-limit TSH value (>4.5 mU/L) that is not associated with thyroid disease.¹⁷² In related studies, this progressive shift with age to higher levels of TSH was associated with extreme longevity in several populations.¹⁷³

After the first 6 months of therapy, the dose should be reassessed, because restoration of euthyroidism increases the metabolic clearance of T_4 . A dose that was adequate during the early phases of therapy may not be adequate when the same patient is euthyroid owing to an acceleration in the clearance of thyroid hormone.

Under usual circumstances, the finding of a normal serum TSH level on an annual basis is adequate to ensure that the proper levothyroxine dose is being taken by the patient. If the serum TSH level is above the normal range and noncompliance is not the explanation, small adjustments, usually in 12- μ g increments, can be made, with reassessment of TSH concentrations after the 6 weeks required for full equilibration have passed. In North America, this strategy is simplified by the availability of multiple tablet strengths, many of which differ by only 12 μ g. Most patients can receive the same dose until they reach the seventh or eighth decade, at which point a downward adjustment of 20% to 30% is indicated because thyroid hormone clearance decreases in the elderly.

Thyroid hormone requirements may be altered in several situations (Table 13-3). A reduction in replacement dosage may be required in women who are receiving androgen therapy for adjuvant treatment of breast carcinoma.¹⁷⁴ Most other conditions or medications increase the levothyroxine requirement in patients receiving maintenance therapy. During pregnancy, the levothyroxine requirement is increased by 25% to 50% in most hypothyroid women,¹⁷⁵ and prospective study has demonstrated that the increased requirement occurs early in the first trimester.¹⁷⁶ The increment of increase is higher in athyreotic patients compared to those with autoimmune hypothyroidism.¹⁷⁷ Athyreotic patients who are planning a pregnancy should be advised to increase their dose by about 30% as soon as the diagnosis is confirmed, because the change in requirement appears soon after implantation. The increased requirement probably results from a combination of factors, including increases in T_4 -binding globulin and the volume of distribution of T_4 , an increase in body mass, and an increase in D3 in placenta and perhaps in the uterus.^{64,124} The increased requirement persists throughout pregnancy but returns to normal within a few weeks after delivery. Therefore, the dose should be reduced to the original, prepregnancy level at the time of delivery. Maternal T_4 is critically important to the athyreotic fetus and to the normal fetus in the first trimester,

TABLE 13-3

**Conditions That Alter
Levothyroxine Requirements**

Increased Levothyroxine Requirements

Pregnancy

Gastrointestinal Disorders

Mucosal diseases of the small bowel (e.g., sprue)
After jejunioileal bypass and small-bowel resection
Impaired gastric acid secretion (e.g., atrophic gastritis)
Diabetic diarrhea

Drugs That Interfere with Levothyroxine Absorption

Cholestyramine
Sucralfate
Aluminum hydroxide
Calcium carbonate
Ferrous sulfate

Drugs That Increase the Cytochrome P450 Enzyme (CYP3A4) Activity

Rifampin
Carbamazepine
Estrogen
Phenytoin
Sertraline

Drugs That Block T₄-to-T₃ Conversion

Amiodarone

Conditions That May Block Deiodinase Synthesis

Selenium deficiency
Cirrhosis

Decreased Levothyroxine Requirements

Aging (≥65 yr)
Androgen therapy in women

T₄, Thyroxine; T₃, triiodothyronine.

before the thyroid gland develops.¹⁷⁸ Maternal hypothyroidism has been associated with fetal loss, preterm delivery, and intellectual deficit in the offspring.^{49-51,97} These findings are not seen in hypothyroid women on T₄ replacement sufficient to normalize their TSH, suggesting that these associations are directly related to maternal thyroid hormone status. A randomized, prospective study in pregnant women with TPO-Ab and normal-range TSH demonstrated the benefit of levothyroxine treatment to prevent these complications.⁵¹

Other conditions in which levothyroxine requirements are increased (see Table 13-3) include malabsorption due to bowel disease, impaired gastric acid secretion,¹⁵⁹ and adsorption of levothyroxine to coadministered medications such as sucralfate, aluminum hydroxide, and calcium carbonate,¹⁷⁹ ferrous sulfate,¹⁸⁰ lovastatin,¹⁸¹ or various resins.¹⁸² Certain medications, notably rifampin,¹⁸³ carbamazepine,¹⁸⁴ phenytoin,¹⁸⁵ and sertraline,¹⁸⁶ increase the clearance of levothyroxine by inducing cytochrome P450 isoenzyme 3A4 (CYP3A4) in the liver. Estrogen given to postmenopausal women may act in the same way, although the changes in Tg and distribution volume make exact resolution of the cause of the increased levothyroxine requirement uncertain.¹⁸⁷ Soy protein and soybean isoflavones have been proposed to interfere directly with thyroid hormone action as well as synthetic T₄ absorption.¹⁸⁸ There is no evidence that soy interferes with thyroid function in euthyroid individuals who are iodine sufficient, and the effect of soy on T₄ absorption in hypothyroid patients is modest.¹⁸⁸ Amiodarone increases levothyroxine requirements by blocking conversion of T₄ to T₃ and perhaps by

interfering with T₃-thyroid hormone receptor binding.¹⁸⁹ Selenium deficiency is rare, but because it is rate-limiting in the synthesis of D1 (see Fig. 11-6 in Chapter 11),⁶⁴ a deficiency, such as may occur in patients receiving diets restricted in protein, may increase levothyroxine requirements.¹⁹⁰

Occasionally in patients who have been treated with radioactive iodine for Graves' disease or toxic nodular goiter, some degree of thyroid hormone secretion persists; although it is insufficient to sustain normal thyroid hormone levels, it is autonomous. Such patients may have a suppressed TSH despite what otherwise would be considered a replacement dose of levothyroxine. The levothyroxine dose in these individuals should be reduced until TSH levels rise to normal, keeping in mind that several months may be required before TSH secretion recovers after its prolonged suppression. Because of either the delayed effects of radioiodine or the natural history of Graves' disease per se, this autonomous T₄ secretion may decrease with time, leading to an increase in levothyroxine requirements in subsequent years. Rarely, the opposite occurs; that is, a patient treated with radioiodine develops an increased TSH level, but after several months of therapy, the requirement for replacement is reduced or eliminated. This may reflect transient impairment of thyroid function by a combination of pre-irradiation anti-thyroid drug therapy and immediate but transient effects of irradiation on the thyroid. In such patients, frequent monitoring of levothyroxine replacement is required to avoid overreplacement.

In North America, based on the recent changes in assessment of levothyroxine bioequivalence (see earlier discussion), the possibility of a difference in tablet levothyroxine content should be considered if a new preparation changes the biologic or biochemical effects of the same dosage. Although the difference in preparation is unlikely to cause a significant difference in most patients, the change in manufacturer introduces another potential source of variability.¹⁵⁴

Adverse Effects of Levothyroxine Therapy

Although the administration of excessive doses of levothyroxine causes accelerated bone loss in postmenopausal patients, most authorities believe that returning thyroid status to normal does not have adverse effects on bone density.¹⁹¹ Administration of excessive doses also increases cardiac wall thickness and contractility, and in elderly patients it increases the risk of atrial fibrillation.^{14,17}

In some patients, TSH levels remain elevated despite the prescription of adequate replacement doses. This is most often a consequence of poor adherence. The combination of normal or even elevated serum fT₄ values and elevated TSH levels can occur if the patient does not take levothyroxine regularly but ingests several pills the day before testing. The integrated dose of levothyroxine over prior weeks is best reflected in the serum TSH level, and nonadherent patients require careful education as to the rationale for treatment. Subtle changes in dietary habits, such as increased ingestion of bran-containing products, soy, or calcium, may decrease levothyroxine absorption, and their recognition requires a careful history.^{179,188}

**Patients with Hypothyroid Symptoms Despite
Restitution of Normal Thyroid Function**

Symptoms consistent with hypothyroidism may persist in patients taking levothyroxine replacement who have a

normal-range serum TSH concentration. In a survey asking patients about symptoms that might be associated with thyroid hormone deficiency,¹⁹² such symptoms were reported by both control patients and those on levothyroxine replacement with normal-range serum TSH, but by a greater fraction of patients in the latter group. Such patients should be educated about the symptoms of hypothyroidism and the role of thyroid hormone in relieving them, and other causes should be sought for the symptomatology. In rare cases, hypothyroid symptoms are associated with hypometabolism despite normal levels of serum thyroid hormones and TSH.¹⁹³ These patients may have RTH in peripheral but not central tissues, a situation that has been documented only rarely.

SPECIAL ASPECTS OF HYPOTHYROIDISM

Subclinical Hypothyroidism

The term *subclinical hypothyroidism* was originally used to describe the patient with a low-normal fT_4 but a slightly elevated serum TSH level. Other terms for this condition are *mild hypothyroidism*, *early thyroid failure*, *preclinical hypothyroidism*, and *decreased thyroid reserve* (see Table 13-2). The TSH elevation in such patients is modest, with values typically between 4 and 15 mU/L, although those patients with a TSH greater than 10 mU/L more often have a reduced fT_4 and may have some hypothyroid symptoms. The definition of this syndrome depends significantly on the reference range for a normal TSH concentration. The syndrome is most often seen in patients with early Hashimoto's disease and is a common phenomenon, occurring in 7% to 10% of older women.⁴⁻⁶

A number of studies on the effects of thyroid hormone treatment in such patients have used physiologic end points (e.g., measurements of various serum enzymes, systolic time intervals, serum lipids, psychometric testing), and results have been variable. In the most carefully controlled studies, one or another of the parameters has returned to normal in 25% to 50% of patients.^{6,22} In general, fT_4 and TSH levels normalize, but free T_3 , usually normal at the outset, does not change. In one study that employed a double-blind, crossover approach, the 4 of 17 women who improved could be differentiated from the remainder only by a somewhat lower serum free T_3 at the start of the study.¹⁹⁴ Modest improvements in cardiac indices and lipid profiles have been noted in most but not all studies.^{6,22} Association of mild hypothyroidism with an increased risk for atherosclerotic heart disease has been shown by some but not other studies.^{6,22} The impact of treatment to reduce the risk of atherosclerotic heart disease, other than reduction in risk factors such as cholesterol and C-reactive protein, have not yet been studied.

One factor favoring a decision to recommend levothyroxine therapy is the likelihood of development of overt hypothyroidism. The risk of progression from *subclinical* to *overt* hypothyroidism (i.e., with elevated serum TSH and reduced serum fT_4 concentrations) is most closely related to the magnitude of serum TSH elevation and the presence of TPO-Ab. Prospective studies of women with subclinical hypothyroidism have shown rates of progression ranging from approximately 3% to 8% per year, with the higher rates seen in individuals with initial TSH concentrations greater than 10 mU/L and in those with positive TPO-Ab.⁷ Although most patients progress slowly to overt hypothyroidism, rapid progression over weeks to months has been

reported.¹⁹⁵ Factors that may predispose to rapid progression include elderly age, high levels of TPO-Ab, intercurrent systemic infection or inflammation, iodinated contrast agents, and medications such as amiodarone and lithium.

The decision to treat with levothyroxine must also take into account the expense and inconvenience of a daily medication, which is not acceptable to some patients, and the possibility that overdosage with levothyroxine may exacerbate osteoporosis or cause cardiac arrhythmias. Ultimately, the decision to treat must depend on a careful consideration of the individual clinical situation and patient preference.⁹ If a therapeutic trial is performed, the TSH concentration should be monitored carefully and should not be reduced below normal. If no therapy is given, patients should be monitored at intervals of 6 to 12 months, both clinically and by measurements of serum TSH.

Metabolic Insufficiency

Nonspecific symptoms of true hypothyroidism include mild lassitude, fatigue, slight anemia, constipation, apathy, cold intolerance, menstrual irregularities, loss of hair, and weight gain (see Fig. 13-5). Some patients with such complaints who have normal laboratory results for thyroid function have been considered candidates for levothyroxine therapy. The response to thyroid hormone therapy is sometimes gratifying, at least initially, but symptomatic improvement usually disappears after a time unless the dose is increased. Eventually, even larger doses fail to alleviate the symptoms, confirming that they do not arise from a deficiency of thyroid hormone.

Therefore, thyroid hormone therapy should be avoided in patients for whom there is no biochemical documentation of impaired thyroid function. Furthermore, even in patients with subclinical hypothyroidism, symptoms may be out of proportion to abnormalities in the fT_4 concentration. It is unwise to raise a patient's expectations that such symptoms will be relieved by correction of mild biochemical abnormalities.

Thyroid Function Testing in Patients Receiving Replacement Therapy for Unclear Reasons

Physicians are frequently confronted with patients who are receiving levothyroxine in whom the basis for the diagnosis cannot be established. It is often difficult to obtain previous clinical findings or laboratory data to determine whether thyroid hormone replacement is indicated. If serum TSH is in the normal range and primary hypothyroidism is suspected, a simple method of assessing the need for levothyroxine therapy is to switch levothyroxine to an every-other-day dosage or to reduce the daily dose by 50% and reevaluate TSH and fT_4 after 4 weeks. If there has been no significant increase in TSH concentration and fT_4 remains constant during that period, residual thyroid function is present, although it may still not be completely normal. To definitively answer this question, levothyroxine can then be withdrawn and blood tests repeated 4 to 8 weeks later.

If the initial TSH level is suppressed, indicating overreplacement, the levothyroxine dose should be reduced until TSH becomes detectable before this trial is instituted. If central hypothyroidism is suspected, the fT_4 must be monitored during these procedures.

Emergent Surgery in the Hypothyroid Patient

The perioperative course of patients with untreated hypothyroidism has been evaluated in several studies. In general, such patients were not recognized to be hypothyroid or did not require surgery despite the presence of significant hypothyroidism. Complications were uncommon. Perioperative hypotension, ileus, and central nervous system disturbances were more common in hypothyroid patients, and patients with major infections had fewer episodes of fever than did euthyroid control subjects.¹⁹⁶ Other complications were delayed recovery from anesthesia and abnormal hemostasis, possibly owing to an acquired form of von Willebrand's disease.²⁷

From these studies, one may conclude that emergent surgery should not be postponed in hypothyroid patients but that such patients should be rigorously monitored for evidence of carbon dioxide retention, bleeding, infection, and hyponatremia. These findings are also relevant to the treatment of symptomatic coronary artery disease in hypothyroid individuals. Considering the lack of significant increase in perioperative complications, the option of surgery for remediable coronary artery lesions is open to hypothyroid individuals without the risk of a myocardial infarction in association with restitution of the euthyroid state (see later discussion).¹⁹⁷

HEART DISEASE AND THYROID HORMONE THERAPY

Coexisting Coronary Artery Disease and Hypothyroidism

In many patients with coronary artery disease and primary hypothyroidism, cardiac function is improved in response to levothyroxine therapy because of a decrease in peripheral vascular resistance and improvement in myocardial function.^{14,15} However, patients with preexisting angina pectoris should be evaluated for correctable lesions of the coronary arteries and treated appropriately before levothyroxine is administered.^{197,198} Retrospective studies indicate that this approach is safer than the institution of replacement therapy before angiography and angioplasty or even coronary artery bypass grafting (CABG).^{198,199}

In a few patients, lesions are not remediable or small-vessel disease is severe even after bypass grafting, so that complete replacement cannot be instituted. Such patients must receive optimal anti-anginal therapy combined with β -adrenergic receptor blockers in judicious quantities, and complete restitution of the euthyroid state may not be possible.

Thyroid Hormone for Compromised Cardiovascular Function

In addition to the issues raised in patients with combined hypothyroidism and coronary artery disease, there is interest in the potential therapeutic use of thyroid hormone in patients with cardiomyopathy and in those who have undergone CABG or other cardiac procedures.^{14,15,199} As expected, T_3 levels are reduced in patients with advanced congestive heart failure, as with any illness. In one report, 23 patients with advanced heart failure (mean ejection fraction, 22%) were given up to 2.7 $\mu\text{g/kg}$ of liothyronine over 6 hours and experienced increased cardiac output and decreased systemic vascular resistance but without an

increase in heart or metabolic rate.²⁰⁰ Similar effects were seen with a dose of liothyronine, 110 μg , administered over 6 hours after CABG.¹⁹⁹

Liothyronine has also been given postoperatively for congenital heart disease; again, an improvement in cardiac output and a decrease in vascular resistance occurred without adverse side effects.²⁰¹ These results suggest that, in certain selected circumstances, liothyronine may be useful as adjunctive therapy in patients with congestive heart failure because of its effect of relaxing vascular smooth muscle.

Although most therapeutic trials of thyroid hormone treatment have used T_3 , thyroid hormone analogues have also been used.¹⁴⁵ The most extensively studied one is 3,5-diiodothyropropionic acid (DITPA), an analogue that binds both $TR\alpha$ and $TR\beta$ with low affinity. A randomized study of DITPA in heart failure showed some improved cardiac performance, but the study was terminated due to significant metabolic side effects including weight loss.²⁰²

SCREENING FOR PRIMARY HYPOTHYROIDISM

The utility of screening for hypothyroidism has been addressed by a number of studies but remains controversial.²⁰³ The conclusions depend, to a great extent, on assumptions regarding the effectiveness and economic value of identifying and treating patients with subclinical hypothyroidism.^{8,204} One study concluded that the cost of TSH determinations performed every 5 years for women and men would be approximately \$9000 per quality-adjusted life-year in women.²⁰⁴ An evidenced-based medicine review of the literature by an expert panel concluded that there was insufficient evidence to support population-based screening.⁸ Aggressive case finding, based on identification of risk factors such as family history, was advocated for pregnant women, women older than 60 years of age, and others at high risk. However, the fraction of patients with hypothyroidism missed when a case finding strategy is used is not known. A report from the U.S. Preventive Services Task Force also concluded that population screening for hypothyroidism in nonpregnant adults was not justified.²⁰³ Large, randomized, prospective studies of levothyroxine treatment in patients with subclinical hypothyroidism to establish benefit have not yet been performed. Given the very high incidence of hypothyroidism in older women and the absence of robust clinical symptoms, an assessment of TSH levels at 5-year intervals in women older than 50 years of age seems justified until more extensive studies have been performed.

A second complex issue involves whether women planning pregnancy should be screened for hypothyroidism as a routine part of a prenatal visit. This question is raised because of the increasing association of adverse outcomes in pregnancy with even subclinical hypothyroidism, including impairment of mental development in infants of hypothyroid mothers, fetal loss, and preterm delivery.⁴⁹⁻⁵¹ The prevalence of overt hypothyroidism during pregnancy is approximately 2%,²⁰⁵ and screening of all patients has been advocated by several professional organizations. Thyroid testing in high-risk patients (case finding), has been advocated, although a prospective study showed that approximately one third of pregnant women with underlying thyroid disease are missed by this testing approach.²⁰⁷

Maternal ft_4 concentrations in the lowest 10% of the normal range, even with normal TSH levels, have also been suggested as a risk factor for impaired neuropsychological

development of the fetus.²⁰⁶ It is not clear why this is a risk factor for impaired fetal neuropsychological development, because such patients are not hypothyroid.

A number of questions have been raised regarding the appropriate timing of testing, whether thyroid autoantibodies should be measured, the relative importance of TSH and fT_4 , the influence of trimester on the normal ranges, and the appropriate threshold for intervention.²⁰⁸ The association of maternal subclinical hypothyroidism and preterm delivery⁴⁶ is a much more proximal and defined end point to study, compared with intellectual performance in offspring. The morbidity and mortality from preterm delivery is significant for the newborn, and these findings are likely to allow for more focused intervention studies to determine the response to T_4 treatment.

For the moment, it appears that any patient with a family history of autoimmune thyroid disease who has symptoms suggesting hypothyroidism or thyroid enlargement should be tested for thyroid dysfunction before pregnancy or as soon after conception as is feasible. If it is possible, optimization of levothyroxine therapy for women known to have hypothyroidism before conception may be the most effective intervention to prevent hypothyroid-related complications of pregnancy. Although the data do not yet reach the threshold to mandate universal screening, the ease of testing, associated adverse outcomes, and demonstrated benefit of intervention make thyroid testing of all pregnant women a reasonable choice.

MYXEDEMA COMA

Myxedema coma is the ultimate stage of severe, long-standing hypothyroidism.^{209,210} This state, which almost exclusively affects older patients, occurs most commonly during the winter months and is associated with a high mortality rate. It is usually accompanied by a subnormal temperature; values as low as 23° C have been recorded. The external manifestations of severe myxedema, bradycardia, and severe hypotension are invariably present. The characteristic delay in deep tendon reflexes may be lacking if the patient is areflexic. Seizures may accompany the comatose state. Although the pathogenesis of myxedema coma is not clear, factors that predispose to its development include exposure to cold, infection, trauma, and use of central nervous system depressants or anesthetics. Alveolar hypoventilation, leading to carbon dioxide retention and narcosis, and dilutional hyponatremia, resembling that seen with inappropriate secretion of arginine vasopressin (AVP), may also contribute to the clinical state.

From the foregoing, it appears that myxedema coma should be readily recognized from its clinical signs, but this is not the case. After a brain stem infarction, elderly patients with features suggestive of hypothyroidism may be both comatose and hypothermic. In addition, hypothermia of any cause (e.g., exposure to cold) may cause changes suggestive of myxedema, including delayed relaxation of deep tendon reflexes. The importance of the difficulty in diagnosing myxedema coma is that a delay in therapy worsens the prognosis. Consequently, a rapid serum T_4 measurement should be obtained on an emergency basis whenever possible. Otherwise, the diagnosis should be made on clinical grounds. After serum is sent for thyroid function tests, therapy should be initiated without awaiting the results of delayed confirmatory tests, because the mortality rate can be 20% or higher.

Treatment consists of administration of thyroid hormone and correction of the associated physiologic

disturbances.²⁰⁹⁻²¹¹ Because of the sluggish circulation and severe hypometabolism, absorption of therapeutic agents from the gut or from subcutaneous or intramuscular sites is unpredictable, and medications should be administered intravenously if possible. Administration of levothyroxine as a single intravenous dose of 500 to 800 µg serves to replete the peripheral hormone pool and may cause improvement within hours. Daily doses of intravenous levothyroxine, 100 µg, are given thereafter. Hydrocortisone (5 to 10 mg/hour) should also be given because of the possibility of relative adrenocortical insufficiency as the metabolic rate increases.

Alternatively, intravenous liothyronine may be given at a dose of 25 µg every 12 hours. Others have used a combination of 200 to 300 µg T_4 and 25 µg T_3 intravenously as a single dose, followed by 25 µg T_3 and 100 µg T_4 24 hours later and then 50 µg T_4 daily until the patient regains consciousness. *Hypotonic* fluids should not be given because of the danger of water intoxication owing to the reduced free water clearance of the hypothyroid patient. *Hypertonic* saline and glucose may be required to alleviate severe dilutional hyponatremia and the occasional hypoglycemia.

A critical element in therapy is support of respiratory function by means of assisted ventilation and controlled oxygen administration. Internal warming by gastric perfusion may be useful, but external warming should be avoided because it may lead to vascular collapse due to peripheral vasodilatation. Further heat loss can be prevented with blankets. An increase in temperature may be seen within 24 hours in response to levothyroxine. General measures applicable to the comatose patient should be undertaken, such as frequent turning, prevention of aspiration, and attention to fecal impaction and urinary retention.

Finally, the physician should assess the patient for the presence of coexisting disease, such as infection, cardiac disease, or cerebrovascular disease. In particular, the myxedematous patient may be afebrile despite the presence of a significant infection. As soon as the patient is able to take medication by mouth, treatment with oral levothyroxine should be instituted.

THYROIDITIS

Thyroiditis is a term indicating the presence of thyroid inflammation. It therefore comprises a large group of diverse inflammatory conditions: autoimmune or quasautoimmune causes and viral or postviral conditions and infections, including those of bacterial and fungal origins; a chronic sclerosing form of thyroiditis, termed *Riedel's thyroiditis* (or struma); and miscellaneous causes of various types, including radiation-induced and granulomatous causes (e.g., sarcoidosis), as well as lithium-related thyroid disease.²¹²

Not only are the causes of thyroiditis extremely varied, but their clinical presentations may also be diverse and are difficult to categorize in a simple fashion (Table 13-4). For example, autoimmune thyroiditis may manifest with hypothyroidism, but often patients remain euthyroid for long periods after the disease is initiated. On the other hand, if a euthyroid patient with Hashimoto's disease becomes pregnant, the postpartum period is often complicated by an acute form of hyperthyroidism caused by the transient exacerbation of thyroiditis, often followed by a period of hypothyroidism (see Chapter 12).

In nonpregnant patients, a similar syndrome, called *silent* or *painless thyroiditis*, is manifested primarily as thyrotoxicosis of sudden onset without localized pain and

TABLE 13-4
Causes of Thyroiditis

Autoimmune thyroiditis
Postpartum, silent, or painless thyroiditis (see Chapter 12)
Subacute (nonsuppurative) thyroiditis (see Chapter 12)
Acute infectious thyroiditis
Riedel's thyroiditis
Postirradiation (¹³¹ I or external-beam therapy) thyroiditis
Sarcoidosis

often without evidence of autoimmune disease. This condition may be viral in origin in some patients; however, the most classic presentation of viral thyroiditis is as *subacute, nonsuppurative thyroiditis*, also known as *de Quervain's thyroiditis*, *pseudotuberculous thyroiditis*, and *migratory* or *creeping thyroiditis*. Unlike typical autoimmune thyroiditis, this condition is characterized by extreme thyroid tenderness, with pain radiating to the oropharynx and ears, and must be differentiated from acute suppurative thyroiditis caused by bacterial or fungal infection.²¹³

Inflammatory conditions of the thyroid present a dilemma because one must decide whether to discuss these entities as a group with the common denominator of inflammation or to categorize them according to their principal clinical effects, namely thyrotoxicosis or thyroid hormone deficiency. We have chosen the latter approach and have already discussed autoimmune thyroiditis, the major cause of thyroid gland failure (see Table 13-1). However, patients with acute autoimmune thyroiditis may also develop thyrotoxicosis (e.g., in postpartum silent thyroiditis, painless thyroiditis) (see Chapter 12). These patients must be differentiated from those with Graves' disease.

In addition, some patients with viral thyroiditis have thyrotoxicosis as a major manifestation, with varying degrees of neck discomfort ranging from none to full-blown subacute, nonsuppurative (granulomatous) thyroiditis. For that reason, this thyroiditis syndrome is also discussed in Chapter 12, even though the pain associated with the typical form of this condition makes the principal differential diagnosis lie between that and pyogenic thyroiditis. In that context, subacute thyroiditis is also mentioned later in this chapter.

ACUTE INFECTIOUS THYROIDITIS

Although the thyroid gland is remarkably resistant to infection, congenital abnormalities of the piriform sinus, underlying autoimmune disease, or immunocompromise of the host may lead to the development of an infectious disease of the thyroid gland.^{213,214} The etiology can involve any bacterium, including *Staphylococcus*, *Pneumococcus*, *Salmonella*, or *Mycobacterium tuberculosis*.^{213,215,216} In addition, infections with certain fungi, including *Coccidioides immitis*, *Candida*, *Aspergillus*, and *Histoplasma*, have been reported.²¹⁷

The most common cause of repeated childhood pyogenic thyroiditis, particularly in the left lobe, is an internal fistula extending from the piriform sinus to the thyroid.^{218,219} This sinus is the residual connection remaining along the path of migration of the ultimobranchial body from the fifth pharyngeal pouch to the thyroid gland. The predominance of thyroiditis of the left lobe is explained by the fact that the right ultimobranchial body is often atrophic, whereas this is not the case for the left side. Nonetheless, bacterial thyroiditis can develop in a patient with a completely normal thyroid gland. This is an extremely rare

disease even as a complication of direct puncture of the thyroid gland (e.g., in fine-needle aspiration). In individuals with midline infections, persistence of the thyroglossal duct should be considered.

Incidence

Infectious thyroiditis is extremely rare, with no more than a few cases being seen in large tertiary care centers.

Clinical Manifestations

The clinical manifestations of infectious thyroiditis are dominated by local pain and tenderness in the affected lobe or in the entire gland. This is accompanied by painful swallowing and difficulty swallowing. Because of the tendency for referral of pain to the pharynx or ear, the patient may not recognize the tenderness in the anterior neck. Depending on the virulence of the organism and the presence of septicemia, symptoms such as fever and chills may also accompany the condition.

The major differential diagnosis lies between an infectious form of thyroiditis and subacute, nonsuppurative thyroiditis. It is instructive to compare the principal features of these two diseases to arrive at an accurate diagnosis (Table 13-5). By and large, patients with acute thyroiditis caused by a bacterium are much sicker than patients with subacute thyroiditis; they have more severe and localized tenderness and are less likely to have laboratory evidence of hyperthyroidism, which is present in approximately 60% of patients with subacute thyroiditis. Ultrasonographic examination often reveals the abscess in the thyroid gland or evidence of swelling, and needle aspiration may help pinpoint the responsible organism. A gallium scan will be positive as a result of the diffuseness of the inflammation. Particularly in children with thyroiditis of the left lobe, a barium swallow showing a fistula connecting the piriform sinus and the left lobe of the thyroid is diagnostic.^{220,221}

Occasionally, pertechnetate scanning is useful in showing normal function in one lobe of the thyroid gland, which is much less common in subacute thyroiditis (which more often affects the entire gland). Needle aspiration should be used to drain the affected lobe, although occasionally surgical drainage is required. If a piriform sinus fistula can be demonstrated, it must be removed to prevent recurrence of the problem.

Antibiotics should be administered as appropriate for the offending organism. Fungal infections should be treated appropriately, especially because many of these patients are immunocompromised. Endemic organisms should be kept in mind as a cause, because both *Echinococcus* and *Trypanosomiasis* infections of the thyroid gland have been reported.

The prognosis is excellent—thyroid function is usually preserved, although post-thyroiditis thyroid function tests should be monitored to ascertain that thyroid failure has not occurred.

RIEDEL'S THYROIDITIS

Riedel's chronic sclerosing thyroiditis is rare and occurs primarily in middle-age women.^{222,223} The etiologic mechanism is uncertain, although some cases appear to be a fibrotic form of Hashimoto's disease.^{224,225} This condition is characterized by fibrosis of the thyroid gland and adjacent structures and may be associated with fibrosis elsewhere,

TABLE 13-5

Features That Are Useful in Differentiating between Acute Suppurative Thyroiditis and Subacute Thyroiditis

Characteristic	Acute Thyroiditis (% with Feature)	Subacute Thyroiditis (% with Feature)
History		
Preceding upper respiratory infection	88	17
Fever	100	54
Symptoms of thyrotoxicosis	Uncommon	47
Sore throat	90	36
Physical Examination of the Thyroid		
Painful thyroid swelling	100	77
Left side affected	85	Not specific
Migrating thyroid tenderness	Possible	27
Erythema of overlying skin	83	Not usually
Laboratory Findings		
Elevated white blood cell count	57	25-50
Elevated ESR (>30 mm/hr)	100	85
Abnormal thyroid hormone levels (elevated or depressed)	5-10	60
Alkaline phosphatase, transaminases increased	Rare	Common
Results of Needle Aspiration		
Purulent, bacteria or fungi present	~100	0
Lymphocytes, macrophages, some polyps, giant cells	0	~100
¹²³ I uptake low	Uncommon	~100
Radiologic Findings		
Abnormal thyroid scan	92	—
Thyroid scan or ultrasound helpful in diagnosis	75	—
Gallium scan positive	~100	~100
Barium swallow showing fistula	Common	0
CT scan useful	Rarely	Not indicated
Clinical Course		
Clinical response to glucocorticoid treatment	Transient	100
Incision and drainage required	85	No
Recurrence following operative drainage	16	No
Piriform sinus fistula discovered	96	No

CT, computed tomography; ESR, erythrocyte sedimentation rate.

especially in the retroperitoneal area.²²³ The presence of eosinophils in specimens obtained by fine-needle aspiration has been demonstrated histologically, suggesting a unique autoimmune response to fibrous tissue.²²⁶

Symptoms develop insidiously and are related chiefly to compression of adjacent structures, including the trachea, esophagus, and recurrent laryngeal nerves. Systemic evidence of inflammation is uncommon. The thyroid gland is moderately enlarged, stony hard, and usually asymmetric. The consistency of the gland and the invasion of adjacent structures suggest carcinoma, but there is no enlargement of regional lymph nodes. Temperature, pulse, and leukocyte count are normal. Severe hypothyroidism is unusual but does occur, as does loss of parathyroid function. The RAIU may be normal or low. Elevated circulating thyroid autoantibodies are less common and are found in lower titers than in Hashimoto's disease.

Surgery may be required to preserve tracheal and esophageal function. If extensive involvement of perithyroid tissues is present, resection of the isthmus may relieve some symptoms. Treatment with thyroid hormone relieves the hypothyroidism but has no effect on the primary

process, which may progress inexorably. Immunosuppressive treatment and even chemotherapy has been tried in individual cases. Glucocorticoids have been used for treatment, with sporadic improvement. The use of tamoxifen has also been successful in some patients.²²⁷

MISCELLANEOUS CAUSES

Only a few causes of generalized inflammation of the thyroid gland have been reported. These include inflammation arising after ¹³¹I treatment for Graves' disease, a residual thyroid lobe in a patient with thyroid cancer of the contralateral lobe, and thyroiditis arising from external-beam therapy for conditions such as Hodgkin's or non-Hodgkin's lymphoma, breast carcinoma, or other lesions of the oropharynx. Anaplastic thyroid carcinoma has been reported in association with a diffuse thyroiditis and elevation of thyroid hormone levels. In general, only radioiodine-induced thyroiditis is associated with pain, and glucocorticoid treatment may be useful in symptomatic therapy.

CHAPTER 14

Nontoxic Diffuse and Nodular Goiter and Thyroid Neoplasia

MARTIN-JEAN SCHLUMBERGER • SEBASTIANO FILETTI • IAN D. HAY

This chapter reviews the imaging techniques available for evaluating thyroid structural abnormalities; the units of measurement used in evaluation of the radiation dose and radioactivity are defined in Table 14-1.

Goiter resulting in thyrotoxicosis and other thyroid conditions arising from autoimmune thyroid disease are considered in Chapters 11 and 12.

This chapter then deals with the increasingly recognized problem of nodular thyroid disease. Thyroid neoplasia, both benign and malignant, is discussed authoritatively. We consider an appropriate histologic classification and staging of thyroid cancer and present a management program for the most common thyroid cancer types. This chapter is based on a consensus from the European Thyroid Association¹ and guidelines from the American Thyroid Association.^{2,3}

EVALUATION OF STRUCTURAL ABNORMALITIES BY IMAGING TECHNIQUES

External Scintiscanning

Localization of functioning or nonfunctioning thyroid tissue in the area of the thyroid gland or elsewhere is made possible by techniques of external scintiscanning. The underlying principle is that isotopes selectively accumulated by thyroid tissue can be detected by a gamma camera and the data can be transformed into a visual display. Radioactivity in specific areas can be quantified.⁴⁻⁷

Several radioisotopes are employed in thyroid imaging. Technetium 99m (^{99m}Tc) pertechnetate is a monovalent anion that is actively concentrated by the thyroid gland

TABLE 14-1

Radiation Nomenclature: Traditional and International System (SI) Units*

Traditional Units	SI Units	Conversion Factors
Radiation Dose		
rad = radiation absorbed dose	Gy = gray 1 Gy = absorption of 1 joule/kg	1 Gy = 100 rad 1 rad = 0.01 Gy = 1 cGy
rem = roentgen-equivalent-man	Sv = sievert	1 Sv = 100 rem
Radioactivity (or Activity)		
Ci = curie	Bq = becquerel 1 Bq = 1 disintegration per second 1 GBq = 10 ³ MBq = 10 ⁶ kBq = 10 ⁹ Bq	1 mCi = 37 MBq

*Prefixes: m (milli), c (centi), k (kilo), M (mega), G (giga).

but undergoes negligible organic binding and diffuses out of the gland as its concentration in the blood decreases. The short physical half-life of ^{99m}Tc (6 hours), its low fractional uptake, and its transient stay within the thyroid make the radiation delivered to the thyroid gland by a standard activity dose very low. Consequently, the intravenous administration of large activities (>37 MBq [1 mCi]) permits, about 30 minutes later, adequate imaging of the thyroid.

Two radioactive isotopes of iodine have been used in thyroid imaging. Iodine 131 (¹³¹I) was commonly used in the past. However, ¹³¹I is a beta emitter, its physical half-life is 8.1 days, and the energy of its main gamma ray is high and thus poorly adapted for its detection.⁶ ¹²³I is, in many respects, ideal, but it is expensive. The energy of its main gamma ray is suitable for its detection by gamma cameras. Its short half-life (0.55 day) and absence of beta radiation result in a radiation dose to the thyroid that is about 1% of that delivered by a comparable activity of ¹³¹I.⁷

The most important use of scintigraphic imaging of thyroid tissue is to define areas of increased or decreased function ("hot" or "cold" areas, respectively) relative to the function of the remainder of the gland. Almost all malignant nodules are hypofunctioning, but more than 80% of benign nodules are also nonfunctioning. Conversely, functioning nodules (hot nodules), particularly if the function of the surrounding tissue is decreased or absent, are rarely malignant.

Several nuclear medical tests (e.g., stimulation test after administration of exogenous thyroid-stimulating hormone [TSH], suppression test by administration of thyroid hormone) were used in the past to evaluate thyroid disorders but should no longer be used because sensitive TSH assays and scanning with a gamma camera permit the diagnosis of most hot nodules.

Scintiscanning with radioactive iodine can also be used to demonstrate that intrathoracic masses represent thyroid tissue and to detect ectopic thyroid tissue in the neck.

In patients with thyroid cancer, the total body scan is used to detect functioning metastases.^{1,2} This scan is performed after the administration of larger activities of radioiodine, for diagnosis (1 to 5 mCi of ¹³¹I or 1 to 5 mCi of ¹²³I) or for therapy (≥30 mCi of ¹³¹I) and after intense

stimulation with TSH. Superimposition of computed tomographic (CT) scans and gamma camera images greatly improves the sensitivity and specificity of the technique and the anatomic localization of any focus of uptake.^{8,9}

Ultrasonography

Sonography is a noninvasive technique that is becoming an integral part of the clinical examination.¹⁰ High-frequency sound waves are emitted by a transducer and reflected as they pass through the body, whereupon the returning echoes are received by the transducer, which also acts as a receiver. The amplitude of the reflections of the sound waves is influenced by differences in the acoustic impedance of the tissues encountered by the sound; for example, *fluid-filled* structures reflect few echoes and therefore have no or few internal echoes and well-defined margins; *solid* structures reflect varying amounts of sound and thus have varying degrees of internal echoes and less well-defined margins; and *calcified* structures reflect virtually all incoming sound and yield pronounced echoes with an acoustic "shadow" posteriorly.

Intrathyroidal nodules as small as 3 mm in diameter and cystic nodules as small as 2 mm can be readily detected. Color flow Doppler ultrasonography allows visualization of very small vessels, so that vascularity of thyroid nodules can be assessed.

The thyroid gland must be examined thoroughly in transverse and longitudinal planes. Imaging of patients with thyroid nodules and during follow-up of thyroid cancer should also include lymph node areas, classified as compartments, to identify enlarged cervical lymph nodes.^{1,2,11-14}

The normal thyroid parenchyma has a characteristic homogeneous, medium-level echogenicity, with little identifiable internal architecture (Fig. 14-1). The surrounding muscles have the appearance of hypoechoic structures. The air-filled trachea in the midline gives a characteristic curvilinear reflecting surface with an associated reverberation artifact. The esophagus is usually hidden from sonographic visualization by the tracheal air shadow.

A diagrammatic representation of the neck showing the locations of any abnormal findings and their characteristics is a useful supplement to the routine film images recorded during an ultrasound examination. Such a cervical map with compartments¹⁴ (Fig. 14-2) can help communicate the anatomic relationships of the pathology more clearly to the referring clinician and serves as a reference for the sonographer on follow-up examinations.

Neck ultrasonography is clinically useful at each step of thyroid evaluation (Table 14-2). It may confirm the presence of a thyroid nodule when the findings on physical examination are equivocal and may reveal the presence of other, nonpalpable nodules.

In patients with a thyroid nodule, gray-scale and color Doppler ultrasound are used to evaluate its sonographic features, including size, shape, echogenicity (hypoechoic or hyperechoic), and composition (cystic, solid, or mixed), and to determine the presence of coarse or fine calcifications, a halo and margins, and internal blood flow. It is used to examine the rest of the thyroid gland and lymph node areas. Elastography that assesses hardness as an indicator of malignancy in thyroid nodules has high specificity and sensitivity independent of nodule size, and this predictive value is maintained in follicular lesions, provided that the nodule is solid and devoid of coarse calcifications.¹⁵ This promising technique requires additional validation with prospective studies.

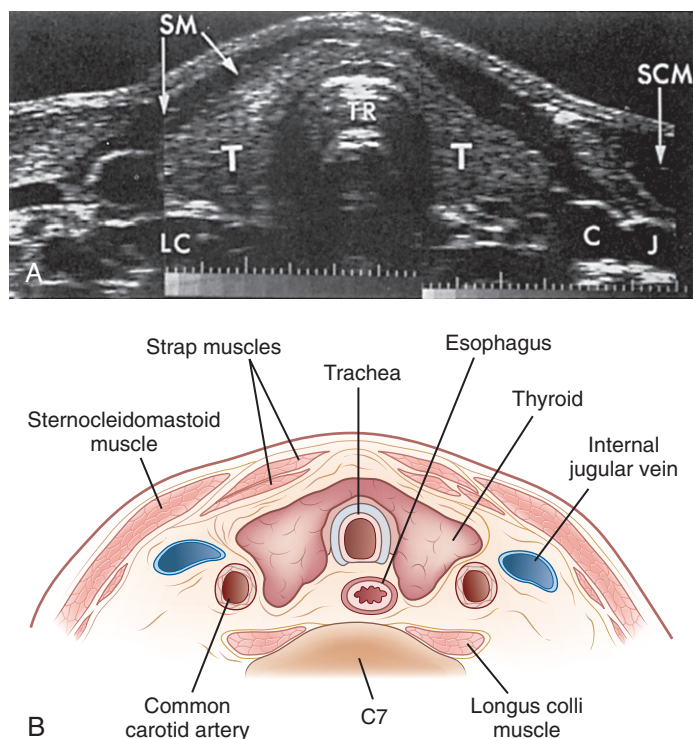

Figure 14-1 Transverse composite sonogram (A) and corresponding anatomic map (B) of the normal thyroid gland. C, common carotid artery; C7, seventh cervical vertebra; LC, longus colli muscle; SM, strap muscles; SCM, sternocleidomastoid muscle; T, thyroid; TR, trachea. (From Rifkin MD, Charboneau JW, Laing FC. Special course: ultrasound 1991. In: Reading CC [ed]. Syllabus: Thyroid, Parathyroid, and Cervical Lymph Nodes. Oak Brook, IL: Radiological Society of North America; 1991:363-377.)

In patients with known thyroid cancer, sonography can be useful in evaluating the extent of disease, both preoperatively and postoperatively. In those who present with cervical lymphadenopathy caused by papillary thyroid carcinoma (PTC) but have a gland that is palpably normal, sonography may be used preoperatively to detect an occult, primary intrathyroid focus. A preoperative sonogram should be obtained in all patients with PTC or medullary thyroid carcinoma (MTC), to identify the anatomic locations of any sonographically suspicious regional lymph nodes and thereby to permit planning of the extent of nodal dissection.^{1-3,16} Occasionally, nonpalpable residual cancer that has been identified by preoperative ultrasonography and proved to be cytologically positive by ultrasound-guided fine-needle aspiration biopsy (FNAB) can be identified intraoperatively with the use of a hand-held ultrasound probe or by preoperative ultrasound-guided charcoal tattooing.¹⁷

After surgery for thyroid cancer, sonography is the preferred method for detecting residual, recurrent, or metastatic disease in the neck.¹¹⁻¹³ In patients who have undergone less than a near-total thyroidectomy, the sonographic appearance of the remaining thyroid tissue may be an important factor in the decision whether to recommend completion thyroidectomy. Also, it is more sensitive than neck palpation in detecting recurrent disease within the thyroid bed and metastatic disease in cervical lymph nodes.

Sonography may also be useful to guide FNAB of thyroid bed masses and lymph nodes.^{2,10}

Computed Tomography

The CT appearance of the anatomic structures depends on the attenuation of the tissue examined. The thyroid gland, because of its high concentration of iodine, has higher attenuation than the surrounding soft tissues. Recent

advances in spiral CT and in reconstruction algorithms have improved the performance of the method.^{18,19}

CT scanning does not distinguish benign from malignant nodules and does not assess functional status; however, it can define the anatomic extent of large goiters with great clarity. CT scanning can provide useful information regarding the presence and extent of intrathoracic (substernal) goiters. The CT findings of an intrathoracic mass in continuity with the thyroid gland, with high attenuation on non-contrast-enhanced images and marked enhancement after injection of intravenous contrast material, suggests intrathoracic goiter. Radioiodine scanning can also be performed in this clinical setting, but false-negative results can occur if little or no functional tissue is present in the intrathoracic goiter. In aggressive pathologic processes such as anaplastic thyroid carcinoma, CT can define the extension of the tumor to the mediastinum and its relationships to surrounding structures and search for lung metastases.^{18,19}

CT imaging is less sensitive than neck ultrasonography for the detection of lymph node metastases. Because of the necessity of infusing iodine-containing contrast agents for CT scanning of the neck and mediastinum, CT should be performed at least 4 weeks before any administration of radioiodine.

Magnetic Resonance Imaging

Because the hydrogen atoms of different tissues have different relaxation times (termed T1 and T2), a computer-assisted analysis of T1-weighted and T2-weighted signals may be used to differentiate thyroid gland from skeletal muscles, blood vessels, or regional lymph nodes. Normal thyroid tissue tends to be slightly more intense than muscles on a T1-weighted image, and tumors often appear more intense than normal thyroid tissue.

Revised management guidelines for patients with thyroid nodules and differentiated thyroid cancer. *Thyroid*, 2009;19:1167-1214.) **B, Cervical map, derived from sonographic images, helps communicate anatomic relationships of pathology to clinicians and serves as a reference for follow-up examinations; standard colours are used to characterize any finding. CCA, common carotid artery.** (Reprinted with permission from J.W. Charboneau, Mayo Clinic.)

TABLE 14-2

Clinical Utility of Neck Ultrasound Examination

Map of the neck: thyroid and lymph node areas
Thyroid gland: size, volume, characteristics
Nodules: number and characteristics of each nodule—diameter, shape, echogenicity, composition, limits, presence of calcifications, vascularization
Lymph node areas
Follow-up: number and diameters of nodules
Guidance for fine-needle aspiration biopsy
Follow-up of thyroid cancer: thyroid bed and neck lymph node areas
Guidance for radiofrequency and ethanol ablation

Magnetic resonance imaging (MRI) does not distinguish benign from malignant nodules and does not assess functional status; however, it can define the anatomic extent of large goiters or aggressive tumors with the same clarity as CT scanning.

Recurrent neoplasms in the thyroid bed or regional lymph nodes can be detected with MRI; MRI is comparable in accuracy to CT. Recurrence is characterized by a mass with low to medium signal intensity on T1-weighted images and medium to high intensity on T2-weighted images. Conversely, scar tissue or fibrous tissue has low signal intensity on both T1- and T2-weighted images.^{18,19} Tumor invasion of adjacent skeletal muscle has high signal

intensity on T2-weighted images. Edema or inflammation in the muscle can cause a similar appearance and can be difficult to differentiate from recurrent tumor.

MRI is useful for assessment of the extent of bone involvement in cases of bone metastasis from follicular cell-derived carcinomas and MTC, which are poorly visualized on bone scintigraphy.^{20,21} Contrast-enhanced MRI is more sensitive than three-phase contrast-enhanced CT for the detection of liver metastases from MTC, and spiral CT scanning is more sensitive than MRI for the detection of small lung metastases.²¹

Positron Emission Tomography

Positron emission tomography (PET) is both quantitative and tomographic. The radionuclide emits a positron that is converted into a pair of photons after a short path of a few millimeters in the tissue. The coincidence detection of the two photons, which travel on a line in opposite directions, permits localization of the site of the radionuclide decay.

The agent most widely used with PET is [¹⁸F]-fluorodeoxyglucose (¹⁸FDG). This agent is transported and phosphorylated as a glucose substitute but remains metabolically trapped inside tumor cells because of its inability to undergo glycolysis.

PET scanners permit *in vivo* images related to regional glucose metabolism, with high sensitivity and a spatial resolution of less than 5 mm. Superimposition of CT and PET images greatly improves the sensitivity and specificity of the technique and the anatomic localization of any focus of abnormal uptake. The uptake in any focus can be quantified; the most frequently used parameter is the standardized uptake value (SUV). The sensitivity of ¹⁸FDG-PET scanning may be slightly improved with TSH stimulation.^{22,23}

PET scanning should be performed only in selected patients with thyroid carcinoma. Low-risk patients are very unlikely to require ¹⁸FDG-PET scanning as part of initial staging or follow-up. ¹⁸FDG-PET scanning in thyroid cancer is used in the following circumstances^{2,22}:

- To localize disease in thyroglobulin-positive (>10 ng/mL), radioiodine scan-negative patients; it is mostly useful for detection of lymph node metastases in the posterior neck and mediastinum or distant metastases
- For the initial staging and follow-up of patients with anaplastic, poorly differentiated, or Hürthle cell thyroid cancers, to identify sites of disease that may be missed with conventional imaging; in these cancers, FDG uptake is usually high
- In patients with known distant metastases in whom high FDG uptake in large metastases indicates a high risk for disease-specific mortality and poor response to radioiodine therapy²⁴
- As a measurement of post-treatment response after local therapy (e.g., external-beam irradiation, surgical resection, radiofrequency ablation, embolization) or systemic therapy

Inflammatory lymph nodes, suture granulomas, and increased muscle activity are common causes of false-positive ¹⁸FDG-PET findings. Also, asymmetric laryngeal uptake is frequently observed in patients with vocal cord paralysis. Therefore, cytologic or histologic confirmation is required before one can be certain that an ¹⁸FDG-positive lesion represents metastatic disease.

High uptake has also been observed in several thyroid diseases such as thyroiditis, but PET cannot be used to differentiate benign from malignant thyroid nodules. The

discovery of thyroid uptake on an FDG-PET scan performed for other reasons should lead to a complete workup, because a third of these nodules may prove to be malignant.^{25,26}

In clinical research settings, PET scanning with ¹²⁴I has also been used for quantitation of uptake and for accurate dosimetry in distant metastases from thyroid cancer.²⁷ PET scanning with ¹⁸F-labeled dihydroxyphenylalanine (DOPA) is used to visualize neoplastic foci of MTC,^{28,29} because the FDG uptake is usually low in MTC patients, and FDG-PET is poorly informative.^{21,30}

NONTOXIC GOITER: DIFFUSE AND NODULAR

Nontoxic goiter may be defined as any thyroid enlargement that is characterized by uniform or selective (i.e., restricted to one or more areas) growth of thyroid tissue, is not associated with overt hyperthyroidism or hypothyroidism, and does not result from inflammation or neoplasia. A thyroid nodule is defined as a discrete lesion, within the thyroid gland, caused by an abnormal, focal growth of thyroid cells.

Epidemiology

The prevalence of goiter, diffuse or nodular, varies widely depending on the iodine intake of the population living in a given area. Goiter may occur endemically (prevalence in children ≥5%), due mainly to iodine deficiency, or sporadically (prevalence <5%). In the general population, the Framingham survey indicated a 4.6% overall prevalence (6.4% in women and 1.5% in men), and the Wickham study reported a 3.2% prevalence (female-to-male ratio, 6.6:1).^{31,32} However, variables such as regional variation in iodine intake, smoking habits, age and sex distribution, and especially the methodology used to determine thyroid volume (palpation versus sonography) may have biased many of these data. With sonography as the screening method, a goiter prevalence of up to 30% to 50% in an unselected adult population has been described. This prevalence is even higher in iodine-deficient areas and among older people.³¹⁻³⁵

A prevalence of thyroid nodules of up to 50% has been described in autopsy series,³³ and greater than 60% in healthy adults screened with sonography.³⁴

Etiology and Pathophysiology

Goiter has been traditionally regarded as the adaptive response of the thyroid follicular cell to any factor that impairs thyroid hormone synthesis. This classic concept no longer appears to encompass the many aspects of goiters. Indeed, goiter is characterized by a variety of clinical, functional, and morphologic presentations, and whether this heterogeneity represents different entities remains to be clarified. Also, iodine deficiency as the sole factor responsible for goiter appears to be an oversimplification. Not all inhabitants in an iodine-deficient region develop goiter. Moreover, endemic goiter has been observed in countries with no iodine deficiency, and even in some regions with iodine excess, and has not been observed in some regions with severe iodine deficiency. These findings suggest that other factors, both genetic and environmental, may play a role in the genesis of diffuse and nodular goiter, and some of these factors may act synergistically. Environmental

factors include cigarette smoking, infections, drugs, and goitrogens.³⁵

The role of genetic factors is suggested by several lines of evidence³⁶: the clustering of goiters within families, the higher concordance rate for goiters in monozygotic compared with dizygotic twins, the female-to-male ratio (1:1 in endemic versus 7:1 to 9:1 in sporadic goiters), and the persistence of goiters in areas where a widespread iodine prophylaxis program has been properly implemented.

By studying families affected by goiter, researchers have been able to detect several gene abnormalities involving proteins related to thyroid hormone synthesis, such as mutations in genes encoding thyroglobulin (Tg), the sodium-iodide symporter (NIS), thyroid peroxidase (TPO), dual oxidase 2 (DUOX2), pendrin (Pendred syndrome, PDS), and the TSH receptor (TSHR). In addition, three loci for this disorder have been identified; they map to chromosomes 14q, Xp22, and 3q26, respectively.^{37,38} Although an autosomal dominant inheritance has been demonstrated in several families, multiple genes may be involved in other families. This may explain why predisposing gene alterations remain unidentified in most patients with nontoxic goiter.

TSH has long been considered the major agent determining thyroid growth in response to any factor that impairs thyroid hormone synthesis. Indeed, in the rare clinical setting of a functioning TSH-secreting pituitary tumor, the increased blood TSH levels typically cause enlargement of the thyroid gland.³⁹ Similarly, goiter is also a typical feature of Graves' disease, in which a stimulatory growth effect on thyroid tissue is induced by TSHR-stimulating antibody through TSHR activation.⁴⁰ Moreover, thyroid enlargement may appear during the course of Graves' disease when increased TSH levels result from overtreatment with antithyroid drugs. In addition, toxic thyroid hyperplasia is usually present in non-autoimmune autosomal dominant hyperthyroidism, a disorder related to germline activating mutations of the TSHR gene.⁴¹ This clinical condition further emphasizes the role of TSH-TSHR system activation in the genesis of thyroid hyperplasia.³⁶

The serum TSH concentration is normal in most patients with nontoxic goiter.³⁵ Experimentally, it has been demonstrated in rats that iodine depletion enhances the promotion of thyroid growth despite normal levels of TSH.⁴² Hence, any factor that impairs intrathyroidal iodine levels may lead to gradual development of goiter in response to normal concentrations of TSH.

Indeed, a complex network of both TSH-dependent and TSH-independent pathways directs thyroid follicular cell growth and function and plays a role in the goitrogenic process. In particular, a variety of growth factors, derived from the bloodstream or through autocrine or paracrine secretion, may serve to regulate thyroid cell proliferation and differentiation processes.³⁶

Typically, early in the course of goiter formation, areas of microheterogeneity of structure and function are intermixed and include areas of functional autonomy and areas of focal hemorrhage. Analysis of hyperplastic nodules by rigid criteria have indicated that morphologically indistinguishable hyperplastic thyroid nodules may be either monoclonal or polyclonal. Monoclonal adenomas within hyperplastic thyroid glands may reflect a stage in progression along the hyperplasia-neoplasia spectrum; accumulation of multiple somatic mutations may subsequently confer a selective growth advantage to this single-cell clone.⁴³

Histologically, nodules contain irregularly enlarged, involuted follicles distended with colloid or clusters of

smaller follicles lined by taller epithelium and containing small colloid droplets. The nodules tend to be incompletely encapsulated; they are poorly demarcated from and merge with the internodular tissue, which also has an altered architecture. However, the nodules in some glands appear to be localized, with areas of apparently normal architecture elsewhere. Here, the distinction from a follicular adenoma may be difficult, and some pathologists apply terms such as *colloid* or *adenomatous* nodules to such lesions.

Natural History

Nontoxic goiter has a female preponderance. There appears to be no physiologic increase in thyroid volume during normal adolescence. Development of a goiter during adolescence, therefore, is a pathologic rather than a physiologic process.⁴⁴ However, as evidenced by sonographic measurement of thyroid volume in women living in an area of moderate iodine intake, normal pregnancy is goitrogenic, especially in women with preexisting thyroid disorders. The increased thyroid volume during pregnancy is associated with biochemical features of thyroid stimulation (i.e., an increased ratio of triiodothyronine [T_3] to thyroxine [T_4] owing to slightly elevated serum TSH levels at delivery or a high concentration of human chorionic gonadotropin (hCG) during the first trimester.⁴⁵ Repeated pregnancies may play a role in the development of later thyroid disorders, and this relation might explain the higher prevalence of thyroid disorders in women.⁴⁶ The natural outcome of nontoxic nodular goiter was examined in an adult population with two main findings: (1) benign thyroid nodules are likely to grow (although slowly) over time, and (2) as a consequence, the concept that growing nodules are malignant whereas stable ones are benign should be discarded.⁴⁷

Clinical Presentation

In an era when patients are advised on methods of self-examination to detect cancer at an early stage, the finding of a palpable abnormality in such a superficial location as the thyroid gland can be disconcerting. The affected patient is likely to seek medical evaluation. At the end of an appropriate investigation, the clinician can usually reassure the patient that the goiter or nodule is benign. Autonomous nodules, or autonomous functional areas in the context of a multinodular goiter, may result in increased thyroid hormone secretion and, subsequently, a subclinical or overt thyrotoxicosis. However, thyroid nodules are usually not associated with abnormal thyroid hormone secretion. Therefore, affected patients do not exhibit clinical symptoms or signs of thyroid dysfunction. The only clinical features of nontoxic goiter are those of thyroid enlargement. Almost 70% of patients with sporadic nontoxic goiter complain of neck discomfort; the remainder have cosmetic concerns or a fear of possible malignancy.³⁵

Large goiters, which may displace or compress the trachea, esophagus, and neck vessels, can be associated with symptoms and signs including inspiratory stridor, dysphagia, and a choking sensation. These obstructive symptoms may be accentuated by the so-called Pemberton maneuver (see Chapter 11). Compression of the recurrent laryngeal nerve, with resulting hoarseness, suggests carcinoma rather than nontoxic goiter, but vocal cord paralysis can occasionally result from benign nodular goiters. Hemorrhage into a nodule or cyst produces acute, painful

enlargement locally and may enhance or induce obstructive symptoms.³⁵

Initial Investigation

Thyroid nodules are generally benign hyperplastic (or colloid) nodules or benign follicular adenomas, and only about 5% to 10% of nodules coming to medical attention are carcinomas. Differentiating true neoplasms from hyperplastic nodules and distinguishing between benign and malignant tumors are major challenges.

Moreover, with the widespread practice of medical checkups in healthy individuals and the increasing use of imaging technology, this problem is likely to become more common. High-resolution ultrasound studies suggest that the prevalence of nodular thyroid disease in healthy adults is greater than 60%.³⁴ However, during 2009 in the United States, only about 32,700 new cases of thyroid cancer were diagnosed.⁴⁸ Therefore, most of these so-called thyroid incidentalomas are obviously benign and do not progress to clinical tumors.³⁴

In identifying the nodules that are likely to be malignant, a thorough history and a careful physical examination should be supplemented with laboratory testing, imaging procedures, and, most important, FNAB of the nodule in question. With this approach, it is possible to assess the likelihood of malignancy and to advise appropriate treatment for most patients.³⁵

History and Physical Examination

Features of the history that favor benign disease include a family history of Hashimoto's thyroiditis, benign thyroid nodule, or goiter; symptoms of hypothyroidism or hyperthyroidism; and a sudden increase in size of the nodule with pain or tenderness, which suggests a cyst or localized subacute thyroiditis.³⁵ Features that suggest malignancy include young age (<20 years) or older age (>60 years); male gender; a history of external neck irradiation during childhood or adolescence; rapid growth; recent changes in speaking, breathing, or swallowing; and a family history of thyroid cancer or multiple endocrine neoplasia type 2 (MEN2).³⁵

On physical examination, manifestations of thyroid malignancy should be sought, including firm consistency of the nodule, irregular shape, fixation to underlying or overlying tissues, vocal cord paralysis, and suspicious regional lymphadenopathy.³⁵

Many studies have shown that a nodule size of less than 4 cm is not predictive of malignancy and that the incidence of cancer in incidentally identified or nonpalpable thyroid nodules is the same as in patients with palpable nodules. For nodules larger than 4 cm in diameter, the incidence of carcinoma may be higher.⁴⁹ However, given the excellent prognosis of micro-PTCs measuring less than 1 cm in diameter, most authors recommend investigation of only those nodules larger than 1 cm and nonpalpable nodules with clinical or sonographic suspicious findings.^{2,10,34,50}

FDG-PET performed for nonthyroid disease detected incidental thyroid nodules in about 2% of patients. These nodules require an accurate assessment because of their increased rate of malignancy, up to 30%.^{25,26} An evaluation of large groups of patients showed that the presence of multiple nodules does not decrease the likelihood of thyroid cancer. In patients with multiple nodules, the rate of malignancy per nodule decreases, but the decrease is approximately proportional to the number of nodules, so the overall rate per patient is the same as in patients with

TABLE 14-3

Clinical and Ultrasound Findings in Favor of Malignant Thyroid Nodules

Clinical Features	Ultrasound Findings
History	Higher Suspicion
Young age (<20 yr) or older age (>60 yr)	Hypoechoic lesions
Male gender	Irregular margins
Neck irradiation during childhood or adolescence	Presence of microcalcifications
Rapid growth	Absence of halo
Recent changes in speaking, breathing, or swallowing	Internal or central blood flow
Family history of thyroid malignancy or MEN2	
Physical Examination	Low Suspicion
Firm and irregular consistency of nodule	Echo-free (cystic) lesion
Fixation to underlying or overlying tissues	Spongiform lesion
Vocal cord paralysis	
Regional lymph adenopathy	

MEN2, multiple endocrine neoplasia type 2.

a solitary nodule. Also, thyroid cancers are often in the dominant nodule, but in approximately one third of cases, the cancer is in a nondominant nodule.⁴⁷

In both prospective and retrospective studies, the sensitivity and specificity rates for detection of thyroid malignancy by history and physical examination (Table 14-3) were approximately 60% and 80%, respectively.^{51,52} In these historical series, only about 20% of patients with later-confirmed malignancy had, when initially seen, neither suspicious features in the history nor evidence of potential malignancy on neck examination.

Laboratory Tests

As a first-line screening test, serum TSH may be measured with a highly sensitive immunometric assay and combined with a single measurement of free thyroid hormone concentrations.

A low or undetectable serum TSH, even if associated with normal free thyroid hormone levels, should suggest the possibility of toxic, autonomously functioning nodular areas in the goiter and should lead to thyroid scintigraphy. Such a finding should prompt further cardiac investigation, especially in elderly patients, whose risk of atrial fibrillation may be increased as much as threefold when serum TSH levels are less than 0.1 mU/L.⁵³ Patients with thyroid cancer rarely have abnormalities in serum TSH levels, but a higher serum TSH value, even if it is within the upper part of the reference range, is associated with increased risk of malignancy in a thyroid nodule.^{54,55}

Measurement of serum anti-TPO antibody and anti-Tg antibody levels may be helpful in the diagnosis of chronic autoimmune thyroiditis, especially if serum TSH is elevated. Chronic thyroiditis has a typical hypoechoic appearance on sonography; the size and consistency of the thyroid gland may simulate either a solitary nodule or bilateral nodules; hypoechoic nodules should be submitted to FNAB, which will distinguish between foci of thyroiditis and nodules of epithelial origin.

Follicular cell-derived thyroid cancers (FCTCs), which include papillary, follicular, Hürthle cell, poorly differentiated, and anaplastic carcinomas, may release increased Tg

into the bloodstream. Serum Tg levels in FCTCs and in a number of benign conditions overlap, so measurement of serum Tg levels is not useful in the initial workup of nodular thyroid disease. Some investigators routinely measure calcitonin levels in all patients with nodular thyroid disease to identify cases of MTC, because calcitonin is increased in almost all patients with clinical MTC.^{56,57} However, because of the rarity of unsuspected MTC, there is a high frequency of false-positive results that may prompt a thyroidectomy despite a reassuring cytologic result; moreover, the clinical relevance of medullary microcarcinomas is unknown. Therefore, it is neither cost-effective nor necessary to measure calcitonin levels in patients with nodular thyroid disease in the absence of clinical suspicion of MTC or abnormal cytologic findings.^{2,35} If the unstimulated serum calcitonin level is greater than 100 pg/mL, medullary cancer is likely to be present.⁵⁷

The molecular abnormality in more than 95% of cases of familial MTC is a germline mutation of the *RET* proto-oncogene that is located on the long arm of chromosome 10.⁵⁸ Many investigators advocate *RET* mutation testing in all patients with MTC, including apparently sporadic cases, because 4% to 6% of such patients have germline mutations of the gene (see Chapter 41).³ If a mutation is found, family members who are at risk are then tested to identify affected individuals. A negative result obviates the need for any further testing. Individuals who harbor such mutations should undergo prophylactic total thyroidectomy to prevent later development of the multicentric MTC that occurs in this disorder.³

Imaging in Nodular Goiter Evaluation

Today, when a nodular goiter is clinically present, ultrasonography represents by far the most useful thyroid imaging technique for providing helpful information for disease management and treatment. Ultrasonography should be used to assess both the morphology and the size of the goiter and may assist in screening and in follow-up of thyroid nodules.^{1,2,10,35} Ultrasonography is capable of detecting even minute thyroid nodules. Of 1000 normal control subjects, 65% had detectable nodularity on high-resolution scanning.³⁴

Attempts have been made to develop criteria for distinguishing benign and malignant nodules (see Table 14-3). Echo-free (cystic), spongiform, and homogeneously hyperechoic lesions are reputed to carry a low risk of malignancy.^{10,35} Positive predictive criteria of malignancy include predominantly solid nodules and absence of cystic elements, hypoechoic nodules, presence of microcalcifications, irregular margins and absence of halo, and a taller rather than a wide shape measured in the transverse dimension.⁵⁹ Nodules that can be clearly identified as benign by sonography are uncommon. The color Doppler finding of predominantly internal or central blood flow appears to increase the risk that a nodule is malignant. However, like other sonographic features, color Doppler cannot be used to diagnose or exclude malignancy with a high degree of confidence.^{10,35} Elastography is a promising technique that requires further evaluation to determine its usefulness in clinical practice.¹⁵

Recently, an equation was devised to predict the probability of malignancy in thyroid nodules, based on 12 ultrasound parameters. It was suggested that such a thyroid imaging reporting and data system could decide optimal strategies for managing thyroid nodules.⁶⁰

Ultrasonography is useful in identifying hypoechoic solid nodules that should be submitted to FNAB, particularly in the presence of microcalcifications, and also in

examining the rest of the thyroid gland and lymph node areas (Fig. 14-3).^{2,10} It may also be used to direct the needle during FNAB—into the nodule in routine practice, or into solid portions in the case of partially cystic nodules—and in the setting of nonpalpable nodules, especially when the diameter of the nodule is 1 cm or more.¹⁰ Cystic lesions may be treated by aspiration of the fluid and ethanol injection to avoid recurrence; this is optimally performed under ultrasonographic guidance.⁶¹

In patients with large goiters, CT or MRI is indicated to define the relationships with surrounding structures.

The traditional imaging procedure of the thyroid in past years has been scintigraphy using ¹³¹I, ¹²³I, or ^{99m}Tc. Most thyroid carcinomas are inefficient in trapping and organizing iodine and appear on scans as areas of diminished isotope uptake, so-called cool or cold nodules. This feature reflects the early decrease of NIS expression during tumorigenesis.⁶² However, most benign nodules also do not concentrate iodine and therefore are cold nodules. Furthermore, not all nodules with normal or slightly increased ^{99m}Tc uptake are benign, and some may appear cold on a thyroid scan with radioactive iodine.^{4,5}

The only situation in which an iodine scan can exclude malignancy with reasonable certainty is in the case of a toxic adenoma, which is characterized by significantly increased uptake within the nodule (hot nodule) and markedly suppressed or absent uptake in the remainder of the gland. These lesions are suspected at clinical examination and are typically associated with a low or suppressed serum TSH level. They account for fewer than 10% of thyroid nodules and are almost invariably benign.³⁵ Thyroid scintigraphy should be used as a second-line technique to detect hyperfunctioning nodules in patients with low or undetectable serum TSH levels.

CT scanning and MRI in the initial diagnosis of thyroid malignancy do not provide higher-quality images of the thyroid and cervical nodes than those obtained by ultrasonography. CT examination of the lower central neck is preferable if tracheal or mediastinal invasion is suspected.³⁵

Fine-Needle Aspiration Biopsy

FNAB of thyroid nodules has eclipsed all other techniques for diagnosis of thyroid cancer, with reported overall rates of sensitivity and specificity exceeding 90% in iodine-sufficient areas.^{2,10,35,50,63,64} The technique is easy to perform and safe, only a handful of complications having been reported in the literature,⁶⁵ and causes little discomfort. However, care must be taken to obtain an adequate specimen; most authors recommend between three and six aspirations per nodule.^{63,64} Routine use of ultrasound-guided biopsy even for clinically palpable solid nodules, combined with on-site cytologic examination, improves the accuracy of sampling and decreases the risk of inadequate sampling.⁶⁶⁻⁶⁸ A satisfactory specimen contains at least five or six groups of 10 to 15 well-preserved cells. The cells are categorized by their cytologic appearances into *benign*, *indeterminate* or *suspicious*, and *malignant* groups (Table 14-4).

The diagnosis of PTC by FNAB on the basis of characteristic nuclear changes is particularly reliable and accurate, with sensitivity and specificity approaching 100%. For follicular neoplasms, however, the performance of FNAB is lower. If strict criteria for malignancy are used, sensitivity may be as low as 8%.⁵² If any follicular neoplasm that is not clearly benign on cytologic examination is classified as cancerous, sensitivity rises to 90% or more, but with a considerable drop in specificity to less than 50% (i.e., a

Figure 14-3 Conventional and color flow Doppler ultrasonography. **A**, Benign lesion. Sonogram shows well-defined, oval, hyperechoic nodule with perinodular and slight intranodular blood flow. **B**, Malignant lesion. Sonogram shows a nodule with inhomogeneous hypoechoic aspect, microcalcifications, irregular borders, and invasion of the thyroid capsule (arrows).

TABLE 14-4		
Probability of Malignancy at Histology Based on Fine-Needle Aspiration Biopsy Cytology (Summary of the Literature)		
Cytology	Percentage of Cases, Mean (Range)	Probability of Malignancy (%)
Inadequate/nondiagnostic	16 (15-20)	10-20
Benign	70 (53-90)	1-2
Suspicious*	10 (5-23)	10-20
Malignant	4 (1-10)	>95

*The suspicious category includes follicular neoplasms (hyperplastic nodules, follicular adenomas, and follicular carcinomas) and some Hürthle cell tumors.

large number of false-positive results).⁶³ This seriously limits the usefulness of FNAB in iodine-deficient regions, where the incidence of follicular thyroid carcinoma (FTC) approaches that of PTC and where both follicular adenomas and hyperplastic adenomatous nodules are prevalent.⁶⁶

The recent National Cancer Institute Thyroid Fine-Needle Aspiration State of the Science Conference proposed a more expanded classification for FNA cytology that adds two additional categories⁶⁹:

1. Malignant (risk of malignancy, >95%)
2. Suspicious for malignancy (risk of malignancy, 50% to 75%)
3. Follicular or Hürthle cell neoplasm (risk of malignancy, 15% to 25%)

4. Follicular lesion of undetermined significance (risk of malignancy, 5% to 10%)

5. Benign lesions (risk of malignancy, <1%)

Attempts have been made to improve the accuracy of cytology and to decrease the percentage of indeterminate cases.⁷⁰ Results of FNAB should be combined with clinical and ultrasound characteristics. A PTC is usually solid or predominantly solid and hypoechoic, often with infiltrative irregular margins and increased nodular vascularity. Microcalcifications, if present, are highly specific for PTC but may be difficult to distinguish from colloid. The predictive value of ultrasonography is increased when several suspicious characteristics are present. Conversely, follicular cancer is more often isoechoic to hyperechoic and has a thick and irregular halo, but it does not have microcalcifications.^{59,71}

Galectin 3 immunochemistry, alone or combined with TPO, may be a valuable adjunct to the standard cytologic techniques in cases of typical follicular lesions, either benign or malignant.⁷² Prospective studies have confirmed the ability of genetic markers such as BRAF, RAS, and RET/PTC to improve preoperative diagnostic accuracy for patients with indeterminate cytology, but no medicoeconomic evaluation has been produced.⁷³ A combination of markers identified with microarray technology has also been advocated, but independent confirmation of their usefulness is required.⁷⁴⁻⁷⁷

The use of large-needle biopsy in addition to standard FNAB has improved diagnostic accuracy in difficult cases, but the technique is more exacting than FNAB alone and is associated with increased morbidity.⁷⁸ Particularly for

cystic thyroid nodules, sampling from the margin of the nodule under ultrasonic guidance, rather than from the cystic fluid and debris in the center, increases accuracy.

In some centers FNAB is combined with preoperative FNAB with intraoperative frozen-section analysis. In the hands of experienced surgeon-pathologist teams, the rate of misdiagnosis with this approach is less than 5%, as evidenced by subsequent review of paraffin-embedded specimens. The approach avoids unnecessarily extensive surgery in patients with benign tumors, achieves resection of almost all malignant tumors, and rarely necessitates a second operation for completion thyroidectomy.⁷⁹ Such an approach is employed at the Mayo Clinic and at the Institut Gustave Roussy, where intraoperative frozen-section analysis is routine.

Apart from its limited utility in the evaluation of follicular neoplasms, the only other limitation of FNAB is with nondiagnostic specimens, which can account for as many as 20% of cases.^{63,64} Although repeated aspiration increases both the accuracy and the rate of diagnostic aspirations, even repeated attempts sometimes fail. Ultrasound-guided FNAB can help overcome this problem in some patients.^{67,68} The rate of cancer in surgically resected nodules with nondiagnostic FNAB results is 10% to 20%. Therefore, either close observation or surgical removal of the nodule is probably the best option. Some authorities recommend a trial of TSH suppression, which can sometimes shrink benign nodules. However, a significant proportion of benign nodules do not shrink, and some carcinomas do shrink; consequently, the diagnostic value of TSH suppression is doubtful. Figure 14-4 is an algorithm for the management of nodular thyroid disease in which FNAB is the first diagnostic test and subsequent management is based on cytologic results.

The most expeditious way to diagnose thyroid malignancy is to obtain a thorough history and physical examination, followed by ultrasonography, FNAB (preferably performed under ultrasound guidance), and evaluation of

the sample by an experienced cytologist. Imaging procedures in addition to ultrasonography and other tests may occasionally be helpful, but diagnostic thyroid scintiscanning, as traditionally practiced, is of little or no value and should be abandoned.^{1,2,35}

In iodine-sufficient areas with a high relative prevalence of PTC, the combination of the history, physical examination, and FNAB is usually sufficient to confirm malignancy. Conversely, if the history and physical examination, ultrasonography, and FNAB do not suggest malignancy, the chances of missing a PTC are probably less than 1%.^{63,64} In areas where the prevalence of follicular tumors is higher, more patients may require neck exploration because their FNAB is not conclusive.⁶⁶

Surgery should also be considered for large tumors (>4 cm), especially in young subjects, to avoid repeated evaluations. In addition, because these tumors may be composed of various cell populations, results of FNAB are less reliable.⁴⁹

Finally, micronodules smaller than 1 cm in diameter that are found incidentally during imaging do not need to be tested any further unless there are sonographic features suggestive of PTC or MTC. The usual advice is to repeat ultrasonography of such lesions after an interval of 6 to 12 months.^{1,2,34}

MANAGEMENT OF BENIGN NONTOXIC DIFFUSE AND NODULAR GOITER

Patients with small, asymptomatic goiters may be monitored by clinical examination and evaluated periodically with ultrasound measurements. Goiter growth can be variable, and some patients have stable goiters for many years. For more than a century, thyroid "feeding" has been employed to reduce the size of nontoxic goiters. The 1953 report of Greer and Astwood, in which two thirds of patients' goiters regressed with thyroid therapy, led to widespread acceptance of suppressive therapy⁸⁰ despite some doubts about the value of such therapy.⁸¹ An overview of studies performed from 1960 to 1992 suggested that 60% or more of sporadic nontoxic goiters respond to suppressive therapy.⁸¹ In a prospective placebo-controlled, double-blind, randomized clinical trial, 58% of the T₄-treated group had a significant response at 9 months, as measured by ultrasonography, compared with 5% of the placebo-treated group.⁸²

Nodular goiters appear to be less responsive than diffuse goiters. A 2002 meta-analysis failed to demonstrate a significant benefit of T₄ therapy, which was found to carry a relative risk of nodule shrinkage of only 1.9 (95% confidence interval, 0.95 to 3.81).⁸³ Statistical significance emerged from a multicenter randomized, double-blind, placebo-controlled trial: after 18 months of follow-up the nodule shrinkage was significantly greater in the group treated with levothyroxine than in the placebo group ($P = .01$); the proportion of responders was also significantly greater ($P = .04$).⁸⁴ It is likely that a subset of patients respond to T₄ suppressive therapy, particularly younger patients with small or recently diagnosed nodules.⁸³ However, thyroid nodules rapidly return to their pretreatment size after discontinuation of therapy,³⁵ so maintenance of size reduction may require continuous treatment.

A major concern in relation to long-term T₄ suppression therapy is the possibility of detrimental effects on the skeleton and heart. It has been reported that TSH suppression therapy is associated with variable degrees of bone loss, particularly in postmenopausal women.^{85,86} However, other

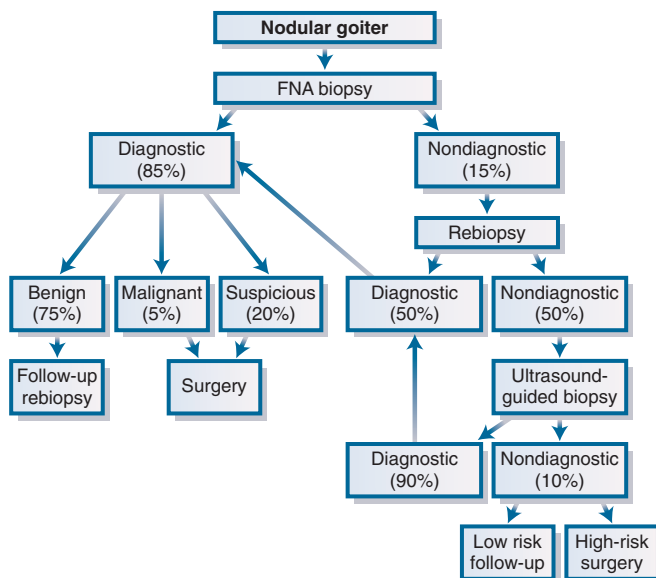

Figure 14-4 Management of nodular goiter based on fine-needle aspiration (FNA) biopsy as the first diagnostic test. Subsequent management is based on cytologic results. Percentages in parentheses indicate satisfactory or unsatisfactory biopsy results. (From Gharib H. Fine-needle aspiration biopsy of thyroid nodules: advantages, limitations, and effect. *Mayo Clin Proc.* 1994;69:44-49.)

studies did not demonstrate significant change in bone mass after long-term T_4 therapy.⁸⁷ Furthermore, there is no evidence that treatment with the natural T_4 isomer, levothyroxine, is detrimental to the heart in young subjects when TSH is decreased to subnormal but still detectable values.^{85,86}

Surgery for nontoxic goiter is physiologically unsound because it further restricts the ability of the thyroid to meet hormone requirements. Nevertheless, surgery may become necessary due to persistence of obstructive manifestations despite a trial of levothyroxine. Surgery should consist of a near-total or total thyroidectomy, but recurrence is seen in 10% to 20% of these patients within 10 years.⁸⁷ Surgical complications have been reported in 7% to 10% of cases and are more common with large goiters and with reoperation.⁸⁸ Prophylactic treatment with levothyroxine after goiter resection probably does not prevent goiter recurrence.⁸⁹

Traditionally, the role of ^{131}I therapy for nontoxic goiter was to reduce the size of a massive goiter in elderly patients who were poor candidates for surgery or to treat goiter that had recurred after resection. Several studies demonstrated that primary treatment of nontoxic goiter with ^{131}I is followed by a reduction in thyroid volume.^{90,91} In one study, thyroid volume (assessed by ultrasonography) was reduced by 40% after 1 year and 55% after 2 years with no further reduction thereafter, and 60% of the total reduction occurred within the first 3 months.⁹⁰ Considering its effectiveness in reducing the size of the thyroid gland, ^{131}I therapy has also been used for the treatment of nonautonomous thyroid nodules, and significant shrinkage, ranging from 31% to 60%, has been observed (Fig. 14-5).^{92,93}

It was formerly argued that ^{131}I treatment of large goiters or goiters with substernal extension should be avoided because of the risks of acute swelling of the gland and consequent tracheal compression. However, ultrasonographic studies of thyroid volume after ^{131}I therapy have failed to demonstrate significant early volume increase. Moreover, decreased tracheal deviation and increased tracheal lumen size were demonstrated by MRI in patients

who had compression from nontoxic goiter with substernal extension.⁹⁰

Therefore, it appears that ^{131}I treatment of nontoxic diffuse or multinodular goiter is effective and safe. Hypothyroidism has been reported in 20% to 40% of cases, and transient thyrotoxicosis and mild pain can occur.⁹⁰ Regular follow-up, preferably by a systematic annual recall scheme, is necessary. The activities used are in the range of those used for ^{131}I treatment of hyperthyroidism; the radiation doses are comparable, and long-term thyroid and nonthyroidal cancer risks after ^{131}I treatment for hyperthyroidism are reassuring.⁹⁴ Stimulation with low doses of recombinant human TSH (rhTSH), 0.01 to 0.03 mg, increases the thyroid ^{131}I uptake and may allow administration of a lower dosage of ^{131}I . However, such treatment also increases thyroid hormone production, and overproduction of thyroid hormones should be excluded before its use.⁹⁵ Long-term randomized studies comparing the effects, side effects, and costs and benefits of surgery and ^{131}I treatment need to be performed.

Percutaneous ethanol injection should be used only for recurrent symptomatic cystic nodules.⁶¹ Laser therapy is still an experimental procedure and may be proposed, in experienced centers, for selected patients with symptomatic nodular goiters when surgery is not possible.⁹⁶

MANAGEMENT OF MALIGNANT NODULAR GOITER

Thyroid tumors are the most common endocrine neoplasms. The management of a typical thyroid cancer is effective and usually consists of surgical resection followed by medical therapy and regular surveillance.⁹⁷⁻⁹⁹ Some degree of consensus has been achieved with regard to the initial management of differentiated thyroid cancer, but important clinical and biologic questions remain unanswered. In the following discussion, we present a widely used scheme for classifying and staging tumors of the thyroid gland. We also review the features of the principal types of benign and malignant thyroid neoplasms and the controversies regarding the management of differentiated thyroid carcinoma, based on recent consensus statements and guidelines.¹⁻³

Classification of Thyroid Tumors

Histologic Classification

Two monographs have had a major impact on the histologic classification of thyroid tumors. One is from the World Health Organization (WHO),⁹⁹ and the other is from the Armed Forces Institute of Pathology (AFIP).¹⁰⁰ The classification described in Table 14-5 is modified from the guidelines described by these organizations.

Lesions of follicular cell origin constitute more than 95% of the cases, and the remainder are largely made up of tumors exhibiting C-cell differentiation. Mixed medullary and follicular carcinomas, comprising cells with both C-cell and follicular differentiation, are rare and of uncertain histogenesis. Nonepithelial thyroid tumors mainly include malignant lymphomas, which may involve the thyroid gland as the only manifestation of the disease or as part of a systemic disease. True sarcomas and malignant hemangioendotheliomas are exceptional. Bloodborne metastases to the thyroid are not uncommon at autopsy in patients with widespread malignancy but rarely cause clinically detectable thyroid enlargement.

Staging of Thyroid Carcinoma

In addition to the histologic classification of thyroid tumors developed by the WHO and AFIP groups, the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) have agreed on a staging system in thyroid cancer.^{101,102} As stated by the AJCC, "the principal purpose served by international agreement on the classification of cancer cases by extent of disease was to provide a method of conveying clinical experience to others without ambiguity."

The AJCC based its system of classification on the older tumor-node-metastasis (TNM) system, which relies on assessing three components: the extent of the primary tumor (T), the absence or presence of regional lymph node metastases (N), and the absence or presence of distant metastases (M). The TNM system allows a reasonably precise description and recording of the anatomic extent of disease. The classification may be either *clinical* (cTNM), based on evidence (including biopsy) acquired before treatment, or *pathologic* (pTNM), by which intraoperative and surgical pathology data are available. Obviously, pTNM classification is preferable because a precise size can be assigned to the primary tumor, the histotype is identified, and extrathyroidal invasion is demonstrated unequivocally.

Typically, in the 1992 TNM classification,¹⁰¹ the primary thyroid tumor status is defined according to the size of the primary lesion as T1 (greatest diameter ≤ 1 cm), T2 (>1 cm but ≤ 4 cm), T3 (>4 cm), or T4 with direct (extrathyroidal) extension or invasion through the thyroid capsule. A thyroid tumor with four degrees of T, two degrees of N, and two degrees of M can have 16 different TNM categories. For purposes of tabulation and analysis, these categories have been condensed into a convenient number of TNM stage-groupings (Table 14-6).

Whereas head and neck cancer is usually staged entirely on the basis of anatomic extent, in thyroid cancer staging both the histologic diagnosis and the age of the patient for

TABLE 14-6

The Tumor-Node-Metastasis (TNM) Scoring System, 1992 and 2002 Versions

DEFINITION OF TNM	
1992 Version	2002 Version
Primary Tumor (T)	
T0—No evidence of primary tumor	T0—No evidence of primary tumor
T1—Tumor ≤ 1 cm limited to the thyroid	T1—Tumor ≤ 2 cm limited to the thyroid
T2—Tumor >1 and ≤ 4 cm limited to the thyroid	T2—Tumor >2 and ≤ 4 cm limited to the thyroid
T3—Tumor >4 cm limited to the thyroid	T3—Tumor >4 cm limited to the thyroid or any tumor with minimal extrathyroidal extension (e.g., to sternothyroid muscle, to parathyroid, to soft tissues)
T4—Tumor of any size extending beyond the thyroid capsule	T4a—Tumor of any size with extension beyond the thyroid capsule and invasion of any of the following: subcutaneous soft tissues, larynx, trachea, esophagus, recurrent laryngeal nerve T4b—Tumor invading prevertebral fascia or mediastinal vessels or encasing the carotid artery
Regional Lymph Nodes (N)	
N0—No regional lymph node metastasis	N0—No regional lymph node metastasis*
N1—Regional lymph node metastasis	N1—Regional lymph node metastasis N1a—Metastases in pretracheal and paratracheal lymph nodes, including prelaryngeal and Delphian lymph nodes N1b—Metastases in other unilateral, bilateral, or contralateral cervical or upper mediastinal lymph nodes
Distant Metastasis (M)	
M0—No distant metastasis	M0—No distant metastasis
M1—Distant metastasis	M1—Distant metastasis
TNM STAGING	
1992 Version	2002 Version
Age < 45 yr	
Stage I—Any T, any N, M0	Stage I—Any T, any N, M0
Stage II—Any T, any N, M1	Stage II—Any T, any N, M1
Stage III—None	Stage III—None
Stage IV—None	Stage IV—None
Age ≥ 45 yr	
Stage I—T1, N0, M0	Stage I—T1, N0, M0
Stage II—T2-T3, N0, M0	Stage II—T2, N0, M0
Stage III—T4, N0, M0 or any T, N1, M0	Stage III—T3, N0, M0 or any T1-3, N1a, M0
Stage IV—Any T, any N, M1	Stage IVA—T1-3, N1b, M0 or T4a, any N, M0 Stage IVB—T4b, any N, M0 Stage IVC—Any T, any N, M1

*To classify as N0, at least six lymph nodes should be examined at histology. Otherwise, the disease is classified as Nx.

From Beahrs OH, Henson DE, Hutter RVP, et al. *Manual for Staging of Cancer*. Philadelphia, PA: Lippincott, 1992; and American Joint Committee on Cancer: Thyroid. In: *AJCC Cancer Staging Handbook*, 6th ed. New York, NY: Springer; 2002:89-98.

PTC and FTC are included because of their importance in predicting the behavior and prognosis of thyroid cancer. According to this staging scheme, all patients younger than 45 years of age with PTC or FTC are in stage I, unless they have distant metastases (DM), in which case they would be in stage II. In young patients and especially in children, the risk of recurrence is high and may be underestimated by the TNM staging system.¹⁰³ Older patients (≥ 45 years) with node-negative papillary or follicular microcarcinoma (T1 N0 M0) are in stage I. Tumors between 1.1 and 4.0 cm are classified as stage II, and those with either nodal spread (N1) or extrathyroidal invasion (T4) are stage III.

For MTC, the scheme is similar in that microcarcinoma is stage I and a node-positive tumor is stage III. There is no age distinction for MTC, although age is a significant independent prognostic indicator in most multivariate analyses,¹⁰⁴⁻¹⁰⁶ and local (extrathyroidal) invasion is grouped within stage II. For patients with MTC and older patients with PTC or FTC, stage IV denotes the presence of distant metastases. Independent of age or tumor extent, all patients with undifferentiated (anaplastic) cancer are considered to be in stage IV.

The 2002 TNM classification is more complicated, and minimal or more extensive thyroid tumor extension may be difficult to define retrospectively.¹⁰² At least six lymph nodes must be examined at histology to qualify for the definition of N0 status, and the prognostic difference between central lymph-node metastases and other regional metastases has yet to be validated. In fact, the risk of persistent or recurrent disease appears to be related to involvement of the central neck compartment and the numbers of involved lymph nodes and lymph nodes with capsular extension.¹⁰⁷ Currently, it is not possible to ascertain whether the modifications included in the 2002 TNM classification will significantly improve its prognostic value and have a clinical impact on therapeutic strategies. One risk is that some centers advocating lobectomy for tumors smaller than 1 cm (T1 in the 1992 classification) may extend this indication to the 2002-redefined T1 group (i.e., tumors up to 2 cm). This attitude, based on cause-specific mortality, may lead to undertreatment of some patients, exposing them to a higher risk of recurrence.

Follicular Adenoma

Follicular adenoma is a benign, encapsulated tumor with evidence of follicular cell differentiation.^{99,100} It is the most common thyroid neoplasm and may be found in 4% to 20% of glands examined at autopsy.¹⁰⁸ The tumor has a well-defined fibrous capsule that is grossly and microscopically complete. There is a sharp demarcation and distinct structural difference from the surrounding parenchyma. These adenomas vary in size, but most have a diameter of 1 to 3 cm at the time of excision. Degenerative changes, such as necrosis, hemorrhage, edema, fibrosis, and calcification, are common features, particularly in larger tumors.

Follicular adenomas can be classified into subtypes according to the size or presence of follicles and degree of cellularity. Each adenoma tends to have a consistent architectural pattern. *Microfollicular*, *normofollicular*, and *macrofollicular* adenomas owe their names to the size of their follicles compared with follicles in the neighboring, non-neoplastic areas of the gland. *Trabecular adenomas* are cellular and consist of columns of cells arranged in compact cords. They show little follicle formation and rarely contain colloid. A variant, the *hyalinizing trabecular adenoma*, has unusually elongated cells and prominent hyaline changes in the extracellular space.¹⁰⁹ The histologic differences

among these subtypes are striking but of no clinical importance. The only practical value of the classification is that the more cellular a follicular nodule is, the more one should search for evidence of malignancy in the form of invasion of blood vessels or of tumor capsule or both.^{99,100}

Atypical adenomas are hypercellular or heterogeneous, or both, with gross and histologic appearances that suggest the possibility of malignancy but not invasion. They account for fewer than 3% of all follicular adenomas. Follow-up indicates that this lesion behaves in a benign fashion. The fact that the tumor does not recur or produce metastases after removal does not prove that it is actually benign; removal may have interrupted a natural history that would have culminated in invasion and metastases. This is why they are classified as tumors of "undefined malignancy."

The most important cytologic variant is the *oxyphilic* or *oncocytic (Hürthle cell) adenoma*, which is composed predominantly (at least 75%) or entirely of large cells with granular, eosinophilic cytoplasm.¹¹⁰ Ultrastructurally, the cells are rich in mitochondria and may exhibit nuclear pleomorphism with distinct nucleoli. Although all such neoplasms are thought by some to be potentially malignant,¹¹¹ the biologic behavior and clinical course of oncocytic tumors correlate closely with the histology and the size of the initial lesion. The absence of invasion predicts a benign outcome,¹¹⁰ but larger tumors may rarely be associated with later recurrence or metastasis, even in the absence of obvious microscopic evidence of invasion. Fortunately, such an occurrence is rare, and usually a diagnosis of benign Hürthle cell adenoma is reliable.^{112,113}

Some normofollicular adenomas may contain pseudopapillary structures that can be confused with the papillae of PTC. These structures are probably an expression of localized hyperactivity and are most common in adenomas that show autonomous function.

In most hyperfunctioning follicular adenomas, activating point mutations have been identified in the TSHR or in the α -subunit of the stimulatory guanyl nucleotide protein ($G_s\alpha$) (Fig. 14-6).^{41,114} Such mutations may trap the G protein in a state of constitutive activation, resulting in

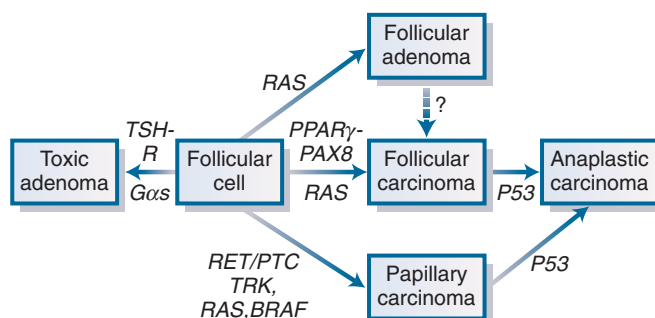

Figure 14-6 Genetic events in thyroid tumorigenesis. Activating point mutations of the RAS gene are found with a high frequency in follicular adenomas and follicular carcinomas and are considered to be an early event in follicular tumorigenesis. The PPAR γ -PAX8 rearrangement is found only in follicular tumors. Rearrangements of transmembrane receptors with tyrosine kinase activity (RET/PTC, TRK genes) and activating point mutation of the BRAF gene are found only in PTCs. Inactivating point mutations of the P53 gene are found only in poorly differentiated and anaplastic thyroid carcinomas. Activation of the cyclic adenosine monophosphate pathway, by point mutation of the thyrotropin receptor (TSH-R) or the α -subunit of the G protein genes, leads to the appearance of hyperfunctioning thyroid nodules. G α s, stimulatory guanyl nucleotide protein; PPAR, peroxisome proliferator-activated receptor; PTC, papillary thyroid carcinoma.

enhanced cyclic adenosine monophosphate (cAMP) production and constitutive hyperstimulation of the cells. Genetic abnormalities found in hypofunctioning adenomas are detailed later.

Papillary Thyroid Carcinoma

PTC has been defined as “a malignant epithelial tumor showing evidence of follicular cell differentiation, and characterized by the formation of papillae and/or a set of distinctive nuclear changes.”^{99,100} The most common thyroid malignancy, PTC constitutes 50% to 90% of differentiated FCTCs worldwide.⁹⁸

Papillary thyroid microcarcinoma (PTM) is defined by the WHO as a PTC 1.0 cm in diameter or smaller.^{98-100,115-117} The incidence rate in the United States for clinically diagnosed PTM (approximately 1 per 100,000) is lower than that reported for tumors larger than 1 cm in diameter (approximately 5 per 100,000) and lower than the incidence of PTM in autopsy material from various continents (4% to 36%).^{99,100} These findings suggest that more extensive screening is largely responsible for the apparently increasing incidence of thyroid carcinomas reported in recent years, which is largely due to increased detection of PTM.¹¹⁸

PTCs appear as firm, unencapsulated or partially encapsulated tumors. PTCs may be partly necrotic, and some are cystic. Typically, PTC shows a predominance of papillary structures, consisting of a fibrovascular core lined by a single layer of epithelial cells, but the papillae are usually admixed with neoplastic follicles having characteristic nuclear features.

The nuclei of PTC cells have a distinctive appearance that has a diagnostic significance comparable to that of the papillae. Indeed, the preoperative diagnosis of PTC can often be made on the basis of the characteristic nuclear changes seen in FNA material: Nuclei are larger than in normal follicular cells and overlap; they may be fissured like coffee beans; chromatin is hypodense (ground-glass nuclei); limits are irregular; and they frequently contain an inclusion corresponding to a cytoplasmic invagination.

Psammoma bodies are often present in the core of papillae or in the tumor stroma; they are microscopic structures made up of calcified layers.

Several subtypes exist and account for about 20% of all PTCs: The tumor is designated a *follicular variant* of PTC if the lining cells of the neoplastic follicles have the same nuclear features as seen in typical PTC and the follicular predominance over the papillae is complete.^{99,100} The *diffuse sclerosing variant* is characterized by diffuse involvement of one or both thyroid lobes, widespread lymphatic permeation, prominent fibrosis, and lymphoid infiltration. The *tall cell variant* is characterized by well-formed papillae that are covered by cells twice as tall as they are wide. The *columnar cell variant* differs from other forms of PTC by the presence of prominent nuclear stratification of elongated cells. The tall cell and columnar cell variants are more aggressive, but controversy exists regarding outcome for the diffuse sclerosing variant.⁹⁸

In children, tumor extension is usually substantial at diagnosis: tumors are large, unencapsulated, and invasive, with solid trabecular features. Extension beyond the thyroid capsule, lymph node metastases, and lung metastases are frequently observed.¹⁰³

Molecular Pathogenesis

The thyroid follicular cell may give rise to benign or malignant tumors, and the malignancy can be of either papillary

or follicular histotype. There is no evidence that human benign tumors ever undergo malignant transformation into classic PTC. Structural abnormalities of the chromosomes occur in about 50% of PTCs and frequently involve the long arm of chromosome 10.^{114,119-122} The *RET* proto-oncogene is located on chromosome 10q11-12. It encodes a transmembrane receptor with a tyrosine kinase domain. Its ligands, such as the glial cell line-derived neurotrophic factor (GDNF), bind to the GDNF family receptor α -1 (GFRA1) and induce *RET* protein dimerization. *RET* (REarranged during Transfection) activation was first demonstrated in transfection experiments and subsequently was found only in PTC tumors. It was therefore called *RET/PTC*.

All activated forms of the *RET* proto-oncogene are the consequence of oncogenic rearrangements fusing the tyrosine kinase domain of the *RET* gene with the 5' domain of other genes. The foreign gene is constitutively expressed, and its 5' domain acts as a promoter, resulting in permanent expression of the *RET* gene. Furthermore, these genes have domains that induce *RET* activation by permanent dimerization. Because of this fusion, the chimeric protein is localized in the cytoplasm and not in the plasma cell membrane.

Three major classes of *RET/PTC* have been identified: *RET/PTC*₁ is formed by an intrachromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene designated *H4*, whose function is still unknown. *RET/PTC*₂ is formed by an interchromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene located on chromosome 17 that encodes the R α regulatory subunit of protein kinase A. *RET/PTC*₃ is formed by an intrachromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene designated *ELE1*, whose function is still unknown. Several other variants of *RET/PTC* have been observed in post-Chernobyl thyroid tumors, including rearrangements formed by fusion of the tyrosine kinase domain of the *RET* gene at other breakpoint sites or with other partners.

The frequency of *RET/PTC* rearrangements occurring in adult PTC patients without prior childhood neck irradiation varies between 2.5% and 35%. In these tumors, the frequencies of *RET/PTC*₁ and *RET/PTC*₃ were similar and that of *RET/PTC*₂ was lower. The *RET/PTC* rearrangements were more frequently found (60% to 80% of cases) in cases of PTC occurring in children even in the absence of radiation exposure or in subjects of any age after radiation exposure during childhood (external irradiation or contamination after the Chernobyl nuclear accident).^{114,122} *RET/PTC*₃ was more frequently found in aggressive tumors that occurred early after the accident and *RET/PTC*₁ in less aggressive tumors that occurred later. The finding of *RET/PTC* rearrangement in micro-PTCs suggests that it constitutes an early event in thyroid carcinogenesis. On the other hand, *RET/PTC*-positive tumors lack evidence of progression to poorly or undifferentiated tumor phenotypes.

An activating point mutation of the *RAS* genes is found in about 10% of PTCs, mostly in the follicular variant.¹²³ A single activating point mutation of the *BRAF* gene at codon 600 is found in 40% (range, 29% to 69%) of PTCs occurring in adults.¹²⁴ Its presence did not overlap with that of *RET/PTC*, and it was rarely found in PTCs occurring in children or after irradiation of the neck.^{118,120} *BRAF* mutation is more frequently found in aggressive PTCs and in the tall cell variant, and it has not been found in other thyroid tumor types.¹²⁴ An intrachromosomal rearrangement of the *BRAF* gene with the *AKAP9*

gene was found in PTCs occurring after the Chernobyl accident.¹²⁵

Several additional oncogenes may occasionally be involved in PTC, including *NTRK1* (also named *TRKA*), which codes for a neural growth factor receptor with a tyrosine kinase domain and is activated by rearrangement in about 10% of PTCs. The receptor for hepatocyte growth factor is a transmembrane tyrosine kinase encoded by the *MET* oncogene; it is overexpressed in some patients with PTC, and low expression has been associated with the occurrence of distant metastases.

In conclusion, the mitogen-activated protein (MAP) kinase (RET/PTC, RAS, BRAF) pathway is activated in approximately 80% of sporadic or radiation-induced PTCs, and mutations affecting this pathway are considered to be initiating events of PTC and to mediate the mitogenic phenotype.¹²⁰ Other signal transduction pathways may also be activated, including the phosphatidylinositol 3 (PI3) kinase pathway,¹²⁶ and activation by cross-talk among these pathways may exist.

A high incidence of PTC has been reported in patients with adenomatous polyposis coli; these cancers have a peculiar histologic appearance with solid areas and elongated cells. There is also a high incidence of follicular cell-derived tumors (mainly FTC) in Cowden's disease (the multiple hamartoma syndrome), suggesting that the predisposing genes may play a role in the occurrence of these tumors. The familial risk of thyroid cancer is higher than for other cancers, and 3% to 10% of cases of PTC are familial.¹²⁷ The behavior of familial thyroid cancers is similar to or slightly more aggressive than that of nonfamilial cases.¹²⁸ At least five loci of predisposition have been identified, but they do not explain all hereditary cases. The gene predisposing to familial thyroid tumors with cellular oxyphilia has been mapped to chromosome 19q13.2, but in a family with PTC and renal carcinoma a separate gene was mapped to chromosome 1p13.2.q22.¹²⁹ Recently, a genome-wide study in PTC identified an association with a single-nucleotide polymorphism (SNP) at chromosomal locus at 9q22, a region that contains the thyroid transcription factor gene, *FOXE1*¹³⁰; the plausible implication of *FOXE1* in PTC was strengthened by a large gene candidate study.^{131,132} A germline mutation in another thyroid transcription factor, TTF1, has also been reported in familial PTC.¹³²

The expression of thyroid-specific genes has been studied at the messenger ribonucleic acid (mRNA) and protein levels in large series of human thyroid tumors. Expression of the NIS gene (*SLC5A5*) was profoundly decreased in benign and malignant thyroid hypofunctioning nodules; in malignant nodules, low expression of TPO, PDS, and Tg was also found.⁶² These abnormalities clearly explain many of the metabolic defects typically observed in thyroid cancer tissues: a low iodine concentration, a low rate of iodine organification, a low hormonal synthesis, and a short intrathyroidal half-life of iodine. NIS expression is heterogeneous among tumor cells.⁶² However, Tg is expressed in variable amounts in almost all FCTCs and can be shown by immunohistochemistry, which can prove useful in cases with atypical histology. Also, TSHRs are expressed in many FCTCs, and TSH may stimulate both their differentiation and growth.⁶²

Multiple other abnormalities have been found in follicular cell-derived tumors, including overexpression of vascular endothelial growth factor (VEGF) and of VEGF receptors (VEGFRs), in line with the hypervascularization observed in these tumors.¹³³ VEGF, VEGFRs, and other angiogenic factors may be targets for experimental therapies.

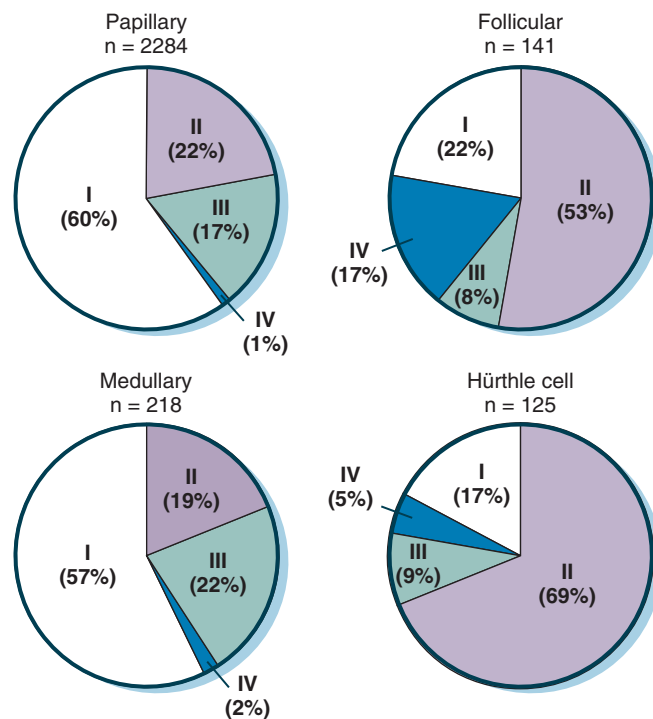

Figure 14-7 Distribution of pathologic tumor-node-metastasis (pTNM) stages I through IV in 2284 patients with papillary thyroid carcinoma (upper left), 218 patients with medullary thyroid cancer (lower left), 141 patients with follicular thyroid cancer (upper right), and 125 patients with Hürthle cell cancer (lower right) undergoing primary surgical treatment at the Mayo Clinic from 1940 to 1997.

Presenting Features

Although PTCs can occur at any age, most patients are between 30 and 50 years of age (mean age, 45 years). Women are affected more frequently than men (female predominance, 60% to 80%). Most primary tumors are 1 to 4 cm in size; they average about 2 to 3 cm in greatest diameter.^{98,115} The increased incidence observed in recent years is mostly related to small PTCs.^{118,134} PTC is frequently multifocal when it occurs in a single lobe, and it is bilateral in 20% to 80% of cases, depending on whether the thyroid was meticulously examined or not. Studies have suggested that contralateral PTC may have independent clonal origins, but this remains controversial.¹³⁵ Extrathyroidal invasion of adjacent soft tissues is present in about 15% of patients (range, 5% to 34%) at primary surgery, and about one third of PTC patients have clinically evident lymphadenopathy at presentation.^{98,115} Between 35% and 50% of excised neck nodes have histologic evidence of involvement, and nodal involvement is present in up to 90% of patients 17 years of age or younger.^{103,136} Only 1% to 7% of PTC patients have distant metastases at diagnosis.^{98,115} Spread to superior mediastinal nodes is usually associated with extensive neck nodal involvement.

The TNM classification is a widely used system for tumor staging.¹³⁷ Most PTC patients present with stage I (60%) or stage II (22%) disease. Patients aged 45 years or older with either nodal metastases or extrathyroidal extension (stage III) account for fewer than 20% of cases.^{98,115} As already noted, few PTC patients (1% to 7%) present with distant metastases and have stage IV disease. Figure 14-7 (upper left) illustrates the distribution of TNM stages in 2284 PTC cases seen at the Mayo Clinic, and Figure 14-8 demonstrates

Figure 14-8 Cause-specific survival according to pathologic tumor-node-metastasis (pTNM) stage in a cohort of 2284 patients with papillary thyroid carcinoma treated at the Mayo Clinic from 1940 to 1997. The numbers in parentheses represent the percentage of patients in each pTNM stage grouping.

survival by TNM stage in this same cohort of PTC patients treated from 1940 to 1997. In these figures and also in the other figures in this chapter that illustrate outcome results from the Mayo Clinic 1940-1997 cohort of PTC patients, the pTNM stages are derived, in part, from the older (pre-2002) definition because of the challenges in defining from available records the N1a versus N1b status and the exact location of the extrathyroidal extension necessary to ascribe T4a or T4b status to the tumor extent at surgery.

Recurrence and Mortality

Three types of tumor recurrence may have been observed in patients with PTC: postoperative *nodal metastases* (NM), *local recurrence* (LR), and postoperative *distant metastases* (DM).

Local recurrence may be defined as “histologically confirmed tumor occurring in the resected thyroid bed, thyroid remnant, or other adjacent tissues of the neck (excluding lymph nodes)” after complete surgical removal of the primary tumor.¹³⁸ Metastases may be considered postoperative if discovered within 180 days for nodal metastases or 30 days for distant metastases.⁹⁸ Ideally, tumor recurrence should be considered only as it occurs in patients without

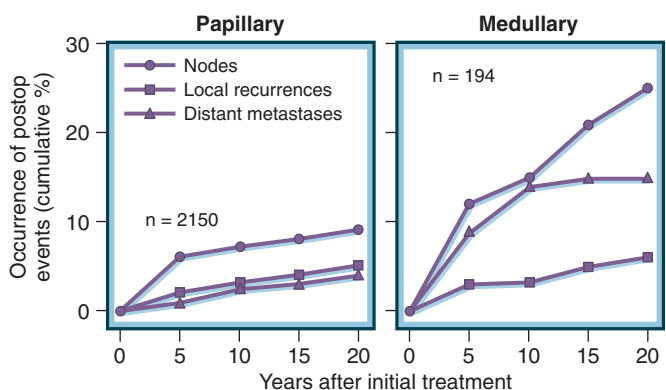

Figure 14-9 Development of neck nodal metastases, local recurrences, and distant metastases in the first 20 years after definitive surgery for papillary thyroid cancer (PTC) or medullary thyroid cancer (MTC) performed at the Mayo Clinic from 1940 to 1997. Based on 2150 consecutive PTC and 194 MTC patients who had complete surgical resection (i.e., no gross residual disease) and were without distant metastases on initial examination.

Figure 14-10 Development of neck nodal metastases (NM), local recurrences (LR), and distant metastases (DM) in the first 20 years after definitive surgery for follicular thyroid cancer (FTC) or Hürthle cell cancer (HCC) performed at the Mayo Clinic from 1940 to 1997. Based on 110 consecutive FTC patients and 115 HCC patients who had complete surgical resection and were without distant metastases on initial examination.

initial distant metastases who had complete surgical resection of the primary tumors.

Figure 14-9 illustrates rates of PTC recurrence at local, nodal, and distant sites in 2150 patients with PTC treated at one institution from 1940 to 1997. After 20 years of follow-up, postoperative nodal metastases had been discovered in 9%, local recurrence in 5%, and distant metastases in 4%. Both local recurrence and distant metastases are less common in PTC than in FTC (Fig. 14-10). However, postoperative cases of nodal metastases were more frequent in PTC than in FTC.

Cause-specific mortality (CSM) rates for differentiated thyroid cancer are shown in Figure 14-11. CSM rates for PTC were 2% at 5 years, 4% at 10 years, and 5% at 20 years. Among those with lethal PTC, 20% of the deaths occurred during the first year after diagnosis, and 80% within 10 years. The 25-year cause-specific survival rate of 95% for PTC was significantly higher than the 79%, 71%, and 66% rates seen with MTC, Hürthle cell cancer (HCC), and FTC, respectively.

Outcome Prediction

Only a fraction (approximately 15%) of patients with PTC are likely to experience relapse of disease, and even fewer

Figure 14-11 Cumulative cause-specific mortality rates for patients with differentiated thyroid carcinoma in the first 25 years after treatment with initial surgery performed at the Mayo Clinic from 1940 to 1997. Based on 2768 consecutively treated patients—2284 with papillary thyroid carcinoma (PTC), 141 with follicular thyroid cancer (FTC), 125 with Hürthle cell cancer (HCC), and 218 with medullary thyroid cancer (MTC).

Figure 14-12 Observed survival to death from all causes and survival to death from thyroid cancer (cause-specific mortality) in 2284 consecutive patients with papillary thyroid carcinoma undergoing initial management at the Mayo Clinic from 1940 to 1997. Also plotted (dashed line) is the expected survival to death from all causes for patients of similar age and sex, based on appropriate Minnesotan life-tables.

(approximately 5%) have a lethal outcome. Exceptional patients who have an aggressive course tend to experience relapse early (Fig. 14-12), and the rare fatalities usually occur within 5 to 10 years after diagnosis.^{98,115} Multivariate analyses have been used to identify variables predictive of CSM.^{115,139-145} Increasing age of the patient and the presence of extrathyroidal invasion were independent prognostic factors in all studies.

The presence of initial distant metastases and large size of the primary tumor are also significant variables in most studies,^{115,139-141,144} and some groups^{98,115,140,141,143} have reported that histopathologic grade (degree of differentiation) is an independent variable. The completeness of initial tumor resection (postoperative status) is also a predictor of mortality.^{98,141,144} The presence of initial neck nodal metastases, although relevant to future nodal recurrence, does not influence CSM (Fig. 14-13).^{98,115,144}

Several scoring systems based on these significant prognostic indicators have been devised. Each system allows one to assign the majority of PTC patients ($\geq 80\%$) to a low-risk group, in which the CSM at 25 years is less than 2%, and the others (a small minority) to a high-risk group, in which almost all of the cancer-related deaths are observed. In general, these systems provide prediction of postoperative events comparable to that of the internationally accepted TNM staging system.¹⁴⁵

One scoring index devised to assign PTC patients to prognostic risk groups¹³⁹ was named the AGES scheme, after the four independent variables: patient's age, tumor grade, tumor extent (local invasion, distant metastases), and tumor size. With the use of such a scoring system, 86% of patients were placed in the minimal risk group (AGES score < 4), and they experienced a 20-year CSM rate of only 1%.⁹⁸ By contrast, patients with AGES scores of 4 or higher (14% of the total) were considered to be at high risk and had a 20-year CSM of 36%.

Figure 14-14 compares the AGES scores with TNM staging and with two other schemes designed to stratify PTC patients as having either minimal risk or high risk of cancer-related death. Such a prognostic scoring system makes it possible to counsel patients and aids in the planning of individualized postoperative management programs in PTC.^{139,144}

Although the AGES scheme had the potential for universal application, some academic centers could not include

Figure 14-13 Lack of influence of nodal metastases at initial operation on cumulative mortality from papillary thyroid carcinoma in 1941 patients with pathologic T1 to T3 intrathyroidal tumors (i.e., completely confined to the thyroid gland) and 209 pathologic T4 patients with extrathyroidal (locally invasive) tumors, with (N1) or without (N0) nodal metastases. All patients had initial surgical treatment at the Mayo Clinic from 1940 to 1997. DM, distant metastases.

the differentiation (G) variable because their surgical pathologists did not recognize higher-grade PTC tumors.¹⁴⁵ Accordingly, a prognostic scoring system for predicting PTC mortality rates was devised with the use of candidate variables that included completeness of primary tumor resection but excluded histologic grade.¹⁴⁴ Cox model analysis and stepwise variable selection led to a final prognostic model, called MACIS, that included five variables: metastasis, age, completeness of resection, invasion, and size. The MACIS score is calculated as follows: 3.1 if the patient is 39 years of age or younger (or $0.08 \times \text{age}$ if ≥ 40 years), plus $0.3 \times \text{tumor size}$ in centimeters, plus 1 if the tumor was not completely resected, plus 1 if local invasion is present, plus 3 if distant metastases are present.

Figure 14-14 Cumulative mortality from papillary thyroid carcinoma in 2284 patients at either minimal risk or higher risk of cancer-related death as defined by International Union Against Cancer (UICC) pathologic tumor-node-metastasis (pTNM) stage (upper left), AGES score (upper right), AMES risk group (lower left), and MACIS score (lower right). The minimal risk group constituted 81% of the patients when defined by pTNM stage I or II, 86% as defined by an AGES score lower than 4, 88% as defined by the AMES low-risk criteria, and 83% when defined by a MACIS score lower than 6. The cause-specific mortality (CSM) rates at 20 years were 25% for those with TNM stage III or IV, 36% for an AGES score of 4 or higher, 39% for AMES high-risk status, and 32% for an MACIS score of 6 or higher. The ratios between the CSM rates for high-risk versus low-risk groups at 20 years were 19 for the pTNM system, 36 for AGES, 35 for AMES, and 40 for MACIS.

Figure 14-15 Cause-specific survival according to MACIS (metastases, age, completeness of resection, invasion, and size) score (<6, 6 to 6.99, 7 to 7.99, and ≥8) in a cohort of 2284 consecutive patients with papillary thyroid carcinoma (PTC) undergoing initial treatment at the Mayo Clinic from 1940 to 1997. The numbers and percentages of PTC patients in each of the four risk groups are shown in parentheses.

As illustrated by Figure 14-15, the MACIS scoring system permits identification of groups of patients with a broad range of risk of death from PTC. Twenty-year cause-specific survival rates for patients with MACIS scores lower than 6, between 6 and 6.99, between 7 and 7.99, and 8 or higher were 99%, 89%, 56%, and 27%, respectively ($P < .0001$). When cumulative mortality from all causes of death was considered, approximately 85% of PTC patients with AGES scores lower than 4 or MACIS scores lower than 6 had no excess mortality over rates predicted for control subjects.^{139,144}

It should be emphasized that the five variables in the MACIS scoring system are easy to define after primary operation; consequently, the system can be applied in any clinical setting. The MACIS system can be used for counseling individual PTC patients and can help guide decision-making concerning the intensity of postoperative tumor surveillance and the appropriateness of adjunctive radioiodine therapy. Because the CIS variables (completeness of resection, invasion, and size) require information obtained at surgery, the system probably should not be used to decide the extent of primary surgery.^{146,147}

Follicular Thyroid Carcinoma

FTC is “a malignant epithelial tumor showing evidence of follicular cell differentiation but lacking the diagnostic features of papillary carcinoma.”⁹⁹ Such a definition excludes the follicular variant of PTC, and it is also customary to exclude both the poorly differentiated carcinoma¹⁴⁸ and the rare mixed medullary and follicular carcinoma.¹⁴⁹ The correct classification of tumors with predominant oncocytic features (i.e., HCCs) is controversial.¹¹⁰ The WHO committee has taken the stance that this tumor is an oxyphilic variant of FTC.⁹⁹ The AFIP monograph, by contrast, stated that “the tumors made up of this cell type have gross, microscopic, behavioral, cytogenetic (and conceivably etiopathogenic) features that set them apart from all others and justify discussing them in a separate section.”¹⁰⁰

Thus categorized, FTC is a relatively rare neoplasm whose identification requires invasion of the capsule, blood vessel, or adjacent thyroid. In epidemiologic surveys, FTC constituted 5% to 50% of differentiated thyroid cancers and tended to be more common in areas with iodine deficiency.¹⁵⁰ Owing to a combination of changing

diagnostic criteria and an increase in the incidence of PTC associated with dietary iodine supplementation, the diagnosis of FTC has decreased in frequency; in one North American experience, minimally invasive nonoxyphilic FTCs made up fewer than 2% of thyroid malignancies.¹⁵¹

The microscopic appearance of FTC varies from well-formed follicles to a predominantly solid growth pattern.^{99,100} Poorly formed follicles and atypical patterns (e.g., cribriform) may occur, and multiple architectural types may coexist. FTC is best divided into two categories on the basis of degree of invasiveness: minimally invasive (or encapsulated) and widely invasive. There is little overlap between these two types.

Minimally invasive FTC is an encapsulated tumor whose growth pattern resembles that of a trabecular or solid, microfollicular, or atypical adenoma. The diagnosis of malignancy depends on the demonstration of blood vessel or capsular invasion, or both. The criteria for invasion must therefore be strict.^{99,100} Blood vessel invasion is almost never seen grossly. Microscopically, the vessels “should be of venous caliber, be located in or immediately outside of the capsule and contain one or more clusters of tumor cells attached to the wall and protruding into the lumen.”⁹⁹ Interruption of the capsule must involve the full thickness to qualify as capsular invasion. Penetration of only the inner half or the presence of tumor cells embedded in the capsule does not qualify for the diagnosis of FTC. Foci of capsular invasion must be distinguished from the capsular rupture that can result from FNA. The acronym WHAFFT (worrisome histologic alterations following FNA of the thyroid) is applied to such changes.¹⁵² The diagnosis of malignancy of these tumors can be difficult and may not be reproducible among pathologists. Immunohistochemistry with markers such as TPO, galectin 3, or HMBE1 may help for this purpose,⁷² but these techniques did not reliably improve the accuracy of pathology in case of suspicious findings. Global gene expression studies with the microarray technology demonstrated different profiles between papillary carcinoma and follicular tumors,⁷⁴⁻⁷⁶ but the reported distinction between follicular adenomas and minimally invasive follicular carcinoma with the expression study of a limited number of genes needs confirmation.⁷⁷

In contrast, the rare *widely invasive* form of FTC can be distinguished easily from benign lesions. Although the tumor may be partially encapsulated, the margins are infiltrative even on gross examination, and vascular invasion is often extensive. The structural features are variable, but a follicular element is always present. If follicular differentiation is poor or absent, or in the presence of a trabecular, insular, or solid component, the tumor may be classified as a poorly differentiated carcinoma (see later discussion).^{100,153}

Focal or extensive clear-cell changes can occur. A rare clear-cell variant of FTC has been described in which glycogen accumulation or dilatation of the granular endoplasmic reticulum is responsible for the clear cells.¹⁵⁴ If more than 75% of cells in an FTC exhibit Hürthle cell (or oncocytic) features, the tumor is classified as a Hürthle cell or oncocytic carcinoma^{100,155} or as an oxyphilic variant FTC.⁹⁹

Molecular Pathogenesis

There is still no accepted paradigm for the pathogenesis of FTC. A multistep adenoma-to-carcinoma pathogenesis, similar to that for colon cancer and other adenocarcinomas, is not universally accepted because pathologists do not recognize follicular carcinoma in situ and documentation of the evolution of adenoma to carcinoma is rare. Nevertheless, several facts about the pathogenesis of FTC

are firmly established.^{114,118,119,121,123} First, most follicular adenomas and all FTCs are probably of monoclonal origin. Second, oncogene activation, particularly by point mutation of the *RAS* oncogene, is common both in follicular adenomas (approximately 20%) and in FTCs (approximately 40%), supporting a role in early tumorigenesis.^{123,156} The *RET* oncogene does not appear to be involved in follicular tumors.^{114,118,119} Third, cytogenetic abnormalities and evidence of genetic loss are more common in FTC than in PTC and also occur in follicular adenomas.^{119,121}

Of the cytogenetic abnormalities described in FTC, the most common are deletions, partial deletions, and deletion-rearrangements involving the short (p) arm of chromosome 3. Loss of heterozygosity (LOH) on chromosome 3p appears to be limited to FTC, because no evidence for 3p LOH has been found in follicular adenomas or in PTC. A translocation, t(2;3)(q13;p25), which results in fusion of the DNA binding domains of the thyroid transcription factor PAX8 to domains of the peroxisome proliferator-activated receptor (PPAR γ 1), was detected in 30% of FTCs (range, 11% to 63%) and in 10% of follicular adenomas but not in PTCs or multinodular hyperplasia.¹⁵⁷⁻¹⁵⁹ The chimeric protein may retard the growth inhibition and follicular differentiation normally induced by PPAR γ 1.¹⁵⁸ The two main genetic alterations found in follicular carcinomas may act through distinct molecular pathways.¹⁵⁹

Presenting Features

FTC tends to occur in older people, with the mean age in most studies being greater than 50 years, or about 10 years older than for typical PTC.¹⁵⁰ The average median age of patients with oxyphilic FTC (HCC) is about 60 years.^{150,155} As in most thyroid malignancies, women outnumber men by more than 2 to 1. Most patients with FTC present with a painless thyroid nodule, with or without background thyroid nodularity, and they rarely (4% to 6%) have clinically evident lymphadenopathy at presentation.¹⁵⁰ Metastases to lymph nodes of the neck in FTC are so exceptional that "wherever they are observed, the alternative possibilities of follicular variant papillary carcinoma, oncocytic carcinoma, and poorly differentiated carcinoma should be considered."¹⁰⁰

In most series in which tumor sizes were reported, the average tumor size in FTC (oxyphilic or nonoxyphilic) was larger than the average tumor size in PTC.^{150,155} Direct extrathyroidal extension, by definition, does not occur with minimally invasive FTC but is common in the rare patients with invasive FTC. Between 5% and 20% of patients with FTC have distant metastases at presentation,¹⁵⁰ most commonly to lung or bone.^{100,150} The bones most often involved are long bones (e.g., femur), flat bones (particularly pelvis, sternum, and skull), and vertebrae. If distant metastasis is the first manifestation of the disease, definitive proof of its thyroid origin should be obtained, usually by biopsy of a metastasis, before any thyroid surgery is performed. It is unusual for patients with FTC to have thyrotoxicosis caused by massive tumor burden.¹⁶⁰

Most patients (53% to 69%) with FTC or HCC have pTNM stage II disease. Patients 45 years of age or older with nodal metastases or extrathyroidal extension (stage III) account for only 4% of FTCs and 9% of HCCs (see Fig. 14-7). About 5% of HCCs and 17% or more of nonoxyphilic FTCs have distant metastases at the time of diagnosis (stage IV).

Recurrence and Mortality

Nodal metastases are rare in typical FTC, and the nodal recurrence rate at 20 years after surgery is the lowest among

Figure 14-16 Postoperative recurrence (any site) during the first 20 years after definitive surgery for differentiated thyroid carcinoma performed at the Mayo Clinic from 1940 to 1997. Based on 2569 consecutive patients who had complete tumor resection and no distant metastases at presentation. The number of patients and the median age at diagnosis are shown in parentheses for each of the four histologic subtypes.

the differentiated thyroid carcinomas, approximately 2% (see Fig. 14-10). About 6% of patients with HCC have node involvement at presentation,¹⁶¹ and within 25 years after primary surgery about 17% of HCC patients have nodal recurrence.¹⁵⁰ When recurrences at either neck or distant sites are taken into consideration, patients with HCC (Fig. 14-16) have the highest number of tumor recurrences after 10 to 20 years. As illustrated by Figure 14-10, local recurrences at 20 years are identified in 20% of FTCs and 30% of HCCs. Comparable distant metastases rates are 23% and 28%, respectively.

CSM rates vary with the presenting TNM stage in both FTC (Fig. 14-17) and HCC. The death rates tend to parallel the curves for development of distant metastases (see Fig. 14-10). In more than 5 decades of experience at the Mayo Clinic, the mortality rate for FTC has been found to exceed that of HCC initially, but by 20 and 30 postoperative years there are no significant differences in cause-specific survival rates (80% and 70%, respectively) between FTC and HCC¹⁵⁰ (Fig. 14-18). Curves representing mortality from all causes differ in FTC and HCC. On average, patients with FTC are about 5 years younger, tend to die within the first 10 postoperative years, and have high all-cause mortality for 10 to 30 postoperative years (Fig. 14-19). Deaths related

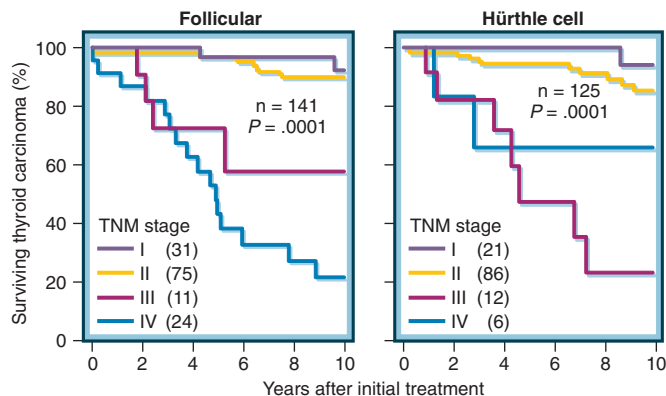

Figure 14-17 Cause-specific survival according to pathologic tumor-node-metastasis (pTNM) stage in a cohort of 141 patients with follicular thyroid carcinoma (left panel) and 125 patients with Hürthle cell carcinoma (right panel) treated at the Mayo Clinic from 1940 to 1997. Numbers in parentheses represent the number of patients in each pTNM stage grouping.

Figure 14-18 Comparison of cause-specific survival in 1472 patients with papillary thyroid carcinoma (PTC) and 250 patients with follicular thyroid carcinoma (FTC) treated at the Mayo Clinic from 1940 to 1990. Of the PTCs, 138 were "pure" papillary in histotype (no follicular elements); 97 of the FTC patients had predominantly oxyphilic tumors. There was a significant difference ($P = .0001$) between the cause-specific survival curves for PTC versus FTC. However, within each group, the survival curves are insignificantly different. (From Grebe SKG, Hay ID. Follicular thyroid cancer. *Endocrinol Metab Clin North Am*. 1995;24:761-801.)

to HCC occur gradually over the first 15 years; however, by 25 years, the average survivor of HCC is 84 years old, and by that time, almost 50% of the treated cohort would be predicted by the actuarial curve to have died from all causes.

Outcome Prediction

The risk factors that predict outcome in FTC are largely the same as in PTC^{150,162-170}: distant metastases at presentation, increasing age of the patient, large tumor size, and the presence of local (extrathyroidal) invasion. To a lesser degree, increased mortality is associated with male gender and higher grade (less well-differentiated tumors). In addition, vascular invasiveness, lymphatic involvement at presentation, DNA aneuploidy, and oxyphilic histology are

Figure 14-19 Survival to death from all causes in 141 consecutive patients with follicular thyroid carcinoma (left) and 125 patients with Hürthle cell cancer (right) undergoing initial management at the Mayo Clinic from 1940 to 1997. Also plotted is the expected survival (all causes) of persons of the same age and sex and with the same date of treatment but living under mortality conditions of the northwest central United States.

Figure 14-20 Cumulative cause-specific survival among 100 patients with nonoxyphilic follicular thyroid carcinoma treated at the Mayo Clinic from 1946 to 1970, plotted by high-risk and low-risk categories. High-risk patients were those for whom two or more of the following factors were present: age older than 50 years, marked vascular invasion, and metastatic disease at time of initial diagnosis. (From Brennan MD, Bergstralh EJ, van Heerden JA, et al. Follicular thyroid cancer treated at the Mayo Clinic, 1946 through 1970: initial manifestations, pathologic findings, therapy, and outcome. *Mayo Clin Proc*. 1991;66:11-22.)

potential prognostic variables unique to FTC.¹⁵⁰ The importance of vascular invasion was underscored by a study showing that FTC patients with minimal capsular invasion and no evidence of vascular invasion had 0% CSM at 10-year follow-up.¹⁶²

Prognostic scoring systems for FTC^{150,163} allow stratification of patients into high-risk and low-risk categories. A multivariate analysis at the Mayo Clinic found that distant metastases at presentation, patient age greater than 50 years, and marked vascular invasion predict a poor outcome.¹⁵⁰ As illustrated by Figure 14-20, if two or more of these factors are present, the 5-year survival rate is only 47%, and 20-year survival is 8%. By contrast, if only one of these factors is present, 5-year survival is 99%, and 20-year survival is 86%.

Systems developed to predict outcome in either PTC or FTC have been applied to FTC patients. The pTNM and the AMES (age, metastasis, extent, size) risk group categorization have proved to be useful in FTC.¹⁶⁴ From a multivariate analysis of 228 patients with FTC treated at the Memorial Sloan-Kettering Cancer Center, the following independent adverse prognostic factors were identified: age older than 45 years, Hürthle cell histotype, extrathyroidal extension, tumor size exceeding 4 cm, and the presence of distant metastases.¹⁶⁵ The prognostic importance in FTC of histologic grade was also confirmed,¹⁶⁵ and this factor was included in the assignment of low, intermediate, and high risk group categories (Fig. 14-21).

The AGES scheme, originally developed for PTC, has also been successfully applied to FTC.^{166,167} Additionally, the MACIS classification has been demonstrated to be a more accurate predictor of survival in FTC than the TNM, AGES, and AMES prognostic schemes.¹⁶⁸ Therefore, scoring systems used in PTC may be cautiously applied to FTC as long as some of the unique features of this tumor, such as

Figure 14-21 Survival differences in low-risk, intermediate-risk, and high-risk groups for 228 consecutive patients with follicular thyroid carcinoma who were seen and treated at the Memorial Sloan-Kettering Cancer Center during a period of 55 years from 1930 to 1985. The number of each patient in each group and the percentage of patients surviving at 10 and 20 years are shown. (From Shaha AR, Loree TR, Shah JP: Prognostic factors and risk group analyses in follicular carcinoma of the thyroid. *Surgery*. 1995;118:1131-1138.)

vascular invasiveness and the remarkable significance of DNA aneuploidy in HCC, are kept in mind.¹⁵⁰

Poorly Differentiated (Insular, Solid, or Trabecular) Carcinoma

Poorly differentiated thyroid carcinoma has been defined as “a tumor of follicular cell origin with morphological and biologic attributes intermediate between differentiated and anaplastic carcinomas of the thyroid.”¹⁰⁰ New diagnostic criteria for poorly differentiated carcinoma have been proposed: (1) solid, trabecular, and insular pattern of growth; (2) absence of conventional nuclear features of papillary carcinomas; and (3) presence of at least convoluted nuclei, mitotic activity greater than 3 mitotic figures per 10 high-power fields, and tumor necrosis.¹⁵³ Similarly, in well-differentiated cancer, necrosis, mitosis, and cellular atypia associated with vascular invasion are considered to be features of poor prognosis and of aggressiveness.¹⁷⁰ Most such tumors are larger than 5 cm in diameter at diagnosis, with extrathyroidal extension and blood vessel invasion. This type of tumor is viewed by the WHO committee⁹⁹ as a morphologic variant of FTC, but others view it as a poorly differentiated variant of either PTC or FTC.¹⁰⁰ *RET* rearrangement and *BRAF* mutation are infrequent in poorly differentiated carcinoma, *NRAS* mutation is found in 25% of tumors, and *TP53* mutation has been evidenced in a significant proportion of these tumors. Activation of the PI3 kinase pathway is frequent, as is overexpression of the vascular endothelial growth factor receptor.^{126,171-173}

The mean age at diagnosis is about 55 years, and the female-to-male ratio is about 2:1.¹⁰⁰ Poorly differentiated carcinoma is aggressive and often lethal. Radioiodine uptake is rarely present, but FDG uptake on PET is frequently high. Production of Tg in blood may be lower than in differentiated carcinomas. Metastases are common in regional nodes and distant sites (lung, bone, brain). In one series, 56% of patients died from their tumor within 8 years of initial therapy.¹⁴⁸

Undifferentiated (Anaplastic) Carcinoma

Anaplastic carcinoma constitutes about 1% to 2% of all thyroid carcinomas, usually occurs after the age of 60 years, and is slightly more common in women (female-to-male

ratio, 1.3:1 to 1.5:1).¹⁷⁴⁻¹⁷⁶ This carcinoma is highly malignant, is nonencapsulated, and extends widely. Evidence of invasion of adjacent structures, such as skin, muscles, nerves, blood vessels, larynx, and esophagus, is common. Distant metastases occur early in the course of the disease in lungs, liver, bones, and brain.

On histopathologic examination, the lesion is composed of atypical cells that exhibit numerous mitoses and form a variety of patterns. Spindle-shaped cells, multinucleated giant cells, and squamoid cells usually predominate. Areas of necrosis and polymorphonuclear infiltration are common, and the presence of PTC or FTC suggests that they may be the precursors of anaplastic carcinoma. Mutations of the *TP53* gene are present in many undifferentiated carcinomas but may not be found in the residual well-differentiated component, suggesting that these mutations occur after the development of the original tumor and may play a key role in tumor progression.^{114,171}

The usual clinical complaint is that of a rapid, often painful enlargement of a mass that may have been present in the thyroid gland for many years. The tumor invades adjacent structures, causing hoarseness, inspiratory stridor, and difficulty in swallowing. On examination, the overlying skin is often warm and discolored. The mass is tender and often is fixed to adjacent structures. It is stony hard in consistency, but some areas may be soft or fluctuant. The regional lymph nodes are enlarged, and there may be evidence of distant metastases. Anaplastic carcinomas do not accumulate iodine and do not typically produce thyroglobulin; high FDG uptake is usually found on PET, and PET is the best tool for tumor staging and for control of treatment efficacy.¹⁷⁷

Treatment should be initiated rapidly to avoid death from locally infiltrative disease and possible suffocation. Treatment consists of surgical resection of the tumor tissue present in the neck, if feasible, followed by a combination of external irradiation and chemotherapy.^{175,176}

Medullary Thyroid Carcinoma

MTC accounts for fewer than 10% of thyroid malignancies (see Chapter 41). It arises from the parafollicular or C cells of the thyroid gland, and the tumor cells typically produce an early biochemical signal (hypersecretion of calcitonin). MTC readily invades the intraglandular lymphatics, spreading to other parts of the gland and to pericapsular and regional lymph nodes. It also regularly spreads through the bloodstream to the lungs, bones, and liver.^{3,104-106,178}

MTC tumors are firm and usually nonencapsulated. On histopathologic examination, the tumor is composed of cells that vary in their morphologic features and arrangement. Round, polyhedral, and spindle-shaped cells form a variety of patterns, from solid and trabecular to endocrine or glandular-like structures. An amyloid stroma is commonly present.^{99,100} Gross or microscopic foci of carcinoma may be present in other parts of the gland, and blood vessels may be invaded. In all cases, the diagnosis can be confirmed by positive immunostaining of tumor tissue for calcitonin and carcinoembryonic antigen (CEA).

MTC first appears either as a hard nodule or mass in the thyroid gland or as an enlargement of the regional lymph nodes. Occasionally, a metastatic lesion at a distant site is found first. The neck masses are frequently painful; they are sometimes bilateral and are often localized to the upper two thirds of each lobe of the gland, reflecting the anatomic location of the parafollicular cells.

Figure 14-22 Cause-specific survival according to pathologic tumor-node-metastasis (pTNM) stage in a cohort of 218 patients with medullary thyroid carcinoma treated at the Mayo Clinic from 1940 to 1997. The number and percentage of patients in each pTNM stage group are shown.

The tumor occurs in both sporadic and hereditary forms, the latter making up about 20% of the total. The hereditary variety can be transmitted as a single entity (familial MTC), or it can arise as part of MEN2A or MEN2B syndrome. The hereditary form is typically bilateral and is usually preceded by a premalignant C-cell hyperplasia. Total thyroidectomy at this premalignant stage can cure the disease in more than 90% of cases.^{3,56-58,178-180} *RET* proto-oncogene testing should be performed in all MTC patients. The finding of a germline mutation in this gene indicates a hereditary disease; the mutation should then be sought in all first-degree family members.

Early series of MTC mainly described sporadic cases, in which 80% of patients presented with TNM stage II or III disease. As more patients with familial MTC or MEN2A have been diagnosed, more patients have had curable (stage I) disease at presentation, and the survival rate has improved, a trend that should continue with widespread application of *RET* proto-oncogene testing.¹⁷⁸⁻¹⁸⁰ Patients with MTC now have outcomes similar to or better than those of patients with nonpapillary FCTC (see Fig. 14-11). The cause-specific survival curves for 218 consecutive MTC cases treated from 1940 to 1997 at the Mayo Clinic, based on TNM stage, are presented in Figure 14-22.

Prognostic factors relevant to outcome in MTC include (1) age at diagnosis, (2) male gender, (3) initial extent of the disease (e.g., nodal metastases, distant metastases), (4) tumor size, (5) extrathyroidal invasion, (6) vascular invasion, (7) calcitonin immunoreactivity and amyloid staining in tumor tissue, (8) postoperative gross residual disease, and (9) postoperative plasma calcitonin levels.¹⁰⁴⁻¹⁰⁶ In a multivariate analysis, only the age of the patient at initial treatment and the stage of the disease remained as significantly independent indicators of survival. This suggests that, in routine practice, clinicians attempting to predict outcome in MTC should take into account not only the presenting disease stage, as assessed by the pTNM system (see Fig. 14-22), but also the age of the patient at diagnosis.¹⁰⁴⁻¹⁰⁶

Cushing's syndrome may occur at an advanced stage of the disease, because of secretion of corticotropin by the tumor. Prostaglandins, serotonin, kinins, and vasoactive intestinal peptide may also be secreted and are variously responsible for flushing and for the attacks of watery diarrhea that about one third of patients experience,

usually at an advanced stage of the disease.^{104-106,178} In MEN2A, hyperparathyroidism occurs late and is usually due to parathyroid hyperplasia rather than adenoma. Pheochromocytomas invariably occur later than MTC; they are often bilateral and may be clinically silent, and patients at risk should be screened with measurements of urinary metanephrine excretion. In MEN2B, MTC and pheochromocytomas are associated with multiple mucosal neuromas (*bumpy lip syndrome*), a marfanoid habitus, and typical facies, but such patients do not have hyperparathyroidism.^{3,178}

Differentiation of sporadic MTC from other types of thyroid nodule on clinical grounds alone may be difficult. In patients with a family history of thyroid cancer associated with hypertension or hyperparathyroidism, the MEN2A syndrome should be suspected. FNAB has made it possible to diagnose MTC before surgery. In some patients, however, cytologic findings are misleading because the type of carcinoma is difficult to determine, and HCC may occasionally be confused with MTC.^{99,100}

Positive immunocytochemical staining for calcitonin allows confirmation of the diagnosis. Basal plasma calcitonin levels are elevated in virtually all patients with clinical MTC.^{56,57} Infusions of pentagastrin or calcium elicit secretion of calcitonin, and the response may be exaggerated in patients with MTC or the antecedent C-cell hyperplasia; the use of such infusions should be restricted to MTC patients with an undetectable or borderline plasma calcitonin level (see Chapter 41).

When the diagnosis of MTC is made based on calcitonin measurements or FNAB, patients should be evaluated for hyperparathyroidism and for pheochromocytoma. If these diagnoses are satisfactorily excluded, a total thyroidectomy with removal of regional nodes can safely be performed.^{3,181,182} In patients with MEN syndrome, surgery should be performed for pheochromocytomas before the surgery for MTC is performed. First-degree relatives of patients with MEN or familial MTC should undergo DNA testing for presence of the mutant *RET* gene (see Chapter 41). Gene carriers should undergo prophylactic total thyroidectomy at an age that depends on the mutation: within the first year of life for those with MEN2B, and before 5 years of age for those with the 634 *RET* mutation (the most common type).^{3,57,179,180} For carriers of other mutations, prophylactic total thyroidectomy may be delayed beyond age 5 years in the setting of a normal annual basal serum calcitonin level (and a normal stimulated level, if performed), normal findings on annual neck ultrasonography, a less aggressive MTC family history, and family preference. Surgery is indicated if none of these features is present.³

Primary Malignant Lymphoma

Primary thyroid lymphomas are rare tumors, accounting for 2.5% of all non-Hodgkin's lymphomas and fewer than 2% of all malignant thyroid tumors. The peak incidence is during the seventh decade of life, and the female-to-male ratio is 3:1.

Primary thyroid lymphoma almost always has a B-cell lineage.¹⁸³ Most thyroid malignant lymphomas are mucosa-associated lymphoid tissue (MALT) lymphomas that arise in a background of Hashimoto's thyroiditis. These small-cell lymphomas are characterized by a low grade of malignancy, a slow growth rate, and a tendency for recurrence at other MALT sites such as the gastrointestinal tract, respiratory tract, thymus, or salivary glands. At diagnosis, diffuse large-cell lymphomas account for about 70% to

80% of tumors, and a substantial proportion of clinical cases arise from the transformation of low-grade MALT lymphoma to high-grade B-cell lymphoma. Other histologies are rare.

Thyroid lymphomas almost invariably manifest as a rapidly enlarging, painless neck mass. One third of the patients have compressive symptoms. The mass is often fixed to surrounding tissues, and half of the patients have unilateral or bilateral cervical lymph node enlargement. Clinically evident distant disease is uncommon. About 20% of patients already have a long-standing goiter, and hypothyroidism is reported in up to 40% of cases. The palpated mass is solid and hypoechoic on ultrasonography, which often depicts a characteristic asymmetric, pseudocystic pattern. Most patients have serum anti-peroxidase and anti-thyroglobulin antibodies.

The diagnosis of lymphoma can often be established by FNA cytology, particularly the diffuse large B-cell type. Large-bore needle biopsy or open surgical biopsy may be needed for immunohistochemical staining to diagnose small-cell lymphomas and the frequently associated chronic autoimmune thyroiditis. Lymphocyte monoclonality for light-chain immunoglobulin may be necessary to confirm malignant lymphoma.

Accurate staging is critical for treatment planning. Staging includes a physical examination; complete blood count; serum lactate dehydrogenase; liver function tests; bone marrow biopsy; CT scan or MRI of the neck; CT scan of the thorax, abdomen, and pelvis; and appropriate biopsies at other sites where tumors are suspected. Involvement of Waldeyer's tonsillar ring and of the gastrointestinal tract has been associated with thyroid lymphomas, so upper gastrointestinal tract radiographs or endoscopy should be performed.

Treatment is guided by the histologic subtype, the extent of disease, and, in case of diffuse large B-cell lymphoma, by the age-adjusted international prognostic index.^{184,185} Surgical debulking of thyroid lymphomas is neither feasible nor necessary. Small tumors are often treated initially as primary thyroid carcinomas with surgery, and additional radiotherapy may be necessary in case of indolent lymphoma.

For high-grade B-cell lymphoma, chemotherapy combined with rituximab (chimeric human-mouse anti-CD20 monoclonal antibody) has become the standard treatment.¹⁸⁶ The chemotherapy prescribed should be an anthracycline-based regimen. It usually consists of 4 to 6 cycles of the CHOP regimen (cyclophosphamide, 750 mg/m² on day 1; doxorubicin, 50 mg/m² on day 1; vincristine, 1.4 mg/m² on day 1; and prednisone, 40 mg/m² per day on days 1 through 5) every 3 weeks. For localized aggressive lymphoma, the combination of chemotherapy and radiotherapy used before the era of rituximab was found to reduce distant recurrence compared with radiotherapy alone. Radiation monotherapy should be used only for elderly patients who cannot receive medical treatment, because one third of the patients will experience recurrence at distant sites, usually within the first year after treatment.

For MALT lymphomas, if the disease is found to be localized after accurate staging, total thyroidectomy (predicted overall survival and disease-free survival, 100% at 5 years) or involved-field radiation therapy alone (2 Gy per fraction for 5 days/week up to a total dose of 30 to 40 Gy; 5-year overall survival rate, 90%) may be adequate.¹⁸⁷ For disseminated MALT lymphoma, chemotherapy alone (with single agent such as chlorambucil) or chemotherapy combined with local radiation therapy may be proposed.

SURGICAL TREATMENT OF THYROID CARCINOMA

Factors that influence the optimal extent of surgery include the histologic diagnosis, the size of the original lesion, the presence of lymph node and distant metastases, the patient's age, and the risk group category.¹⁻³ Obviously, the surgeon must be appropriately skilled in thyroid surgery, and the goal of surgery should be to remove all of the malignant neoplastic tissue that is present in the neck. A preoperative ultrasound examination of the thyroid gland and of neck lymph node areas should be routinely performed, and detected lesions should be adequately resected.¹⁻³

In the case of PTC and FTC, a near-total thyroidectomy (i.e., leaving no more than 1 g of thyroid tissue) or a total thyroidectomy is recommended for all patients.^{1,2,97,98,137-139,188} Total thyroidectomy reduces the recurrence rate, compared with more limited surgery, because many PTCs are both multifocal and bilateral. Removal of most, if not all, of the thyroid gland facilitates postoperative remnant ablation with ¹³¹I.

For extremely low-risk patients (i.e., those with unifocal intrathyroidal PTM), a lobectomy may be an appropriate primary surgical procedure.^{1,2,116,117} A completion thyroidectomy should be offered to those patients who have undergone a unilateral lobectomy for a supposedly benign tumor that proves to be a cancer and for whom a total thyroidectomy would have been recommended had the diagnosis been available before the initial surgery. This includes all patients with thyroid cancer except those with small (<1 cm), unifocal, intrathyroidal, node-negative, low-risk tumors.²

Surgical treatment of lymph nodes is based on the preoperative workup, including neck ultrasound examination. In the presence of clinically involved lymph nodes, a therapeutic lymph node dissection is routinely performed.^{2,16} This includes dissection of the central compartment VI (paratracheal and tracheoesophageal areas) and may also include dissection of the ipsilateral supraclavicular area and the lower third of the jugulocarotid chain (compartments III and IV, respectively).^{2,16,189} A modified ipsilateral neck dissection is performed if palpable lymph node metastases are present in the jugulocarotid chain or if a preoperative ultrasound examination demonstrates biopsy-proven lateral neck nodal disease; in such cases, a compartment VI dissection is also performed. Dissection is preferable to lymph node picking. In patients with PTC, in the absence of any evidence of lymph node involvement, a prophylactic central neck dissection is controversial and may be performed either routinely or only for advanced primary tumors (T3 or T4).^{2,16,190,191}

Although this type of lymph node dissection has not been shown to improve the recurrence and survival rates,^{107,161,162,191} several arguments support its routine use in patients with PTCs. Histologic evidence of lymph node metastases is present in up to two thirds of PTC patients, of whom more than 80% have involvement of the central compartment, and metastases are difficult to detect by palpation in lymph nodes located behind the vessels or in the paratracheal groove; moreover, preoperative neck ultrasound detects only half of the involved lymph nodes.¹⁹³ Knowledge of the initial lymph node status is a requisite for TNM classification, is useful for the indication of postsurgical radioiodine treatment,¹⁸⁹ and helps in the interpretation of any cervical abnormality identified during postoperative follow-up.^{1,2} The major drawback of lymph node dissection

is that it may increase the morbidity rate, and for this reason it should be performed by a skilled surgeon.

In the case of FTC, lymph node metastases are less frequent, and a lymph node dissection should be performed if involved lymph nodes are detected.

MTC is treated by total thyroidectomy, with a dissection of the central compartment of the neck and the lower two thirds of the jugulocarotid chains. A modified neck dissection is performed either routinely or for MTC affecting the lateral neck nodes.¹⁸⁰⁻¹⁸²

Ideally, patients with anaplastic carcinoma should be treated with near-total thyroidectomy and lymph node dissection, but lesions are frequently too extensive for any procedure but palliative surgery.¹⁷⁴⁻¹⁷⁶ In these cases, surgery may be performed later in those patients with tumor regression after a combination of chemotherapy and external radiotherapy.

In recommending surgery, the endocrinologist should discuss potential operative complications with the patient. Unilateral lobectomy almost never causes permanent hypocalcemia but can cause temporary vocal cord paralysis in as many as 3% of patients. Total thyroidectomy causes temporary hypocalcemia in 7% to 10% of patients and permanent hypocalcemia in 0.5% to 1%; permanent vocal cord paralysis occurs in fewer than 1% and may benefit from specific treatments.¹⁹⁴ The risk of hypoparathyroidism should be reduced by identification of the parathyroid glands, possibly with the use of methylene blue staining and certainly, if viability is in doubt, by autotransplantation of the parathyroid glands at the time of initial neck exploration. The experience of the surgeon is important in regard to the finer technical points of thyroidectomy, including preservation of the external branch of the recurrent laryngeal nerve, which is important in the fine regulation of voice pitch.

A history of irradiation in childhood increases the risk of both benign and malignant thyroid nodules in later life.¹⁹⁵ The risk increases with younger age at exposure and with larger radiation dose. Several issues are relevant for the thyroidologist. With respect to the extent of surgery, a total thyroidectomy should be performed in all patients who have a thyroid carcinoma^{195,196} and also in those with benign lesions.

Indeed, one must weigh the relative risk of complications associated with a more extensive surgical procedure against the possibility of recurrence of thyroid nodules in the residual thyroid tissue. In one irradiated population, both benign and malignant nodules recurred after subtotal thyroidectomy. The overall risk of recurrence in this study was approximately 20% and was lower in those who had more thyroid tissue removed than in those who underwent less extensive procedures. In those patients after surgery, suppression of TSH by thyroid hormone led to a reduction in recurrence from 35% to approximately 8%, but TSH suppression had no influence on the occurrence of malignant nodules.¹⁹⁵ Therefore, the recommendations for patients with thyroid nodules after neck exposure to radiation during childhood must take into account the estimated risk of developing a thyroid nodule and the experience of the operating surgeon. All irradiated patients who have had thyroid nodules removed should receive TSH-suppressive doses of levothyroxine regardless of the extent of surgery. The appearance of new thyroid nodules is, however, fairly common, and patients should be monitored indefinitely for this possibility.

It is not clear whether the experience just described should be extrapolated to prescribe routine TSH suppression therapy for all irradiated patients, even if nodularity

is not present, because its beneficial effects have not been quantified and the risks of long-term TSH suppression in women, especially in regard to osteoporosis, have not been clearly defined and may be significant. At present, this approach cannot be recommended for all irradiated patients but can be recommended for patients who are at high risk for development of a thyroid nodule.¹⁹⁵

POSTOPERATIVE MANAGEMENT

In view of the uncertainties reviewed in the previous section and the different needs of individual patients, postoperative treatment of thyroid carcinoma cannot always accord with a rigid algorithm.^{1,2} One must consider the extent of disease at surgery, the histotype and differentiation of the tumor, the age of the patient, and the risk group category.

Iodine ¹³¹I Therapy

¹³¹I is an effective agent for delivering high radiation doses to the thyroid tissue with low spillover to other portions of the body. The radiation dose to the thyroid tissue is related to the tissue concentration, the ratio between total tissue uptake and volume of functional tissue, and the effective half-life of ¹³¹I in the tissue.^{62,197} Thyroid tissue is able to concentrate iodine only after TSH stimulation, but even after optimal TSH stimulation, iodine uptake in neoplastic tissue is always lower than in normal thyroid tissue and may not be detectable in about one third of cases.⁶²

¹³¹I therapy is given postoperatively for three reasons.^{1,2} First, it destroys normal thyroid remnants (this is termed *ablation*), thereby increasing the sensitivity of subsequent ¹³¹I total-body scanning and the specificity of measurements of serum Tg for the detection of persistent or recurrent disease.¹⁹⁸ Second, it may destroy occult or known microscopic carcinomas, thereby potentially decreasing the long-term recurrence rate. Finally, it makes it possible to perform a postablative ¹³¹I total-body scan, a sensitive tool for detecting persistent carcinoma.

It cannot be emphasized too strongly that postoperative ¹³¹I therapy should be used *selectively* and that not all patients with a diagnosis of FCTC benefit from routine postoperative radioiodine ablative therapy.^{1,2,91} In very-low-risk patients, the long-term prognosis after surgery alone is so favorable that ¹³¹I ablation is not recommended.^{1,2,199,200} However, patients who are at high risk of recurrence (Table 14-7) are routinely treated with ¹³¹I because such therapy can potentially decrease both the recurrence rate and the death rate. Young children are also usually candidates for postoperative radioiodine therapy because they may have extensive neck lymph node involvement and frequently harbor pulmonary metastases that are not detectable with standard radiography or even with CT imaging of the chest.^{103,136} In other patient groups, there is currently no evidence that ¹³¹I therapy improves the long-term outcome; radioiodine is administered postoperatively if surgery was or could have been incomplete.

Postoperatively, no levothyroxine treatment is given for 4 to 6 weeks, but liothyronine can be substituted for at least 3 to 4 weeks and then discontinued for 2 weeks before radioiodine studies. At that time, the serum TSH level should be greater than an empirically determined level of 25 to 30 mU/L; an undetectable serum Tg level indicates a very low risk of finding persistent disease or of subsequent recurrence.²⁰¹ Intramuscular injections of rhTSH (0.9 mg/day for 2 consecutive days, with ¹³¹I administered 1 day

TABLE 14-7

Indications for Iodine 131 Treatment in Patients with Papillary, Follicular, or Hürthle Cell Thyroid Carcinoma after Initial Definitive Near-Total Thyroidectomy

No Indication

Adult patients at very low risk for cause-specific mortality or relapse: complete surgical resection, favorable histology, and limited extent of disease (e.g., PTC patients with MACIS scores <6; patients with tumor size <1 cm, N0, and M0).

Definite Indications

Distant metastasis at diagnosis
Incomplete tumor resection
Complete tumor resection but high risk for mortality or recurrence (e.g., PTC patients with MACIS scores ≥6 and pTNM stage II/III FTC or HCC)

Probable Indications

Incomplete surgery (less than near-total thyroidectomy, no lymph node dissection)
PTC or FTC in a child <16 yr of age
If PTC, tall cell or columnar cell variant and diffuse sclerosing variant
If FTC, widely invasive or poorly differentiated tumor
Bulky nodal metastases

FTC, follicular thyroid carcinoma; HCC, Hürthle cell carcinoma; MACIS, scoring system based on metastasis, age, completeness of resection, invasion, and size; PTC, papillary thyroid carcinoma; pTNM, pathologic tumor-node-metastasis classification.

after the second injection) given on levothyroxine treatment may achieve an effective stimulation of radioiodine uptake by normal thyroid remnant, with ablation rates similar to those obtained with withdrawal²⁰²; its use prevents hypothyroidism because levothyroxine is initiated soon after surgery and is not discontinued, maintains quality of life, leads to a lower radiation exposure to the body, and permits earlier discharge from the hospital.²⁰²⁻²⁰⁵ In addition, short-term recurrence rates have been found to be similar in patients prepared with thyroid hormone withdrawal versus rhTSH, even in patients with initial lymph node involvement.^{206,207} rhTSH is approved for remnant ablation in the United States, Europe, and many other countries around the world.

In case of incomplete thyroidectomy, neck uptake may be measured with a tracer activity of ¹³¹I or ¹²³I; the activity used should be small enough to avoid stunning (i.e., a decrease of thyroid uptake with the subsequent high activity of radioiodine).^{208,209} High uptake (>10%) and high risk of persistent disease should lead to completion surgery. ¹³¹I therapy can be administered to other patients, with no pretherapy total-body scan because of its low impact on the decision to ablate and because of concerns about ¹³¹I-induced stunning, usually with 24-hour uptakes considerably less than 10%.²¹⁰ A total-body scan is performed 3 to 7 days after the radioiodine treatment and is highly informative in patients with a low uptake (<1%) in the thyroid bed. Additional metastatic foci have been reported in 10% to 26% of patients scanned after high-dose radioiodine treatment, compared with the diagnostic scan.²¹¹ Single-photon emission computed tomography (SPECT)/CT fusion imaging with ¹³¹I may provide superior lesion localization after remnant ablation.^{8,9}

Levothyroxine therapy is then initiated or continued. Total ablation (defined as no visible uptake) may be verified by an ¹³¹I total-body scan 6 to 12 months later, typically with 2 to 5 mCi (74 to 185 MBq). However, such control ¹³¹I total-body scanning is not more routinely performed

when postablation scan has been informative, because it does not afford any further information,^{212,213} and total ablation is currently defined by an undetectable serum Tg level after rhTSH stimulation and normal findings on neck ultrasonography.^{1,2}

Total ablation can be achieved after administration of either 100 mCi (3700 MBq) or 30 mCi (1100 MBq) in more than 80% of patients who had at least a near-total thyroidectomy, after preparation with either withdrawal or rhTSH.^{214,215} After less extensive surgery, ablation is achieved in only two thirds of patients with 30 mCi (1100 MBq). Therefore, a near-total thyroidectomy should be performed in all patients who are to be treated with ¹³¹I. Also, in high-risk patients, a high activity (100mCi or more) should be administered with the aims of ablating normal thyroid remnants and irradiating residual neoplastic tissue. Total ablation requires that a dose of at least 300 Gy (30,000 rad) be delivered to thyroid remnants. A dosimetric study can allow a more precise estimate of the ¹³¹I activity to be administered and avoids the administration of excessive activities, particularly in elderly patients.^{197,216}

¹³¹I ablation therapy does not play a regular role in the management of anaplastic thyroid cancer, MTC, or thyroid lymphoma.

External Radiotherapy

External radiotherapy to the neck and mediastinum is indicated only for older patients (>45 years) with extensive PTC in whom complete surgical excision is impossible and in whom the tumor tissue does not take up ¹³¹I. Retrospective studies have shown that, in these selected patients, external radiotherapy decreases the risk of neck recurrence.^{217,218} The target volume encompasses the thyroid bed, bilateral neck lymph node areas, and the upper part of the mediastinum. Typically, 50 Gy (5000 rad) is delivered in 25 fractions over 5 weeks, with a boost of 5-10 Gy on any residual macroscopic focus.

In patients with MTC, this protocol may be applied after incomplete resection of the tumor. After apparently complete surgery, if plasma calcitonin remains detectable in the absence of distant metastases, it may decrease the risk of neck recurrence by a factor of 2 to 4.^{104,178}

In patients with anaplastic thyroid carcinoma, if the extent of disease is limited and surgery is feasible, accelerated external radiotherapy in combination with chemotherapy permits local control of the disease in two thirds of patients and long-term survival in about 20%.^{175,176}

Levothyroxine Treatment

The growth of thyroid tumor cells is controlled by TSH, and inhibition of TSH secretion with levothyroxine is thought to improve the recurrence and survival rates.²¹⁹ Therefore, levothyroxine should be given to all patients with FCTC, whatever the extent of thyroid surgery and other treatment. The initial effective dose is about 2 µg/kg body weight in adults; children require a higher dose and elderly patients a lower dose. The adequacy of therapy is monitored by measuring serum TSH 3 months after it is begun, the initial goal being a serum TSH concentration of less than 0.1 mU/L for high-risk thyroid cancer patients; maintenance of the TSH at or slightly below the lower limit of normal (0.1 to 0.5 mU/L) is appropriate for low-risk patients, including those who have not undergone remnant ablation.^{1,2,219}

In patients with anaplastic thyroid carcinoma, MTC, or thyroid lymphoma, a replacement dose of levothyroxine

is given, with the aim of obtaining a serum TSH level in the normal range.

FOLLOW-UP

In patients with PTC or FTC, the goals of follow-up after initial therapy are to maintain adequate levothyroxine therapy and to detect persistent or recurrent thyroid carcinoma. Most recurrences occur during the first years of follow-up, but some occur late. Therefore, follow-up is necessary throughout the patient's life.

Early Detection of Recurrent Disease

Clinical and Ultrasonographic Examinations

Palpation of the thyroid bed and lymph node areas is routinely performed at all follow-up visits for patients with thyroid cancer. Ultrasonography is more sensitive and may detect lymph nodes as small as 2 to 3 mm in diameter.¹¹⁻¹³ Metastatic lymph nodes should be differentiated from frequent benign lymph node hyperplasia, and false-positive findings can have deleterious consequences. If lymph nodes are small, thin, or oval; are located in the posterior neck chains; and, especially, decrease in size after an interval of 3 months, they are considered benign. By contrast, malignant lymph nodes are much more likely to occur in compartments III, IV, and VI. The feature with the highest sensitivity for malignancy is absence of a hilus (100%), but this has a low specificity of only 29%; the most specific criteria are short axis (>5 mm), hyperechogenicity, presence of hyperechoic punctuations and of a cystic component, and peripheral hypervascularization.¹⁹³ These characteristics can be difficult to recognize in patients with small lymph nodes, so they should be monitored at short intervals.

With the use of an assay that has a functional sensitivity of 1 ng/mL, serum Tg is undetectable in more than 20% of patients receiving levothyroxine treatment who have isolated lymph node metastases detected by palpation or by ¹³¹I total-body scanning, and probably in a higher proportion of patients with lymph node metastases detected only by neck ultrasonography.^{97,198} Therefore, undetectable values do not exclude metastatic lymph node disease. Ultrasonographically, suspicious lymph nodes larger than 5 to 8 mm in the smallest diameter should be biopsied for cytology with thyroglobulin measurement in the needle washout fluid.²²⁰ The reverse transcriptase-polymerase chain reaction (RT-PCR) technique to amplify Tg mRNA in the fluid aspirate appears to be even more sensitive but is not yet being used by commercial laboratories.²²¹

Radiography

Bone and chest radiographs are no longer routinely obtained for patients with undetectable serum Tg concentrations. The reason is that virtually all patients with abnormal radiographs have readily detectable serum Tg concentrations.

Serum Thyroglobulin Determinations

Tg is a glycoprotein that is produced only by normal or neoplastic thyroid follicular cells. Methods used for serum Tg determination and serum interferences are detailed in Chapter 11.²²² Tg should not be detectable in patients who have had total thyroid ablation, which improves both the sensitivity and the specificity for detection of persistent or recurrent disease.¹⁹⁸ Serum Tg antibodies may induce falsely

negative results and should be *quantitatively* assessed with every measurement of serum Tg.^{1,2,222} Serum Tg antibodies in patients who are in complete remission after total thyroid ablation decline gradually to low or undetectable levels, with a median time of 3 years.²²³ Their persistence or reappearance during follow-up should be considered suspicious for persistent or recurrent disease.

There is a close relationship between tumor burden and the Tg level, both during levothyroxine therapy and after TSH stimulation.^{222,224} This explains why serum Tg may be undetectable in patients who have isolated lymph node metastases in the neck or small lung metastases not visible on x-ray films. The production of Tg by both normal and neoplastic thyroid tissue is in part TSH dependent. High serum TSH concentrations can be achieved by withdrawing levothyroxine for 4 to 6 weeks. However, the resulting hypothyroidism is poorly tolerated by some patients. This effect can be attenuated by substituting the more rapidly metabolized liothyronine for levothyroxine for 3 to 4 weeks and withdrawing it for 2 weeks, or simply by reducing the dose of levothyroxine by 50%. The serum TSH concentration should be above an empirically determined value (25 to 30 mU/L) in patients treated in this way; if it is not, withdrawal should be prolonged until it is. Intramuscular injections of rhTSH (0.9 mg for 2 consecutive days) are an alternative because levothyroxine treatment need not be discontinued and side effects are minimal. After rhTSH stimulation, the peak of serum Tg is usually obtained 3 days after the second injection.^{205,225} Although the increase in serum Tg is frequently less important after rhTSH than after withdrawal, the diagnostic efficiency of rhTSH for stimulating Tg production in the serum is comparable to that of levothyroxine withdrawal in most patients.^{198,225}

If serum Tg is detectable during levothyroxine treatment, it will increase after TSH stimulation obtained by treatment discontinuation or injections of rhTSH. If the serum Tg is undetectable during levothyroxine treatment in a blood test performed 3 months after initial treatment, it will increase in 14% to 20% of patients after TSH stimulation at 9 to 12 months.^{198,212,213} At that time, the serum Tg concentration is an excellent prognostic indicator.

Most patients with undetectable serum Tg concentrations who are not receiving levothyroxine therapy will remain free of relapse after more than 15 years of follow-up, and fewer than 1% will have a neck lymph node recurrence detected by sonography.^{198,212,213} Persistent or recurrent disease is found in one third of the patients with detectable serum Tg concentrations and is twice as frequently located in neck lymph nodes than at distant sites; in these patients, serum Tg levels increase with time or remain elevated. In the other patients, serum Tg levels obtained after TSH stimulation at blood tests performed months or years later will decrease to low or undetectable levels, even in the absence of any further treatment, these patients can also be considered cured.^{198,226} Persistent thyroid cells may produce Tg for several months after ¹³¹I treatment, disappearing during subsequent months. These data demonstrate that the trend in serum Tg level is probably much more relevant than the actual serum Tg level by itself.

Modern Tg assays with a functional sensitivity of 0.1 ng/mL have an improved sensitivity for the detection of persistent disease during levothyroxine treatment, but at the expense of a decreased specificity; when using modern sensitive assays, the benefits of routine rhTSH stimulation in low-risk patients with undetectable serum Tg on levothyroxine treatment appear not to be significant.²²⁷⁻²²⁹

TABLE 14-8
Nonthyroidal Conditions Associated with ¹³¹ I Accumulation
Contamination
Skin, hair, clothes
Physiologic Accumulations
Salivary glands (mouth, esophagus), nose
Stomach, colon (in hypothyroidism)
Bladder
Breast in young women
Diffuse hepatic uptake (¹³¹ I-labeled iodoproteins)
Inflammatory Processes
Lung or bronchial, cutaneous, dental, sinusoidal
Other Conditions
Nonthyroidal neoplasms: salivary glands, stomach, lung, meningioma
Struma ovarii
Cysts: renal, pleuropericardial, hepatic, salivary, mammary, testicular
hydrocele
Thymus: normal or hyperplastic
Ectasia of the common carotid artery with stasis
Esophagus: dilatation, hiatal hernia
Pericardial effusion, cardiac insufficiency

Iodine 131 Total-Body Scan

The results of a ¹³¹I total-body scan depend on the ability of neoplastic thyroid tissue to take up ¹³¹I in the presence of high serum TSH concentrations, which are achieved by withdrawal of levothyroxine or intramuscular injections of rhTSH (0.9 mg for 2 consecutive days, with radioiodine administration on the day following the second injection).²⁰⁵

If ¹³¹I scanning is planned, patients should be instructed to avoid iodine-containing medications and iodine-rich foods, and urinary iodine should be measured in doubtful cases. Pregnancy must be excluded in women of child-bearing age. For routine diagnostic scans, 2 to 5 mCi (74 to 185 MBq) of ¹³¹I is given; higher activities may reduce the uptake of a subsequent therapeutic dose of ¹³¹I.^{208,209} The scan is done, and uptake, if any, is measured 48 to 72 hours after the administration of radioiodine, preferably with the use of a double-head gamma camera equipped with thick crystals and high-energy collimators. False-positive results are rare and usually are easily recognized (Table 14-8).

Total-Body Scans after Iodine 131 Therapy

Assuming equivalent fractional uptake after administration of either a diagnostic or a therapeutic dose of ¹³¹I, uptake that is too low to be detected with 2 to 5 mCi (74 to 185 MBq) may be detectable after administration of 100 mCi (3700 MBq). Therefore, a total-body scan should be routinely performed 3 to 7 days after a high-activity of radioiodine (Fig. 14-23). This is also the rationale for administering a large activity of ¹³¹I in patients with persistently elevated or increasing Tg levels (>10 ng/mL in the absence of levothyroxine treatment) even if the diagnostic scan is negative.²¹¹

Other Tests

Other tests should be performed only in selected cases and may include spiral CT or MRI of the neck and chest, bone scintigraphy, MRI of bones, and ¹⁸FDG-PET scanning. FDG-PET scanning is performed both for diagnosis of

remote neoplastic foci and for prognostic assessment. The sensitivity of FDG-PET may be improved by TSH stimulation, obtained after levothyroxine withdrawal or injections of rhTSH.²²⁻²³ The FDG-PET scan is particularly useful for discovery of mediastinal lymph nodes, and it complements neck ultrasonography for detection of posterior neck lymph node metastases (Fig. 14-24). A spiral CT scan is more sensitive for discovery of small lung metastases. FDG uptake in metastases as quantified by SUV is closely related to clinical prognostic parameters: responses to radioiodine treatment are observed in metastases with radioiodine uptake and with no FDG uptake. Metastases with high SUV values are likely to progress rapidly and will not respond to therapy with radioiodine even when radioiodine uptake is present.²⁴

Follow-Up Strategy

If the total-body scan performed after administration of ¹³¹I to destroy the thyroid remnants is informative (when uptake in normal thyroid remnants is low, <1%) and does not show any uptake outside the thyroid bed, physical examination is performed and serum TSH and Tg levels are measured during levothyroxine treatment 3 months later (Fig. 14-25). In most centers, a neck ultrasonographic examination is performed and the serum Tg level is measured after thyroid hormone withdrawal or rhTSH

Figure 14-23 Total-body scans in an asymptomatic, 34-year-old patient who underwent surgery for a papillary thyroid carcinoma. The results of chest radiography were normal. **A**, This total-body scan was performed 4 days after postoperative administration of 100 mCi (3700 MBq) of radioactive iodine (¹³¹I). Note the presence of diffuse uptake in the lungs and uptake in thyroid remnants and in the left supraclavicular lymph nodes. **B**, A total-body scan performed 6 months later, after the administration of a second treatment with 100 mCi of radioactive iodine, demonstrated the disappearance of all foci of uptake. The thyroglobulin level became undetectable during levothyroxine therapy, and 6 years later the patient is still considered to be in complete remission.

Figure 14-24 This patient was being monitored for a papillary thyroid carcinoma treated by total thyroidectomy and postoperative radioiodine. The serum thyroglobulin level was 45 ng/mL during levothyroxine suppressive treatment. **A**, A total-body scan was performed 3 days after administration of 100 mCi (3.7 GBq). There is no visible uptake in the neck and thorax. Notice the accumulation of radioiodine in the stomach, colon, and bladder. **B**, Positron emission tomography scan using [^{18}F]-fluorodeoxyglucose (^{18}FDG) with maximal intensity projection demonstrates significant uptake in the upper mediastinum. **C**, In fusion images of ^{18}FDG -PET and CT scans, axial and coronal slices localized the FDG uptake in the right paratracheal mediastinum, corresponding to a lymph node metastasis that was subsequently excised. Serum thyroglobulin became undetectable during thyroid hormone treatment.

stimulation 6 to 12 months later.^{1,2} A diagnostic ^{131}I total-body scan is no longer routinely performed in low-risk patients with undetectable serum Tg, because almost all patients with ^{131}I uptake in their metastases also have detectable serum Tg levels. Visible uptake in the thyroid bed that is too low to be quantified should not be considered evidence of disease in the absence of any other abnormality. Ablation is currently established by an undetectable serum Tg level after TSH stimulation. Neck ultrasonography can identify lymph node metastases that are too small to produce detectable serum Tg levels and may be not seen on ^{131}I total-body scans (Table 14-9).¹¹⁻¹³

Patients who have undetectable serum Tg after TSH stimulation and normal findings on neck ultrasonography are considered cured, the risk of long-term recurrence being less than 1%.^{212,213} The dose of levothyroxine is decreased to maintain a serum TSH concentration within the normal range of 0.5 to 2.5 mU/L. In high-risk patients, higher doses of levothyroxine are given, the goal being a serum TSH concentration between 0.1 and 0.5 mU/L.^{219,230} Clinical and biochemical evaluations with serum TSH and Tg determinations on levothyroxine treatment are performed annually; neck ultrasonography is performed in case of doubt and in high-risk patients, but any other testing is unnecessary as long as the patient's serum Tg concentration is undetectable and the patient does not produce an interfering anti-Tg autoantibody. There is no indication to obtain another rhTSH-stimulated Tg.²³¹ The use of sensitive assays for serum Tg determination should be permitted to avoid routine rhTSH stimulation in low-risk patients with undetectable serum Tg during levothyroxine treatment; rhTSH stimulation should still be performed in those low-risk patients with detectable serum Tg on levothyroxine treatment and in high-risk patients.²²⁸ Such assays permit early diagnosis of persistent or recurrent

disease and should be used in clinical practice during short- and long-term follow-up.²²⁷⁻²²⁹ Tests performed at 9 to 12 months after initial treatment permit a reassessment of the initial prognostication; patients with no abnormal findings are considered to be at low risk and should be reassured, whereas those with any abnormal finding should be followed up more extensively.

Suspicious abnormalities discovered at neck ultrasonography should be submitted to FNAB, even if the serum Tg level remains undetectable after TSH stimulation. Lymph

TABLE 14-9

Sensitivity (%) of Various Methods and Combinations of Methods for Detection of Lymph Node Metastases*

Method	STUDY (NI/TOTAL NO. OF PATIENTS)

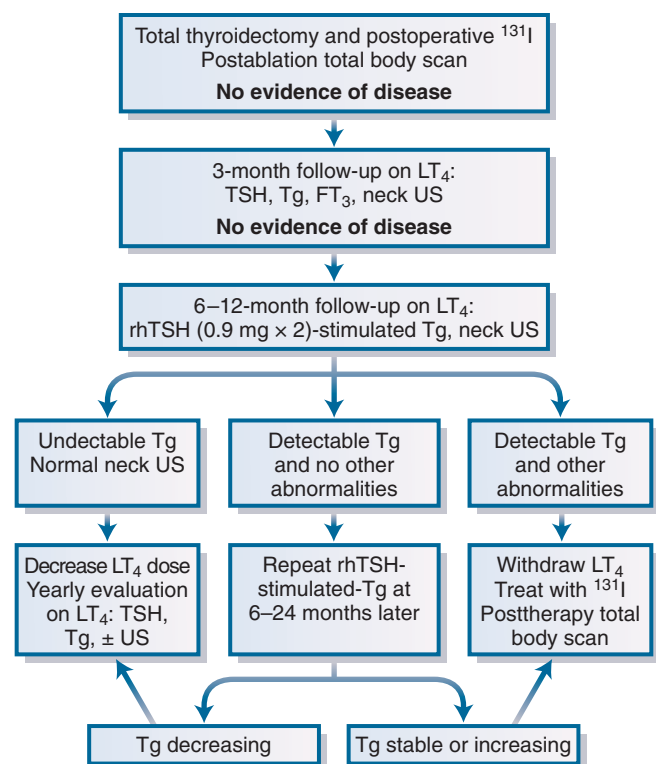

Figure 14-25 Follow-up of patients with papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC) after near-total thyroidectomy and ablation with iodine ^{131}I , based on serum thyroglobulin (Tg) measurements and neck ultrasonography (US). Tg levels are considered undetectable if they are below the detection limit of the assay; the institutional threshold should be determined by each institution for each assay used for serum Tg determination. LT₄, levothyroxine; rhTSH, recombinant human thyroid-stimulating hormone; TBS, total-body scan; TSH, thyrotropin (thyroid-stimulating hormone). (From Pacini F, Schlumberger M, Dralle H, et al. European consensus for the management of patients with differentiated thyroid cancer of the follicular epithelium. *Eur J Endocrinol*. 2006;154:787-803.)

node metastases are indeed treated, but currently there is no evidence that treatment at a very early stage (i.e., <5 mm in diameter) improves the outcome, compared with treatment at a stage when they measure 5 to 10 mm in diameter.

At 9 to 12 months after initial treatment, serum Tg becomes detectable after TSH stimulation in 14% to 20% of patients. The discovery of any other abnormality will dictate specific treatments. Otherwise, suppressive levothyroxine treatment is maintained and another rhTSH stimulation test is performed months or years later, depending on the serum Tg level and the clinical context. Serum Tg decreases or becomes undetectable in the absence of any further treatment in two thirds of patients, who then will be considered cured. Serum Tg increases in the remaining third of patients, who should then be submitted to an extensive workup, which may include ultrasound of the neck, spiral CT of the lungs, bone scintigraphy, FDG-PET/CT scanning, and administration of a large activity of ^{131}I with a total-body scan 3 to 5 days later. Clinical recurrence will likely be found in time in most of this third of patients treated for PTC or FTC.²²⁶

In very low-risk PTC patients who have had a near-total or total thyroidectomy but were not given ^{131}I postoperatively, the intensity of the follow-up strategy depends largely on the serum Tg level and on the results of neck

ultrasonography. If the Tg level is not detectable during levothyroxine treatment and a neck ultrasound study is negative, ^{131}I total-body scanning may be avoided. However, if the Tg is readily detectable despite adequate TSH suppression and increases with time, an ablative ^{131}I treatment may be necessary, with a post-treatment scan some days later.²¹¹ The follow-up protocol previously described is then applied on the basis of serum Tg determinations.

In very low-risk PTC patients who have initially undergone only a unilateral lobectomy for PTM, yearly follow-up should consist of a careful neck examination and serum Tg determination during levothyroxine treatment. With time, ultrasonography is likely to show focal nodular abnormalities in the remaining lobe in most patients with detectable Tg concentrations. Usually, biopsies of these lesions can be performed under sonographic guidance, and most prove to be cytologically benign. However, if recurrent PTC is found on biopsy, a completion thyroidectomy should be performed.

In MTC patients, the tumor marker for follow-up is the plasma calcitonin level. In about 90% of young patients whose disease was treated at a preclinical stage on the basis of a *RET* oncogene mutation, the postoperative basal calcitonin level returns to normal and peak calcitonin levels, if measured after stimulation with pentagastrin or calcium, are absent.^{179,180} About 5% of these patients have subsequent biologic recurrence of the disease.¹⁰⁶

In adults with sporadic MTC, who most often present with TNM stage III (node-positive) disease, postoperative basal calcitonin levels are rarely normal.²³²⁻²³⁴ In general, basal calcitonin levels correlate with MTC tumor mass, but many MTC patients who have undergone surgery with a curative intent still have postoperative elevations in calcitonin levels without clinical or imaging evidence of persistent disease. In these patients, the disease may be located in the neck if the basal calcitonin level is lower than 150 pg/mL; the risk of distant spread increases with higher calcitonin levels. The localization of neoplastic foci can be difficult and may require morphologic examinations, including neck and liver ultrasonography, CT scans of the neck and chest, or MRI of bones and liver^{20,21}; if the results are negative, a venous sampling catheterization with calcitonin measurements may be indicated.^{233,234} PET scanning with FDG is poorly sensitive,^{21,30} and ^{18}F -DOPA PET seems more promising for localizing neoplastic MTC foci.^{28,29} Reinterventions based on the results of selective venous sampling catheterization allow the removal of neoplastic foci in most patients but are not likely to improve the cure rate by more than 5% to 30%.²³³⁻²³⁵ Such a situation may exist for several postoperative years, and slowly rising calcitonin levels may not necessarily imply a prognosis worse than that indicated by the presenting stage of disease.²³²

A second major tumor marker for MTC is CEA. In general, serum CEA levels are higher in patients with more malignant MTC, whereas the plasma calcitonin levels are higher in those with better differentiated tumors. The doubling times of calcitonin and CEA levels appear to be highly significant prognostic indicators for survival.^{236,237}

Papillary and Follicular Thyroid Carcinoma

Locoregional Recurrences

Locoregional recurrences occur in 5% to 20% of patients with PTC or FTC. More than one third of reoperations for persistent or recurrent disease are related to inadequate initial thyroid surgery.²³⁸ Small metastases may be treated with radioiodine, but their persistence after two or three

treatments should lead to surgery.²³⁹ A recurrence that is palpable or easily visualized with ultrasonography or CT scanning should be excised.^{239,240} Compartmental dissection of previously unexplored compartments with clinically significant persistent or recurrent disease while sparing vital structures is performed, because microscopic lymph node metastases are commonly more extensive than would appear from imaging studies alone. Conversely, compartmental surgical dissections may not be feasible in compartments that have been previously explored due to extensive scarring, and only a more limited or targeted lymph node resection may be possible.

Total excision may be facilitated by total-body scanning 3 to 5 days after administration of 100 mCi (3700 MBq) of ¹³¹I because it may identify additional tissue that should be excised. In some centers, surgery is performed 1 day later, typically with the use of an intraoperative probe. The completeness of resection is verified 1 to 2 days after surgery by another total-body scan, and in one series complete resection was achieved in 92% of cases.²⁴⁰ In the absence of detectable uptake, other methods may be used to facilitate the excision of small neoplastic foci located in scar tissue or in sites that are difficult to redissect, such as intraoperative ultrasonography or preoperative ultrasound-guided charcoal tattooing.¹⁷ External radiotherapy is indicated in FCTC patients with soft tissue recurrences that cannot be completely excised and do not take up ¹³¹I.

Some patients with PTC who were not eligible for further surgery or ¹³¹I therapy have been treated for regional nodal recurrence with ultrasound-guided radiofrequency ablation or percutaneous ethanol injections.²⁴¹⁻²⁴³ For tumors that invade the upper aerodigestive tract, patient outcome is related to complete resection of all gross disease, with techniques ranging from shaving tumor off the trachea or esophagus for superficial invasion, with preservation of function, to more aggressive techniques for direct intraluminal invasion, including tracheal resection and anastomosis or laryngopharyngoesophagectomy.²⁴⁴ Surgery is usually combined with ¹³¹I or external-beam irradiation, or both.

Distant Metastases

In a large group of patients with differentiated carcinoma (PTC, FTC, or HCC), only 9% developed distant metastases.²⁴⁵ Mortality rates at 5 and 10 years after the diagnosis of metastasis were 65% and 75% for all patients with distant metastases, and almost 80% of the deaths were due to thyroid cancer.²⁴⁵⁻²⁴⁷ Therefore, the development of distant metastases in FCTC portends an ominous prognosis. Lung metastases are more frequent in young patients with PTC, and the lung is almost the only site of distant spread in children. Bone metastases are more common in older patients and in those with FTC. Other less common sites are the brain, liver, and skin.²⁴⁵⁻²⁴⁷

Clinical symptoms of lung involvement are uncommon; in contrast, pain, swelling, or fracture occurs in more than 80% of patients with bone metastases. The pattern of lung involvement may vary and ranges from macronodular to diffuse infiltrates. The latter, when not detected by chest radiography, are usually diagnosed by ¹³¹I total-body scanning and may be confirmed by spiral CT; enlarged mediastinal lymph nodes are often present in patients with PTC, especially children. Bone metastases are osteolytic and are often difficult to visualize on radiography or bone scintigraphy; bone involvement is better visualized by MRI. FDG-PET scanning is useful in these patients for determining the extent of disease and for prognostic assessment.^{2,22} Almost all patients with distant metastases have high

serum Tg concentrations unless the lung metastases are not visible on radiographs, and two thirds of such patients have ¹³¹I uptake in their sites of metastasis.²⁴⁶

Palliative surgery is required for bone metastases if there are neurologic or orthopedic complications or a high risk of such complications. Radiofrequency ablation and cement injection may be effective alternatives. Surgery may also be performed with a curative intent in patients who have only one or a few bone metastases.²⁴⁸

Patients with distant metastases that take up ¹³¹I are treated with 100 to 200 mCi (3700 to 7400 MBq) every 4 to 6 months during the first 2 years and then at longer intervals. Between ¹³¹I treatments, suppressive doses of levothyroxine are given. In one study, the radiation dose to the tumor tissue and the outcome of ¹³¹I therapy were correlated.¹⁹⁷ A radiation dose higher than 80 Gy (8000 rads) should be delivered to obtain cure; with radiation doses lower than 35 Gy (3500 rads), there is little chance for success. This is the rationale for using higher activities of radioiodine, either as a standard approach or based on individual dosimetry, and for using lithium salts in these patients, because their use may increase ¹³¹I retention in tumor foci; however, there are no demonstrated benefits for any of these techniques.²⁴⁹

In patients with functioning metastases, PET scanning with ¹²⁴I showed that uptake in a given patient can vary among the metastases and also within a given metastasis.²⁷ Uptake may also be heterogeneous at the cellular level.^{27,62} This heterogeneity in the dose distribution in neoplastic foci may explain the ineffectiveness of ¹³¹I treatment despite significant uptake on total-body scanning. For treatment to be effective in this clinical setting, appropriate levels of TSH stimulation and absence of iodine contamination are essential. Prolonged withdrawal usually induces higher uptake in neoplastic foci than rhTSH does, and withdrawal should be the preferred method of TSH stimulation before radioiodine treatment in patients with metastatic disease.²⁵⁰ Therapy mediated by rhTSH may be indicated in selected patients with underlying comorbidities that make iatrogenic hypothyroidism a potential risk, in patients with pituitary disease who are unable to raise their serum TSH, and in patients for whom a delay in therapy might be deleterious.²⁰⁵ Such patients should be given the same or higher activity than would have been given had they been prepared with hypothyroidism or a dosimetrically determined activity. Lower doses, such as 1 mCi (37 MBq) per kilogram of body weight, are given to children. There is no limit to the cumulative activity of ¹³¹I that can be given to patients with distant metastases, although the risk of leukemia and of solid cancers rises significantly with a cumulative activity greater than 500 mCi (18,500 MBq); moreover, further ¹³¹I therapy may rarely provide significant benefit above this activity level.²⁴⁶

External radiotherapy is given to bone metastases visible on radiographs, even in the presence of iodine uptake.²⁴⁶ Alternatively, embolization, radiofrequency ablation, or cement injection may be considered. Chemotherapy is poorly effective and should be given only to patients with radioresistant and progressing metastases.²⁵¹ Retinoic acid analogues that increased iodine uptake and decreased the growth rate of neoplastic tissue in several *in vitro* models were found to be poorly effective in clinical settings.^{252,253} Kinase inhibitors that target tumor cells (MAP kinase pathway and eventually other targets) and endothelial cells (VEGFRs) and are anti-angiogenic are significantly more effective than cytotoxic chemotherapy agents and should be used as first-line treatment, preferably in the frame of a controlled trial.²⁵⁴⁻²⁵⁹

Disappearance of imaging abnormalities has been obtained overall in about 45% of patients with distant metastases showing avidity for ^{131}I , and responses are even more frequent in patients with radiosensitive disease, younger patients, those with small pulmonary metastases, and those who had a well-differentiated cancer and who have no FDG uptake on PET scanning; complete responses may be obtained several years after initiation of therapy.²⁴⁵⁻²⁴⁷ When response was judged to have been complete after ^{131}I therapy, subsequent relapse rarely occurred even though serum Tg levels were persistently detectable in some patients.²⁴⁶

Overall survival after the discovery of distant metastasis is more favorable in young patients who have well-differentiated tumors that take up ^{131}I and whose metastases are small when discovered. When the tumor mass is considered, the location of the distant metastasis (lungs or bone) has no independent prognostic influence.²⁴⁶ The poor prognosis of patients with bone metastases is linked to the large size of their lesions.²⁴⁶⁻²⁴⁸ Large distant metastases with high FDG uptake on PET scanning almost never respond to ^{131}I therapy, confirming the clinical prognostic classification.^{22,24} The prognostic importance of the small size of the metastases at their discovery has led to the administration of 100 mCi (3700 MBq) of ^{131}I activity to patients who have elevated serum Tg concentrations that increase with time in the absence of obvious disease.²¹¹ Some believe that there is no conclusive evidence that ^{131}I treatment of these asymptomatic patients meaningfully prolongs life. Others have reported a 33% complete remission rate in treated patients who had a positive total-body scan after ^{131}I therapy.

Complications of Treatment with Iodine 131

Acute side effects (nausea, sialadenitis, loss of taste) after treatment with ^{131}I are common but are typically mild and resolve rapidly. Radiation thyroiditis is usually trivial, but if the thyroid remnant is large, the patient may have enough pain to warrant corticosteroid therapy for a few days. Tumors in certain locations, such as the brain, spinal cord, and paratracheal region, may swell in response to TSH stimulation or after ^{131}I therapy, causing compressive symptoms. Xerostomia and obstruction of lacrimal ducts occurs in 5% to 10% of patients treated with ^{131}I .^{260,261} Radiation fibrosis may develop in patients with diffuse lung metastases and can eventually prove fatal if high activities (>150 mCi [5550 MBq]) are administered at short intervals (<3 months).²⁴⁵⁻²⁴⁷

Particular attention must be paid to avoiding administration of ^{131}I to pregnant women. After ^{131}I treatment, spermatogenesis may be transiently depressed,²⁶² and women may have transient ovarian failure. Genetic damage induced by exposure to ^{131}I before conception has been a major subject of concern, but no anomalies have been reported to date. Therefore, it is recommended that conception be postponed for 6 months after treatment with ^{131}I .²⁶³ There is no evidence that pregnancy affects tumor growth in women receiving adequate levothyroxine therapy. In case of pregnancy in a patient treated with replacement levothyroxine, the dose of levothyroxine is increased by 30% as soon as the pregnancy is confirmed, and the serum TSH level is measured every month during the first half of pregnancy.²⁶⁴ In a patient treated with a suppressive dose of levothyroxine, the serum TSH level is measured every month, and the daily dose of levothyroxine is increased when serum TSH is found increased.

Mild pancytopenia may occur after repeated ^{131}I therapy, especially in patients who have bone metastases also being

treated with external radiotherapy. The overall relative risk of leukemia and of solid tumors was found to be increased in patients treated with a high cumulative dose of ^{131}I (>500 mCi [18,500 MBq]) and in association with external radiotherapy.²⁶⁵

Medullary Thyroid Carcinoma

For patients with locoregional recurrence of MTC, a complete diagnostic workup should be obtained, principally to exclude distant metastases. Surgery is performed, if feasible, and is typically followed by external radiotherapy.^{2,178}

Distant metastases are usually multifocal in each involved organ and frequently involve multiple organs, including liver, lungs, and bones. They may progress slowly and may be compatible with decades of survival. Systemic chemotherapy is poorly efficient and may be indicated only in cases of rapid tumor progression.²⁶⁶ Symptomatic treatments are given, in particular against diarrhea. Chemembolization of liver metastases with adriamycin was reported to provide a high response rate for both symptoms and tumor mass.²⁶⁷ Kinase inhibitors directed against tumor cells (RET and other kinases) and endothelial cells (VEGFRs) provide a significantly higher response rate than cytotoxic chemotherapy and should be proposed to MTC patients who have progressive disease as first-line treatment.^{268,269}

The Adrenal Cortex

PAUL M. STEWART • NILS P. KRONE

THE ADRENAL CORTEX—HISTORICAL MILESTONES

The anatomy of the adrenal glands was described almost 450 years ago by Bartholomeo Eustacius,¹ and the zonation of the gland and its distinction from the medulla was elucidated shortly thereafter. However, a functional role for the adrenal glands was not accurately defined until the pioneering work of Thomas Addison, who described the clinical and autopsy findings in 11 cases of “Addison’s disease” in his classic monograph in 1855.² Just a year later, Brown-Séquard demonstrated that the adrenal glands were “organs essential for life” by performing adrenalectomies in dogs, cats, and guinea pigs.³ In 1896, William Osler first administered adrenal extract to a patient with Addison’s disease, a feat that was repeated by others in animal and human studies over the next 40 years. Between 1937 and 1955, the adrenocorticosteroid hormones were isolated, and their structures were defined and synthesized.⁴ Notable breakthroughs included the discovery of cortisone and clinical evaluation of its anti-inflammatory effect in patients with rheumatoid arthritis⁵ and the isolation of aldosterone.⁶

The control of adrenocortical function by a pituitary factor was demonstrated in the 1920s, and this led to the isolation of sheep adrenocorticotrophic hormone (ACTH) by

Li, Evans, and Simpson in 1943.⁷ Such a concept was supported through clinical studies, notably by Harvey Cushing in 1932, who associated his original clinical observations of 1912 (a “polyglandular syndrome” caused by pituitary basophilism) with adrenal hyperactivity.⁸ The neural control of pituitary ACTH secretion by corticotropin-releasing factor (later renamed corticotropin-releasing hormone, or CRH) was defined by Harris and other workers in the 1940s, but CRH was not characterized and synthesized until 1981 in the laboratory of Wylie Vale.⁹ Jerome Conn described primary aldosteronism in 1955,¹⁰ and the control of adrenal aldosterone secretion by angiotensin II was confirmed shortly afterward. Advances in radioimmunoassay, and particularly molecular biology, have facilitated an exponential increase in the understanding of adrenal physiology and pathophysiology (Table 15-1).

ANATOMY AND DEVELOPMENT

The cells forming the adrenal cortex originate from the intermediate mesoderm. These cells derive from the urogenital ridge and have a common embryologic origin with the gonad and the kidney. Early differentiation of the adrenogonadal primordium from the urogenital ridge requires signaling cascades and transcription factors GLI3, SALL1, FOXD2, WT1, PBX1, WNT4, and the regulator of

TABLE 15-1
History of the Adrenal Cortex: Important Milestones

Year	Event
1563	Eustachius describes the adrenals (published by Lancisi in 1714).
1849	Thomas Addison, while searching for the cause of pernicious anemia, “stumbles” on a bronzed appearance associated with the adrenal glands—“melasma suprarenale.”
1855	Thomas Addison describes the clinical features and autopsy findings in 11 cases of diseases of the suprarenal capsules, at least 6 of which were tuberculous in origin.
1856	In adrenalectomy experiments, Brown-Séquard demonstrates that the adrenal glands are essential for life.
1896	William Osler gives an oral glycerin extract derived from pig adrenals and demonstrates clinical benefit in patients with Addison’s disease.
1905	Bulloch and Sequeria describe patients with congenital adrenal hyperplasia.
1929	Liquid extracts of cortical tissue are used to keep adrenalectomized cats alive indefinitely (Swingle and Pfiffner); subsequently, this extract was used successfully to treat a patient with Addison’s disease (Rowntree and Greene).
1932	Harvey Cushing associates the “polyglandular syndrome” of pituitary basophilism, which he first described in 1912, with hyperactivity of the pituitary-adrenal glands.
1936	The concept of stress and its effect on pituitary-adrenal function are described by Seyle.
1937-1952	Isolation and structural characterization of adrenocortical hormones are reported by Kendall and Reichstein.
1943	Li and colleagues isolate pure adrenocorticotrophic hormone from sheep pituitary.
1950	Hench, Kendall, and Reichstein share Nobel Prize in Medicine for describing the anti-inflammatory effects of cortisone in patients with rheumatoid arthritis.
1953	Isolation and analysis of the structure of aldosterone are reported by Simpson and Tait.
1956	Conn describes primary aldosteronism.
1981	Characterization and synthesis of corticotropin-releasing hormone are reported by Vale.
1980-present	The “molecular era”: cloning and functional characterization of steroid receptors, steroidogenic enzymes, and adrenal transcription factors are reported, and the molecular basis for human adrenal diseases is defined.

telomerase activity, ACD (Fig. 15-1). The adrenogonadal primordium can be seen as the medial part of the urogenital ridge at 4 weeks. Separation of the adrenogonadal primordium and formation of the adrenal primordium seem to depend on the actions of transcription factors SF1, DAX1, WNT4, and CITED2. The adrenocortical primordium develops at approximately 8 weeks of gestation and can be differentiated into two distinct layers, the inner fetal zone (FZ) and the outer definitive zone (DZ). At approximately 9 weeks, the adrenal blastema encapsulates and the adrenal medulla develops when neural crest cells migrate into the adrenal gland.¹¹ During the second trimester, the FZ enlarges, becomes larger than the fetal kidney, and secretes abundant amounts of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS). Concentrations of these hormones abruptly decline postnatally, in parallel with the postnatal involution of the FZ. The neocortex develops over the subsequent years into the adult adrenal gland.

In fetal life and up to 12 months of age, two distinct zones are evident, an inner, prominent FZ and an outer DZ that differentiates into the adult adrenal gland. After birth, the FZ regresses and the DZ, which contains an inner zona fasciculata (ZF) and an outer zona glomerulosa (ZG), proliferates.^{12,13} The innermost zone, the zona reticularis (ZR), is evident after 2 years of life. The differentiation of the adrenal cortex into distinct zones has important functional consequences and is thought to depend on the temporal expression of transcription factors including Pref-1/ZOG, inner zone antigen, and steroidogenic factor 1 (SF1).^{14,15} In preadrenachal children focal reticular zone islets can be found, but the ZG and ZF are clearly differentiated.¹⁶ The occurrence of these ZR islets is consistent with the observation that DHEA and DHEAS concentrations gradually begin to rise from about 3 years of age.¹⁷ At adrenache, the inner zone (ZR) thickens, corresponding with increased production of DHEA and DHEAS. Concurrently, changes in zone-specific enzyme expression patterns, such as decreased

Figure 15-1 Schematic diagram of the development of the human adrenal cortex during prenatal and postnatal life. Transcription factors that are active at each stage (see text for details). DZ, definitive zone; FZ, fetal zone; POMC, pro-opiomelanocortin; SPARC, secreted protein, acidic, cysteine-rich (osteonectin); ZG, zona glomerulosa; ZF, zona fasciculata; ZR, zona reticularis.

Figure 15-2 Schematic diagram of the structure of the human adrenal cortex, depicting the outer zona glomerulosa and inner zona fasciculata and zona reticularis.

3 β -hydroxysteroid dehydrogenase type 2 (HSD3B2) and increased cytochrome *b₅* and sulfotransferase (SULT2A1) in the ZR, lead to increased flux toward DHEA. Clinically, adrenarche becomes apparent at 6 to 8 years of age. Adrenal androgen production peaks in the third decade and then declines at a variable rate. Mineralocorticoids and glucocorticoids show a less age-specific variation.

The adult gland is a pyramidal structure, approximately 4 g in weight, 2 cm wide, 5 cm long, and 1 cm thick, that lies immediately above the kidney on its posteromedial surface. Beneath the capsule, the ZG comprises approximately 15% of the cortex (depending on sodium intake) (Fig. 15-2). Cells are clustered in spherical nests and are small, with smaller nuclei in comparison with cells in other zones. The ZF comprises 75% of the cortex; cells are large and lipid-laden and form radial cords within the fibrovascular radial network. The innermost ZR is sharply demarcated from both the ZF and the adrenal medulla. Cells there are irregular with little lipid content. The maintenance of normal adrenal size appears to involve a progenitor cell

population lying between the ZG and ZF; cell migration and differentiation occur within the fasciculata and senescence occurs within the ZR, but the factors regulating this important aspect of adrenal regeneration are unknown. ACTH administration results in glomerulosa cells' adopting a fasciculata phenotype, and, in turn, the innermost fasciculata cells adopt a reticularis phenotype that is reversible on withdrawal of ACTH.

The vasculature of the adrenal cortex is complex. Arterial supply is conveyed by up to 12 small arteries from the aorta and the inferior phrenic, renal, and intercostal arteries. These branch to form a subcapsular arteriolar plexus from which radial capillaries penetrate deeper into the cortex. In the ZR, a dense sinusoidal plexus is created, which empties into a central vein. The right adrenal vein is short, draining directly into the inferior vena cava, whereas the longer left adrenal vein usually drains into the left renal vein.

ADRENAL STEROIDS AND STEROIDOGENESIS

Three main types of hormone are produced by the adrenal cortex—glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone), and sex steroids (mainly androgens). All steroid hormones are derived from the cyclopentanoperhydrophenanthrene structure, that is, three cyclohexane rings and a single cyclopentane ring (Fig. 15-3). Steroid nomenclature is defined in two ways: by trivial names (e.g., cortisol, aldosterone) or by the chemical structure as defined by the International Union of Pure and Applied Chemistry (IUPAC).¹⁸ The IUPAC classification is inappropriate for clinical use but does provide an invaluable insight into steroid structure. The basic structure, trivial name, and IUPAC name of some common steroids are given in Figure 15-3 and Table 15-2. Estrogens have 18 carbon atoms (C18

TABLE 15-2

IUPAC and Trivial Names of Natural and Synthetic Steroids

Trivial Name	IUPAC Name
Aldosterone	4-Pregnen-11 β ,21-diol-3,18,20-trione
Androstenedione	4-Androsten-3,17-dione
Cortisol	4-Pregnen-11 β ,17 α ,21-triol-3,20-dione
Cortisone	4-Pregnen-17 α ,21-diol-3,11,20-trione
Dehydroepiandrosterone	5-Androsten-3 β -ol-17-one
Deoxycorticosterone	4-Pregnen-21-ol-3,20-dione
Dexamethasone	1,4-Pregnadien-9 α -fluoro-16 α -methyl-11 β ,17 α ,21-triol-3,20-dione
Dihydrotestosterone	5 α -Androstan-17 β -ol-3-one
Estradiol	1,3,5(10)-Estratrien-3,17 β -diol
Fludrocortisone	4-Pregnen-9 α -fluoro-11 β ,17 α ,21-triol-3,20-dione
17-Hydroxyprogesterone	4-Pregnen-17 α -ol-3,20-dione
Methylprednisolone	1,4-Pregnadien-6 α -methyl-11 β ,17 α ,21-triol-3,20-dione
Prednisolone	1,4-Pregnadien-11 β ,17 α ,21-triol-3,20-dione
Prednisone	1,4-Pregnadien-17 α ,21-diol-3,11,20-trione
Pregnenolone	5-Pregnen-3 β -ol-20-one
Progesterone	4-Pregnen-3,20-dione
Testosterone	4-Androsten-17 β -ol-3-one
Triamcinolone	1,4-Pregnadien-9 α -fluoro-11 β ,16 α ,17 α ,21-tetrol-3,20-dione

IUPAC, International Union of Pure and Applied Chemistry.

Figure 15-3 The cyclopentanoperhydrophenanthrene structure of corticosteroid hormones, highlighting the structure of some endogenous steroid hormones together with their nomenclature.

steroids) and androgens have 19 carbon atoms (C19), whereas glucocorticoids and progestogens are C21-steroid derivatives.

Cholesterol is the precursor for adrenal steroidogenesis. It is provided principally from the circulation, in the form of low-density lipoprotein (LDL) cholesterol.¹⁹ Uptake is by specific cell-surface LDL receptors present on adrenal tissue²⁰; LDL is then internalized via receptor-mediated endocytosis,²¹ the resulting vesicles fuse with lysosomes, and free cholesterol is produced after hydrolysis. However, it is clear that this cannot be the sole source of adrenal cholesterol, because patients with abetalipoproteinemia who have undetectable circulating LDL and patients with defective LDL receptors in the setting of familial hypercholesterolemia still have normal basal adrenal steroidogenesis. Cholesterol can be generated *de novo* within the adrenal cortex from acetyl coenzyme A (CoA). In addition, there is evidence that the adrenal can utilize high-density lipoprotein (HDL) cholesterol after uptake through the putative HDL receptor, SR-B1.²²

The biochemical pathways involved in adrenal steroidogenesis are shown in Figure 15-4. The initial hormone-dependent, rate-limiting step is the transport of intracellular cholesterol from the outer to inner mitochondrial membrane for conversion to pregnenolone by

cytochrome P450 side-chain cleavage enzyme (P450_{scc}). Naturally occurring human mutations have confirmed the importance of a 30-kd protein, steroidogenic acute regulatory protein (StAR), in mediating this effect. StAR is induced by an increase in intracellular cyclic adenosine monophosphate (cAMP) after binding of ACTH to its cognate receptor, providing the first important rate-limiting step in adrenal steroidogenesis.²³ Other transporters, including the peripheral benzodiazepine-like receptor, may be involved.²⁴

Steroidogenesis involves the concerted action of several enzymes, including a series of cytochrome P450 enzymes, all of which have been cloned and characterized (Table 15-3). Cytochrome P450 enzymes are classified into two types according to their subcellular localization and their specific electron shuttle system. Mitochondrial (type I) cytochrome P450 enzymes such as CYP11A1 (P450_{scc}), 11 β -hydroxylase (CYP11B1, or P450_{c11b1}), and aldosterone synthase (CYP11B2, or P450_{aldo}) rely on electron-transfer facilitated by adrenodoxin and adrenodoxin reductase.^{25,26} Microsomal (type II) cytochrome P450 enzymes localized to the endoplasmic reticulum include the steroidogenic enzymes 17 α -hydroxylase (CYP17A1, or P450_{c17}), 21-hydroxylase (CYP21A2, or P450_{c21}), and P450 aromatase (CYP19A1, or P450_{aro}). The functions of

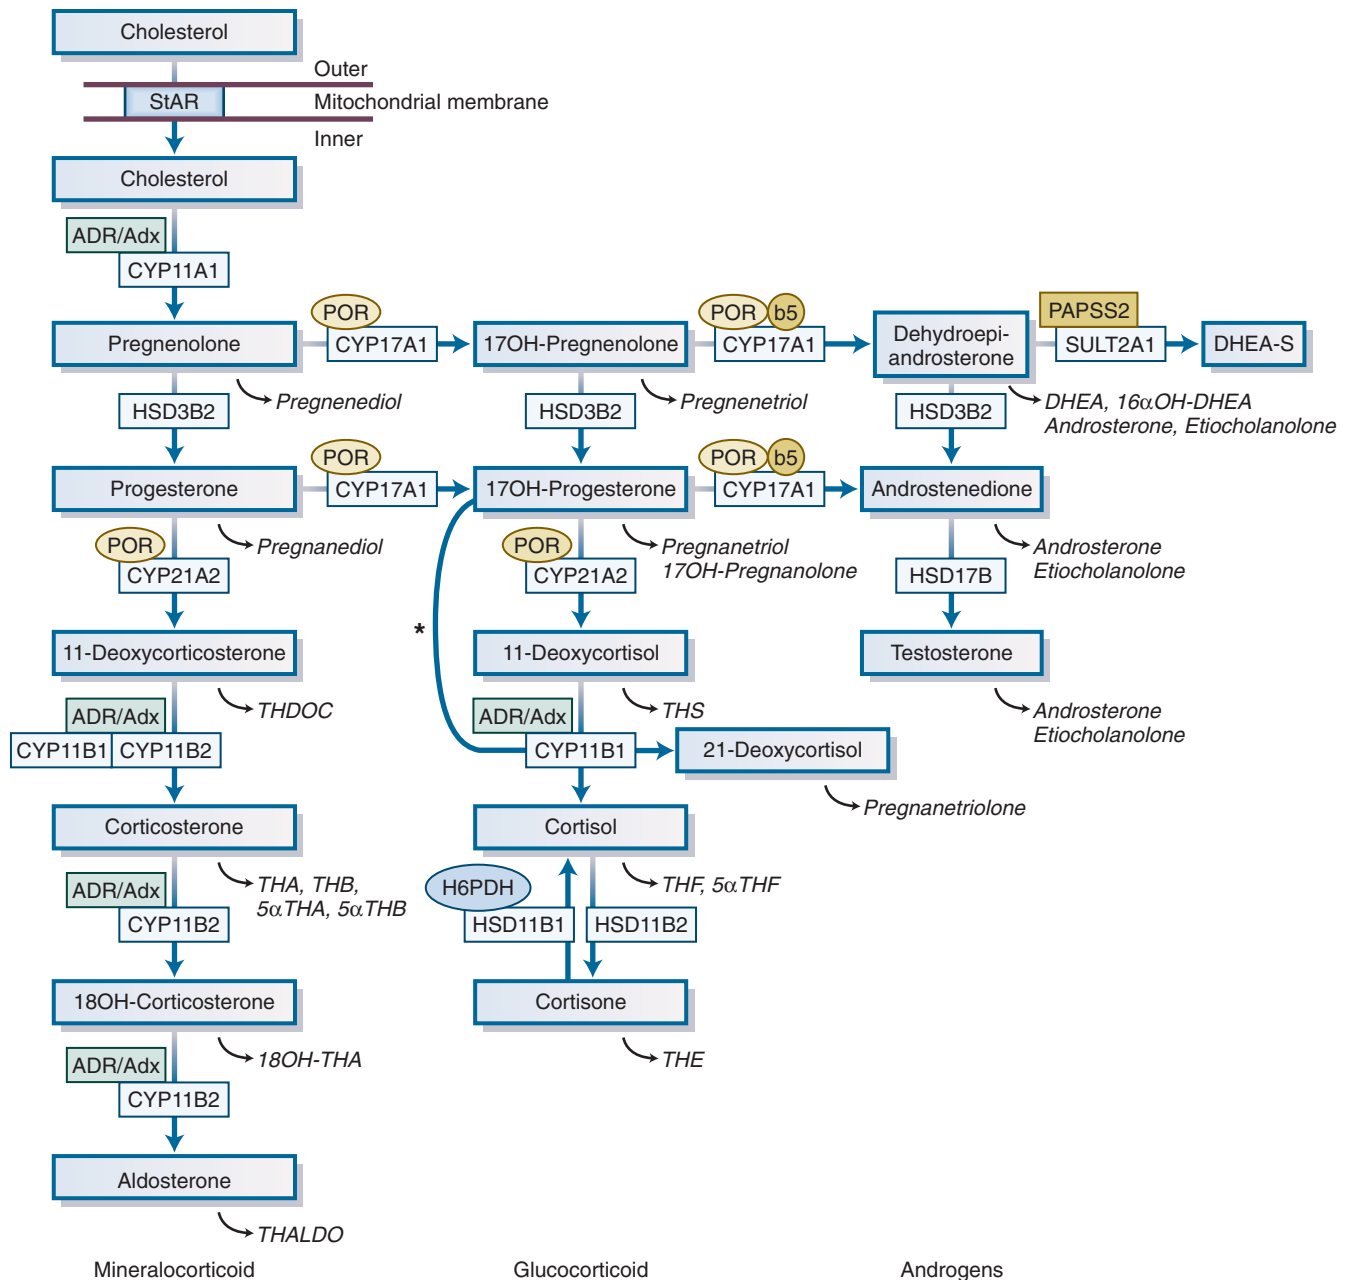

Figure 15-4 Adrenal steroidogenesis. After the steroidogenic acute regulatory (StAR) protein-mediated uptake of cholesterol into mitochondria within adrenocortical cells, aldosterone, cortisol, and adrenal androgens are synthesized through the coordinated action of a series of steroidogenic enzymes in a zone-specific fashion. The mitochondrial cytochrome P450 (CYP) type I enzymes (CYP11A1, CYP11B1, CYP11B2) requiring electron transfer via adrenodoxin reductase (ADR) and adrenodoxin (Adx) are marked with a box labeled ADR/Adx. The microsomal CYP type II enzymes (CYP17A1, CYP21A2) receive electrons from P450 oxidoreductase (circle labeled POR). The 17,20-lyase reaction catalyzed by CYP17A1 requires, in addition to POR, cytochrome b_5 , indicated by a circle labeled b_5 . Urinary steroid hormone metabolites are given in italics below the plasma hormones. The asterisk (*) indicates 11-hydroxylation of 17OH-progesterone to 21-deoxycortisol in cases of 21-hydroxylase deficiency. The adrenal conversion of androstenedione to testosterone is catalyzed by the aldo-keto reductase AKR1C3 (HSD17B5). CYP11A1, P450 side-chain cleavage enzyme; CYP11B1, 11 β -hydroxylase; CYP11B2, aldosterone synthase; CYP17A1, 17 α -hydroxylase; CYP21A2, 21-hydroxylase; DHEA, dehydroepiandrosterone; DHEA-S, dehydroepiandrosterone sulphate; H6PDH, hexose-6-phosphate dehydrogenase; HSD11B1, 11 β -hydroxysteroid dehydrogenase 1; HSD11B2, 11 β -hydroxysteroid dehydrogenase 2; HSD17B, 17 β -hydroxysteroid dehydrogenase; HSD3B2, 3 β -hydroxysteroid dehydrogenase type 2; 17OH-progesterone, 17 α -hydroxyprogesterone; PAPSS2, 3'-phosphoadenosine 5'-phosphosulfate synthase 2; SULT2A1, sulfotransferase 2A1; THA, tetrahydro-11-dehydrocorticosterone; THB, tetrahydro-corticosterone; THALDO, tetrahydro-aldosterone; THDOC, tetrahydro-11-deoxycorticosterone; THF, tetrahydro-cortisol; THS, tetrahydro-11-deoxycortisol.

cytochrome P450 type II enzymes crucially depend on P450 oxidoreductase (POR), which provides electrons required for monooxygenase reaction catalyzed by the P450 enzyme.^{26,27} This category also includes hepatic P450 enzymes involved in drug metabolism and enzymes involved in sterol and bile acid synthesis.^{26,27} In addition,

the 17,20-lyase activity of P450 CYP17A1 is dependent on a flavoprotein cytochrome b_5 , which functions as an allosteric facilitator of CYP17A1, and POR interaction (Fig. 15-5; see Fig. 15-4).²⁸

Mutations in the genes encoding these enzymes result in human disease, so some understanding of the underlying

TABLE 15-3

Nomenclature for Adrenal Steroidogenic Enzymes and Their Genes

Enzyme Name	Enzyme Family	Gene	Chromosome
P450 Cholesterol side-chain cleavage (SCC) (desmolase)	Cytochrome P450 type I	<i>CYP11A1</i>	15q23-q24
3 β -Hydroxysteroid dehydrogenase (3 β -HSD) (type II isozyme)	Short-chain alcohol dehydrogenase reductase superfamily	<i>HSD3B2</i>	1p13.1
17 α -Hydroxylase/17,20 lyase	Cytochrome P450 type II	<i>CYP17A1</i>	10q24.3
21-Hydroxylase	Cytochrome P450 type II	<i>CYP21A2</i>	6p21.3
11 β -Hydroxylase	Cytochrome P450 type I	<i>CYP11B1</i>	8q24.3
Aldosterone synthase	Cytochrome P450 type I	<i>CYP11B2</i>	8q24.3

pathways and steroid precursors is required.²⁹ After uptake of cholesterol to the mitochondrion, cholesterol is cleaved by the P450_{SCC} enzyme to form pregnenolone.³⁰ In the cytoplasm, pregnenolone is converted to progesterone by the type II isozyme 3 β -HSD through a reaction involving dehydrogenation of the 3-hydroxyl group and isomerization of the double bond at C5.³¹ Progesterone is hydroxylated to 17-hydroxyprogesterone (17-OHP) through the 17 α -hydroxylase activity of CYP17A1. 17 α -Hydroxylation is an essential prerequisite for glucocorticoid synthesis, and the ZG does not express 17 α -hydroxylase. CYP17A1 also possesses 17,20-lyase activity, which results in production of the C19 adrenal androgens, dehydroepiandrosterone and androstenedione.³² In humans, however, 17-OHP is not an efficient substrate for CYP17A1, and there is negligible conversion of 17-OHP to androstenedione. Adrenal androstenedione secretion is dependent on the conversion of dehydroepiandrosterone to androstenedione by 3 β -HSD. This enzyme also converts 17-hydroxypregnenolone to

17-OHP, but the preferred substrate is pregnenolone. The human adrenal gland is capable of synthesis of small but significant amounts of testosterone, which increases in clinical conditions associated with androgen excess. This conversion is facilitated by the enzyme 17 β -HSD type 5 (HSD17B5), also called aldoketoreductase 1C3 (AKR1C3).³³ 21-Hydroxylation of either progesterone (in the ZG) or 17-OHP (in the ZF) is carried out by the product of the *CYP21A2* gene, 21-hydroxylase, to yield deoxycorticosterone (DOC) or 11-deoxycortisol, respectively.³⁴ The final step in cortisol biosynthesis takes place in the mitochondria and involves the conversion of 11-deoxycortisol to cortisol by the enzyme CYP11B1 (11 β -hydroxylase).³⁵ In the ZG, 11 β -hydroxylase may also convert DOC to corticosterone. The enzyme CYP11B2 (aldosterone synthase) may also carry out this reaction, and in addition, it is required for conversion of corticosterone to aldosterone via the intermediate 18-OH corticosterone; CYP11B1 lacks these two enzymatic activities.^{36,37} Therefore, CYP11B2 can carry out 11 β -hydroxylation, 18-hydroxylation, and 18-methyloxylation to yield the characteristic C11-18 hemiacetyl structure of aldosterone.

Regulation of Adrenal Steroidogenesis: “Functional Zonation” of the Adrenal Cortex

Glucocorticoids are secreted in relatively high amounts (cortisol, 10 to 20 mg/day) from the ZF under the control of ACTH; mineralocorticoids are secreted in low amounts (aldosterone, 100 to 150 μ g/day) from the ZG under the principal control of angiotensin II. As a class, adrenal androgens (DHEA, DHEAS, androstenedione) are the most abundant steroids secreted from the adult adrenal gland (>20 mg/day). In each case, secretion is facilitated through the expression of steroidogenic enzymes in a specific “zonal” manner. The ZG cannot synthesize cortisol because it does not express 17 α -hydroxylase. In contrast, aldosterone secretion is confined to the outer ZG because of the restricted expression of CYP11B2. Although CYP11B1 and CYP11B2 share 95% homology, the 5' promoter sequences differ, permitting regulation of the final steps in glucocorticoid and mineralocorticoid biosynthesis by ACTH and angiotensin II, respectively. In the ZR, high levels of cytochrome *b*₅ confer 17,20-lyase activity on CYP17A1 and androgen production. DHEA is sulfated in the ZR by the DHEA sulfotransferase (SULT2A1) to form DHEAS. This sulfonation reaction facilitated by SULT2A1 relies on the donor 3'-phosphoadenosine 5'-phosphosulfate (PAPS) to transfer a sulfonate group to an acceptor molecule. PAPS is synthesized by PAPS synthase, of which two isoenzymes exist (PAPSS1 and PAPSS2).³⁸

In the fetal adrenal, steroidogenesis occurs primarily within the inner FZ. The FZ is a characteristic feature of higher primates, but the biologic role of fetal androgen

Figure 15-5 **A**, Electron shuttle system for the mitochondrial enzymes, CYP11A1, CYP11B1, and CYP11B2. Adrenodoxin reductase receives electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduces adrenodoxin, which transfers reducing equivalents to the cytochrome P450 (CYP) enzyme. The enzyme then transfers electrons, by way of oxygen, to the steroid. Fp, Flavoprotein; Fp[•], reduced form of flavoprotein; NADP⁺, nicotinamide adenine dinucleotide phosphate. **B**, Electron shuttle system for the microsomal enzymes, CYP17A1 and CYP21A2. P450 oxidoreductase, a flavoprotein, accepts electrons from NADPH and transfers them to the NADPH-P450 enzyme. The enzyme then transfers electrons, by way of oxygen, to the steroid. A second reducing equivalent may be supplied to CYP17A1 by NADPH-P450 oxidoreductase or cytochrome b₅.

production remains unclear. Because of a relative lack of 3 β -HSD and high SULT2A1 activity, the principal steroidogenic products are DHEA and DHEAS, which are then aromatized by placental trophoblast to estrogens. Therefore, the majority of maternal estrogen across pregnancy is, indirectly, fetally derived.³⁹

Classic endocrine feedback loops are in place to control the secretion of both hormones. Cortisol inhibits the secretion of CRH from the hypothalamus and ACTH from the pituitary, and aldosterone-induced sodium retention inhibits renal renin secretion.

Glucocorticoid Secretion: The Hypothalamus-Pituitary-Adrenal Axis

Pro-opiomelanocortin and ACTH

ACTH is the principal hormone stimulating adrenal glucocorticoid biosynthesis and secretion. ACTH has 39 amino acids but is synthesized within the anterior pituitary as part of a much larger, 241-amino-acid precursor called pro-opiomelanocortin (POMC). A transcription factor, TPIT, appears to be essential for differentiation of POMC-expressing cells within the anterior pituitary.⁴⁰ POMC is cleaved in a tissue-specific fashion to yield smaller peptide hormones. In the anterior pituitary, this results in the secretion of β -lipoprotein (β -LPH) and pro-ACTH, the latter being further cleaved to an amino-terminal peptide, joining peptide, and ACTH itself (Fig. 15-6).^{41,42} Postsecretion cleavage of the precursor to γ -melanocyte stimulating hormone (pro- γ -MSH) by a serine protease (AsP) expressed in the outer adrenal cortex is thought to mediate the trophic action of "ACTH" on the adrenal cortex.⁴³ The first 24 amino acids of ACTH are common to all species, and a synthetic ACTH(1-24), Synacthen, is available commercially for clinical testing of the hypothalamic-pituitary-adrenal (HPA) axis and assessing adrenal glucocorticoid reserve. The hormones α -, β -, and γ -MSH are also cleaved products from POMC, but the

increased pigmentation characteristic of Addison's disease is thought to arise directly from increased ACTH concentrations binding to the melanocortin-1 receptor (MC1R) rather than from α -MSH secretion.⁴⁴

POMC is also transcribed in many extrapituitary tissues, notably brain, liver, kidney, gonad, and placenta.^{41,45,46} In these normal tissues, POMC messenger RNA (mRNA) is usually shorter than the pituitary 1200-base-pair species due to lack of exons 1 and 2 and the 5' region of exon 3.⁴⁷ As a result, it is probable that this POMC-like peptide is neither secreted nor active. However, in ectopic ACTH syndrome, additional POMC mRNA species are described that are longer than the normal pituitary POMC species (typically 1450 base pairs) due to the use of alternative promoters in the 5' region of the gene.^{48,49} This may in part explain the resistance of POMC secretion to glucocorticoid feedback in these tumors. Others factors, including interaction with tissue-specific transcription factors⁵⁰ and POMC methylation,⁵¹ may explain the ectopic expression of ACTH in some malignant tissues. The cleavage of POMC is also tissue specific,⁵² and it is possible, at least in some cases of ectopic ACTH syndrome, that circulating ACTH precursors (notably pro-ACTH) may cross-react in current ACTH radioimmunoassays.^{53,54} The biologic activity of POMC itself on adrenal function is thought to be negligible.

POMC expression and processing within neurons in the hypothalamus, specifically the generation of α -MSH that interacts with melanocortin-4 receptors (MC4R), appears to be of crucial importance in appetite control and energy homeostasis (see later discussion).⁵⁵

Corticotropin-Releasing Hormone and Arginine Vasopressin

POMC secretion is tightly controlled by numerous factors, notably CRH and arginine vasopressin (AVP) (Fig. 15-7).^{56,57} Additional control is provided through an endogenous circadian rhythm and by stress and feedback inhibition by

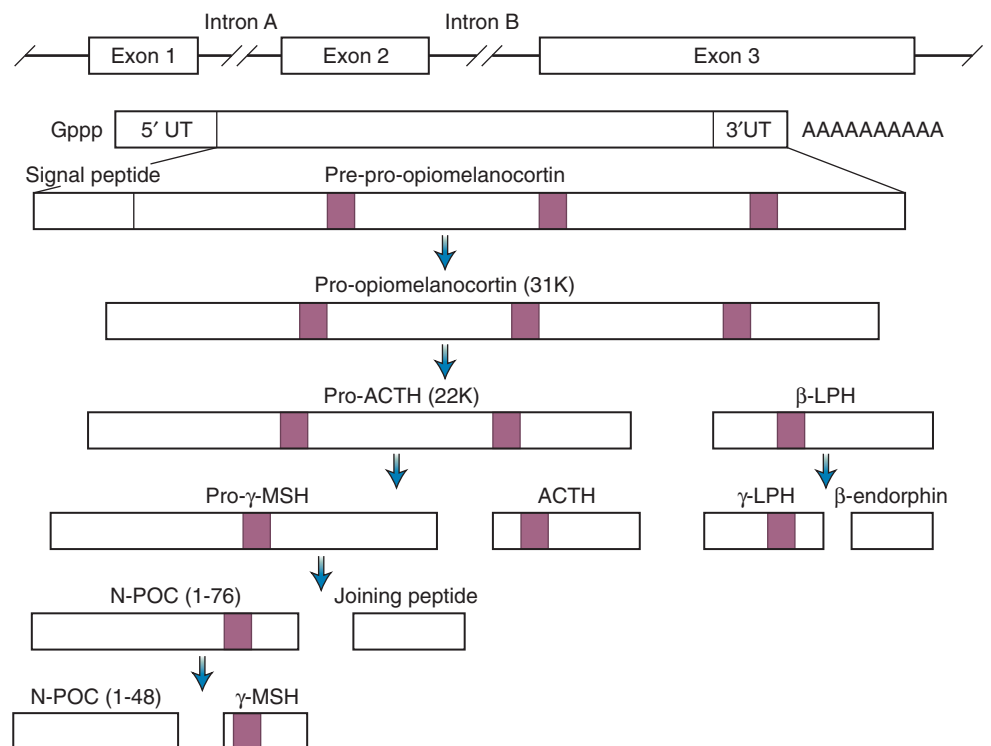

Figure 15-6 Synthesis and cleavage of pro-opiomelanocortin (POMC) within the human anterior pituitary gland. Prohormone convertase enzymes sequentially cleave POMC to adrenocorticotrophic hormone (ACTH). Shaded areas represent melanocyte-stimulating hormone (MSH) structural units. β -LPH, β -lipoprotein; γ -LPH, γ -lipoprotein; N-POC, amino-terminal pro-opiomelanocortin.

Figure 15-7 Normal negative feedback regulation of cortisol and aldosterone secretion. **A**, Hypothalamic-pituitary-adrenal axis. Adrenocorticotropic hormone (ACTH) is secreted from the anterior pituitary under the influence of two principal secretagogues, corticotropin-releasing hormone (CRH) and arginine vasopressin; other factors, including cytokines, also play a role. CRH secretion is regulated by an inbuilt circadian rhythm and by additional stressors operating through the hypothalamus. Secretion of CRH and ACTH is inhibited by cortisol, highlighting the importance of negative feedback control. **B**, Renin-angiotensin-aldosterone system (RAAS). Renin is secreted from the juxtaglomerular cells in the kidney dependent on renal arterial blood pressure. Renin converts angiotensinogen to angiotensin I, which is converted in the lungs by angiotensin converting enzyme (ACE) into angiotensin II. Angiotensin stimulates adrenal aldosterone synthesis. Extracellular fraction (ECF) of potassium has an important direct inhibitory influence on aldosterone secretion. ACE, Angiotensin converting enzyme; ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; ANP, atrial natriuretic peptide; CRH, corticotropin-releasing hormone.

cortisol itself. CRH is a 41-amino-acid peptide that is synthesized in neurons within the paraventricular nucleus of the hypothalamus.^{9,58,59} Human and rat CRH are identical, but ovine CRH differs by 7 amino acids^{60,61}; ovine CRH is slightly more potent than human CRH in stimulating ACTH secretion but has a longer half-life and is therefore used diagnostically.

CRH is secreted into the hypophyseal portal blood, where it binds to specific type I CRH receptors on anterior pituitary corticotrophs⁶² to stimulate POMC gene transcription through a process that includes activation of adenylate cyclase. It is unclear whether hypothalamic CRH contributes in any way to circulating levels; CRH is also synthesized in other tissues, and it is likely that circulating CRH reflects synthesis from testis, gastrointestinal tract, adrenal medulla, and particularly the placenta,⁶³ where the increased secretion across pregnancy results in a threefold increase in circulating CRH levels.⁶⁴ In the circulation, CRH is bound to CRH-binding protein (CRH-BP); levels of CRH-BP also increase during pregnancy so that cortisol secretion is not markedly elevated.⁶⁵

CRH is the principal stimulus for ACTH secretion,⁶⁶ but AVP is able to potentiate CRH-mediated secretion.⁶⁷ In this case, AVP acts through the V1B receptor to activate protein kinase C. The peak response of ACTH to CRH does not differ across the day, but it is affected by endogenous function of the HPA axis in that responsiveness is reduced in subjects treated with corticosteroids but increased in subjects with Cushing's disease. Other reported ACTH secretagogues, including angiotensin II, cholecystokinin, atrial

natriuretic factor, and vasoactive peptides, probably act to modulate the CRH control of ACTH secretion.⁶⁸

The Stress Response and Immune-Endocrine Axis. The proinflammatory cytokines, notably interleukin 1 (IL-1), IL-6, and tumor necrosis factor- α also increase ACTH secretion, either directly or by augmenting the effect of CRH.^{69,70} Leukemia inhibitory factor (LIF), a cytokine of the IL-6 family, is a further activator of the HPA axis.⁷¹ This explains the response of the HPA axis to an inflammatory stimulus and is an important immune-endocrine interaction (see Chapter 7). Physical stresses increase ACTH and cortisol secretion, again through central actions mediated via CRH and AVP. Cortisol secretion rises in response to fever, surgery,⁷² burn injury,⁷³ hypoglycemia,⁷⁴ hypotension, and exercise.⁷⁵ In all of these cases, this increased secretion can be viewed as a normal counterregulatory response to the insult. Acute psychological stress raises cortisol levels,⁷⁶ but secretion rates appear to be normal in patients with chronic anxiety states and underlying psychotic illness. However, depression is associated with high circulating cortisol concentrations, and this is an important consideration in the differential diagnosis of Cushing's syndrome (see later discussion).

Circadian Rhythm. ACTH is secreted in a pulsatile fashion with a circadian rhythm; levels are highest on waking and decline throughout the day, reaching nadir values in the evening (Fig. 15-8).⁷⁷ The average ACTH pulse frequency is higher in normal adult men compared with women (18 versus 10 pulses/24 hours, respectively). The circadian ACTH rhythm appears to be mediated

Figure 15-8 Circadian and pulsatile secretion of adrenocorticotrophic hormone (ACTH) and cortisol in a normal subject (*top two panels*) and in a patient with Cushing's disease. In a normal subject, secretion of ACTH and cortisol is highest in early morning and falls to a nadir at midnight. ACTH pulse frequency and pulse amplitude are increased in Cushing's disease, and circadian rhythmic secretion is lost.

principally by an increased ACTH pulse amplitude occurring between 5 and 9 a.m. but also by a reduction in ACTH pulse frequency occurring between 6 p.m. and midnight.^{78,79} Food ingestion is a further stimulus to ACTH secretion.

Circadian rhythm is dependent on both day-night⁸⁰ and sleep-wake⁸¹ patterns and is disrupted by alternating day-night shift work and by long-distance travel across time

zones.⁸² It can take up to 2 weeks for the circadian rhythm to reset to an altered day-night cycle.

Negative Feedback. An important aspect of CRH and ACTH secretion is the negative feedback control exerted by glucocorticoids themselves. Glucocorticoids inhibit POMC gene transcription in the anterior pituitary⁵⁶ and CRH and AVP mRNA synthesis and secretion in the hypothalamus.^{83,84} Annexin 1 (previously called lipocortin 1) may also play a critical role in effecting the negative feedback of glucocorticoids on ACTH and CRH release.⁸⁵ The negative feedback effect depends on the dose, potency, half-life, and duration of administration of the glucocorticoid and has important physiologic and diagnostic consequences. Suppression of the HPA axis by pharmacologic corticosteroids may persist for many months after cessation of therapy, and adrenocortical insufficiency should be anticipated. Diagnostically, the feedback mechanism explains ACTH hypersecretion in Addison's disease, as well as undetectable ACTH levels in patients with a cortisol-secreting adrenal adenoma. Feedback inhibition is principally mediated via the glucocorticoid receptor (GR); patients with glucocorticoid resistance resulting from mutations in the GR⁸⁶ and mice lacking the GR gene⁸⁷ have ACTH and cortisol hypersecretion due to perceived lack of negative feedback.

The ACTH Receptor and ACTH Effects on the Adrenal

ACTH binds to a G protein-coupled, melanocortin-2 receptor (MC2R),⁸⁸ of which there are approximately 3500 on each adrenocortical cell. Melanocortin-2 receptor accessory protein (MRAP) is required for correct localization and signaling of MC2R.⁸⁹ Current data suggest that MRAP might promote three different activities: as a chaperone assisting correct folding of MC2R in the endoplasmic reticulum, as an accessory protein essential for trafficking of MC2R to the plasma membrane, and as a coreceptor enabling MC2R to bind or to signal ACTH response.⁹⁰ Downstream signal transduction is mediated principally through the stimulation of adenylate cyclase and intracellular cAMP,⁹¹ although both extracellular and intracellular Ca²⁺ play a role.⁹² Other factors synergize with or inhibit the effects of ACTH on the adrenal cortex, including angiotensin II, activin, inhibin, and cytokines (tumor necrosis factor- α and leptin).⁹³ Cell-to-cell communication via gap junctions is also important in mediating the effects of ACTH.⁹⁴

ACTH produces both immediate and chronic effects on the adrenal gland; the end result is the stimulation of adrenal steroidogenesis and growth. Acutely, steroidogenesis is stimulated through a StAR-mediated increase in cholesterol delivery to the CYP11A1 enzyme in the inner mitochondrial membrane.²³ Chronically (within 24 to 26 hours of exposure), ACTH acts to increase the synthesis of all steroidogenic CYP enzymes (CYP11A1, CYP17A1, CYP21A2, CYP11B1) in addition to adrenodoxin,^{95,96} the effects of which are mediated at the transcriptional level. ACTH increases synthesis of the LDL and HDL receptors and possibly also synthesis of 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, the rate-limiting step in cholesterol biosynthesis. ACTH increases adrenal weight by inducing both hyperplasia and hypertrophy. Adrenal atrophy is a feature of ACTH deficiency.

Mineralocorticoid Secretion: The Renin-Angiotensin-Aldosterone Axis

Aldosterone is secreted from the ZG under the control of three principal secretagogues: angiotensin II, potassium,

and, to a lesser extent, ACTH (Fig. 15-7). Other factors, notably somatostatin, heparin, atrial natriuretic factor, and dopamine, can directly inhibit aldosterone synthesis. The secretion of aldosterone and its intermediary 18-hydroxylated metabolites is restricted to the ZG because of the zone-specific expression of CYP11B2 (aldosterone synthase).⁹⁷ Corticosterone and DOC, synthesized in both the ZF and ZG, can act as mineralocorticoids, which becomes significant in some clinical diseases, notably some forms of congenital adrenal hyperplasia (CAH) and adrenal tumors. Similarly, it is now established that cortisol can act as a mineralocorticoid in the setting of impaired metabolism of cortisol to cortisone by the enzyme 11 β -hydroxysteroid dehydrogenase type 2 (HSD11B2); this is important in patients with hypertension, ectopic ACTH syndrome, or renal disease. The renin-angiotensin system is described in detail in Chapter 16.

Angiotensin II and potassium stimulate aldosterone secretion principally by increasing the transcription of CYP11B2 through common intracellular signaling pathways. cAMP response elements in the 5' region of the CYP11B2 gene are activated after an increase in intracellular Ca²⁺ and activation of calmodulin kinases. The potassium effect is mediated through membrane depolarization and opening of calcium channels, and the angiotensin II effect after binding of angiotensin II to the surface AT₁ receptor and activation of phospholipase C.⁹⁷

The effect of ACTH on aldosterone secretion is modest and differs in the acute and chronic situation (see Chapter 16). An acute bolus of ACTH will increase aldosterone secretion, principally by stimulating the early pathways of adrenal steroidogenesis (see earlier discussion), but circulating levels increase by no more than 10% to 20% above baseline values. ACTH has no effect on CYP11B2 gene transcription or enzyme activity. Chronic continual ACTH stimulation has either no effect or an inhibitory effect on aldosterone production, possibly because of receptor down-regulation or suppression of angiotensin II-stimulated secretion because of a mineralocorticoid effect of cortisol, DOC, or corticosterone. Dopamine and atrial natriuretic peptide inhibit aldosterone secretion, as does heparin.

These separate lines of control—through the HPA axis for glucocorticoid biosynthesis and via the renin-angiotensin system for mineralocorticoid synthesis—have important clinical consequences. Patients with primary adrenal failure invariably have both cortisol and aldosterone deficiency, whereas patients with ACTH deficiency due to pituitary disease have glucocorticoid deficiency but normal aldosterone concentrations because the renin-angiotensin system is intact.

Adrenal Androgen Secretion

Adrenal androgens represent an important component (>50%) of circulating androgens in premenopausal women.⁹⁸ In men, this contribution is much smaller because of the testicular production of androgens, but adrenal androgen excess even in men may be of clinical significance, notably in patients with CAH, which results in a suppression of the hypothalamic-pituitary-gonadal axis. The adult adrenal secretes approximately 4 mg/day of DHEA, 7 to 15 mg/day of DHEAS, 1.5 mg of androstenedione, and 0.05 mg/day of testosterone.

DHEA is a crucial precursor of human sex steroid biosynthesis and exerts androgenic or estrogenic activity after conversion by the activities of the 3 β -HSD superfamily (β -HSD isozymes and aromatase); these enzymes are expressed in peripheral target tissues, a fact that is of clinical

TABLE 15-4

Dissociation of Adrenal Androgen and Glucocorticoid Secretion: Evidence for an Adrenal-Stimulating Hormone

Dexamethasone studies: Complete cortisol suppression with chronic high-dose dexamethasone; DHEA falls by only 20% (greater sensitivity of DHEA to acute low-dose dexamethasone administration).
Adrenarche: Clinically significant rise in circulating DHEA at 6 to 8 years of age; cortisol production unaltered.
Aging: Reduction in DHEA production; no change in cortisol.
Anorexia nervosa and illness: Fall in DHEA, no change (or increase) in cortisol.

DHEA, dehydroepiandrosterone.

importance in many diseases.⁹⁹ Some studies have postulated direct effects of DHEA acting as a classic hormone in peripheral tissues. Specific plasma membrane receptors have been identified but await full characterization.¹⁰⁰ Conventionally, desulfated DHEA is thought to be converted downstream to a biologically active hormone. Serum DHEAS was previously thought to represent a circulating storage pool for DHEA regeneration, but it was later suggested that conversion of DHEAS to DHEA by steroid sulfatase plays a minor role in adult physiology and that the equilibrium between serum DHEA and DHEAS is mainly regulated by SULT2A1 activity. This implies that serum DHEAS may not always appropriately reflect the active DHEA pool, particularly if SULT2A1 activity is impaired, as in the inflammatory stress response.¹⁰¹

DHEAS stimulates androgen secretion; DHEA (but not DHAS because of its increased plasma half-life) and androstenedione demonstrate a circadian rhythm similar to that of cortisol.¹⁰² However, there are many discrepancies between adrenal androgen and glucocorticoid secretion, leading to the suggestion of an additional cortical androgen-stimulating hormone (CASH). Many putative CASHs have been proposed, including POMC derivatives such as joining peptide, prolactin, and insulin-like growth factor type 1 (IGF1), but conclusive proof is lacking. Efficient adrenal steroidogenesis toward androgen synthesis is crucially dependent on the relative activities of 3 β -HSD and 17 α -hydroxylase and, in particular, on the 17,20-lyase activity of 17 α -hydroxylase. Factors that determine whether the 17-hydroxylated substrates, 17-OH pregnenolone and 17-OHP, will undergo 21-hydroxylation to form glucocorticoid or side-chain cleavage by 17 α -hydroxylase to form DHEA and androstenedione are unresolved and seem likely to be important in defining the activity of any putative CASH (Table 15-4).

CORTICOSTEROID HORMONE ACTION

Receptors and Gene Transcription

Both cortisol and aldosterone exert their effects after uptake of free hormone from the circulation and binding to intracellular receptors; these are termed, respectively, the *glucocorticoid receptor* (GR, encoded by NR3C1) and the *mineralocorticoid receptor* (MR, encoded by NR3C2).¹⁰³⁻¹⁰⁵ These are members of the thyroid/steroid hormone receptor superfamily of transcription factors; they consist of a carboxy-terminal ligand-binding domain, a central DNA-binding domain that interacts with specific DNA sequences on target genes, and an N-terminal hypervariable region. Although only single genes encode the GR and MR, splice

Figure 15-9 Schematic structure of the human genes encoding the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR). In both cases, splice variants have been described. In the case of the GR, there is evidence that the GRβ isoform can act as a dominant negative inhibitor of GRα action. mRNA, messenger ribonucleic acid.

variants have been described in both receptor types; this, together with tissue-specific post-translational modification (phosphorylation, sumoylation, and ubiquitination) is thought to account for many of the diverse actions of corticosteroids (Fig. 15-9).^{106,107}

Glucocorticoid hormone action has been studied in more depth than mineralocorticoid action. The binding of steroid to the GRα in the cytosol results in activation of the steroid-receptor complex through a process that involves the dissociation of heat shock proteins (HSP90 and HSP70).¹⁰⁸ Following translocation to the nucleus, gene transcription is stimulated or repressed after binding of the dimerized GR-ligand complex to a specific DNA sequence in the promoter regions of target genes.¹⁰⁹ This sequence, known as the glucocorticoid-response element (GRE), is invariably a palindromic CGTACAnnnTGTA sequence that binds with high affinity to two loops of DNA within the DNA-binding domain of the GR (zinc fingers). This stabilizes the RNA polymerase II complex, facilitating gene transcription. The GRα variant may act as a dominant negative regulator of GRβ transactivation.¹⁰⁶

Naturally occurring mutations in the GR (as seen in patients with glucocorticoid resistance) and GR mutants generated in vitro have highlighted critical regions of the receptor that are responsible for binding and transactivation,¹¹⁰ but numerous other factors are required (e.g., coactivators, corepressors¹¹¹), and this may make responses tissue specific. This is a rapidly evolving field and beyond the scope of this chapter. However, the interaction between GR and two particular transcription factors are important in mediating the anti-inflammatory effects of glucocorticoids and explain the effect of glucocorticoids on genes that do not contain obvious GREs in their promoter regions.¹¹² Activator protein 1 (AP1) comprises Fos and Jun subunits and is a proinflammatory transcription factor induced by a series of cytokines and phorbol ester. The GR-ligand complex can bind to c-Jun and prevent interaction with the AP1 site, thereby mediating the so-called transrepressive effects of glucocorticoids.¹¹³ Similarly, functional antagonism exists between the GR and nuclear factor-κB (NF-κB), a ubiquitously expressed transcription factor that activates a series of genes involved in lymphocyte development, inflammatory response, host defense, and apoptosis (Fig. 15-10).¹¹⁴ In keeping with the

diverse array of actions of cortisol, many hundreds of glucocorticoid-responsive genes have been identified. Some glucocorticoid-induced genes and repressed genes are listed in Table 15-5.

In contrast to the diverse actions of glucocorticoids, mineralocorticoids have a more restricted role, principally stimulation of epithelial sodium transport in the distal nephron, distal colon, and salivary glands.¹¹⁵ This action is mediated through induction of the apical sodium channel (comprising three subunits—α, β, and γ)¹¹⁶ and the α₁ and β₁ subunits of the basolateral sodium-potassium adenosine triphosphatase pump (Na⁺,K⁺-ATPase)¹¹⁷ through transcriptional regulation of serum- and glucocorticoid-induced kinase (SGK).¹¹⁸ Aldosterone binds to the MR, principally in the cytosol (although there is evidence for expression of the unliganded MR in the nucleus), and the hormone-receptor complex is then translocated to the nucleus (Fig. 15-11).

The MR and GR share considerable homology—57% in the steroid-binding domain and 94% in the DNA-binding domain. It is perhaps not surprising, therefore, that there is promiscuity of ligand binding, with aldosterone (and the synthetic mineralocorticoid, fludrocortisone) binding to the GR and cortisol binding to the MR. For the MR, this is particularly impressive: in vitro, the MR has the same inherent affinity for aldosterone, corticosterone, or cortisol.¹⁰⁴ Specificity on the MR is conferred through the “pre-receptor” metabolism of cortisol via the enzyme HSD11B2, which inactivates cortisol and corticosterone to inactive 11-keto metabolites, enabling aldosterone to bind to the MR.^{119,120} Mineralocorticoid hormone action was extended beyond this classic action in sodium-transporting epithelia with the demonstration that aldosterone can induce cardiac fibrosis and inflammatory changes in renal vasculature. The underlying signaling pathways remain to be fully clarified, but the effects are reversible with MR antagonists.¹²¹

Finally, for both glucocorticoids and mineralocorticoids, there is accumulating evidence for so-called nongenomic effects involving hormone response obviating the genomic GR or MR. A series of responses have been reported to occur within seconds or minutes after exposure to corticosteroids and are thought to be mediated by as yet uncharacterized membrane-coupled receptors.^{122,123}

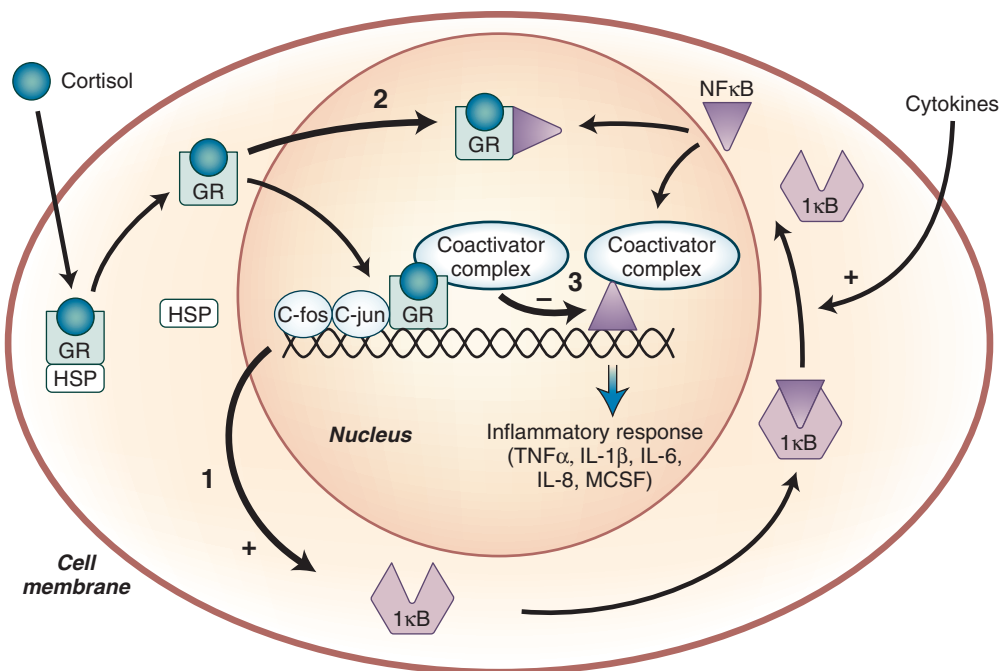

Figure 15-10 The anti-inflammatory action of glucocorticoids. Cortisol binds to the cytoplasmic glucocorticoid receptor (GR). Conformational changes in the receptor-ligand complex result in dissociation from heat shock proteins (HSP70 and HSP90) and migration to the nucleus. Binding occurs to specific DNA motifs—glucocorticoid response elements—in association with the activator protein 1 (AP1) comprising C-fos and C-jun. Glucocorticoids mediate their anti-inflammatory effects through several mechanisms: (1) the inhibitory protein 1κB, which binds and inactivates nuclear factor-κB (NFκB), is induced; (2) the GR-cortisol complex is able to bind NFκB and thereby prevent initiation of an inflammatory process; (3) GR and NFκB compete for the limited availability of coactivators, which include cyclic adenosine monophosphate response element-binding protein (CREB) and steroid receptor coactivator-1. IL, interleukin; MCSF, macrophage colony stimulating factor; TNFα, tumor necrosis factor-α.

Cortisol-Binding Globulin and Corticosteroid Hormone Metabolism

More than 90% of circulating cortisol is bound, predominantly to the α_2 -globulin, cortisol-binding globulin (CBG).¹²⁴ This 383-amino-acid protein is synthesized in the liver and binds cortisol with high affinity. Affinity for synthetic corticosteroids is negligible except for prednisolone, which has an affinity for CBG approximately half that of cortisol. Circulating CBG concentrations are approximately 700 nmol/L. Levels are increased by estrogens and in some patients with chronic active hepatitis; they are reduced by glucocorticoids and in patients with cirrhosis, nephrosis, and hyperthyroidism. The estrogen effect can be marked, with levels increasing twofold to threefold across pregnancy, a fact that should be taken into account when measuring plasma “total” cortisol in pregnancy and in women taking estrogens.

Inherited abnormalities in CBG synthesis are much rarer than those described for thyroxine-binding globulin but include cases of elevated CBG, partial or complete deficiency of CBG, and CBG variants with reduced affinity for cortisol.^{125,126} In each case, alterations in CBG concentrations change the total circulating cortisol concentrations accordingly, but free cortisol concentrations are normal. Only this free circulating fraction is available for transport into tissues for biologic activity. The excretion of free cortisol through the kidneys is termed *urinary free cortisol* and represents only 1% of the total cortisol secretion.

The circulating half-life of cortisol varies between 70 and 120 minutes. The major steps in cortisol metabolism are depicted in Figure 15-12¹²⁷ and can be summarized as follows:

- Interconversion of the 11-hydroxyl group (cortisol, Kendall's compound F) to the 11-oxo group (cortisone,

compound E) through activity of the 11β-HSD system (EC 1.1.1.146).^{128,129} The metabolism of cortisol and that of cortisone then follow similar pathways.

- Reduction of the C4-5 double bond to form dihydrocortisol or dihydrocortisone, followed by hydroxylation of the 3-oxo group to form tetrahydrocortisol (THF) or tetrahydrocortisone (THE). The reduction of the C4-5 double bond can be carried out by either 5β-reductase or 5α-reductase, yielding, respectively, 5β-THF (THF) and 5α-THF (allo-THF). In normal subjects, the ratio of THF to allo-THF is 2:1. THF, allo-THF, and THE are rapidly conjugated with glucuronic acid and excreted in the urine.
- Further reduction of the 20-oxo group by either 20α- or 20β-HSD to yield α- and β-cortols and cortolones from cortisol and cortisone, respectively. Reduction of the C20 position may also occur without A-ring reduction, giving rise to 20α- and 20β-hydroxycortisol.
- Hydroxylation at C6 to form 6β-hydroxycortisol.
- Cleavage of THF and THE to the C19 steroids, 11-hydroxy- or 11-oxo- androsterone or etiocholanolone.
- Oxidation of the C21 position of cortols and cortolones to form the extremely polar metabolites, cortolic and cortolonic acids.

Approximately 50% of secreted cortisol appears in the urine as THF, allo-THF, and THE; 25% as cortols/cortolones; 10% as C19 steroids; and 10% as cortolic/cortolonic acids. The remaining metabolites are free unconjugated steroids (cortisol, cortisone, and their 6β-, and 20α/20β-metabolites).

The principal site of cortisol metabolism has been considered to be the liver, but many of the enzymes listed have been described in mammalian kidney, notably the interconversion of cortisol to cortisone by HSD11B2.

TABLE 15-5

Some of the Genes Regulated by Glucocorticoids or Glucocorticoid Receptors

Site of Action	Induced Genes	Repressed Genes
Immune system	I κ B (nuclear factor- κ B inhibitor)	Interleukins
	Haptoglobin	Tumor necrosis factor- α (TNF- α)
Metabolic	T-cell receptor (TCR)- ζ	Interferon- γ
	p21, p27, and p57	E-selectin
	Lipocortin	Intercellular adhesion molecule-1
		Cyclooxygenase 2
		Inducible nitric oxide synthase (iNOS)
	PPAR- γ	Tryptophan hydroxylase
		Metalloprotease
	Tyrosine aminotransferase	
	Glutamine synthase	
	Glycogen synthase	
Bone	Glucose-6-phosphatase

Modified from McKay LI, Cidlowski JA. Molecular control of immune/inflammatory responses: interactions between nuclear factor- κ B and steroid receptor-signalling pathways. *Endocr Rev.* 1999;20:435-459.

Quantitatively, this is the most important pathway. Furthermore, the bioactivity of glucocorticoids is in part related to the hydroxyl group at C11; because cortisone with a C11-oxo group is an inactive steroid, expression of 11 β -HSD in peripheral tissues plays a crucial role in regulating corticosteroid hormone action. Two distinct 11 β -HSD isozymes have been reported—a type 1, reduced

nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxo-reductase expressed principally in the liver, which confers bioactivity on orally administered cortisone by converting it to cortisol,¹²⁹ and a type 2, nicotinamide adenine dinucleotide (NAD)-dependent dehydrogenase. It is the HSD11B2, coexpressed with the MR in the kidney, colon, and salivary gland, that inactivates cortisol to cortisone and permits aldosterone to bind to the MR in vivo. If this enzyme-protective mechanism is impaired, cortisol is able to act as a mineralocorticoid; this explains some forms of endocrine hypertension (apparent mineralocorticoid excess, licorice ingestion) and the mineralocorticoid excess state that characterizes the ectopic ACTH syndrome.^{128,130}

Hyperthyroidism results in increased cortisol metabolism and clearance, and hypothyroidism produces the converse, principally because of an effect of thyroid hormone on hepatic HSD11B1 and 5 α /5 β -reductases.¹²⁹ IGF1 increases cortisol clearance by inhibiting hepatic HSD11B1 (conversion of cortisone to cortisol).¹³¹ 6 β -Hydroxylation is normally a minor pathway, but cortisol itself induces 6 β -hydroxylase so that 6 β -hydroxycortisol excretion is markedly increased in patients with Cushing's syndrome.¹³² Some drugs, notably rifampicin and phenytoin, increase cortisol clearance through this pathway.¹³³ Patients with renal disease have impaired cortisol clearance because of reduced conversion of renal cortisol to cortisone.¹³⁴ These observations have clinical implications for patients with thyroid disease, acromegaly, or renal disease and for patients taking cortisol replacement therapy. Adrenal crisis has been reported in steroid-replaced Addisonian patients given rifampicin,¹³⁵ and hydrocortisone replacement therapy may need to be increased in treated patients who develop hyperthyroidism or reduced in patients with untreated growth-hormone deficiency.

Aldosterone is also metabolized in the liver and kidneys. In the liver, it undergoes tetrahydro reduction and is excreted in the urine as a 3-glucuronide tetrahydroaldosterone derivative. However, glucuronide conjugation at the

Figure 15-11 Mineralocorticoid hormone action. An epithelial cell in the distal nephron or distal colon is depicted. The much higher concentrations of cortisol are inactivated by the type 2 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β -HSD2) to cortisone, permitting the endogenous ligand, aldosterone, to bind to the mineralocorticoid receptor (MR). Relatively few mineralocorticoid target genes have been identified, but they include serum- and glucocorticoid-induced kinase (SGK), subunits of the epithelial sodium channel (ENaC), and basolateral Na⁺/K⁺-adenosine triphosphatase.

Figure 15-12 The principal pathways of cortisol metabolism. Interconversion of hormonally active cortisol to inactive cortisone is catalyzed by two isozymes of 11 β -hydroxysteroid dehydrogenase (11 β -HSD), with HSD11B1 principally converting cortisone to cortisol and HSD11B2 doing the reverse. Cortisol can be hydroxylated at the C6 and C20 positions. A ring reduction is undertaken by 5 α -reductase or 5 β -reductase and 3 α -HSD.

18 position occurs directly in the kidney, as does 3 α and 5 α /5 β metabolism of the free steroid.¹³⁶ Because of the aldehyde group at the C18 position, aldosterone is not metabolized by HSD11B2.¹³⁷ Hepatic aldosterone clearance is reduced in patients with cirrhosis, ascites, or severe congestive heart failure.

Effects of Glucocorticoids

The principal sites of action of glucocorticoids and some of the consequences of glucocorticoid excess are shown in Figure 15-13.

Carbohydrate, Protein, and Lipid Metabolism

Glucocorticoids increase blood glucose concentrations through their action on glycogen, protein, and lipid metabolism. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilizing enzyme, glycogen phosphorylase.¹³⁸ Hepatic glucose output increases through the activation of key enzymes involved in gluconeogenesis, principally glucose-6-phosphatase and phosphoenolpyruvate kinase (PEPCK).^{139,140} In peripheral tissues (e.g., muscle, fat), cortisol inhibits glucose uptake and utilization.¹⁴¹ In adipose

Figure 15-13 The principal sites of action of glucocorticoids in humans, highlighting some of the consequences of glucocorticoid excess. CNS, central nervous system; GI, gastrointestinal; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

tissue, lipolysis is activated, resulting in the release of free fatty acids into the circulation. An increase in total circulating cholesterol and triglycerides is observed, but HDL-cholesterol levels fall. Glucocorticoids also have a permissive effect on other hormones, including catecholamines and glucagon. The result is insulin resistance and an increase in blood glucose concentrations, at the expense of protein and lipid catabolism.

Glucocorticoids stimulate adipocyte differentiation, promoting adipogenesis through the transcriptional activation of key differentiation genes, including lipoprotein lipase, glycerol-3-phosphate dehydrogenase, and leptin.¹⁴² Long-term, the effects of glucocorticoid excess on adipose tissue is more complex, at least in humans, in whom the deposition of visceral or central adipose tissue is stimulated,¹⁴³ providing a useful discriminatory sign for the diagnosis of Cushing's syndrome. The predilection for visceral obesity may relate to the increased expression of the GR¹⁴⁴ and HSD11B1 in omental compared with subcutaneous adipose tissue.¹⁴⁵

Skin, Muscle, and Connective Tissue

In addition to inducing insulin resistance in muscle tissue, glucocorticoids also cause catabolic changes in muscle,

skin, and connective tissue. In the skin and connective tissue, glucocorticoids inhibit epidermal cell division and DNA synthesis and reduce synthesis and production of collagen.¹⁴⁶ In muscle, glucocorticoids cause atrophy (but not necrosis), which seems to be specific for type II (phasic) muscle fibers. Muscle protein synthesis is reduced.

Bone and Calcium Metabolism

Glucocorticoids inhibit osteoblast function, which is thought to account for the osteopenia and osteoporosis that characterize glucocorticoid excess.¹⁴⁷ Up to 1% of Western populations are taking long-term glucocorticoid therapy,¹⁴⁸ and glucocorticoid-induced osteoporosis is becoming a prevalent health concern, affecting 50% of patients treated with corticosteroids for longer than 12 months. However, the complication perhaps most feared by physicians is osteonecrosis. Osteonecrosis (also termed *avascular necrosis*) produces rapid and focal deterioration of bone quality and primarily affects the femoral head, leading to pain and ultimately to collapse of the bone, often necessitating hip replacement. It can affect individuals of any age and may occur with relatively low doses of glucocorticoids (e.g., during corticosteroid replacement therapy for adrenal failure).¹⁴⁹ Importantly, defects may not be

detectable on conventional x-ray films but are readily seen on magnetic resonance imaging (MRI). Glucocorticoid-induced osteocyte apoptosis has been implicated in the pathogenesis of the condition,¹⁵⁰ and the lack of a direct role for an interrupted blood supply suggests that the term *osteonecrosis* is preferable to *avascular femoral necrosis*. However, there is still no explanation for individual susceptibility.

Glucocorticoids also induce negative calcium balance by inhibiting intestinal calcium absorption and increasing renal calcium excretion. As a consequence, parathyroid secretion is usually increased. In children, glucocorticoids suppress growth, but the increases in body mass index are thought to offset a deleterious effect on bone mineral density.¹⁵¹

Salt and Water Homeostasis and Blood Pressure Control

Glucocorticoids increase blood pressure by a variety of mechanisms involving actions on the kidney and vasculature.¹⁵² In vascular smooth muscle, they increase sensitivity to pressor agents such as catecholamines and angiotensin II while reducing nitric oxide-mediated endothelial dilatation. Angiotensinogen synthesis is increased by glucocorticoids.¹⁵³ In the kidney, depending on the activity of HSD11B2, cortisol can act on the distal nephron to cause sodium retention and potassium loss (mediated via the MR).¹³⁰ Elsewhere across the nephron, glucocorticoids increase the glomerular filtration rate, proximal tubular epithelial sodium transport, and free water clearance.¹⁵⁴ This last effect involves antagonism of the action of vasopressin and explains the dilutional hyponatremia seen in patients with glucocorticoid deficiency.¹⁵⁵

Anti-Inflammatory Actions and the Immune System

Glucocorticoids suppress immunologic responses, and this has been the stimulus to develop a series of highly potent pharmacologic glucocorticoids to treat a variety of autoimmune and inflammatory conditions. The inhibitory effects are mediated at many levels. In the peripheral blood, glucocorticoids reduce lymphocyte counts acutely (T lymphocytes > B lymphocytes) by redistributing lymphocytes from the intravascular compartment to the spleen, lymph nodes, and bone marrow. Conversely, neutrophil counts increase after glucocorticoid administration. Eosinophil counts rapidly fall, an effect that was historically used as a bioassay for glucocorticoids. The immunologic actions of glucocorticoids involve direct actions on both T and B lymphocytes, including inhibition of immunoglobulin synthesis and stimulation of lymphocyte apoptosis. Inhibition of cytokine production from lymphocytes is mediated through inhibition of the action of NF- κ B. NF- κ B plays a crucial and generalized role in inducing cytokine gene transcription; glucocorticoids can bind directly to NF- κ B to prevent nuclear translocation, and they induce NF- κ B inhibitor, which sequesters NF- κ B in the cytoplasm, thereby inactivating its effect.¹¹⁴

Additional anti-inflammatory effects involve the inhibition of monocyte differentiation into macrophages and macrophage phagocytosis and cytotoxic activity. Glucocorticoids reduce the local inflammatory response by preventing the actions of histamine and plasminogen activators. Prostaglandin synthesis is impaired through the induction of lipocortins, which inhibit phospholipase A2 activity.¹⁵⁶

Central Nervous System and Mood

Clinical observations of patients with glucocorticoid excess and deficiency reveal that the brain is an important target tissue for glucocorticoids, with depression, euphoria, psychosis, apathy, and lethargy being important manifestations. Both GRs and MRs are expressed in discrete regions of the rodent brain, including hippocampus, hypothalamus, cerebellum, and cortex.¹⁵⁷ Glucocorticoids cause neuronal death, notably in the hippocampus¹⁵⁸; this may underlie the interest in glucocorticoids in relation to cognitive function, memory, and neurodegenerative diseases such as Alzheimer's.¹⁵⁹ Local blockade of cortisol generation by HSD11B1 has been shown to improve cognitive function.¹⁶⁰ DHEA has been shown to have neuroprotective effects in the hippocampus region.¹⁶¹ CYP7B, an enzyme that metabolizes DHEA to its 7 α -hydroxylated metabolite, is highly expressed in brain, but expression was decreased in dentate neurons in the hippocampus.¹⁶²

Eye

In the eye, glucocorticoids act to raise intraocular pressure through an increase in aqueous humor production and deposition of matrix within the trabecular meshwork, which inhibits aqueous drainage. Steroid-induced glaucoma appears to have a genetic predisposition, but the underlying mechanisms are unknown.¹⁶³

Gut

Long-term but not acute administration of glucocorticoids increases the risk of developing peptic ulcer disease.¹⁶⁴ Pancreatitis with fat necrosis is reported in patients with glucocorticoid excess. The GR is expressed throughout the gastrointestinal tract, and the MR in the distal colon; they mediate the corticosteroid control of epithelial ion transport.

Growth and Development

Although glucocorticoids stimulate transcription of the gene encoding growth hormone (GH) in vitro, glucocorticoids in excess inhibit linear skeletal growth,^{151,165} probably as a result of catabolic effects on connective tissue, muscle, and bone and through inhibition of the effects of IGF1. The results of experiments on mice lacking the GR gene⁸⁷ have emphasized the role of glucocorticoids in normal fetal development. In particular, glucocorticoids stimulate lung maturation through the synthesis of surfactant proteins (SP-A, SP-B, and SP-C),¹⁶⁶ and mice lacking the GR die shortly after birth due to hypoxia from lung atelectasis. Glucocorticoids also stimulate the enzyme phenylethanolamine N-methyltransferase (PNMT), which converts noradrenaline to adrenaline in adrenal medulla and chromaffin tissue. Mice lacking the GR do not develop an adrenal medulla.⁸⁷

Endocrine Effects

Glucocorticoids suppress the thyroid axis, probably through a direct action on the secretion of thyroid-stimulating hormone (TSH). In addition, they inhibit 5' deiodinase activity that mediates the conversion of thyroxine to active triiodothyronine.

Glucocorticoids also act centrally to inhibit gonadotropin-releasing hormone (GnRH) pulsatility and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

TABLE 15-6

Therapeutic Use of Corticosteroids

Endocrine: Replacement therapy (Addison's disease, pituitary disease, congenital adrenal hyperplasia), Graves' ophthalmopathy
Skin: Dermatitis, pemphigus
Hematology: Leukemia, lymphoma, hemolytic anemia, idiopathic thrombocytopenic purpura
Gastrointestinal: Inflammatory bowel disease (ulcerative colitis, Crohn's disease)
Liver: Chronic active hepatitis, transplantation, organ rejection
Renal: Nephrotic syndrome, vasculitides, transplantation, rejection
Central nervous system: Cerebral edema, raised intracranial pressure
Respiratory: Angioedema, anaphylaxis, asthma, sarcoidosis, tuberculosis, obstructive airway disease
Rheumatology: Systemic lupus erythematosus, polyarteritis, temporal arteritis, rheumatoid arthritis
Muscle: Polymyalgia rheumatica, myasthenia gravis

Therapeutic Corticosteroids

Since the dramatic anti-inflammatory effect of cortisone was first demonstrated in the 1950s, a series of synthetic corticosteroids have been developed for therapeutic purposes. These are used to treat a diverse variety of human diseases, principally relying on their anti-inflammatory and immunologic actions (Table 15-6). The main corticosteroids used in clinical practice, together with their relative glucocorticoid and mineralocorticoid potencies, are listed in Table 15-7.

The structures of common synthetic steroids are depicted in Fig. 15-14. The biologic activity of a corticosteroid depends on a 4-3-keto, 11 β -hydroxy, 17 α ,21-trihydroxyl configuration.¹⁶⁷ Conversion of the C11 hydroxyl group to a C11 keto group (i.e., cortisol to cortisone) inactivates the steroid. The addition of a 1,2 unsaturated bond to cortisol results in prednisolone, which is four times more potent than cortisol in classic glucocorticoid bioassays such as hepatic glycogen deposition, suppression of eosinophils, and anti-inflammatory actions. Prednisone, widely prescribed in the United States, is the cortisone-equivalent of prednisolone and relies on conversion by HSD11B1 in the liver for bioactivity.¹⁶⁸ Potency is further increased by the addition of a 6 α -methyl group to prednisolone (methylprednisolone).

Fludrocortisone is a synthetic mineralocorticoid having 125-fold greater potency than cortisol in stimulating sodium reabsorption. This is achieved through the addition of a 9 α -fluoro group to cortisol. Fludrocortisone also

has glucocorticoid potency (12-fold greater than cortisol). The addition of a 16 α -methyl group and 1,2, saturated bond to fludrocortisone results in dexamethasone, a highly potent glucocorticoid (25-fold greater than cortisol) that has negligible mineralocorticoid activity.^{167,169}

Figure 15-14 Structures of the natural glucocorticoid cortisol, some of the more commonly prescribed synthetic glucocorticoids, and the mineralocorticoid fludrocortisone. Triamcinolone is identical to dexamethasone except that a 16 α -hydroxyl group is substituted for the 16 α -methyl group. Betamethasone, another widely used glucocorticoid, has a 16 β -methyl group. Beclomethasone is derived from betamethasone by replacement of the 9 α -fluoro group with a chloro group. Fluticasone is identical to dexamethasone except that an additional 6 α -fluoro group has been added, and the hydroxymethyl group at position 21 has been exchanged by an 5-fluoro-methyl group.

TABLE 15-7

Relative Biologic Potencies of Synthetic Steroids in Bioassay Systems

Steroid	Anti-Inflammatory Action	Hypothalamic-Pituitary-Adrenal Suppression	Salt Retention
Cortisol	1	1	1
Prednisone	3	4	0.75
Prednisolone	3	4	0.75
Methylprednisolone	6.2	4	0.5
Fludrocortisone	12	12	125
Δ^1 Fludrocortisone	14	—	225
Triamcinolone	5	4	0
Dexamethasone	26	17	0

Administration

Widely used synthetic glucocorticoids in respiratory and nasal aerosol sprays are betamethasone, beclomethasone, and fluticasone. Betamethasone has the same structure as dexamethasone but with a 16 β -methyl group. Beclomethasone has the same structure as betamethasone apart from the replacement of the 9 α -fluoro group with a 9 α -chloro group. Fluticasone has the same structure as dexamethasone with an additional 6 α -fluoro group and an 5-fluoromethyl group replacing the hydroxymethyl group.

Corticosteroids are given orally, parenterally, and by numerous topical routes (e.g., eyes, skin, nose, inhalation, rectal suppositories).¹⁶⁹ Unlike hydrocortisone, which has a high affinity for CBG, most synthetic steroids have low affinity for this binding protein and circulate as free steroid (approximately 30%) or bound to albumin (approximately 70%). Circulating half-lives vary depending on individual variability and underlying disease, particularly renal and hepatic impairment. Cortisone acetate should not be used parenterally because it requires metabolism by the liver to active cortisol.

It is beyond the scope of this chapter to describe which steroid should be given and by which route for the non-endocrine conditions listed in Table 15-6. Acute and long-term corticosteroid therapy in patients with hypoadrenalism or CAH is discussed in later sections.

Long-Term Therapy

In addition to the undoubted benefit that corticosteroids provide, there is an increasing incidence of overuse, particularly in patients with respiratory or rheumatologic disease, to such an extent that up to 1% of the population is now prescribed long-term corticosteroid therapy.¹⁴⁸ Because of their established euphoric effect, corticosteroids often make patients feel better but without any objective improvements in underlying disease parameters. In view of the long-term harm of chronic glucocorticoid excess,¹⁷⁰ decisions regarding treatment should be evidence based and subject to constant review based on efficacy and side effects. The endocrinologic consequences of chronic glucocorticoid excess, notably suppression of the HPA axis, are an important aspect of modern clinical practice. Endocrinologists need to be aware of the effects of long-term therapy and of steroid withdrawal. Selective glucocorticoid receptor agonists (SEGRAs) are being developed with the aim of dissociating the transrepressive, anti-inflammatory actions of glucocorticoids from the transactivating effects that, by and large, mediate deleterious side effects.¹⁷¹

The negative feedback control of the HPA axis by endogenous cortisol has been discussed. Synthetic corticosteroids similarly suppress the function of the HPA axis through a process that depends on the dose and duration of treatment. Consequently, the sudden cessation of corticosteroid therapy can result in adrenal failure.¹⁶⁹ This may also occur after treatment with high doses of the synthetic progestogen, medroxyprogesterone acetate, which possesses glucocorticoid agonist activity.¹⁷² Among patients taking any steroid dose for less than 3 weeks' duration, clinically significant suppression of the HPA axis is rarely a problem, and patients can withdraw from steroids suddenly with no ill effect. The possible exception is the patient who receives frequent short courses of corticosteroid therapy (e.g., with recurrent episodes of severe asthma). Suppression of the HPA axis is inevitable in patients taking the equivalent of 15 mg/day or more of

prednisolone for a long period¹⁷³; with lower long-term doses (prednisolone 5 to 15 mg/day or equivalent), suppression of the HPA axis is variable. Defects in the response of the HPA axis to insulin-induced hypoglycemia or exogenous ACTH have been reported in patients taking doses as low as 5 mg/day of prednisolone,¹⁷⁴ but clinically significant suppression at these low doses is debatable. Alternate-day therapy has been associated with less suppression of the HPA axis. Inhaled steroids, particularly very potent synthetic corticosteroids such as the widely used beclomethasone and fluticasone preparations, can also cause HPA axis suppression.^{175,176}

All patients receiving long-term therapy with corticosteroids should be treated in a similar fashion to patients with chronic ACTH deficiency; they should carry steroid cards and be offered steroid alert bracelets or necklaces. In the event of an intercurrent stress (e.g., infection, surgery), supplemental steroid cover should be given. If the patient is unable to take drugs orally, parenteral therapy is required.

Recovery from suppression may take 6 to 9 months. CRH secretion returns to normal, and within a few weeks the ACTH level begins to increase, rising above normal values until adrenal steroidogenesis recovers. In the interim, and without replacement therapy, patients may experience symptoms of glucocorticoid deficiency, including anorexia, nausea, weight loss, arthralgia, lethargy, skin desquamation, and postural dizziness (see the later discussions of adrenal insufficiency).¹⁷⁷

To avoid symptoms of glucocorticoid deficiency, steroids should be cautiously withdrawn over a period of months.¹⁷⁸ Assuming that the underlying disease permits steroid reduction, doses should be reduced from pharmacologic levels to physiologic levels (equivalent to 7.5 mg/day prednisolone) over a few weeks. Thereafter, doses should be reduced by 1 mg/day of prednisolone every 2 to 4 weeks depending on patient well-being. An alternative approach is to switch the patient to hydrocortisone 20 mg/day and reduce the daily dose by 2.5 mg/day every week to a level of 10 mg/day. Corticosteroids should not be taken at night, because this results in greater suppression of early-morning ACTH secretion. After 2 to 3 months on reduced doses, endogenous function of the HPA axis can be assessed by a corticotropin (ACTH-Synacthen) stimulation test or an insulin-induced hypoglycemia test. A "pass" response to these tests indicates adequate function of the HPA axis, and corticosteroid therapy can be safely withdrawn. In those patients who are taking physiologic doses of prednisolone (less than 5 to 7.5 mg/day) or equivalent corticosteroid, a Synacthen stimulation test (SST) given 12 to 24 hours after omitted steroid therapy will provide an immediate answer as to whether sudden or gradual withdrawal of steroid therapy is indicated (Table 15-8).¹⁷⁶

Iatrogenic-induced Cushing's syndrome occurs in patients who take suppressive doses of corticosteroids for longer than 3 weeks.¹⁷⁸ The rapidity of onset of clinical features depends on the administered dose but can occur within 1 month of therapy.

Adrenocortical Diseases

Adrenocortical diseases are relatively rare. Their importance lies in their high morbidity and mortality if untreated, coupled with the relative ease of diagnosis and the availability of effective therapy. The diseases are most readily classified on the basis of hormone excess or deficiency (Table 15-9).

TABLE 15-8

Suggested Plan for Steroid Replacement in Patients Withdrawing from Chronic Corticosteroid Therapy

Pred Dose (mg/day)	DURATION OF GLUCOCORTICOID TREATMENT			
	≤3 wk*	>3 wk		
≥7.5	Can stop	↓ rapidly (e.g., 2.5 mg q3-4d) THEN	OR	Convert 5 mg pred to 20 mg HC, then ↓ 2.5 mg/wk to 10 mg/day THEN After 2-3 mo at HC 10 mg/day, administer SST/ITT: Pass → Withdraw Fail → Continue
5-7.5	Can stop	↓ 1 mg q2-4 wk THEN		
<5	Can stop	↓ 1 mg q2-4 wk		

*Beware of frequent steroid courses (e.g., in asthma).

HC, hydrocortisone; ITT, insulin tolerance test; pred, prednisolone; SST, short Synacthen test.

Glucocorticoid Excess

Cushing's Syndrome

In 1912, Harvey Cushing first described a 23-year-old female with obesity, hirsutism, and amenorrhea, and 20 years later he postulated that this “polyglandular syndrome” was due to a primary pituitary abnormality causing adrenal hyperplasia.⁸ Adrenal tumors were shown to cause the syndrome in some cases,¹⁷⁹ but ectopic ACTH production was not characterized until much later, in 1962.¹⁸⁰ The term *Cushing's syndrome* is used to describe all causes, whereas *Cushing's disease* is reserved for cases of pituitary-dependent Cushing's syndrome.

Cushing's syndrome comprises the symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoids. The use of the term *glucocorticoid* in the definition covers excess from both endogenous (cortisol) and exogenous (e.g., prednisolone, dexamethasone) sources. Iatrogenic Cushing's syndrome is common,^{169,178} occurring to some degree in most patients taking long-term corticosteroid therapy. Endogenous causes of Cushing's syndrome are rare and result in loss of the normal feedback mechanism of the HPA axis and the normal circadian rhythm of cortisol secretion.

The incidence of pituitary-dependent Cushing's syndrome is estimated to be 5 to 10 cases per million population per year. The incidence of ectopic ACTH syndrome

parallels that of bronchogenic carcinoma, and although 0.5% of lung cancer patients have ectopic ACTH syndrome, rapid progression of the underlying disease often precludes an early diagnosis. Cushing's disease and adrenal adenomas are four times more common in women, whereas ectopic ACTH syndrome is more common in men.

Clinical Features of Cushing's Syndrome

The classic features of Cushing's syndrome—centripetal obesity, moon face, hirsutism, and plethora—have been well known since Cushing's initial descriptions in 1912 and 1932 (Figs. 15-15, 15-16, and 15-17). However, this gross clinical picture is not always present, and a high index of suspicion is required in many cases. Once the

In this case, the bruising occurred without obvious injury.

normal physiologic effects of glucocorticoids are appreciated (see Fig. 15-13), the clinical features of glucocorticoid excess are easier to define. These are summarized in Table 15-10 together with the most discriminatory features that will assist in distinguishing Cushing's syndrome from simple obesity.^{181,182}

Obesity. Weight gain and obesity are the most common signs of Cushing's syndrome. At least in adults, this weight gain is invariably centripetal in nature.^{143,183} In fact, generalized obesity is more common in the general population than it is in patients with Cushing's syndrome. One exception is in pediatric patients, in whom glucocorticoid excess may result in generalized obesity. In addition to centripetal obesity, patients develop fat depots over the thoracocervical spine (buffalo hump), in the supraclavicular region, and over the cheeks and temporal regions, giving rise to the rounded, moon-like facies. The epidural space, another site of abnormal fat deposition, may lead to neurologic deficits.

Reproductive Organs. Gonadal dysfunction is common, with menstrual irregularity in females and loss of libido in both sexes. Hirsutism is frequently found in female patients, as is acne. The most common form of hirsutism is vellus hypertrichosis on the face; this should be distinguished from the darker, terminal differentiated hirsutism that may occur because of ACTH-mediated adrenal androgen excess. Hypogonadotropic hypogonadism occurs because of a

direct inhibitory effect of cortisol on GnRH pulsatility and LH/FSH secretion, and it is reversible on correction of the hypercortisolism.^{184,185}

Psychiatric Features. Psychiatric abnormalities occur in approximately 50% of patients with Cushing's syndrome, regardless of cause.^{186,187} Agitated depression and lethargy are among the most common problems, but paranoia and overt psychosis are also well recognized. Memory and cognitive function may also be affected, and increased irritability may be an early feature. Insomnia is common, and both rapid eye movement and delta-wave sleep patterns are reduced.¹⁸⁸ Lowering of plasma cortisol by medical or surgical therapy usually results in a rapid improvement in the psychiatric state. Overall quality of life is significantly reduced in patients with Cushing's syndrome, particularly affecting physical health and functioning. Quality-of-life scores improve after treatment but do not return to normal.¹⁸⁹

Bone. In childhood, the most common presentation is with poor linear growth and weight gain¹⁴⁹; as discussed earlier, glucocorticoids have profound effects on growth and development.¹⁶⁵ Many patients with longstanding Cushing's syndrome have lost height because of osteoporotic vertebral collapse. This can be assessed by measuring the patient's sitting height or comparing the height with arm span; in normal subjects, height and arm span should be equal. Pathologic fractures, occurring spontaneously or

Figure 15-17 Bone abnormalities in Cushing's disease. **A**, Aseptic necrosis of the right humeral head in a 43-year-old woman with Cushing's disease of about 8 months' duration. **B**, Aseptic necrosis of the right femoral head in a 24-year-old woman with Cushing's disease of about 4½ years' duration. The arrows indicate the crescent subchondral radiolucency, best seen in this lateral view. **C**, Diffuse osteoporosis, vertebral collapse, and subchondral sclerosis in the same patient as in **A**. **D**, Rib fracture in a 38-year-old man with Cushing's disease. (**A** through **C**, from Phillips KA, Nance EP Jr, Rodriguez RM, et al. Avascular necrosis of bone: a manifestation of Cushing's disease. *South Med J*. 1986;79:825-829.)

after minor trauma, are not uncommon. Rib fractures, in contrast to those of the vertebrae, are often painless. The radiographic appearance is typical, with exuberant callus formation at the site of the healing fracture. In addition, osteonecrosis of the femoral and humeral heads is a recognized feature of endogenous Cushing's syndrome (see Fig. 15-17). Hypercalciuria may lead to renal calculi, but hypercalcemia is not a feature.

Skin. Hypercortisolism results in thinning of the skin and separation and exposure of the subcutaneous vascular tissue. On examination, wrinkling of the skin on the dorsum of the hand may be seen, resulting in a "cigarette paper" appearance (Liddle's sign). Minimal trauma may result in bruising, which frequently resembles the appearance of senile purpura. The plethoric appearance of the

patient with Cushing's syndrome is secondary to the thinning of the skin¹⁹⁰ combined with loss of facial subcutaneous fat and is not caused by true polycythemia. Acne and papular lesions may occur over the face, chest, and back.

The typical, almost pathognomic, red-purple livid striae greater than 1 cm in width are most frequently found on the abdomen but may also be present on the upper thighs, breasts, and arms. They are very common in younger patients and less so in those older than 50 years of age. They must be differentiated from the paler, less pigmented striae that occur as a result of pregnancy (striae gravidarum) or in association with rapid weight loss.

Skin pigmentation is rare in Cushing's disease but common in the ectopic ACTH syndrome. It arises because of overstimulation of melanocyte receptors by POMC-derived peptides.

TABLE 15-10

Prevalence of Symptoms and Signs in Cushing's Syndrome and Discriminant Index Compared with Prevalence of Features in Patients with Simple Obesity

Findings	% of Patients	Discriminant Index
Symptoms

Data from Ross EJ, Linch DC. Cushing's syndrome-killing disease: discriminatory value of signs and symptoms aiding early diagnosis. *Lancet*. 1982;2:646-649.

Muscle. Myopathy and bruising are two of the most discriminatory features of the syndrome.¹⁸¹ The myopathy of Cushing's syndrome involves the proximal muscles of the lower limbs and the shoulder girdle.¹⁹¹ Complaints of weakness, such as inability to climb stairs or get up from a deep chair, are relatively uncommon, but testing for proximal myopathy by asking the patient to rise from a crouching position often reveals the problem.

Cardiovascular. Hypertension is another prominent feature, occurring in up to 75% of cases. Even though epidemiologic data show a strong association between blood pressure and obesity, hypertension is much more common in patients with Cushing's syndrome than in those with simple obesity.¹⁵² This, together with the established metabolic consequences of the disease (diabetes, hyperlipidemia), is thought to explain the increased cardiovascular mortality in untreated cases.¹⁹²⁻¹⁹⁴ Cardiovascular events are also more common in patients with presumed iatrogenic Cushing's syndrome resulting from prescribed corticosteroids.¹⁷⁰ In addition, thromboembolic events may be more common in Cushing's patients.

Infections. Infections are more common in patients with Cushing's syndrome.^{195,196} In many instances, infections

are asymptomatic and occur because the normal inflammatory response is suppressed. Reactivation of tuberculosis has been reported¹⁹⁷ and has even been the presenting feature in some cases. Fungal infections of the skin (notably tinea versicolor) and nails may occur, as may opportunistic fungal infections. Bowel perforation is more common in patients with extreme hypercortisolism, and the hypercortisolism may mask the usual symptoms and signs of the condition. Wound infections are more common and contribute to poor wound healing.

Metabolic and Endocrine Features. Glucose intolerance occurs, and overt diabetes mellitus is present in up to one third of patients in some series. Hepatic lipoprotein synthesis is stimulated, and increases in circulating cholesterol and triglycerides may be found.¹⁹⁸ Hypokalemic alkalosis is found in 10% to 15% of patients with Cushing's disease but in more than 95% of patients with ectopic ACTH syndrome. Several factors may contribute to this mineralocorticoid excess state, including corticosterone and DOC excess, but the principal culprit is thought to be cortisol itself. Depending on the prevailing cortisol production rate, cortisol swamps HSD11B2 in the kidney and acts as a mineralocorticoid. Hypokalemic alkalosis is more common in ectopic ACTH syndrome because cortisol production rates are higher than in patients with Cushing's disease.¹³⁰ This can be diagnosed by documenting an increase in the ratio of urinary cortisol to cortisone metabolites. In addition, hepatic 5 α -reductase activity is inhibited, resulting in a greater excretion of 5 α -cortisol metabolites.¹⁹⁹

The functions of the pituitary-thyroid axis and the pituitary-gonadal axis are suppressed in patients with Cushing's syndrome because of a direct effect of cortisol on TSH and gonadotropin secretion.^{200,201} Cortisol causes a reversible form of hypogonadotropic hypogonadism but also directly inhibits Leydig cell function. Growth hormone secretion is reduced, possibly mediated through an increase in somatostatinergic tone.

Eye. Ocular effects include raised intraocular pressure²⁰² and exophthalmos²⁰³ (in up to one third of patients in Cushing's original series), the latter occurring because of increased retroorbital fat deposition. Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon,²⁰⁴ except as a complication of diabetes. In our experience, chemosis is a sensitive and underreported feature of Cushing's syndrome.

CLASSIFICATION AND PATHOPHYSIOLOGY OF CUSHING'S SYNDROME

Cushing's syndrome is most readily classified into ACTH-dependent and ACTH-independent causes (Table 15-11).

ACTH-Dependent Causes

Cushing's Disease

When iatrogenic causes are excluded, the most common cause of Cushing's syndrome is Cushing's disease, accounting for approximately 70% of cases. The adrenal glands in these patients show bilateral adrenocortical hyperplasia with widening of the ZF and ZR.¹⁸²

Cushing himself raised the question as to whether this disease was a primary pituitary condition or secondary to an abnormality in the hypothalamus, and there has been

TABLE 15-11

Classification of Causes of Cushing's Syndrome**ACTH-Dependent Causes**

Cushing's disease (pituitary-dependent)
 Ectopic ACTH syndrome
 Ectopic CRH syndrome
 Macronodular adrenal hyperplasia
 Iatrogenic (treatment with 1-24 ACTH)

ACTH-Independent Causes

Adrenal adenoma and carcinoma
 Primary pigmented nodular adrenal hyperplasia and Carney's syndrome.
 McCune-Albright syndrome
 Aberrant receptor expression (gastric inhibitory polypeptide, interleukin-1 β)
 Iatrogenic (e.g., pharmacologic doses of prednisolone, dexamethasone)

Pseudo-Cushing's Syndromes

Alcoholism
 Depression
 Obesity

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone.

an ongoing debate on this issue ever since.²⁰⁵ The hypothalamic theory states that ACTH-secreting adenomas arise because of dysfunctional regulation of corticotrophs through chronic stimulation by CRH (or AVP). Other studies provide data to support a primary pituitary defect as the cause of the condition (Table 15-12).

The hypothalamus may have an initiating role, but the overwhelming evidence is that, at presentation, the condition is pituitary dependent. In 85% to 90% of cases, the disease is caused by a pituitary adenoma of monoclonal origin^{206,207}; basophil hyperplasia alone is found in 9% to 33% of pathologic series.²⁰⁵ The majority of tumors are small microadenomas (<1 cm), but larger macroadenomas occur in up to 10% of cases and usually signify a more

TABLE 15-12

Etiology of Cushing's Disease: Hypothalamic Theory Versus Pituitary Theory

Hypothalamic Theory	Pituitary Theory
Neuroendocrine abnormalities ^{282,283}	Lack of "cure" after pituitary stalk section
Loss of circadian rhythm, sleep disturbance, other "hypothalamic defects" (TSH, LH/FSH secretion)	Circulating and CSF CRH levels are suppressed. ²⁸⁴
Efficacy of centrally acting drugs ^{285,286} (bromocriptine, cyproheptadine, sodium valproate)	Reversal of "hypothalamic defects" on correction of hypercortisolism
Recurrences after pituitary surgery	High surgical cure rate (recurrences resulting from regrowth of inadequately resected tumor rather than "real" recurrence) ^{287,289}
Ectopic CRH-secreting tumors cause Cushing's disease, ²⁸¹ but pathology shows basophil hyperplasia, not adenomas.	Secondary hypoadrenalism after successful pituitary surgery (may be prolonged and associated with reduced ACTH expression in surrounding adjacent normal corticotrophs) ²⁹⁰
	Pituitary ACTH-secreting adenoma in almost 90% of cases are monoclonal in origin. ^{291,292}

invasive tumor.²⁰⁸ Selective surgical removal of a microadenoma results in cure with a very low recurrence rate. However, it is possible, particularly in cases with no identifiable pituitary adenoma, that Cushing's disease is heterogeneous with different subtypes.

A key biochemical hallmark of the disease is a relative resistance of ACTH secretion to normal glucocorticoid feedback inhibition.²⁰⁹ ACTH-secreting pituitary adenomas function at a higher than normal set point for cortisol feedback. The predominant finding in Cushing's disease is an increase in ACTH pulse amplitude with loss of normal circadian rhythm, but ACTH pulse frequency is also increased in some cases (see Fig. 15-8).²¹⁰

Ectopic ACTH Syndrome

In 15% of cases, Cushing's syndrome is associated with nonpituitary tumors secreting ACTH—the ectopic ACTH syndrome.²¹¹⁻²¹⁵ On clinical grounds, these can be divided into two entities: cases occurring in the setting of highly malignant tumors such as small-cell carcinoma of bronchus (Table 15-13) and more indolent cases occurring in patients with underlying neuroendocrine tumors such as bronchial carcinoids. In the former group, the clinical presentation more commonly resembles Addison's disease than Cushing's syndrome. Circulating ACTH concentrations and cortisol secretion rates can be extremely high. As a result, duration of symptoms from onset to presentation is short (<3 months); patients are commonly pigmented, and the metabolic manifestations of glucocorticoid excess are often rapid and progressive. Weight loss, myopathy, and glucose intolerance are prominent symptoms and signs. The association of these features with hypokalemic alkalosis and peripheral edema should alert the clinician to the diagnosis.

Depending on local referral practice, approximately 20% of cases of ectopic ACTH syndrome are explained by indolent tumors, such as benign bronchial carcinoids, that produce ACTH.^{215,216} In these cases, symptoms and signs are commonly present for 18 months before clinical presentation. Such patients present with the typical features of Cushing's syndrome and may be biochemically similar to patients with Cushing's disease. Therefore, once a diagnosis of Cushing's syndrome is established, the principal diagnostic dilemma is in the distinction of pituitary-dependent Cushing's disease from these indolent causes of ectopic ACTH syndrome.^{212,214}

POMC is expressed in some normal extrapituitary tissues and in many tumors (lung, testis) regardless of the presence of Cushing's syndrome, raising the appropriateness of the

designation “ectopic” ACTH syndrome.²¹⁷ Tumors most commonly associated with ectopic ACTH syndrome arise from neuroendocrine tissues, the cells of which possess the ability to uptake and decarboxylate amine precursors (APUD cells). However, only 0.5% to 1% of tumors in small-cell lung cancer are associated with ectopic ACTH syndrome, and the explanation for the development of ectopic ACTH secretion remains unclear. POMC mRNA transcripts are usually shorter in tumors not associated with ectopic ACTH syndrome, whereas those with the syndrome express larger POMC mRNA species as well as the “pituitary-size” transcript. In addition to aberrant transcriptional regulation of the POMC gene, interaction with tissue-specific transcription factors or methylation status of the POMC gene may be involved. Once secreted, POMC is cleaved in the pituitary by specific serine endoproteases to produce ACTH precursors; in ectopic ACTH syndrome, aberrant peripheral processing of POMC may lead to increased concentrations of circulating ACTH precursors (pro-ACTH, N-POC) (see Fig. 15-6). In contrast to ACTH secretion from pituitary adenomas, ectopic POMC/ACTH production is not responsive to normal glucocorticoid feedback²¹⁷ because of the defective GR or GR-signaling mechanism.²¹⁸ However, this sensitivity to glucocorticoid feedback is far from clearcut, which is one reason why the differential diagnosis of ACTH-dependent Cushing’s syndrome can be challenging.²¹²

Ectopic Corticotropin-Releasing Hormone Syndrome

Ectopic production of CRH is a very rare cause of pituitary-dependent Cushing’s. A number of cases have now been described in which a tumor (usually bronchial carcinoid, medullary thyroid, or prostate carcinoma) has been shown to secrete CRH alone or in combination with ACTH.^{215,219-221} Where available, pituitary histology has revealed corticotroph hyperplasia but not adenoma formation. Biochemically, these patients, like those with ectopic ACTH syndrome, lose the normal negative glucocorticoid feedback mechanism—50% have resistance to high-dose dexamethasone therapy. Ectopic CRH production may explain the suppression of cortisol secretion after high-dose dexamethasone that is observed in some patients with the “ectopic” ACTH syndrome.

Macronodular Adrenal Hyperplasia

In 10% to 40% of patients with Cushing’s disease, there is bilateral adrenocortical hyperplasia associated with one or more nodules, which may be up to several centimeters in diameter.²²²⁻²²⁵ Patients tend to be older and to have had symptoms for a longer time, but they otherwise present with the classic clinical features of Cushing’s syndrome. Pathologically, the nodules are lobulated and can be markedly enlarged, but internodular hyperplasia is invariably found. Macronodular adrenal hyperplasia (MAH) is thought to result from long-standing adrenal ACTH stimulation, which leads to autonomous adrenal adenoma formation. Therefore, as the adrenals in a patient with Cushing’s disease become more hyperplastic, they secrete more cortisol for a given ACTH level, which ultimately can lead to autosuppression. Individual clinical cases support this hypothesis, and MAH should be regarded as an ACTH-dependent form of Cushing’s syndrome, even though ACTH levels may be relatively low and dexamethasone suppressibility less marked than in other cases of Cushing’s disease.²²⁶ The adenomas can be a trap for the unwary because they may be mistaken for primary adrenal tumors.

ACTH-Independent Causes

Cortisol-Secreting Adrenal Adenoma and Carcinoma

Excluding iatrogenic cases, adrenal adenomas are responsible for about 10% to 15% of Cushing’s syndrome cases, and carcinomas for less than 5%. By contrast, 65% of cases of Cushing’s syndrome in children have an adrenal etiology (15% adenomas, 50% carcinomas).²²⁴⁻²²⁶ Onset of clinical features is gradual in patients with adenomas, but it is often rapid in adrenal carcinoma. In addition to the features of hypercortisolism, patients may complain of loin or abdominal pain, and a tumor may be palpable. The tumor may secrete other steroids, such as androgens or mineralocorticoids. Therefore, in females, there may be features of virilization, with hirsutism, clitoromegaly, breast atrophy, deepening of the voice, temporal recession, and severe acne. In “pure” cortisol-secreting adenomas, hirsutism is uncommon. Subclinical Cushing’s syndrome has been reported in up to 10% of patients with adrenal “incidentalomas” (see later discussion).

Primary Pigmented Nodular Adrenal Hyperplasia and Carney’s Syndrome

About 100 cases of ACTH-independent Cushing’s syndrome have been reported in association with bilateral, small, pigmented adrenal nodules. Pathologically, these nodules are usually 2 to 4 mm in diameter (although they can be larger) and black or brown on cut section. Adjacent adrenal tissue is atrophic, distinguishing this primary pigmented nodular adrenal hyperplasia (PPNAD) from MAH. Presentation is with typical features of Cushing’s syndrome in persons younger than 30 years of age and, in 50% of cases, in persons younger than 15 years of age.²²⁷ Cases of PPNAD have been reported without Cushing’s syndrome. Bilateral adrenalectomy is curative.

A familial autosomal dominant variant, called *Carney’s complex* (Table 15-14), comprises mesenchymal tumors (especially atrial myxomas), spotty skin pigmentation, peripheral nerve tumors, and various other tumors including breast lesions, testicular tumors, and GH-secreting pituitary tumors.²²⁸ Mutations of the gene encoding the protein kinase A (PKA) regulatory subunit type 1A (*PRKAR1A*) lead

to abnormal PKA signaling and explain the phenotype in some cases.²²⁹ Other cases have been mapped to chromosome 2p16, but the underlying genetic mutation is unknown.

McCune-Albright Syndrome

In McCune-Albright syndrome, fibrous dysplasia and cutaneous pigmentation may be associated with pituitary, thyroid, adrenal, and gonadal hyperfunction. The most common manifestation is with sexual precocity and GH excess, but Cushing's syndrome has been reported.²³⁰ The underlying abnormality is a somatic mutation in the α -subunit of the stimulatory G protein, which is linked to adenyl cyclase. The mutation results in constitutive activation of the G protein, mimicking constant ACTH stimulation at the level of the adrenal. ACTH levels are suppressed, and adrenal adenomas may occur.

Macronodular Hyperplasia and Aberrant Receptor Expression

Although MAH commonly occurs in patients with ACTH-dependent Cushing's syndrome, truly ACTH-independent macronodular hyperplasia (AIMAH) is also recognized as a distinct entity.²³¹ The nodules are nonpigmented and greater than 5 mm in diameter; occasionally, the adrenals are massively enlarged. Most cases are explained on the basis of aberrant receptor expression within the adrenal cortex.²³² Food-induced hypercortisolism due to enhanced adrenal responsiveness to gastric inhibitory polypeptide (GIP) was the first cause of AIMAH described, due to expression of GIP receptors within the adrenal cortex, but aberrant expression of the vasopressin V_1 , β -adrenergic, LH, serotonin, and angiotensin (AT_1) receptors have also been linked to AIMAH. Protocols have been suggested for the further investigation of AIMAH.²³²

Iatrogenic Cushing's Syndrome

The basis for iatrogenic Cushing's syndrome was discussed earlier. Development of the features of Cushing's syndrome depends on the dose, duration, and potency of the corticosteroids used in clinical practice. ACTH is rarely prescribed, but it will also result in cushingoid features if administered long-term. Some features, such as an increase in intraocular pressure, cataracts, benign intracranial hypertension, aseptic necrosis of the femoral head, osteoporosis, and pancreatitis, are more common in iatrogenic than endogenous Cushing's syndrome, whereas other features, notably hypertension, hirsutism, and oligomenorrhea/amenorrhea, are less prevalent.

Special Features of Cushing's Syndrome

Cyclic Cushing's Syndrome

Of particular clinical interest has been a group of patients with cyclic Cushing's syndrome, characterized by periods of excess cortisol production interspersed with intervals of normal cortisol production (Fig. 15-18). Some of these patients demonstrate a paradoxical rise in plasma ACTH and cortisol when treated with dexamethasone, and occasionally a patient is benefited by dopamine agonist (bromocriptine) or serotonin antagonist (cyproheptadine) therapy. Most patients have been thought to have pituitary-dependent disease, and in many of these patients, basophil adenomas have been removed, with long-term cure in some cases. However, cortisol secretion may show some evidence of cyclicity in patients with an ectopic source of ACTH.^{233,234}

Figure 15-18 Patterns of cortisol secretion in three patients with cyclic Cushing's syndrome. In each case, the ratio of early-morning urinary cortisol (in nanomoles per liter) to creatinine (in millimoles per liter) are plotted against time. Variable periodicity in cortisol hypersecretion is shown. (From Atkinson AB, McCance DR, Kennedy L, et al. Cyclic Cushing's syndrome first diagnosed after pituitary surgery: a trap for the unwary. *Clin Endocrinol.* 1992;36:297-299.)

Children

Cushing's syndrome can occur at any age, but the causes differ across age groups (Fig. 15-19). In children, adrenal causes account for 65% of all cases, and in addition to the previously mentioned features, growth arrest is almost invariable.²³⁵ The dissociation between height and weight is obvious, with the height most commonly below the mean, whereas the body mass index (BMI) is almost always above the mean. If the height and weight are increasing along the same percentile line, then the diagnosis of Cushing's syndrome is highly unlikely. Obesity in childhood Cushing's tends to be generalized. Most patients have a delayed bone age that is negatively correlated with height standard deviation score (SDS), duration of symptoms, and age at diagnosis. The observed growth failure often precedes other manifestations such as weight gain, pubertal arrest, fatigue, depression, hypertension, and acne. Pubertal development can be advanced in patients with virilizing

Figure 15-19 Etiology and age-dependency of pediatric Cushing's syndrome. (From Storr HL, Chan LF, Grossman AB, et al. Paediatric Cushing's syndrome: epidemiology, investigation and therapeutic advances. *Trends Endocrinol Metab.* 2007;18:167-174.)

tumors causing precocious pseudopuberty. However, in patients with true puberty, glucocorticoid-mediated suppression of gonadotropins may occur.²³⁶

Glucocorticoid excess influences not only the hypothalamic-pituitary-gonadal axis but also the GH-IGF1 axis, leading to both reduction of spontaneous GH secretion and pharmacologic GH response. Furthermore, direct effects of glucocorticoids on epiphyseal chondrocytes, probably together with disturbance of microvascularization of the growth plate, result in a negative effect on growth. Poor catch-up has been reported in children after cure of Cushing's disease, and evidence exists for GH inhibition by hypercortisolemia for 1 to 2 years after cure of Cushing's disease. GH secretion should be assessed 3 months after treatment. If GH deficiency is demonstrated, GH in a replacement dose of 25 µg/kg per day should be given. Catch-up growth is observed in most patients and target adult height is achieved. However, many patients remain obese.

Pregnancy

Pregnancy is rare in women with Cushing's syndrome because of associated amenorrhea due to androgen excess or hypercortisolism. However, pregnancy has been reported in approximately 100 such women, 50% of whom had adrenal adenomas.²³⁷ A few cases of true pregnancy-induced Cushing's syndrome have been described, with regression after delivery.²³⁸ In these cases, the etiology is unknown. Establishing a diagnosis and a cause can be difficult. Clinically, striae, hypertension, and gestational diabetes are common features in normal pregnancies, yet hypertension and diabetes are also the most common signs of Cushing's syndrome in a pregnant woman (70% and 30%, of all cases, respectively). Furthermore, biochemically normal pregnancy is associated with a threefold increase in plasma cortisol due to increased production of cortisol and cortisol-binding globulin. Urinary free cortisol also rises, and dexamethasone does not suppress plasma cortisol to the same degree as the nonpregnant state. Left untreated, the condition is associated with high maternal and fetal morbidity and mortality. Any adrenal or pituitary adenomas should be excised. Metirapone, which is not teratogenic, has been effective in many cases in controlling the hypercortisolism.

Pseudo-Cushing's Syndromes

A pseudo-Cushing's state can be defined as the presence of some or all of the clinical features of Cushing's syndrome together with some evidence for hypercortisolism. Resolution of the underlying cause results in disappearance of the cushingoid state. Several causes are described.

Alcohol

In the original description of alcohol-related pseudo-Cushing's syndrome, urinary and plasma cortisol levels were elevated and failed to suppress with dexamethasone. Plasma ACTH has been found to be normal or suppressed. The condition is rare but should be suspected in a patient with an ongoing history of heavy alcohol intake and biochemical or clinical evidence of chronic liver disease.²³⁹ The pathogenesis of this condition remains unknown, but a two-hit hypothesis has been put forward. Chronic liver disease of any cause is associated with impaired cortisol metabolism, but in alcoholic patients there is an increased cortisol secretion rate, rather than concomitant suppression in the face of impaired metabolism.²⁴⁰ In some studies, alcohol has directly stimulated cortisol secretion; alternatively, AVP levels are elevated in patients with decompensated liver disease and may stimulate the HPA axis. With abstinence from alcohol, the biochemical abnormalities rapidly revert to normal.

Depression

Although the cause is unknown, it is recognized that patients with depression may exhibit the hormonal abnormalities of patients with Cushing's syndrome.²⁴¹ These abnormalities are reversible on correction of the psychiatric condition. Conversely, patients with Cushing's syndrome are frequently depressed, and a careful clinical and endocrinologic assessment is required.

Obesity

Although one of the most common referrals to a clinical endocrinologist is for exclusion of an underlying endocrine cause in a patient with obesity, the diagnosis of Cushing's syndrome in such patients should not cause difficulties. Patients with obesity have mildly increased cortisol secretion rates, and the data suggest that this is due to activation of the HPA axis.^{242,243} However, circulating cortisol concentrations are invariably normal, and urinary free cortisol concentrations are either normal or only slightly elevated. The stimulus for the increased secretion of cortisol appears to be increased peripheral metabolism and clearance of cortisol—principally, reduced hepatic conversion of cortisone to cortisol by HSD11B1 and increased conversion of cortisol to 5α-reduced derivatives.²⁴³

Investigation of Patients with Suspected Cushing's Syndrome

There are two stages in the investigation of suspected Cushing's syndrome: (1) Does this patient have Cushing's syndrome? and (2) If the answer is "Yes," what is the cause? Unfortunately, many investigators fail to make this distinction and ill-advisedly use tests that are relevant to the second question in trying to answer the first question. In particular, it is essential that radiologic investigations not be undertaken until Cushing's syndrome has been confirmed biochemically. The major tests are listed in Table 15-15.^{182,241,244,245}

Question 1: "Does This Patient Have Cushing's Syndrome?"

Circadian Rhythm of Plasma Cortisol. In normal subjects, plasma cortisol levels are at their highest early in the morning and reach a nadir (<50 nmol/L [<2 μ g/dL] in a nonstressed subject) at about midnight.²⁴⁶ This circadian rhythm is lost in patients with Cushing's syndrome; in the majority, the 9 a.m. plasma cortisol is normal but nocturnal levels are raised. Random morning plasma cortisol levels are therefore of little value in making the diagnosis, whereas a midnight cortisol level greater than 200 nmol/L (>7.5 μ g/dL) indicates Cushing's syndrome. However, various factors such as stress of venipuncture, intercurrent illness, and admission to hospital may lead to false-positive results. Ideally, patients should be hospitalized for 24 to 48 hours before the midnight cortisol level is measured, but some centers have reported discriminant results for midnight levels measured in outpatients.

Very few laboratories have developed methods for the measurement of free serum cortisol.²⁴⁷ Because more than 90% of serum cortisol is protein bound, the results of the conventional assay are affected by drugs and by conditions that alter CBG levels. Estrogen therapy or pregnancy may elevate CBG and total serum cortisol. Loss of circadian rhythm is a sensitive diagnostic test, but for the reasons stated it is not a widely used screening test.

Salivary Cortisol. CBG is absent from saliva, and the use of salivary cortisol measurements offers a sensible alternative in that it does not require hospitalization. The diagnostic accuracy of a single midnight salivary cortisol level has been established in several studies: a cortisol value greater than 2.0 ng/mL (5.5 nmol/L) has a 100% sensitivity and a 96% specificity for diagnosis of Cushing's syndrome.^{244,248,249}

Urinary Free Cortisol Excretion. For many years, the diagnosis of Cushing's syndrome was based on the measurement of urinary metabolites of cortisol (24-hour urinary 17-hydroxycorticosteroid or 17-oxogenic steroid excretion, depending on the method used). However, the sensitivity and specificity of these methods is poor, and most centers have replaced these assays with the more

sensitive measurement of urinary free cortisol. This is an integrated measure of plasma free cortisol: as cortisol secretion increases, the binding capacity of CBG is exceeded, resulting in a disproportionate rise in urinary free cortisol. Normal values are less than 220 to 330 nmol/24 hours (80 to 120 μ g/24 hours), depending on the assay used. Patients should make two or three complete consecutive collections to account for patient error in collecting samples and for episodic cortisol secretion, notably from adrenal adenomas. Simultaneous creatinine excretion (which differs by no more than 10% from day to day) may be used to ensure adequacy of collection. Urinary free cortisol is a useful screening test, although it is accepted that the value can be normal in up to 8% to 15% of patients with Cushing's syndrome.^{244,245,250} Conversely, moderately elevated results should always be verified by further testing before a diagnosis of Cushing's syndrome is made.

Measurement of the cortisol-to-creatinine ratio in the first urine specimen passed on waking obviates the need for a timed collection and has been used as a screening test, particularly when cyclic Cushing's syndrome is suspected.²⁵¹ Urine aliquots may be sent to the local endocrinology laboratory, with cortisol-to-creatinine ratios greater than 25 nmol/mmol on repeated measurement being indicative of hypercortisolism.

Low-Dose Overnight Dexamethasone Suppression Tests. In normal subjects, the administration of a supra-physiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing's syndrome of whatever cause, there is a failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given.²⁰⁹

The overnight test is a useful outpatient screening test.^{241,244,252} Various doses of dexamethasone have been used, but usually 1 mg of dexamethasone is given at midnight. A normal response is a plasma cortisol level of less than 140 nmol/L (<5 μ g/dL) between 8 and 9 a.m. the following morning. A dose of 1.5 or 2 mg gives a 30% false-positive rate, but after a dose of 1 mg this rate is only 12.5%, with a false-negative rate of less than 2%. In addition, sensitivity can be improved by reducing the plasma cortisol cut-off value: a postdexamethasone cortisol value of less than 50 nmol/L (<2 μ g/dL) effectively excludes Cushing's syndrome. Therefore, the outpatient overnight test has high sensitivity (95%) but low specificity, and further investigation is often required.^{253,254}

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 a.m. on day 0 and again 48 hours later, after administration of dexamethasone 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (<2 μ g/dL) as the cutoff point, this test is reported to have a 97% to 100% true-positive rate and a false-positive rate of less than 1%.^{241,253} Sensitivity is higher if plasma rather than urinary cortisol is measured.

Certain drugs (e.g., phenytoin, rifampicin) may increase the metabolic clearance rate of dexamethasone, leading to false-positive results. Simultaneous measurement of plasma dexamethasone may be useful in such cases and will also detect whether patients failed to take the drug.²⁵⁴

Pseudo-Cushing's or True Cushing's Syndrome? In patients with depression, urinary free cortisol concentrations may be elevated and may overlap with those seen in patients with true Cushing's syndrome. Compared with patients with Cushing's disease, depressed patients have

greater suppressibility after dexamethasone and reduced response to CRH, but neither of these tests is diagnostic.^{241,255} However, use of a CRH test after the standard 2-day low-dose dexamethasone suppression test has been reported to separate true from pseudo-Cushing's syndrome. In normal subjects and in patients with endogenous depression, insulin-induced hypoglycemia results in a rise in ACTH and cortisol levels, a response that usually is not seen in patients with Cushing's syndrome. Finally, loperamide lowers cortisol values in patients with pseudo-Cushing's but not in those with true Cushing's syndrome.²⁴¹

Clinical Guidelines. The Endocrine Society, in collaboration with the European Society for Endocrinology, has issued evidence-based guidelines for the diagnosis of Cushing's syndrome.²⁵⁶ Recommendations are to proceed initially with one of four highly sensitive screening tests: urinary free cortisol, late-night salivary cortisol, long overnight dexamethasone, or the 2-mg/48-hour dexamethasone screening test. Abnormality detected by any of these tests in a patient with clinically suspected Cushing's syndrome should be confirmed with one of the additional tests; if both test results are abnormal, patients should then undergo testing for the cause of the Cushing's syndrome (Fig. 15-20).

Question 2: "What Is the Cause of Cushing's Syndrome in This Patient?"

Having confirmed Cushing's syndrome clinically and biochemically, the clinician's next step is to determine the cause (Fig. 15-21).

Morning Plasma ACTH. Ideally, ACTH should be measured with the use of a modern, two-site immunoradiometric assay. Such a test differentiates ACTH-dependent from ACTH-independent causes. In Cushing's disease, 50% of patients have a 9 a.m. ACTH level within the normal reference range (2 to 11 pmol/L [9 to 52 pg/mL]); in the remainder, it is modestly elevated. ACTH levels in the ectopic ACTH syndrome are high (usually >20 pmol/L [>90 pg/mL]); nevertheless, overlap values are seen in Cushing's disease in 30% of cases.²⁵⁷ Therefore, this test cannot be used to differentiate the two conditions (Fig. 15-22). The most discriminatory time of day to measure ACTH is between 11 p.m. and 1 a.m., when ACTH/cortisol secretion is at a nadir; in our practice, ACTH is usually measured alongside cortisol in circadian rhythm studies. A midnight ACTH result greater than 5 pmol/L (>22 pg/mL) in a patient with biochemical hypercortisolism confirms that the underlying disease is ACTH dependent. The measurement of ACTH precursors (pro-ACTH, POMC) is not routinely available but may be more useful in detecting an ectopic source of ACTH; more data are required regarding "occult" tumors as a cause of the syndrome.

In patients with adrenal tumors, plasma ACTH is invariably undetectable (<1 pmol/L). This can also occur with degradation of ACTH; as a result, nonhemolyzed blood samples should be placed in ice and immediately separated.

The presence of plasma ACTH levels that are low-normal or intermittently detectable, which may occur in MAH, is problematic. The danger is that in some patients the asymmetry of the nodular hyperplasia may lead to a diagnosis of adrenal adenoma, the plasma ACTH is ignored, and an inappropriate adrenalectomy is performed. Conversely, in some patients with this syndrome, an autonomous adrenal

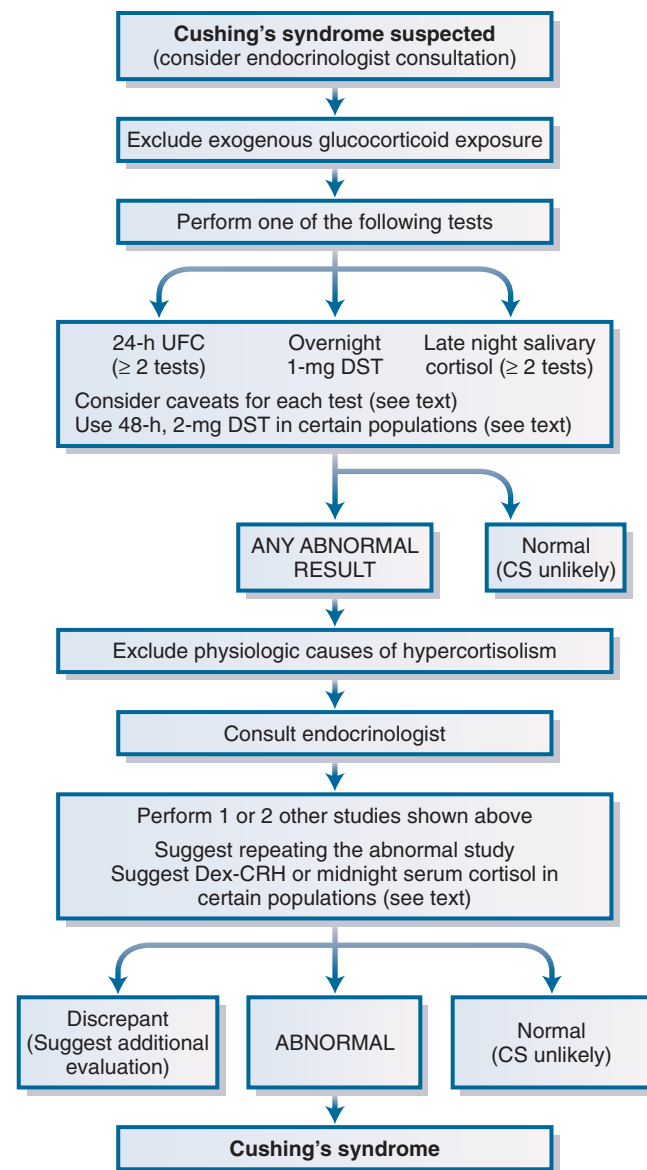

Figure 15-20 Algorithm for testing patients with suspected Cushing's syndrome (CS) according to the 2008 Endocrine Society clinical practice guideline. All statements are recommendations except for those prefaced by the word "Suggest." Diagnostic criteria that point to Cushing's syndrome are a urinary free cortisol (UFC) value greater than the normal range for the assay, a serum cortisol level greater than 1.8 µg/dL (>50 nmol/L) after administration of 1 mg dexamethasone (1-mg DST), and a late-night salivary cortisol concentration greater than 145 ng/dL (>4 nmol/L). CRH, corticotropin-releasing hormone; Dex, dexamethasone; DST, dexamethasone suppression test. (From Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab*. 2008;93:1526-1540.)

tumor develops and unilateral adrenalectomy is required despite the detectable ACTH.

Plasma Potassium. Hypokalemic alkalosis is present in more than 95% of patients with the ectopic ACTH syndrome but in fewer than 10% of those with Cushing's disease. The etiology of this mineralocorticoid excess state is now established. Patients with the ectopic syndrome usually have higher rates of cortisol secretion. Cortisol saturates the renal-protective HSD11B2 enzyme, resulting in cortisol-induced mineralocorticoid hypertension (see

Figure 15-21 The tests to uncover the cause of Cushing's syndrome are debatable and differ in any given center depending on many factors, including familiarity and turnaround time of hormone assays and local expertise in techniques such as inferior petrosal sinus sampling. Depicted here is an algorithm in use within many endocrine units based on the reported sensitivity and specificity of each endocrine test. ACTH, adrenocorticotropin; CT, computed tomography; MRI, magnetic resonance imaging.

Chapter 16).¹³⁰ In addition, these patients have higher levels of the ACTH-dependent mineralocorticoid, DOC.

High-Dose Dexamethasone Suppression Test. The rationale for the high-dose dexamethasone suppression test is that in Cushing's disease the negative feedback control of ACTH is reset to a higher level than normal. Therefore, cortisol levels do not suppress with low-dose dexamethasone but do so after high doses. The original test introduced by Liddle was based on giving 2 mg dexamethasone every 6 hours for 48 hours and demonstrating a fall of greater than 50% in urinary 17-hydroxycorticosteroids.²⁰⁹ In the modern test, the plasma or urinary free cortisol (or both) is measured at 0 and +48 hours, and a greater than 50% suppression of plasma cortisol from the basal value has been used to define a positive response. In all cases, the response is graded and is dependent on the original cortisol secretion rate: greater suppression is often observed in patients with lower basal cortisol values. About 90% of patients with Cushing's disease have a positive 48-hour test, compared with 10% of those with the ectopic ACTH syndrome. The robustness of the test can be improved by

altering the cortisol cutoff value; the test has 100% specificity for diagnosing pituitary disease if more than 90% suppression in urinary free cortisol is used. Less commonly, 8 mg dexamethasone is given orally at 11 p.m., with plasma cortisol measured at 8 a.m. on the same day (basal sample) and at 8 a.m. on the following morning.²⁵⁸ A further variation on this test is the timed (5- to 7-hour) infusion of dexamethasone (1 mg/hour).²⁵⁹

Up to 50% of patients with ectopic ACTH syndrome due to indolent bronchial carcinoid tumors exhibit some suppression after high-dose dexamethasone. Conversely, some patients with Cushing's disease, usually those with large, invasive ACTH-secreting pituitary macroadenomas, show no suppression after high-dose dexamethasone.²⁶⁰

Metyrapone Test. Metyrapone blocks the conversion of 11-deoxycortisol to cortisol, and DOC to corticosterone, by inhibiting 11 β -hydroxylase (see Fig. 15-4). This lowers the plasma cortisol concentration and, via negative feedback control, increases plasma ACTH. This in turn stimulates increased secretion of adrenal steroids proximal to the block. Metyrapone is given in doses of 750 mg every 4

Figure 15-22 Plasma adrenocorticotrophic hormone (ACTH) concentrations in patients with Cushing's disease, Cushing's syndrome associated with adrenocortical tumors, or the ectopic ACTH syndrome. To convert values to picomoles per liter, multiply by 0.2202. (From Besser GM, Edwards CRW. Cushing's syndrome. *Clin Endocrinol Metab*. 1972;1:451-490.)

hours for 24 hours, and patients with Cushing's disease exhibit an exaggerated rise in plasma ACTH, with 11-deoxycortisol levels at 24 hours exceeding 1000 nmol/L (35 µg/dL). In most patients with the ectopic ACTH syndrome there is little or no response, but occasionally patients (possibly those producing both ACTH and CRH) have an 11-deoxycortisol response that is similar to that observed in Cushing's disease.²⁶¹

The metyrapone test was originally used to differentiate patients with Cushing's disease from those with a primary adrenal cause. However, these conditions can be more reliably distinguished by measurement of plasma ACTH followed by computed tomography (CT) scanning of the adrenals. As indicated, the test does not reliably distinguish between Cushing's disease and the ectopic ACTH syndrome, and its value in modern endocrine practice has been questioned. It should be reserved for patients in whom the results of other tests are equivocal.

Corticotropin-Releasing Hormone Test. CRH is a 41-amino-acid peptide that was identified by Vale in 1981 from ovine hypothalami. The ovine sequence differs by seven amino acid residues from that of the human hormone but is slightly more effective in stimulating the release of ACTH in humans.²⁶² The test involves the intravenous injection of either ovine or human CRH in a dose of 1 µg/kg body weight or a single dose of 100 µg (Fig. 15-23). In some centers, CRH is combined with AVP, which results in

an augmented ACTH response. The test can be performed in the morning or afternoon. After basal sampling, CRH is administered and blood samples for ACTH and cortisol are then taken every 15 minutes for 1 to 2 hours.^{251,253,263,264}

In normal subjects, CRH produces a rise in ACTH and cortisol of 15% to 20%. This response is exaggerated in Cushing's disease, in which typically an ACTH increase greater than 50% and a cortisol rise greater than 20% over baseline values are seen. No response is seen in the ectopic ACTH syndrome, but false-positive results have been reported. In distinguishing pituitary-dependent Cushing's from the ectopic ACTH syndrome, the response of ACTH and cortisol to CRH has a specificity and a sensitivity of approximately 90%. However, a positive response defined as an ACTH increase of 100% or a cortisol rise of 50% over baseline values effectively eliminates a diagnosis of ectopic ACTH syndrome, which is the real benefit of this test. Up to 10% of patients with Cushing's disease do not respond to CRH.

Inferior Petrosal Sinus Sampling and Selective Venous Catheterization. The most robust test to distinguish Cushing's disease from the ectopic ACTH syndrome is inferior petrosal sinus sampling (IPSS).^{182,214} As blood from each half of the pituitary drains into the ipsilateral inferior petrosal sinus, catheterization and venous sampling of both sinuses simultaneously can distinguish a pituitary from an ectopic source of ACTH (Fig. 15-24).^{260,265} In virtually all patients with the ectopic ACTH syndrome, the ratio of the ACTH concentration in the inferior petrosal sinus and that in simultaneously drawn peripheral venous blood is less than 1.4:1. In contrast, the ratio is elevated to greater than 2.0 in Cushing's disease. However, because of the problem of intermittent ACTH secretion, it is useful to take measurements before and at intervals (e.g., 2, 5, and 15 minutes), after intravenous injection of 100 µg synthetic ovine CRH.^{266,267} Using this approach, an ACTH petrosal sinus/peripheral ratio greater than 3.0 after CRH administration has a sensitivity of 97% and specificity of 100% for diagnosing Cushing's disease.²⁶⁷

IPSS may also be of value in lateralizing a pituitary tumor in a patient in whom imaging techniques have failed to demonstrate a microadenoma; however, some centers have found this procedure to be of little value in predicting tumor location. Coadministration of desmopressin with CRH may help in localizing the tumor. However, because many tumors are central and drain into both sinuses, current evidence suggests that it is unwise to base the surgical procedure on the results of IPSS studies alone.

IPSS is technically demanding; it has been associated with complications (referred aural pain, thrombosis) and should be performed only in an experienced tertiary referral center. In our practice, we adopt a clinical diagnostic algorithm (see Fig. 15-21) and use IPSS if the differential diagnosis remains in doubt (i.e., lack of adequate suppression after high-dose dexamethasone or CRH response or identified lesion on pituitary MRI scanning).

Rarely, selective catheterization of vascular beds may be required to identify the source of ectopic ACTH secretion (e.g., from a small pulmonary carcinoid or thymic tumor). Tumors causing ectopic ACTH syndrome may also produce peptide hormones other than ACTH or its precursors.

Imaging

CT/MRI Scanning of Pituitary and Adrenals. High-resolution, thin-section, contrast-enhanced CT or MRI imaging has revolutionized the investigation of Cushing's

Figure 15-23 Comparison of cortisol and adrenocorticotrophic hormone (ACTH) responses to an intravenous injection of ovine corticotropin-releasing hormone (1 µg/kg) in normal subjects, patients with Cushing's disease, and patients with the ectopic ACTH syndrome. (From Chrousos GP, Schulte HM, Oldfield EH, et al. The corticotropin-releasing factor stimulation test: an aid in the evaluation of patients with Cushing's syndrome. *N Engl J Med.* 1984;310:622-626.)

syndrome.^{260,265} However, it is essential that the results of any imaging technique be interpreted alongside the biochemical results if mistakes are to be avoided. When the adrenals are imaged, asymmetric nodular hyperplasia may lead to a false diagnosis of adrenal adenoma. In the presence of so-called pituitary incidentalomas,²⁶⁸ pituitary CT/MRI scanning may produce false-positive results, particularly for lesions smaller than 5 mm in diameter.

Pituitary MRI is the investigation of choice once the biochemical tests have suggested Cushing's disease, with a sensitivity of 70% and specificity of 87%. About 90% of ACTH-secreting pituitary tumors are microadenomas (i.e., <10 mm in diameter). The classic features of a pituitary microadenoma are a hypodense lesion after contrast enhancement, associated with deviation of the pituitary stalk, and a convex upper surface of the pituitary gland (Fig. 15-25). With such small tumors, it is not surprising that the sensitivity and specificity of CT scanning are relatively low (20% to 60%).

For adrenal imaging, CT offers better spatial resolution²⁶⁹ (Fig. 15-26) and is the investigation of choice, but MRI may provide diagnostic information in patients with suspected adrenal carcinoma. Once again, so-called adrenal incidentalomas are present in up to 5% of normal subjects,

Figure 15-25 **A**, Magnetic resonance imaging (MRI) scan of pituitary demonstrates the typical appearance of a pituitary microadenoma. A hypodense lesion is seen in the right side of the gland (arrow), with deviation of the pituitary stalk away from the lesion. After a biochemical diagnosis of Cushing's disease, this patient was cured by transsphenoidal hypophysectomy. **B**, MRI scan of the pituitary gland demonstrates a large macroadenoma (arrow) in a patient with Cushing's disease. In contrast to smaller tumors, large macroadenomas are invariably invasive and recur after surgery.

so adrenal imaging should not be performed unless biochemical investigation has suggested a primary adrenal cause (i.e., undetectable ACTH concentrations). Adrenal carcinomas are large and are often associated with metastatic spread at presentation (Fig. 15-27).

In patients with occult ectopic ACTH syndrome, high-definition CT/MRI scanning of thorax, abdomen, and pelvis with images obtained every 0.5 cm may be required to detect small ACTH-secreting carcinoid tumors (Fig. 15-28).

Figure 15-26 **A**, Adrenal computed tomographic (CT) scan demonstrates bilateral adrenal hyperplasia in a patient with Cushing's disease. **B**, CT scan of a typical solitary left adrenal adenoma causing Cushing's syndrome. **C**, Cushing's syndrome caused by massive macronodular hyperplasia. Adrenal glands are replaced by multiple nodules (arrows). The combined weight of the adrenal glands was more than 100 g. **D**, Cushing's syndrome caused by surgically proven primary pigmented nodular adrenal disease in a 21-year-old patient. Figure 15-27 Computed tomographic scan of a patient with rapidly progressing Cushing's syndrome caused by an adrenal carcinoma. An irregular right adrenal mass is shown in **A**, and a large liver metastasis in **B**.

Scintigraphy Studies. Scintigraphy is of value in certain patients with primary adrenal pathology. The most commonly used agent is iodine 131-labeled 6 β -iodomethyl-19-norcholesterol,²⁷⁰ a marker of adrenocortical cholesterol uptake. In patients with adrenal adenomas, the isotope is taken up by the adenoma but not by the contralateral suppressed adrenal. Adrenal scintigraphy is useful in patients with suspected adrenocortical macronodular hyperplasia;

CT scanning may misleadingly suggest unilateral pathology, whereas isotope scanning identifies the bilateral adrenal involvement.

Many neuroendocrine tumors giving rise to the ectopic ACTH syndrome express somatostatin receptors and can be imaged by administering radiolabeled analogues of somatostatin (most commonly indium 111-labeled octreotide). This technique can detect tumors only a few millimeters

in diameter and should be considered for patients with ACTH-dependent Cushing's syndrome in whom pituitary disease has been excluded.²⁷¹

Treatment of Cushing's Syndrome

Adrenal Causes

Unilateral adrenal adenomas should be removed by adrenalectomy; the cure rate is 100%.²⁷² With the increasing experience of laparoscopic adrenalectomy in most tertiary centers, this has now become the surgical treatment of choice for unilateral tumors, offering reduced surgical morbidity and postoperative hospital stay compared with traditional open approaches.²⁷³ After the operation, it may take many months or even years for the contralateral suppressed adrenal to recover. It is wise, therefore, to give slightly suboptimal replacement therapy: dexamethasone 0.5 mg in the morning, with intermittent measurement of the morning plasma cortisol concentration before dexamethasone is taken. If the morning plasma cortisol is higher than 180 nmol/L (6.5 µg/dL), dexamethasone can be stopped. A subsequent insulin tolerance test may then demonstrate whether the response to stress is normal. In the interim, all patients should carry a steroid alert card and increase their dose of replacement therapy in the event of an intercurrent illness.

Adrenal carcinomas have had a very poor prognosis, and most patients have died within 2 years of diagnosis.²⁷⁴ It is usual practice to try to remove the primary tumor, even though metastases may be present, so as to enhance the response to the adrenolytic agent *o,p'*-DDD²⁷⁵ (mitotane). Radiotherapy to the tumor bed and to some metastases, such as those in the spine, may be of limited value. However, in recent years significant progress has been made by implementing collaborative multicenter studies. Phase III trials of mitotane therapy achieving therapeutic plasma mitotane levels have shown significant benefit²⁷⁶; drug combinations include etoposide, doxorubicine, and cisplatin plus mitotane or streptozotocin plus mitotane. Several targeted therapies, including IGF1 inhibitors, sunitinib, and sorafenib, may be of value in cases of "mitotane failure." The 10-year survival rate for patients with T1 N0 M0 disease is about 80% but is significantly impaired with increased tumor mass, positive lymph nodes, and distant metastases, reaching less than 20% for patients with T1-4 N0-1 M1.²⁷⁷

Pituitary-Dependent Cushing's Syndrome

The treatment of Cushing's disease has been significantly enhanced with transsphenoidal surgery conducted by an experienced surgeon.²⁷⁸ Before the capability of selective removal of a pituitary microadenoma was developed, the treatment of choice was bilateral adrenalectomy. This had an appreciable mortality even in the best centers (up to 4%) and significant morbidity. The major risk was the subsequent development of Nelson's syndrome (postadrenalectomy hyperpigmentation with a locally aggressive pituitary tumor) (Fig. 15-29), which was attributed to loss of any negative feedback after adrenalectomy.²⁷⁹ In an attempt to avoid this complication, pituitary irradiation was often carried out at the time of bilateral adrenalectomy.²⁸⁰ In addition, these patients required lifelong replacement therapy with hydrocortisone and fludrocortisone. Currently, bilateral adrenalectomy is rarely indicated for patients with Cushing's disease but may be performed if pituitary surgery has failed or the condition has recurred.

The surgical outcome for transsphenoidal hypophysectomy varies from center to center and with surgical

expertise.²⁸¹ Because of the hazards of untreated Cushing's disease and the potential complications of surgery, the endocrinologist should refer cases only to a recognized surgical specialist at a center in which outcome data have been established. In optimal centers, cure rates are 80% to 90% for microadenomas and 50% for macroadenomas.²⁸² Rates for postoperative hypopituitarism and permanent diabetes insipidus depend on how aggressive the surgeon was in removing pituitary tissue. The ideal outcome is a cured patient with intact pituitary function, but this may not be possible for a patient with Cushing's disease in whom a pituitary adenoma was not identified preoperatively or during the operation itself.

At the time of surgery, patients should be treated with corticosteroids, like other patient with potential or confirmed deficit of the HPA axis. In centers that lack facilities for frequent monitoring of cortisol levels, postoperative hydrocortisone cover is advised; this can be reduced to maintenance replacement doses usually within 3 to 7 days. On day 5 postoperatively, a 9 a.m. plasma cortisol level should be measured with the patient having omitted hydrocortisone for 24 hours. After selective removal of a microadenoma, the surrounding corticotrophs are usually suppressed (Fig. 15-30). As a result, plasma cortisol levels are less than 30 nmol/L (<1 µg/dL) postoperatively, and ongoing glucocorticoid replacement therapy is required. When the dexamethasone regimen described earlier (after removal of an adrenal adenoma) is used, the HPA axis usually (but not invariably) exhibits gradual recovery (Fig. 15-31). A nonsuppressed plasma cortisol postoperatively suggests that the patient is not "cured," even though cortisol secretion may have fallen to normal or subnormal values.^{283,284} The recurrence rate in patients with an established "cure" after pituitary surgery is 2%, but this value is higher in children (up to 40%).^{285,286} A detailed assessment of residual pituitary function is required in each case, and close follow-up of such individuals is warranted.

In the past, pituitary irradiation was often used in the treatment of Cushing's disease. However, because of the improvements in pituitary surgery, far fewer patients are so treated. In children, pituitary irradiation appears to be more effective.²⁸⁷ Radiotherapy is not recommended as a primary treatment but is reserved for patients not responding to pituitary microsurgery, those who have undergone bilateral adrenalectomy, and patients with established Nelson's syndrome.

The management of recurrent Cushing's disease involves a consideration of repeat surgery, gamma knife radiosurgery, and medical therapies.^{278,288}

Ectopic ACTH Syndrome

Treatment of the ectopic ACTH syndrome depends on the cause. If the tumor can be found and has not spread, then its removal can lead to cure (e.g., bronchial carcinoid, thymoma). However, the prognosis for small-cell lung cancer associated with the ectopic ACTH syndrome is poor. The cortisol excess and associated hypokalemic alkalosis and diabetes mellitus can be ameliorated by medical therapy. Treatment of the small-cell tumor itself will also, at least initially, produce improvement. Sometimes, if the ectopic source of ACTH cannot be found, it may be necessary to perform bilateral adrenalectomy and then monitor the patient carefully (sometimes for several years) before the primary tumor becomes apparent.

Medical Treatment of Cushing's Syndrome

Several drugs have been used in the treatment of Cushing's syndrome.²⁷⁸ Metyrapone inhibits 11β-hydroxylase and

Figure 15-29 A young woman with Cushing's disease, photographed initially beside her identical twin sister (**A**). In this case, treatment with bilateral adrenalectomy was undertaken. Several years later, the patient presented with Nelson's syndrome and a right third cranial nerve palsy (**B** and **C**) related to cavernous sinus infiltration from a locally invasive corticotropinoma (**D**). Hypophysectomy and radiotherapy were performed with reversal of the third nerve palsy (**E**). Note the advancing skin pigmentation of Nelson's syndrome.

has been the most commonly given agent, often with a goal of lowering cortisol concentrations before definitive therapy or while awaiting benefit from pituitary irradiation. The daily dose must be determined by measurements of plasma or urinary free cortisol. The aim should be to achieve a mean plasma cortisol concentration of about 300 nmol/L (11 µg/dL) during the day or a normal urinary free cortisol level. The drug is usually given in doses ranging

from 250 mg twice daily to 1.5 g every 6 hours. Nausea is a side effect that can be helped (if it is not caused by adrenal insufficiency) by giving the drug with milk.²⁸⁹

Aminoglutethimide is a more toxic drug; high dose blocks earlier enzymes in the steroidogenic pathway and therefore affect the secretion of steroids other than cortisol. In doses of 1.5 to 3 g daily (starting with 250 mg every 8 hours), it commonly produces nausea, marked lethargy,

Figure 15-30 Selective removal of a microadenoma and its effect on the hypothalamic-pituitary-adrenal axis. **A**, Pretreatment. **B**, Total removal of adenoma. **C**, Incomplete excision. Because the surrounding normal pituitary corticotrophs are suppressed in a patient with an adrenocorticotrophic hormone (ACTH)-secreting pituitary adenoma, successful removal of the tumor results in ACTH, and hence adrenocortical, deficiency, with an undetectable (<50 nmol/L [2 µg/dL]) plasma cortisol level. A postoperative plasma cortisol level higher than 50 nmol/L (2 µg/dL) implies that the patient is not cured. (Courtesy of Professor Peter Trainer.)

and a high incidence of skin rash.²⁹⁰ It is commonly prescribed as combination therapy with metyrapone.

Trilostane, a 3β-HSD inhibitor, is ineffective in Cushing's disease, because the block in steroidogenesis is overcome by the rise in ACTH. However, it can be effective in patients with adrenal adenomas.²⁹¹

Ketoconazole is an imidazole that has been widely used as an antifungal agent but causes abnormal liver function tests in about 15% of patients. Ketoconazole blocks a variety of steroidogenic cytochrome P450-dependent enzymes and thus lowers plasma cortisol levels. For

effective control of Cushing's syndrome, 400 to 800 mg daily has been required.²⁹²

Following the demonstration of the expression of the PPAR-γ receptor in ACTH-secreting pituitary tissue, a novel therapy for Cushing's disease was devised: the thiazolidinedione, rosiglitazone.²⁹³ Doses up to 8 mg/day are required to suppress cortisol secretion, and the drug seems to have lasting benefit in approximately 20% of cases studied.²⁹⁴ Further studies are required.

Mitotane (*o,p'*-DDD) is an adrenolytic drug that is taken up by both normal and malignant adrenal tissue, causing adrenal atrophy and necrosis.²⁷⁵ Because of its toxicity, it has been used mainly in the management of adrenal carcinoma. Doses of up to 5 g/day are required to control glucocorticoid excess, although evidence that the drug causes tumor shrinkage or improves long-term survival is lacking. This agent also produces mineralocorticoid deficiency, and concomitant glucocorticoid and mineralocorticoid replacement therapy may be required. Side effects are common and include fatigue, skin rashes, neurotoxicity, and gastrointestinal disturbance.

Somatostatin analogues such as octreotide and lanreotide are generally ineffective in Cushing's disease. However, promising results have been reported with a novel somatostatin analogue, pasireotide, which demonstrates high-affinity binding to somatostatin receptor subtypes 1, 2, 3, and 5.²⁹⁵ A fall in cortisol secretion was reported in 75% of Cushing's disease patients treated for 15 days with pasireotide, 600 µg given subcutaneously twice daily, but normalization of urinary free cortisol was achieved in fewer than 20% of these patients.

Prognosis of Cushing's Syndrome

Studies carried out before the introduction of effective therapy revealed that 50% of patients with untreated Cushing's syndrome died within 5 years, principally from vascular disease.¹⁹² Even with modern management, an increased prevalence of cardiovascular risk factors persists for many years after an apparent "cure."^{193,194} Paradoxically, on correction of the hypercortisolism, patients often feel worse. Skin desquamation, steroid-withdrawal arthropathy, profound lethargy, and mood changes may occur and can take several weeks or months to resolve.²⁹⁶ In our experience, these features, together with postural hypotension, are particularly severe in "cured" patients who are also rendered vasopressin deficient. They can usually be ameliorated by a transient increase in glucocorticoid replacement therapy. Patients are invariably GH deficient, and GH replacement therapy may produce clinical benefit.

Features of Cushing's syndrome disappear over a period of 2 to 12 months after treatment. Hypertension and diabetes mellitus improve, but, as with other secondary causes, they may not resolve completely. The osteopenia of Cushing's syndrome improves rapidly during the first 2 years after treatment but resolves more slowly thereafter.²⁹⁷ Vertebral fractures and osteonecrosis are irreversible, and permanent deformity results. Visceral obesity and myopathy are both reversible features. Reproductive and sexual function return to normal within 6 months, provided that anterior pituitary function was not compromised. Long-term health-related quality of life in adults significantly improves after treatment, but quality-of-life scores do not return to normal levels.¹⁸⁹ Similar observations have been made in pediatric patients, in whom significant improvement was noted before and after treatment but residual impairment of health-related quality of life persisted 1 year after cure.²⁹⁸

Figure 15-31 Gradual recovery of function of the hypothalamic-pituitary-adrenal axis in a patient after removal of a pituitary adrenocorticotrophic hormone-secreting microadenoma. Morning (9 a.m.) plasma cortisol levels were measured. The insulin hypoglycemia test (I.H.T.) eventually demonstrated the return of a normal stress response.

Glucocorticoid Resistance

A small number of patients have been described as having increased cortisol secretion but without the stigmata of Cushing's syndrome.^{86,299} These patients are resistant to suppression of cortisol with low-dose dexamethasone but respond to high doses. ACTH levels are elevated and lead to increased adrenal production of androgens and DOC. Therefore, these patients may present with the features of androgen or mineralocorticoid excess, or both. Treatment with a dose of dexamethasone (usually >3 mg/day) adequate to suppress ACTH results in a fall in adrenal androgens and often returns plasma potassium and blood pressure to normal levels. Many of these patients have been found to have point mutations in the steroid-binding domain of the GR, with consequent reduction of glucocorticoid-binding affinity, but this is not invariable. A useful clinical discriminatory test to differentiate this condition from Cushing's syndrome is to measure bone mineral density: it is preserved in patients with glucocorticoid resistance or even increased in females because of the androgen excess. In addition, the circadian rhythm for ACTH and cortisol is preserved in patients with glucocorticoid resistance.

GLUCOCORTICOID DEFICIENCY

Primary and Secondary Hypoadrenalism

Primary hypoadrenalism refers to glucocorticoid deficiency occurring in the setting of adrenal disease, whereas secondary hypoadrenalism arises because of deficiency of ACTH (Table 15-16). A major distinction between these two is that mineralocorticoid deficiency invariably accompanies primary hypoadrenalism, but this does not occur in secondary hypoadrenalism: only ACTH is deficient, and the renin-angiotensin-aldosterone (RAA) axis is intact. A further important cause of adrenal insufficiency in which there may be dissociation of glucocorticoid and mineralocorticoid secretion is CAH.

Primary Hypoadrenalism

Addison's Disease

Thomas Addison described the condition now known as primary hypoadrenalism in his classic monograph published in 1855.² Addison's disease is a rare condition with an estimated incidence in the developed world of 0.8 cases per 100,000 and a prevalence of 4 to 11 cases per 100,000 population. Nevertheless, it is associated with significant morbidity and mortality, but once the diagnosis is made it can be easily treated.^{300,301} Causes of Addison's disease are listed in Table 15-16.

Autoimmune Adrenalitis. In the Western world, autoimmune adrenalitis accounts for more than 70% of all cases of primary hypoadrenalism.³⁰² Pathologically, the adrenal glands are atrophic with loss of most of the cortical cells, but the medulla is usually intact. In 75% of cases, adrenal autoantibodies can be detected.³⁰³ Fifty percent of patients with this form of Addison's disease have an associated autoimmune disease (Table 15-17), thyroid disease being the most common. Conversely, only 1% to 2% of patients with more common autoimmune diseases such as insulin-dependent diabetes mellitus or thyrotoxicosis have antiadrenal autoantibodies and develop adrenal disease, although the figure is higher in patients with autoimmune hypoparathyroidism (16%).

TABLE 15-16

Etiology of Adrenocortical Insufficiency (Excluding Congenital Adrenal Hyperplasia)

Primary Causes: Addison's Disease

Autoimmune
Sporadic
Autoimmune polyendocrine syndrome type I (Addison's disease, chronic mucocutaneous candidiasis, hypoparathyroidism, dental enamel hypoplasia, alopecia, primary gonadal failure—see Chapter 42)
Autoimmune polyendocrine syndrome type II (Schmidt's syndrome) (Addison's disease, primary hypothyroidism, primary hypogonadism, insulin-dependent diabetes, pernicious anemia, vitiligo—Chapter 42)
Infections
Tuberculosis
Fungal infections
Cytomegalovirus
HIV
Metastatic tumor
Infiltrations
Amyloid
Hemochromatosis
Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome) after meningococcal septicemia
Adrenoleukodystrophies
Congenital adrenal hypoplasia
DAX1 (<i>NR0B1</i>) mutations
SFI mutations
ACTH resistance syndromes
MC2R gene mutations
MRAP gene mutations
AAAS (<i>ALADIN</i>) gene mutations (triple-A syndrome)
Bilateral adrenalectomy

Secondary Causes

Exogenous glucocorticoid therapy
Hypopituitarism
Selective removal of ACTH-secreting pituitary adenoma
Pituitary tumors and pituitary surgery; craniopharyngiomas
Pituitary apoplexy
Granulomatous disease (tuberculosis, sarcoid, eosinophilic granuloma)
Secondary tumor deposits (breast, bronchus)
Postpartum pituitary infarction (Sheehan's syndrome)
Pituitary irradiation (effect usually delayed for several years)
Isolated ACTH deficiency
Idiopathic
Lymphocytic hypophysitis
TPIT (<i>TBX19</i>) gene mutations
POMC gene mutation (POMC processing defect)
POMC gene mutations
Multiple pituitary hormone deficiencies
HESX1 gene mutations
LHX4 gene mutations
SOX3 gene mutations
PROPI gene mutations

ACTH, Adrenocorticotrophic hormone; HIV, human immunodeficiency virus; POMC, pro-opiomelanocortin.

These autoimmune polyglandular syndromes (APS) have been classified into two distinct variants.³⁰³ APS type I, or autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED), is a rare autosomal recessive condition comprising Addison's disease, chronic mucocutaneous candidiasis, and hypoparathyroidism. The more common APS type II, comprises Addison's disease, autoimmune thyroid disease, diabetes mellitus, and hypogonadism. Here, autoantibodies to 21-hydroxylase are usually present and are predictive for the development of adrenal destruction.³⁰³ Polyglandular autoimmune syndromes are discussed in greater detail in Chapter 42.

TABLE 15-17

Incidence of Other Endocrine and Autoimmune Diseases in Patients with Autoimmune Adrenal Insufficiency

Disease	Incidence (%)
Thyroid disease	
Hypothyroidism	8
Nontoxic goiter	7
Thyrotoxicosis	7
Gonadal failure	
Ovarian	20
Testicular	2
Insulin-dependent diabetes mellitus	11
Hypoparathyroidism	10
Pernicious anemia	5
None	53

Infections. Worldwide, infectious diseases are the most common cause of primary adrenal insufficiency. These diseases include tuberculosis, fungal infections (histoplasmosis, cryptococcosis), and cytomegalovirus. Adrenal failure may also occur in the acquired immunodeficiency syndrome (AIDS).³⁰⁴

Tuberculous Addison's disease results from hematogenous spread of the infection from elsewhere in the body; extra-adrenal disease is usually evident. The adrenals are initially enlarged, with extensive epithelioid granulomas and caseation, and both the cortex and the medulla are affected. Fibrosis ensues, and the adrenals become normal or smaller in size, with calcification evident in 50% of cases.

The adrenals are frequently involved in patients with AIDS^{304,305}; adrenalitis may occur after infection with cytomegalovirus or atypical mycobacteria, and Kaposi's sarcoma may result in adrenal replacement. Onset is often insidious, but if tested, more than 10% of patients with AIDS will demonstrate a subnormal cortisol response to a short Synacthen test. Adrenal insufficiency may be precipitated through the concomitant administration of appropriate anti-infectives such as ketoconazole (which inhibits cortisol synthesis) or rifampicin (which increases cortisol metabolism). Rarely, patients with AIDS and features of adrenal insufficiency are found to have elevated circulating ACTH and cortisol concentrations that fail to suppress normally after low-dose dexamethasone administration. This is thought to reflect an "acquired" form of glucocorticoid resistance resulting from reduced GR affinity, but the underlying cause remains unknown.³⁰⁶

Acquired Primary Adrenal Insufficiency

With the exception of tuberculosis and autoimmune adrenal failure, other causes of Addison's disease are rare (see Table 15-16). Adrenal metastases (most commonly from primary tumors in the lung or breast) are often found at postmortem examinations, but they uncommonly cause adrenal insufficiency,³⁰⁷ perhaps because more than 90% of the adrenal cortex must be compromised before symptoms and signs become apparent. Necrosis of the adrenals due to intra-adrenal hemorrhage should be considered in any severely sick patient, particularly a patient with underlying infection, trauma, or coagulopathy.³⁰⁸ Intra-adrenal bleeding may be found in patients with severe septicemia of any cause, particularly in children, in whom a common cause is infection with *Pseudomonas aeruginosa*. When caused by meningococci, the association with adrenal insufficiency is known as the Waterhouse-Friederichsen syndrome.

Adrenal replacement may also occur with amyloidosis and hemochromatosis.

Inherited Primary Adrenal Insufficiency

Adrenal hypoplasia congenita (AHC) is an X-linked disorder comprising congenital adrenal insufficiency and combined primary and central hypogonadotropic hypogonadism. The condition is caused by mutations in the *DAX1 (NROB1)* gene, a member of a nuclear receptor family that is expressed in the adrenal cortex, gonads, and hypothalamus.^{309,310} Depending on the molecular defect, the clinical presentation can be highly variable. Severe cases often manifest with mineralocorticoid deficiency and gradually develop glucocorticoid deficiency. Hypogonadism is combined with primary testicular abnormalities and low gonadotropin levels. However, the so-called minipuberty of infancy can be normal.^{311,312} Patients presenting with late-onset adrenal failure have also been described.³¹³

Mutations in another transcription factor, steroidogenic factor-1 (SF1), may also result in adrenal insufficiency due to lack of development of a functional adrenal cortex. The transcriptional regulation of many P450 steroidogenic enzymes is dependent on SF1.¹⁵ When it was first described, SF1 mutation was associated with complete sex reversal causing 46,XY disorder of sex development (DSD).³¹⁴ However, novel clinical phenotypes in SF1-deficient patients are now emerging; they range from isolated adrenal failure³¹⁵ to isolated gonadal failure³¹⁶ and ovarian insufficiency.³¹⁷ AHC may also occur in association with glycerol kinase deficiency and muscular dystrophy caused by gene deletion, including the *DAX1* gene.³¹⁸

Adrenoleukodystrophy has a prevalence rate of 1:20,000 and is a cause of adrenal insufficiency in association with demyelination within the nervous system; demyelination results from a failure of β -oxidation of fatty acids within peroxisomes due to reduced activity of very-long-chain acyl-CoA synthetase.³¹⁹ Increased accumulation of very-long-chain fatty acids (VLCFA) occurs in many tissues, and serum assays can be used diagnostically. Only males have the fully expressed condition, and carrier females are usually normal. Several forms are recognized: a childhood cerebral form (30% to 40% of cases), adult adrenomyeloneuropathy (40%), and Addison's disease (7%). The childhood-onset form manifests at 5 to 10 years of age with progression eventually to a blind, mute, and severely spastic tetraplegic state. Adrenal insufficiency is usually present but does not appear to correlate with the neurologic deficit. Nevertheless, this is the most common form of adrenal insufficiency in a child younger than 7 years of age.³²⁰ Adrenomyeloneuropathy, by contrast, manifests later in life with the gradual development of spastic paresis and peripheral neuropathy. Both the childhood and the adult condition result from mutations in the *ABCD1* gene on chromosome Xq28, which encodes for an ABC peroxisomal membrane protein involved in the import of VLCFA into the peroxisome.³²¹ So far, more than 400 mutations have been reported in the *ABCD1* gene with no relationship between genotype and phenotype.^{322,323} Treatment options are few. Monounsaturated fatty acids, which block the synthesis of the saturated VLCFA, have been used; a combination of erucic acid and oleic acid (Lorenzo's oil) has led to normal levels of VLCFA. Treatment does not alter the rate of neurologic deterioration but may prevent new neurologic damage in asymptomatic cases.³²³ Bone marrow transplantation is a further possibility.

Familial glucocorticoid deficiency (FGD), or inherited unresponsiveness to ACTH, is a rare autosomal recessive cause of hypoadrenalism that usually manifests in childhood.

Most patients present with neonatal hypoglycemia or later in life with increasing pigmentation, and they often have enhanced growth velocity. Primary adrenal failure in a child with normal activity of the RAA system is highly suggestive of FGD. The diagnosis can be confirmed by demonstrating low cortisol in combination with increased ACTH concentrations and normal plasma renin and aldosterone measurements.⁹⁰ The type 1 variant accounts for approximately 25% of all cases and is explained by inactivating mutations in the ACTH-binding receptor, MC2R.³²⁴⁻³²⁶ The FGD type 2 variant caused by mutations in *MRAP* gene, which is thought to mediate intracellular trafficking of the MC2R, has been reported in some families.⁸⁹ However, 50% of patients with FGD do not have mutations in either MC2R or *MRAP*; other loci are being defined.

A variant called the *triple A syndrome* or *Allgrove's syndrome* refers to the triad of adrenal insufficiency due to ACTH resistance, achalasia, and alacrima. It is caused by mutations in the *AAAS* gene, which encodes ALADIN, a tryptophan/aspartate WD-repeat-containing protein of the nuclear pore complex.^{327,328} The exact function of ALADIN is unknown, but its interaction with other proteins of the nuclear pore complex suggest that it is part of a structural scaffold.

Several syndromic disorders are associated with adrenal insufficiency for which the underlying molecular genetic defect remains to be elucidated.¹¹

Secondary Hypoadrenalism (ACTH deficiency)

Acquired Secondary Adrenal Insufficiency

Acquired secondary adrenal insufficiency is a common clinical problem and is most often caused by a sudden cessation of exogenous glucocorticoid therapy. Such therapy suppresses the HPA axis with consequent adrenal atrophy, which may last for months after the glucocorticoid treatment is stopped. Adrenal atrophy and subsequent deficiency should be anticipated in any subject who has taken more than the equivalent of 30 mg hydrocortisone per day orally (>7.5 mg/day prednisolone or >0.75 mg/day dexamethasone) for longer than 3 weeks. In addition to the magnitude of the dose of glucocorticoid, the timing of administration may affect the degree of adrenal suppression. If prednisolone is given as 5 mg at night and 2.5 mg in the morning, there will be more marked suppression of the HPA axis compared with 2.5 mg at night and 5 mg in the morning, because the larger evening dose blocks the early-morning surge of ACTH.

Secondary hypoadrenalism may also occur after failure to give adequate glucocorticoid replacement therapy for intercurrent stress in a patient who has been on long-term glucocorticoid therapy.

Inherited Secondary Adrenal Insufficiency

Other causes of secondary adrenal insufficiency (see Table 15-16) reflect inadequate ACTH production from the anterior pituitary gland. In many of these conditions, other pituitary hormones are also deficient, so that the patient presents with partial or complete hypopituitarism. The clinical features of hypopituitarism make this a relatively easy diagnosis to make. Isolated ACTH deficiency is rare, and the diagnosis is difficult to make. It may occur in patients with lymphocytic hypophysitis. Mutations in the *TBX19*, the product of which (TPIT) regulates POMC expression, have been reported in a few cases of isolated ACTH deficiency occurring in neonatal life.³²⁹ A rare but fascinating cause relates to a defect in the normal

post-translational processing of POMC to ACTH by the prohormone convertase enzymes (PC1 and PC2).³³⁰ Such patients may have more generalized defects in peptide processing (e.g., cleavage of proinsulin to insulin) giving rise to diabetes mellitus.

Some patients have mutations in the *POMC* gene that interrupt the synthesis of ACTH and causes ACTH deficiency. Elucidation of the phenotype of these patients has uncovered a novel role for POMC peptides in regulating appetite and hair color: in addition to adrenal insufficiency, *POMC* mutations result in severe obesity and red hair pigmentation.³³¹ A central role for α -MSH in regulating food intake via the hypothalamic MC4R has been established,⁵⁵ and in recombinant mice lacking the *POMC* gene, the obese phenotype can be reversed by giving an α -MSH agonist peripherally.³³²

Other rare inborn causes of secondary insufficiency are the result of mutations in genes involved in pituitary development, such as *HESX1*,³³³ *LHX4*,³³⁴ *SOX3*,³³⁵ and *PROP1*.³³⁶ These defects result in congenital hypopituitarism with multiple pituitary hormone deficiencies: ACTH deficiency may not be present at the time of diagnosis, it but develops progressively over time.

Secondary hypoadrenalism is also observed in patients with Cushing's disease after successful and selective removal of the ACTH-secreting pituitary adenoma. The function of adjacent "normal" pituitary corticotrophs is suppressed and may remain so for many months after curative surgery.²⁸³⁻²⁸⁵

Hypoadrenalism during Critical Illness

Hypoadrenalism may also complicate critical illness, even in individuals with a previously intact HPA axis.³³⁷ This has been termed *functional adrenal insufficiency* to reflect the notion that hypoadrenalism is transient and is not caused by a structural lesion. Functional adrenal insufficiency has been difficult to define biochemically and is of uncertain etiology. Inability to mount an adequate and appropriate cortisol response to overwhelming stress or sepsis is frequently encountered in intensive care units and substantially increases the risk of death during acute illness.³³⁸ This has stimulated attempts to define functional adrenal insufficiency quantitatively and to treat it with supplemental corticosteroids. Although this diagnosis remains highly contentious, if a suboptimal cortisol response is suspected, the current recommendations suggest (1) treatment with hydrocortisone, 200 mg/day in four divided doses or, preferably, 10 mg/hour as a continuous infusion, for patients with septic shock and (2) treatment with methylprednisolone, 1 mg/kg per day, for patients with severe early acute respiratory distress syndrome. Glucocorticoid treatment should be tapered off rather than stopped abruptly. Treatment of critical illness-related adrenal insufficiency with dexamethasone is not recommended.³³⁹

Clinical Features of Adrenal Insufficiency

Patients with primary adrenal failure usually have both glucocorticoid and mineralocorticoid deficiency. In contrast, those with secondary adrenal insufficiency have an intact RAA system. This accounts for differences in salt and water balance in the two groups of patients, which in turn result in different clinical presentations. The most obvious feature that differentiates primary from secondary hypoadrenalism is skin pigmentation (Table 15-18), which is almost always present in cases of primary adrenal insufficiency (unless of short duration) and absent in secondary insufficiency. The pigmentation is seen in sun-exposed

TABLE 15-18

Clinical Features of Primary Adrenal Insufficiency

areas, recent rather than old scars, axillae, nipples, palmar creases, pressure points, and mucous membranes (buccal, vaginal, vulval, anal). The cause of the pigmentation has long been debated but is thought to reflect increased stimulation of the MC1R by ACTH itself. In autoimmune Addison's disease, there may be associated vitiligo (Fig. 15-32).

The clinical features relate to the rate of onset and the severity of adrenal deficiency.³⁰⁰ In many cases, the disease has an insidious onset and a diagnosis is made only when the patient presents with an acute crisis during an intercurrent illness. Acute adrenal insufficiency, termed an adrenal crisis or Addisonian crisis, is a medical emergency manifesting as hypotension and acute circulatory failure (Table 15-19). Anorexia may be an early feature; it progresses to nausea, vomiting, diarrhea, and, sometimes, abdominal pain. Fever may be present, and hypoglycemia may occur.

TABLE 15-19

Clinical and Laboratory Features of an Adrenal Crisis

Dehydration, hypotension, or shock out of proportion to severity of current illness
Nausea and vomiting with a history of weight loss and anorexia
Abdominal pain, so-called acute abdomen
Unexplained hypoglycemia
Unexplained fever
Hyponatremia, hyperkalemia, azotemia, hypercalcemia, or eosinophilia
Hyperpigmentation or vitiligo
Other autoimmune endocrine deficiencies, such as hypothyroidism or gonadal failure

Patients presenting acutely with adrenal hemorrhage have hypotension; abdominal, flank, or lower chest pain; anorexia; and vomiting. The condition is difficult to diagnose, but evidence of occult hemorrhage (rapidly falling hemoglobin), progressive hyperkalemia, and shock should alert the clinician to the diagnosis.

Alternatively, the patient may present with vague features of chronic adrenal insufficiency—weakness, tiredness, weight loss, nausea, intermittent vomiting, abdominal pain, diarrhea or constipation, general malaise, muscle cramps, arthralgia, and symptoms suggestive of postural hypotension (see Table 15-18). Salt craving may be a feature, and a low-grade fever may be present. Supine blood pressure is usually normal, but almost invariably there is a fall in blood pressure on standing. Adrenal androgen secretion is lost; this is clinically more apparent in women, who may complain of loss of axillary and pubic hair and frequently have dry and itchy skin. Psychiatric symptoms may occur in long-standing cases and include memory impairment, depression, and psychosis. Formal quality-of-life measures indicate significant impairment in patients with primary or secondary adrenal insufficiency.³⁴⁰ Tiredness is often profound, and patients may be inappropriately diagnosed with chronic fatigue syndrome or anorexia nervosa.

In secondary adrenal insufficiency due to hypopituitarism, the presentation may relate to deficiency of hormones other than ACTH, notably LH/FSH (infertility, oligorrhea/amenorrhea, poor libido) and TSH (weight gain, cold intolerance). Fasting hypoglycemia occurs because of loss of the gluconeogenic effects of cortisol. It is rare in adults unless there is concomitant alcohol abuse or additional GH deficiency. However, hypoglycemia is a common presenting feature of ACTH/adrenal insufficiency in childhood.³⁴¹ In addition, patients with ACTH deficiency present with malaise, weight loss, and other features of chronic adrenal insufficiency. Rarely, the presentation is more acute in patients with pituitary apoplexy.

Investigation of Hypoadrenalism

Routine Biochemical Profile

Among patients with established primary adrenal insufficiency, hyponatremia is present in about 90% and hyperkalemia in 65%. The blood urea concentration is usually elevated. Hyperkalemia occurs because of aldosterone deficiency, so it is usually absent in patients with secondary adrenal failure. Hyponatremia may be depletional in an Addisonian crisis, but in addition vasopressin levels are elevated, resulting in increased free water retention.³⁴² Therefore, in secondary adrenal insufficiency, there may be a dilutional hyponatremia with normal or low blood urea.

Reversible abnormalities in liver transaminases frequently occur. Hypercalcemia occurs in 6% of all cases³⁴³ and may be particularly marked in patients with coexisting thyrotoxicosis. Free thyroxine concentrations are usually low or normal, but TSH values are frequently moderately elevated.³⁴⁴ This is a direct effect of glucocorticoid deficiency and reverses with replacement therapy. Persistent elevation of TSH in association with positive thyroid autoantibodies suggests concomitant autoimmune thyroid disease.

Mineralocorticoid Status

In primary hypoadrenalism, mineralocorticoid deficiency usually occurs, manifested by elevated plasma renin activity and either low or low-normal plasma aldosterone. The investigation of ZG activity is frequently neglected in

Figure 15-32 Pigmentation in Addison's disease. **A**, Hands of an 18-year-old woman with autoimmune polyendocrine syndrome and Addison's disease. Addison's disease, compared with assessment of ZF function. In secondary adrenal insufficiency, the RAA system is intact.

Assessing Adequacy of Function of the HPA Axis

Clinical suspicion of the diagnosis should be confirmed with definitive diagnostic tests. Basal plasma cortisol and urinary free cortisol levels are often in the low-normal range and cannot be used to exclude the diagnosis. However, a basal cortisol value greater than 400 nmol/L (14.5 µg/dL) invariably indicates an intact HPA axis.³⁴⁵ In practice, rather than wait for results of insensitive basal tests, all patients with suspected adrenal insufficiency should have an ACTH stimulation test; in patients with an Addisonian crisis, however, treatment should be instigated

immediately and stimulation tests conducted at a later stage.

The ACTH stimulation test or SST involves intramuscular or intravenous administration of 250 µg tetracosactin, a synthetic ACTH(1-24) comprising the first 24 amino acids of normally secreted ACTH(1-39).³⁴⁶ Plasma cortisol levels are measured at 0 and 30 minutes after ACTH administration, and a normal response is defined by a peak plasma cortisol level greater than 550 nmol/L (>20 µg/dL).³⁴⁷ This value equates to the 5th percentile response in normal subjects but is very much assay-dependent, with different cortisol radioimmunoassays giving different results. Incremental responses (i.e., the difference between peak and basal values) are of no value in defining a "pass" response, with the possible exception of diagnosing relative adrenal

insufficiency in patients with critical illness. Response is unaffected by the time of day of the test, and the test can be performed in patients who have commenced corticosteroid replacement therapy, so long as this therapy is of short duration and does not include hydrocortisone (which would cross-react in the cortisol assay). A prolonged ACTH stimulation test involving the administration of depot or intravenous infusions of tetracosactin for 24 to 48 hours differentiates primary from secondary hypoadrenalism. In normal subjects, the plasma cortisol level at 4 hours is greater than 1000 nmol/L (36 µg/dL); beyond that time, there is no further increase. Patients with secondary hypoadrenalism show a delayed response and usually have a much higher value at 24 and 48 hours than at 4 hours. In patients with primary hypoadrenalism, there is no response at either time. However, the test is rarely required if plasma ACTH has been appropriately measured at baseline. In primary adrenal insufficiency, the ACTH level is disproportionately elevated in comparison to plasma cortisol.³⁴⁸

Whereas there is agreement on the investigation of suspected primary adrenal failure, the diagnosis of secondary hypoadrenalism, notably in patients with existing hypothalamic/pituitary disease, is contentious. Based on correlations with the response of circulating cortisol to surgery, the insulin-induced hypoglycemia test or insulin tolerance test (ITT) was introduced more than 40 years ago as a laboratory test to assess integrity of the HPA axis, and it should be considered the gold standard in this regard.³⁴⁹ It should not be performed in patients with ischemic heart disease (always check an electrocardiogram before the test), epilepsy, or severe hypopituitarism (i.e., 9 a.m. plasma cortisol <180 nmol/L [<6.5 µg/dL]). The test involves the intravenous administration of soluble insulin in a dose of 0.1 to 0.15 U/kg body weight, with measurement of plasma cortisol at 0, 30, 45, 60, 90, and 120 minutes. Adequate hypoglycemia (blood glucose <2.2 mmol/L with signs of neuroglycopenia—sweating and tachycardia) is essential. In normal subjects, the peak plasma cortisol concentration exceeds 500 nmol/L (18 µg/dL). However, the cortisol response to hypoglycemia can be reliably predicted by the SST—a safer, cheaper, and quicker test.^{346,350}

The SST relies on the principle that the cortisol response to an exogenous bolus of ACTH is determined by the endogenous ACTH trophic drive to the adrenal cortex; impaired ACTH secretion from the anterior pituitary results in an impaired cortisol response after Synacthen administration. However, the ACTH test should not be used to diagnose secondary hypoadrenalism in patients with a recent pituitary insult (e.g., surgery, apoplexy). Total hypophysectomy results in a failed cortisol response to ITT immediately thereafter, but it takes 2 to 3 weeks for the adrenal cortex to readjust to the reduced level of ACTH secretion; in the interim, a false-positive cortisol response is seen. The SST should also be avoided in patients with a primary diagnosis of Cushing's disease, in whom an exaggerated cortisol response to ACTH may persist.

In clinical practice, if the ACTH test is normal, insulin hypoglycemia testing is not necessary in most cases unless there is also a need to document endogenous GH reserve in a patient with pituitary disease. In our practice, an ITT is performed in a patient with suspected hypopituitarism if there is a subnormal response to ACTH. Some patients have an inadequate response to ACTH but then respond normally to hypoglycemia³⁵⁰; they do not require corticosteroid replacement therapy. This approach is open to debate, and even taking into account the caveats listed, false-positive results have been reported for the SST.³⁵¹ Although these are rare (<2%), the possibility should be

noted, particularly in patients with ongoing symptoms and signs indicative of hypoadrenalism.

A low-dose SST giving only 1 µg ACTH has been proposed as a screen for adequacy of function of the HPA axis, with the suggestion that it may be more sensitive than the conventional 250-µg test.³⁵²⁻³⁵⁴ Other researchers dispute this suggestion,^{355,356} and further validation of this test is required to support such a concept.

Two other tests have been advocated to assess adequacy of function of the HPA axis, but their use in modern clinical practice should be restricted to difficult diagnostic cases. In the overnight metyrapone test, 30 mg/kg (maximum, 3 g) metyrapone is given at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 a.m. the following morning. In patients with an intact axis, ACTH levels rise after the blockade of cortisol synthesis by metyrapone, and a normal result is signified by a peak 11-deoxycortisol value greater than 7 µg/dL.³⁵⁷ The CRH stimulation test has been used to diagnose adrenal insufficiency; unlike the metyrapone test, it differentiates primary from secondary causes. Patients with primary adrenal failure have high ACTH levels that rise further after CRH stimulation. Patients with secondary adrenal failure have low ACTH levels that fail to respond to CRH. Patients with hypothalamic disease show a steady rise in ACTH levels after CRH administration.³⁵⁸

Testing the HPA Axis during Critical Illness. Many factors complicate investigation of the HPA axis during critical illness. Cortisol levels vary broadly with disease severity, making it difficult to define appropriate responses. Additionally, CBG levels decrease substantially, leading to increases in the ratio of free to bound serum cortisol; for this reason, tests that assess the whole axis (e.g., ITT) are not appropriate in the critical care setting. Investigations are therefore limited to basal cortisol levels or values measured after the SST.

Recent guidance has indicated that a random cortisol value of less than 400 nmol/L (<15 µg/dL) suggests corticosteroid insufficiency, whereas a level greater than 900 nmol/L (>33 µg/dL) is unlikely to occur in patients with compromised HPA axis function. For individuals with intermediate cortisol levels, an SST should be performed; a cortisol increment of less than 250 nmol/L (<9 µg/dL) is an independent prognostic marker for death in critically ill patients.³³⁸

An initial multicenter randomized trial of patients with septic shock showed that those with an increment less than 250 nmol/L across an SST had a significant improvement in mortality when given replacement corticosteroids.³⁵⁹ However, in a more recent study hydrocortisone treatment hastened reversal of shock but did not improve overall survival in patients with septic shock.³⁶⁰ The SST was not useful in predicting benefit from glucocorticoids. It is possible that differences in results between these two trials were due to differences in patient selection (e.g., severity of sepsis) and the speed of administration of glucocorticoids.

In light of this uncertainty, recent recommendations continue to suggest hydrocortisone treatment for septic shock and methylprednisolone for patients with severe early acute respiratory distress syndrome, particularly those with poor response to fluid resuscitation and vasopressor agents.³³⁹ The role of glucocorticoids in the management of critically ill patients with other conditions requires further research.

Other Tests. Radioimmunoassays to detect autoantibodies such as those against the 21-hydroxylase antigen are now

Figure 15-33 Computed tomographic (CT) scans of patients with primary adrenal insufficiency. The affected adrenal glands are indicated by arrows. **A**, CT scan of a 59-year-old man with histoplasmosis. Notice the subcapsular calcium in both glands. **B**, CT scan of a 59-year-old man with metastatic melanoma. **C**, CT scan of an 80-year-old man with bilateral adrenal hemorrhage resulting from anticoagulation for pulmonary emboli. **D**, Bilateral adrenal tuberculomas in a 79-year-old man with tuberculosis affecting the urogenital tract. (**A** and **B** courtesy of Dr. William D. Salmon, Jr.; **C**, courtesy of Dr. Craig R. Sussman.)

available and should be analyzed in patients with primary adrenal failure. In autoimmune Addison's disease, it is also important to look for evidence of other organ-specific autoimmune disease. A CT scan may reveal enlarged or calcified adrenals, suggesting an infective, hemorrhagic, or malignant diagnosis (Fig. 15-33). Chest radiography, tuberculin testing, and early-morning urine samples cultured for *Mycobacterium tuberculosis* should be performed if tuberculosis is suspected. CT-guided adrenal biopsy may reveal an underlying diagnosis in patients with suspected malignant deposits in the adrenal. Adrenoleukodystrophy can be diagnosed by measuring circulating levels of VLCFA. Finally, appropriate investigations, including pituitary MRI scans and an assessment of anterior function, are required for patients with suspected secondary hypoadrenalism who are not taking corticosteroid therapy.

Treatment of Acute Adrenal Insufficiency

Acute adrenal insufficiency is a life-threatening emergency, and treatment should not be delayed while waiting for definitive proof of diagnosis (Table 15-20). However, in addition to measurement of plasma electrolytes and blood glucose, appropriate samples for ACTH and cortisol should be taken before corticosteroid therapy is given. If the

patient is not critically ill, an acute ACTH stimulation test can be performed.

In adults, intravenous hydrocortisone should be given in a dose of 100 mg every 6 to 8 hours. If this is not possible, then the intramuscular route should be used. In the patient with shock, 1 L of normal saline should be given intravenously over the first hour. Because of possible hypoglycemia, it is normal to give 5% dextrose in saline. Subsequent saline and dextrose therapy will depend on biochemical monitoring and the patient's condition. Clinical improvement, especially in the blood pressure, should be seen within 4 to 6 hours if the diagnosis is correct. It is important to recognize and treat any associated condition (e.g., infection) that may have precipitated the acute adrenal crisis.

After the first 24 hours, the dose of hydrocortisone can be reduced, usually to 50 mg intramuscularly every 6 hours and then to oral hydrocortisone, 40 mg in the morning and 20 mg at 6 p.m.. This can then be rapidly reduced to a more standard replacement dose of 20 mg on waking and 10 mg at 6 p.m..

Long-Term Replacement Therapy

The aim of long-term therapy is to give replacement doses of hydrocortisone to mimic the normal cortisol secretion

TABLE 15-20

Treatment of Acute Adrenal Insufficiency (Adrenal Crisis) in Adults**Emergency Measures**

1. Establish intravenous access with a large-gauge needle.
2. Draw blood for "stat" serum electrolytes and glucose and routine measurement of plasma cortisol and ACTH. Do not wait for laboratory results.
3. Infuse 2-3 L of 154 mmol/L NaCl (0.9% saline) solution, or 50 g/L (5%) dextrose in 154 mmol/L NaCl (0.9% saline) solution, as quickly as possible. Monitor for signs of fluid overload by measuring central or peripheral venous pressure and listening for pulmonary rales. Reduce infusion rate if indicated.
4. Inject intravenous hydrocortisone (100 mg immediately and every 6 hr)
5. Use supportive measures as needed.

Subacute Measures After Stabilization of the Patient

1. Continue intravenous 154 mmol/L NaCl (0.9% saline) solution at a slower rate for next 24-48 hr.
2. Search for and treat possible infectious precipitating causes of the adrenal crisis.
3. Perform a short ACTH stimulation test to confirm the diagnosis of adrenal insufficiency (if patient does not have known adrenal insufficiency).
4. Determine the type of adrenal insufficiency and its cause, if not already known.
5. Taper glucocorticoids to maintenance dosage over 1-3 days, if precipitating or complicating illness permits.
6. Begin mineralocorticoid replacement with fludrocortisone (0.1 mg by mouth daily) when saline infusion is stopped.

ACTH, adrenocorticotropic hormone.

rate (Table 15-21). In the past, this rate was thought to be approximately 25 to 30 mg/day, but stable isotope studies have indicated lower normal cortisol production rates of 8 to 15 mg/day.³⁶¹ Most patients can cope with less than 30 mg/day (usually 15 to 25 mg/day in divided doses). Doses are usually given on waking, with a smaller dose at 6 p.m., but some patients feel better with three-times-a-day dosing. In cases of primary adrenal failure, cortisol day curves with simultaneous ACTH measurements are advocated to provide some insight into the adequacy of replacement therapy.³⁶² There are no good objective tests in secondary adrenal failure. Decisions regarding doses of replacement therapy are largely based on crude yet important end points such as weight, well-being, and blood pressure.³⁶³ Bone mineral density is moderately reduced in a dose-dependent manner in patients treated with more than 25 mg/day of hydrocortisone,³⁶⁴ highlighting the need to strive for minimally effective but safe doses.^{365,366} Possibly because of the known action of IGF1 to increase cortisol clearance,¹³¹ it is our experience that glucocorticoid requirements are slightly lower in hypopituitary, GH-deficient subjects than in patients with primary adrenal insufficiency.

In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone (or 9 α -fluorinated hydrocortisone), 0.05 to 0.2 mg/day. The mineralocorticoid activity of this is about 125 times that of hydrocortisone. After the acute phase has passed, the adequacy of mineralocorticoid replacement should be assessed by measuring electrolytes, supine and erect blood pressures, and plasma renin activity.³⁶⁷ Too little fludrocortisone may cause postural hypotension with elevated plasma renin activity, whereas too much causes the converse. Mineralocorticoid replacement therapy is all too frequently neglected in patients with adrenal failure.

Patients on glucocorticoid replacement therapy should be advised to double their daily dose in the event of intercurrent febrile illness, accident, or mental stress such as an important examination. If the patient is vomiting and cannot take medication by mouth, parenteral hydrocortisone must be given urgently. For minor surgery, 50 to 100 mg hydrocortisone hemisuccinate is given with the premedication. For major operations, this pretreatment is followed by the same regimen as for acute adrenal insufficiency (see Table 15-21). Pregnancy proceeds normally in patients taking replacement therapy, but daily doses of hydrocortisone are usually increased modestly (5 to 10 mg/day) in the last trimester. Progesterone is a mineralocorticoid antagonist, and the rising levels across pregnancy may necessitate an increased dose of fludrocortisone. During labor, patients should be well hydrated with a saline drip and should receive hydrocortisone 50 mg intramuscularly every 6 hours until delivery. Thereafter, doses can be rapidly tapered to prepregnancy levels.

Every patient on glucocorticoid therapy should be advised to register for a medical alert bracelet or necklace

TABLE 15-21

Treatment of Chronic Primary Adrenal Insufficiency in Adults**Maintenance Therapy****Glucocorticoid Replacement**

- Hydrocortisone 15-20 mg on awakening and 5-10 mg in early afternoon
- Monitor clinical symptoms and morning plasma ACTH

Mineralocorticoid Replacement

- Fludrocortisone 0.1 (0.05-0.2) mg orally
- Liberal salt intake
- Monitor lying and standing blood pressure and pulse, edema, serum potassium, and plasma renin activity
- Educate patient about the disease, how to manage minor illnesses and major stresses, and how to inject steroid intramuscularly
- Obtain MedicAlert bracelet/necklace, Emergency Medical Information Card

Treatment of Minor Febrile Illness or Stress

- Increase glucocorticoid dose twofold to threefold for the few days of illness; do not change mineralocorticoid dose
- Contact physician if illness worsens or persists for more than 3 days or if vomiting develops
- No extra supplementation is needed for most uncomplicated, outpatient dental procedures with local anesthesia. General anesthesia or intravenous sedation should not be used in the office.

Emergency Treatment of Severe Stress or Trauma

- Inject contents of prefilled dexamethasone (4-mg) syringe intramuscularly
- Get to physician as quickly as possible

Steroid Coverage for Illness or Surgery in Hospital

- For moderate illness, give hydrocortisone 50 mg bid PO or IV. Taper rapidly to maintenance dose as patient recovers.
- For severe illness, give hydrocortisone 100 mg IV q8h. Taper to maintenance level by decreasing by half every day. Adjust dose according to course of illness.
- For minor procedures under local anesthesia and most radiologic studies, no extra supplementation is needed.
- For moderately stressful procedures such as barium enema, endoscopy, or arteriography, give a single 100-mg IV dose of hydrocortisone just before the procedure.
- For major surgery, give hydrocortisone 100 mg IV just before induction of anesthesia and continue q8h for first 24 hr. Taper dose rapidly, decreasing by half per day, to maintenance level.

ACTH, adrenocorticotropic hormone.

and to carry a “steroid card.” Patients should receive regular education regarding the requirements of stress-related glucocorticoid dose adjustment, which should involve the patient’s partner and family as well. Parental preparations of hydrocortisone for self-administration may be required for patients living far from hospitals and those planning vacations.

For patients with both primary and secondary adrenal failure, beneficial effects of adrenal androgen replacement therapy with 25 to 50 mg/day of DHEA have been reported. To date, reported benefit is principally confined to female patients and includes improvement in sexual function and well-being.³⁶⁸ However, patients with adrenal insufficiency on current steroid replacement regimens have significantly impaired health-related subjective health status irrespective of the origin of disease or concomitant disease.³⁴⁰

CONGENITAL ADRENAL HYPERPLASIA

CAH comprises a group of autosomal recessive disorders caused by deficient adrenal corticosteroid biosynthesis.^{369,370} It results from defects in one of the steroidogenic enzymes involved in cortisol biosynthesis or in the electron-providing factor, P450 oxidoreductase (POR). Congenital lipid adrenal hyperplasia, caused by StAR deficiency affecting mitochondrial cholesterol uptake, is a subform of this disease complex with the unique feature of lipid

accumulation leading to cell destruction. In each case, there is reduced negative feedback inhibition of cortisol and, depending on the steroidogenic pathway involved, alteration in adrenal mineralocorticoid and androgen secretion (Table 15-22).

Aldosterone synthase deficiency does not affect glucocorticoid biosynthesis and does not lead to adrenal hyperplasia, but it has been historically grouped into this disease complex. All forms of CAH together represent a disease continuum, ranging from severe forms caused by complete loss-of-function defects to milder forms in which the defective proteins have partial residual activity.

21-Hydroxylase Deficiency

Between 90% and 95% of cases of CAH are caused by 21-hydroxylase deficiency.³⁶⁹ In Western societies, the incidence varies from 1 in 10,000 to 1 in 15,000 live births, but in isolated communities the incidence may be much higher (e.g., 1:300 in Alaskan Inuit populations). Nonclassic CAH is more common, with an incidence of about 1 in 500 to 1000 live births. The condition arises because of defective conversion of 17 α -OHP to 11-deoxycortisol. Reduced cortisol biosynthesis results in reduced negative feedback drive and increased ACTH secretion; as a consequence, adrenal androgens are produced in excess (Fig. 15-34). Seventy-five percent of patients have clinically manifest mineralocorticoid deficiency because of failure to convert sufficient progesterone to DOC in the ZG.

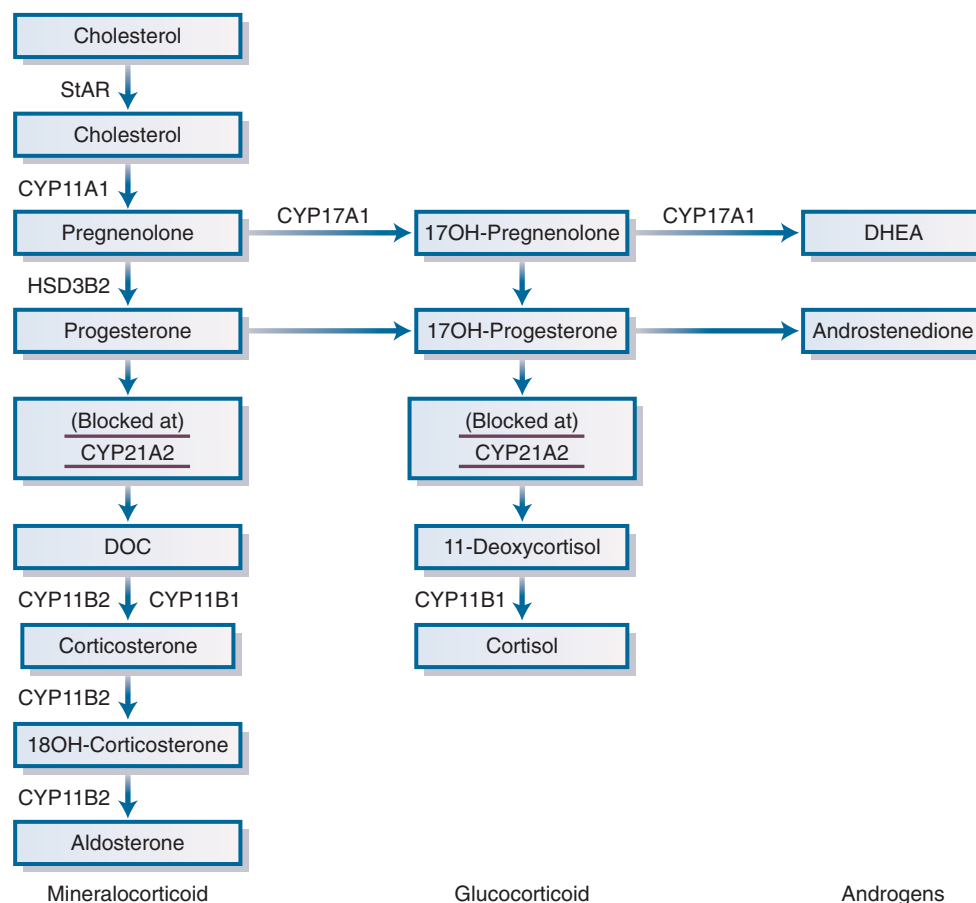

Figure 15-34 Congenital adrenal hyperplasia related to 21-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotrophic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition, resulting in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, variable mineralocorticoid deficiency, and excessive secretion of adrenal androgens. CYP, cytochrome P450; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory protein.

ACTH, adrenocorticotrophic hormone; 17-OHP, 17-hydroxyprogesterone; SD, standard deviation.

Clinically, several distinct variants of 21-hydroxylase deficiency have been recognized (Table 15-23).

Simple Virilizing Form

In the simple virilizing form of 21-hydroxylase deficiency, the enhanced ACTH drive to adrenal androgen secretion in utero leads to virilization of an affected female fetus. Depending on the severity, clitoral enlargement, labial fusion, and development of a urogenital sinus may occur, leading to sexual ambiguity at birth and even inappropriate sex assignment. Males are phenotypically normal at birth and are at risk of not being diagnosed; this explains the skewed female-to-male ratio of simple virilizing CAH diagnosed in the preneonatal screening era. Such patients may present in early childhood with signs of precocious pseudopuberty such as sexual precocity, pubic hair development, or growth acceleration due to premature androgen excess. If left untreated, this stimulates premature epiphyseal closure and final adult height is invariably diminished.^{371,372}

Salt-Wasting Form

Seventy-five percent of patients of both sexes who have the salt-wasting form of 21-hydroxylase deficiency also have concomitant, clinically manifested aldosterone deficiency. In addition to the described features, neonates commonly present after the first 2 weeks of life with a salt-wasting crisis and hypotension. The clinical signs and symptoms of salt wasting include poor feeding, vomiting, failure to thrive, lethargy, and sepsis-like symptoms. These features may alert the clinician to the diagnosis in a male baby, but the diagnosis is still delayed in many cases, and the condition carries a significant neonatal mortality rate.

Nonclassic or Late-Onset 21-Hydroxylase Deficiency

Patients with nonclassic 21-hydroxylase deficiency present in childhood or early adulthood with premature pubarche or with a phenotype that may masquerade as polycystic ovary syndrome (PCOS).^{369,373,374} Indeed, nonclassic CAH is a recognized secondary cause of PCOS and appears to be more common than the classic variant. Recent evidence suggests that at least 30% of adult patients have an impaired cortisol response to ACTH(1-24)³⁷⁵ and may be prone to stress-induced adrenal insufficiency. Routine assessment of adrenal glucocorticoid reserve is indicated. In some series

from tertiary referral centers, nonclassic 21-hydroxylase deficiency accounts for up to 12% of all "PCOS" patients, but more realistic prevalence rates are probably 1% to 3%.³⁷⁶ Females present with hirsutism, primary or secondary amenorrhea, or anovulatory infertility.³⁷³ Androgenic alopecia and acne may be other presenting features.

Heterozygote 21-Hydroxylase Deficiency

Salt-wasting, simple virilizing, and late-onset 21-hydroxylase deficiency are all caused by homozygous or compound heterozygote mutations in the human 21-hydroxylase gene (*CYP21A2*). In the carrier or heterozygote state, only one allele is mutated. The clinical significance of the heterozygote state is uncertain; it does not appear to disadvantage reproductive capability but may cause signs of hyperandrogenism in adult women.³⁶⁹

Molecular Genetics

21-Hydroxylase deficiency is inherited as an autosomal recessive trait, and the higher incidence of the condition in some ethnic communities almost certainly relates to consanguinity. The *CYP21A2* gene and its highly homologous pseudogene (*CYP21A1P*) are located on the short arm of chromosome 6 (6p21.3). Because of the genomic localization within the human leukocyte antigen (HLA) locus, a region with a high frequency of genomic recombinations, most of the mutations causing 21-hydroxylase deficiency are generated by gene conversion events. Complete gene deletions or conversions of the *CYP21A2* gene, eight pseudogene-derived point mutations, and an 8-base-pair deletion are found in more than 95% of cases. Other rare pseudogene-independent *CYP21A2*-inactivating mutations have been reported in single families or small populations. Approximately 65% to 75% of CAH patients are compound heterozygous for the disease-causing mutations.³⁷⁷

The genotype-phenotype correlation in CAH due to 21-hydroxylase deficiency is well established. The clinical phenotype correlates with the less severely mutated allele and, consequently, with the residual 21-hydroxylase activity (Fig. 15-35).^{378,379} This correlation appears to be high, although divergence between genotype and phenotype has been observed.³⁸⁰ The 21-hydroxylase activity measured by in vitro analysis provides a possibility for estimating disease severity, although some phenotypic variability (e.g., salt wasting, age at onset) seems likely to depend on other

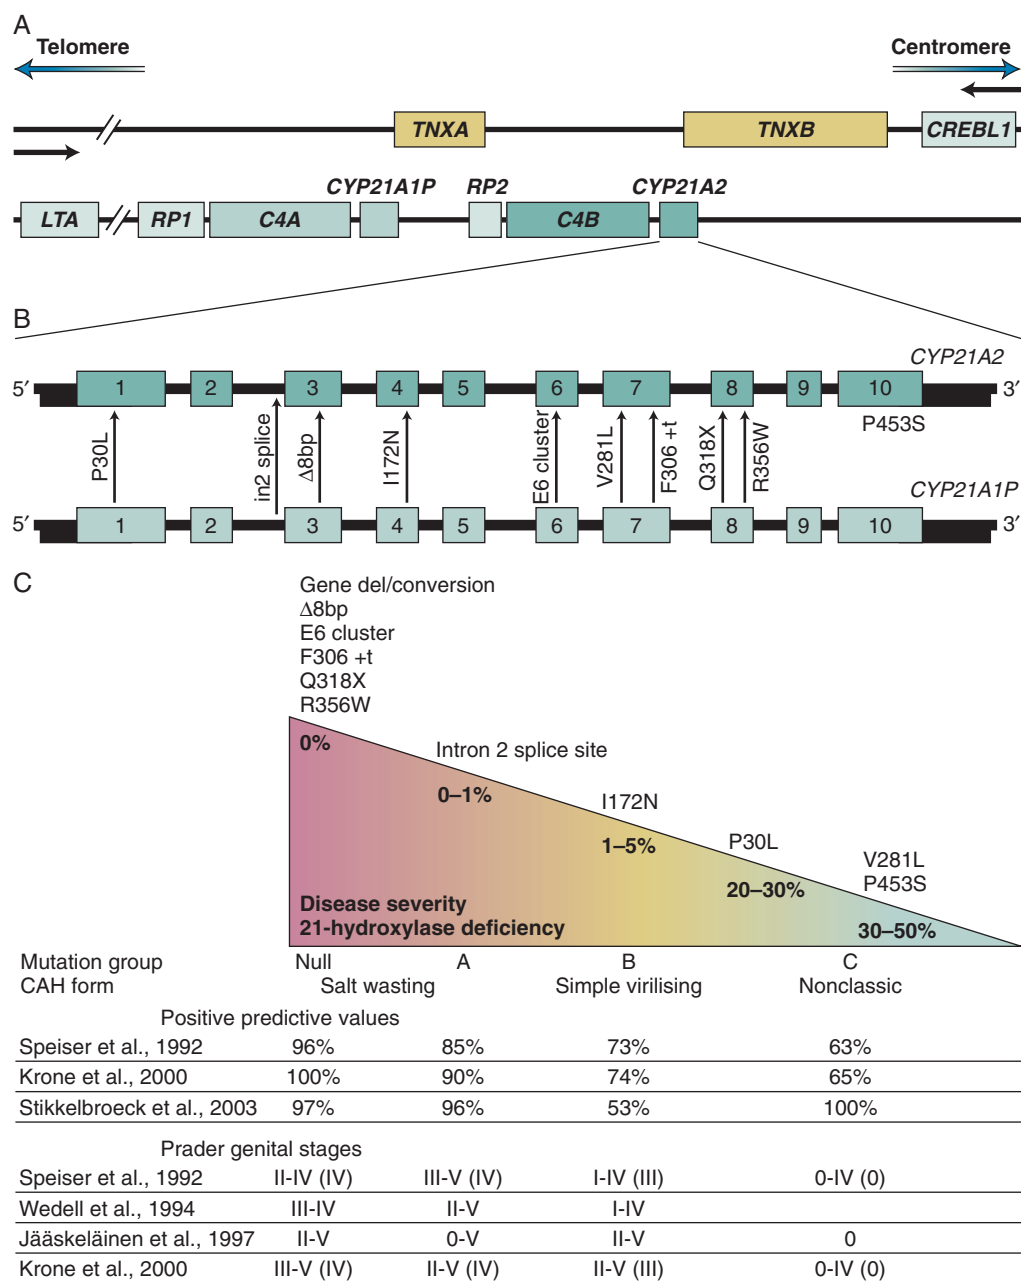

Figure 15-35 Genetics of 21-hydroxylase deficiency. **A**, Genomic organization of the functional *CYP21A2* gene and its nonfunctional *CYP21A1P* pseudogene. **B**, Nine out of 10 common mutations are transferred by microconversions from the *CYP21A1P* pseudogene into the *CYP21A2* gene. **C**, Genotype-phenotype correlation in 21-hydroxylase deficiency is well established. Based on the in vitro enzyme activity, the *CYP21A2* gene-inactivating mutations can be categorized into four major mutation groups. Although variation has been reported for the milder mutations, the overall correlation is high regarding expression of the adrenal phenotype. Considerable variability exists for the correlation with genital virilization. CAH, congenital adrenal hyperplasia; NC, nonclassic congenital adrenal hyperplasia; SW, salt wasting; SV, simple virilizing.

interacting genes and maturation processes rather than *CYP21A2* itself. One such factor might be the length of the CAG repeats in the androgen receptor modulating androgen action.³⁸¹ Potential variations in the degree of recovery from glucocorticoid and mineralocorticoid deficiency during later life might be explained by significant 21-hydroxylase activity of the cytochrome P450 enzymes *CYP2C19* and *CYP3A4*.³⁸²

Diagnostic Criteria

A diagnosis of 21-hydroxylase deficiency should be considered in any newborn infant with genital ambiguity and salt

wasting, hypotension, or hypoglycemia. Hyponatremia and hypokalemia with raised plasma renin activity are found in salt-wasters. In later life, adrenal androgen excess (DHEAS, androstenedione) is found in patients presenting with sexual precocity or a PCOS-like phenotype. Randomly timed measurements of the plasma 17-OHP concentration are significantly increased in classic 21-hydroxylase deficiency. Commonly, 17-OHP concentrations in patients with salt-wasting CAH are higher than in non-salt-losing patients.

In nonclassic CAH, an SST is required to establish normal adrenal glucocorticoid reserve. Clinically useful

Figure 15-36 Basal and stimulated plasma 17 α -hydroxyprogesterone (17-OHP) concentrations in patients with 21-hydroxylase (21-OH, CYP21A2) deficiency. To convert values to nmol/L, multiply by 0.0303. The mean for each group is indicated by a large cross and an adjacent letter: c, patients with classic CYP21A2 deficiency; v, patients with nonclassic (acquired and cryptic) CYP21A2 deficiency; h, heterozygotes for all forms of CYP21A2 deficiency; p, general population; u, known unaffected persons (e.g., siblings of patients with CYP21A2 deficiency who carry neither affected parental haplotype as determined by human leukocyte antigen typing). (From White PC, New MI, Dupont B. Congenital adrenal hyperplasia: part 1. *N Engl J Med*. 1987;316:1519-1524.)

nomograms have been developed that compare circulating concentrations of 17-OHP before and 60 minutes after exogenous ACTH administration to investigate borderline cases and to differentiate between nonclassic CAH and heterozygous carriers (Fig. 15-36).³⁸³ This separates patients with classic and nonclassic 21-hydroxylase deficiency from heterozygote carriers and normal subjects, but there is some overlap between values seen in heterozygotes and in normal subjects. 17-OHP is measured basally and then 60 minutes after administration of 250 μ g Synacthen. Stimulated values are invariably grossly elevated (>35 nmol/L [>11 μ g/L]) in patients with classic and nonclassic forms of the disorder. Heterozygote patients usually have stimulated values between 10 and 30 nmol/L (330 to 1000 ng/dL) (see Fig. 15-36). Stimulation tests are not always required to make a diagnosis; for example, a basal 17-OHP concentration of less than 5 nmol/L (<150 ng/dL) in the follicular phase of the menstrual cycle effectively excludes late-onset 21-hydroxylase deficiency.³⁷³ CYP21A2 genotyping to confirm the clinical and biochemical diagnosis is a useful adjunct to hormonal measurements. Androgen excess in 21-hydroxylase deficiency is readily suppressed after glucocorticoid administration.

Prenatal diagnosis of 21-hydroxylase deficiency has been advocated, because treatment of an affected female may prevent masculinization in utero.³⁸⁴ 17-OHP can be

assayed in amniotic fluid, but the most robust approach is the rapid genotyping of fetal cells obtained by chorionic villous sampling in early gestation. In patients with known 21-hydroxylase deficiency (male or female) seeking fertility, determination of 17-OHP levels across an SST in the partner before conception will uncover nonclassic or heterozygote cases and provide the endocrinologist/geneticist with some assignment of risk before pregnancy.

Treatment

The objectives for treatment of 21-hydroxylase deficiency differ with age, but at all ages treatment and overall patient management can be fraught with difficulties.

In childhood, the overall goal is to replace glucocorticoid and mineralocorticoid, thereby preventing further salt-wasting crises, but also to normalize adrenal androgen secretion so that normal growth and skeletal maturation can proceed. Accurate replacement is essential; in excess, glucocorticoids will suppress growth, whereas inadequate replacement will result initially in accelerated linear growth and ultimately in short stature due to premature epiphyseal closure.³⁶⁹ Response is best monitored through growth velocity and bone age, with biochemical markers from blood (17-OHP, androstenedione, testosterone), urine, and saliva (17-OHP, androstenedione, testosterone) being useful adjuncts. In difficult cases, a day curve study, as described for patients with primary adrenal failure but measuring the ACTH and 17-OHP response before and after corticosteroid replacement, may confirm overreplacement or underreplacement. The optimal glucocorticoid dose fails to suppress 17-OHP and its metabolites and maintains sex hormone concentrations in the middle of the age- and sex-specific normal range. Ideally, the biochemical investigations will indicate the need for dose adjustments before physical changes, growth, and skeletal maturation indicate inadequate or excessive glucocorticoid treatment.³⁸⁵

Corrective surgery (e.g., clitoral reduction, vaginoplasty) is frequently required during childhood. The method of choice should be a one-stage complete repair using the newest techniques of vaginoplasty, clitoral, and labial surgery.³⁸⁵

In late childhood and adolescence, appropriate replacement therapy is equally important. Overtreatment may result in obesity and delayed menarche/puberty with sexual infantilism, whereas underreplacement will result in sexual precocity. Compliance with regular medication is often an issue through adolescence.

Although much has been written about adequate control in childhood, adults with CAH often provide an ongoing dilemma for the endocrinologist. The follow-up of such patients should involve multidisciplinary clinics, initially with transition adolescence clinics to facilitate transfer from pediatric to adult care. Problems in adulthood relate to fertility concerns, hirsutism, and menstrual irregularity in women; obesity, metabolic consequences, probable increased cardiovascular risk, and impact of short stature; sexual dysfunction; and psychological problems.^{369,386,387} Counseling is often required in addition to endocrine support. Males may develop enlargement of the testes due to so-called testicular adrenal rest tumors—that is, ectopic adrenal tissue, which may regress after glucocorticoid suppression. These patients need adequate endocrine therapy rather than urologic referral with ensuing risk of removal of testis mistaken for a tumor.³⁸⁸

In the absence of any evidence-based data, there are no prescriptive steroid regimens to treat patients with CAH at any age, and, as a result, many individualized regimens are

used in clinical practice. Hydrocortisone is recommended for replacement therapy from the newborn period to adolescence.³⁸⁵ Usual starting doses of hydrocortisone in childhood are 10 to 15 mg/m² per day in three divided doses per day, with up to 25 mg/m² in infancy only seldom required. These doses are higher than those employed for replacement of adrenal insufficiency because treatment also aims at normalization of ACTH-driven adrenal androgen excess. The optimal timing for providing the highest dose of hydrocortisone remains an ongoing matter of debate, with no data supporting either “circadian” replacement (giving the highest dose in the morning) or “reverse-phase” therapy (giving the largest dose of hydrocortisone at night). Long-acting steroids such as prednisone, prednisolone, and dexamethasone are more effective in this regard but should not be given before the end of puberty, to avoid oversuppression and reduction in linear growth.

Fludrocortisone is required for patients with salt wasting (although this may spontaneously improve with age). Fludrocortisone doses during the first year of life are commonly 150 µg/m² per day. Sodium needs to be supplemented, as milk feeds provide only maintenance sodium requirements. Adequate mineralocorticoid replacement usually leads to hydrocortisone dose reduction. The relative dose in relation to body surface decreases throughout life. Fludrocortisone doses of 100 µg/m² per day after the first 2 years of life are commonly sufficient. This requirement drops further with adolescence and adulthood to a daily dose of 100 to 200 µg (50 to 100 µg/m² per day). Mineralocorticoid substitution is monitored by measurements of plasma renin activity (low or suppressed levels indicating overtreatment) and blood pressure.³⁸⁹

Adrenomedullary dysplasia has been reported in the CAH adrenal, probably because of relative glucocorticoid deficiency, which results in epinephrine deficiency.³⁹⁰ Benefits of epinephrine replacement on the metabolic response to exercise have been reported in children,³⁹¹ but further studies are required before routine catecholamine replacement therapy can be advocated. In clinical practice, sufficient supplementation of glucose during exercise and illness should be guaranteed, to prevent hypoglycemic episodes. Bilateral adrenalectomy is effective but should be regarded as a last resort³⁹²; in addition, the requirement for lifelong corticosteroid replacement therapy, patients could also develop feedback ACTH-secreting pituitary tumors.³⁹³ This procedure bears also a number of risks, including surgical and anesthetic complications, and the patient is left completely adrenal insufficient.

Prenatal dexamethasone treatment is effective to avoid virilization of the external genitalia in the female fetus. Unlike hydrocortisone, which is inactivated by placental 11β-HSD, maternally administered dexamethasone can cross the placenta to suppress the fetal HPA axis. One approach is to advocate use of dexamethasone therapy as soon as pregnancy is confirmed in high-risk cases and to continue this therapy until the diagnosis is excluded in the female fetus. If the fetus is affected, only those of female sex require dexamethasone therapy across gestation. Therapy must be instigated at 6 to 7 weeks' gestation to be effective. The suggested dexamethasone dose is 20 to 25 µg/kg in three divided doses per day (total maximum dose, 1.5 mg/day).³⁶⁹ However, because only one in eight pregnancies treated in this way will result in an affected female fetus, the use of steroid therapy in this setting has been questioned.³⁹⁴ The fetal sex can be determined as early as week 6 of gestation with the use of novel molecular diagnostic methods that analyze free fetal DNA from maternal blood using real-time polymerase chain reaction.

In this way, the number of unnecessarily treated cases can be reduced to three out of eight. Dexamethasone can lead to maternal Cushingoid effects in pregnancy³⁹⁵ and may in turn have long-term, deleterious effects on the fetus, including metabolic and psycho-intellectual consequences. Prenatal treatment is controversial and has to be regarded as experimental; patients treated should be included in ongoing multicenter studies.³⁹⁶

In adult women with hyperandrogenism and untreated nonclassic CAH, there is no evidence that final height is affected. In this setting, glucocorticoid suppression in isolation rarely controls hirsutism, and additional antiandrogen therapy is often required (e.g., cyproterone acetate, spironolactone, flutamide together with an oral estrogen contraceptive pill). However, ovulation induction rates with gonadotropin therapy are improved after suppression of nocturnal ACTH levels with 0.25 to 0.5 mg dexamethasone. Hypogonadotropic hypogonadism in male patients is a consequence of increased aromatization of adrenal androgens, in particular androstenedione to estrone resulting in suppression of pituitary LH and FSH secretion. The condition is reversible after optimization of glucocorticoid therapy. However, overreplacement in men or women may also lead to hypogonadotropic hypogonadism due to glucocorticoid-mediated suppression of GnRH secretion.

Long-Term Complications and Comorbidities

Outcome assessed by final height is not optimal in many patients treated for 21-hydroxylase deficiency. In a meta-analysis including 18 studies published between 1977 and 2001, the mean adult height of patients with classic CAH was 10 cm (−1.4 SDS) below the population mean and −1.2 SDS calculated for target height. The pubertal growth spurt occurs earlier and is less pronounced than normal. An often overlooked problem is glucocorticoid overtreatment during the first 2 years of life; overtreatment suppresses the infant growth spurt, which is characterized by the highest postnatal growth velocity. Therefore, the lowest optimal dose of glucocorticoid replacement should be established as early in life as possible.

Increased fat mass and obesity are common among children and adolescents with CAH.³⁹⁷⁻³⁹⁹ Glucocorticoid dose, chronologic age, advanced bone age maturation, and parental obesity all contribute to elevated BMI SDS.³⁹⁸

Increased fat mass and higher insulin levels have been described in women older than 30 years of age with CAH. However, clear evidence of cardiovascular risk factors had not been shown. Women with CAH do have a significantly higher rate of gestational diabetes, a possible forerunner for the development of type 2 diabetes,⁴⁰⁰ and women with nonclassic CAH⁴⁰¹ and young adult CAH patients⁴⁰² have reduced insulin sensitivity. Increased intima media thickness as a marker of atherosclerosis has been detected.⁴⁰²

Daytime systolic blood pressure in children and adolescents with CAH is elevated, and the physiologic nocturnal dip in blood pressure is absent.⁴⁰³ Elevated systolic blood pressure correlates with the degree of overweight and obesity.⁴⁰⁴ There are no long-term outcome data on adults.

11β-Hydroxylase Deficiency

11β-Hydroxylase deficiency accounts for 7% of all cases of CAH, with an incidence of 1:100,000 live births.⁴⁰⁵ The condition arises because of mutations in the 11β-hydroxylase (*CYP11B1*) gene that result in loss of enzyme activity and a block in the conversion of 11-deoxycortisol to cortisol. The *CYP11B1* gene is located on chromosome 8q24.3, approximately 40 kilobases from the highly homologous

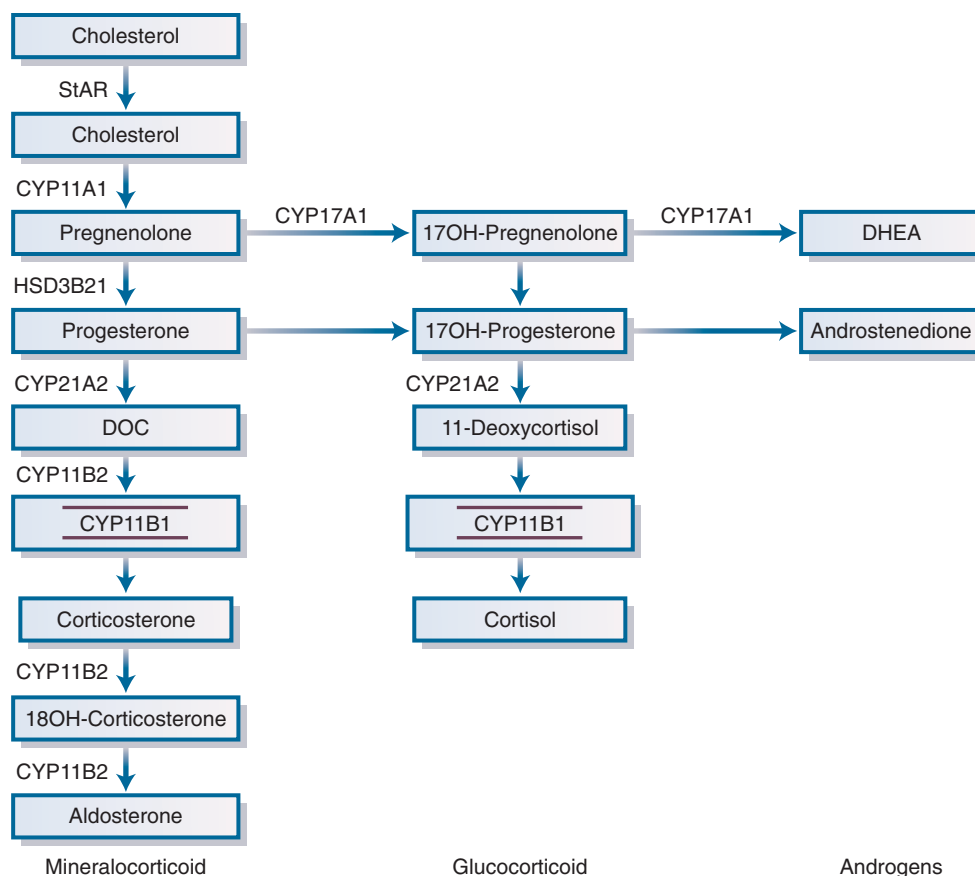

Figure 15-37 Congenital adrenal hyperplasia related to 11 β -hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotrophic hormone (ACTH) levels increase because of the loss of normal negative feedback inhibition, which results in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, mineralocorticoid excess related to excessive deoxycorticosterone (DOC) secretion, and excessive secretion of adrenal androgens. CYP, cytochrome P450; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory protein.

aldosterone synthase gene (*CYP11B2*).⁴⁰⁵ *CYP11B1*-inactivating mutations have been shown to be distributed over the entire coding region consisting of nine exons. Although mutation clusters are reported in exons 2, 6, 7, and 8,^{377,405} real hot spots, as seen in 21-hydroxylase deficiency, do not exist. Most of the reported mutations lead to absent or almost absent 11 β -hydroxylase enzyme activity, with only some cases of mild or nonclassic 11-hydroxylase deficiency reported.^{406,407}

Loss of negative cortisol feedback and enhanced ACTH-mediated adrenal androgen excess occur in 11 β -hydroxylase deficiency (Fig. 15-37). Clinical features therefore are very similar to those reported in the simple virilizing form of CAH (46,XX DSD including virilization of the external genitalia and sexual ambiguity); and again, milder cases can manifest later in childhood or even young adulthood. The principal difference from 21-hydroxylase deficiency is hypertension, which is thought to be secondary to the mineralocorticoid effect of DOC excess. However, there is a poor correlation between DOC secretion and the presence of hypertension, and unexplained salt wasting has been reported in few patients during early life. On this clinical background, the diagnosis can be made by measuring a plasma ACTH-stimulated 11-deoxycortisol value, which will be higher than three times the 95th percentile for an age-matched normal group. Basal concentrations of 17-OHP are commonly increased but may be normal even during the first weeks of life.⁴⁰⁸

Although established heterozygotes may not demonstrate an increase in 11-deoxycortisol above normal values after Synacthen stimulation⁴⁰⁹ (unlike the 17-OHP response observed in heterozygote patients with 21-hydroxylase deficiency), exaggerated ACTH-stimulated responses have been observed in patients with hirsutism⁴¹⁰ and in patients with essential hypertension,⁴¹¹ suggesting partial defects in 11 β -hydroxylase activity.

Treatment is with replacement glucocorticoid therapy; with suppression of DOC secretion, the plasma renin activity, which is suppressed at baseline, increases into the normal range. In general, higher glucocorticoid doses are needed to suppress hyperandrogenism compared with the situation in 21-hydroxylase deficiency, and add-on antihypertensive therapy may be necessary in some cases. Anti-hypertensive treatment should be commenced at an early stage to avoid excessive glucocorticoid exposure.

17 α -Hydroxylase Deficiency

Approximately 150 cases of 17 α -hydroxylase deficiency have been reported.⁴¹²⁻⁴¹⁴ Mutations within the *CYP17A1* gene result in failure to synthesize cortisol (17 α -hydroxylase activity), adrenal androgens (17,20-lyase activity), and gonadal steroids (Fig. 15-38). Therefore, in contrast to 21- and 11 β -hydroxylase deficiencies, 17 α -hydroxylase deficiency results in adrenal and gonadal insufficiency and causes 46,XY DSD. A single enzyme is expressed in

steroid profile, allowing for prenatal biochemical diagnosis.^{421,422} The analysis of serum steroids only may lead to misdiagnosis.⁴²³ Cortisol baseline secretion may be normal, but most, if not all, patients show an insufficient cortisol response to ACTH stimulation and therefore require glucocorticoid replacement. Impaired 17,20-lyase activity results in deficient androgen synthesis, and affected boys are often born undervirilized. Most of the affected girls are born with virilized genitalia. Therefore, patients can present with 46,XY or 46,XX DSD or with appropriate development of the external genitalia in both sexes. After birth, virilization does not progress, and circulating androgen concentrations are typically low. Some mothers develop signs of virilization during midpregnancy with an affected child; this commonly resolves soon after birth, further indicating intrauterine androgen excess.⁴²¹ In addition to these features of CAH, affected children may also present with bone malformations, including midface hypoplasia, craniosynostosis, and radiohumeral synostosis, in some cases resembling the Antley-Bixler congenital malformation syndrome.^{424,425} The bone phenotype in affected patients with POR deficiency is most likely caused by an impairment of sterol biosynthesis, specifically of POR-dependent 14 α -lanosterol demethylase (CYP51A1).

The paradox of fetal virilization but sex hormone deficiency in postnatal life might be mediated by a newly discovered “backdoor” pathway of androgen synthesis in fetal life that relies on neither androstenedione nor testosterone as an intermediate.^{425–427} Pubertal development in POR deficiency appears to be dominated by the consequences of sex steroid deficiency,⁴²⁷ and most patients

require sex hormone substitution. The overall incidence of POR deficiency has not been established. However, a relatively large number of patients with POR deficiency were reported within a short period after the initial description of the molecular cause of the disease.^{427,428}

The *POR* gene is located on chromosome 7q11.2 and consists of 15 translated exons spanning 32.9 kilobytes and encoding a protein of 680 amino acids. A variety of *POR*-inactivating mutations have been reported, including missense, frameshift, and splice site mutations. A287P is the most common mutation in Caucasians, whereas R457H is the most frequent founder mutation in the Japanese population. All patients carry *POR* mutations that are either partially inactivating or, in case of major loss-of-function mutations, manifest only in the compound heterozygous state. Homozygous mutations with total loss of function are most likely not viable—a view supported by the nonviability of complete *POR* gene deletion in the murine model.⁴²⁹

3 β -Hydroxysteroid Dehydrogenase Deficiency

In this rare form of CAH, the secretion of all classes of adrenal and ovarian steroids is impaired due to mutations within the *HSD3B2* gene encoding 3 β -HSD type 2.^{430,431} There are two isoforms of 3 β -HSD, encoded by *HSD3B1* and *HSD3B2*, respectively. The *HSD3B2* gene is located on chromosome 1p13.1 and consists of four exons. *HSD3B2* is expressed mainly in the adrenal and the gonad, whereas *HSD3B1* is expressed in the placenta and almost ubiquitously in peripheral target tissues.^{27,431} The enzyme

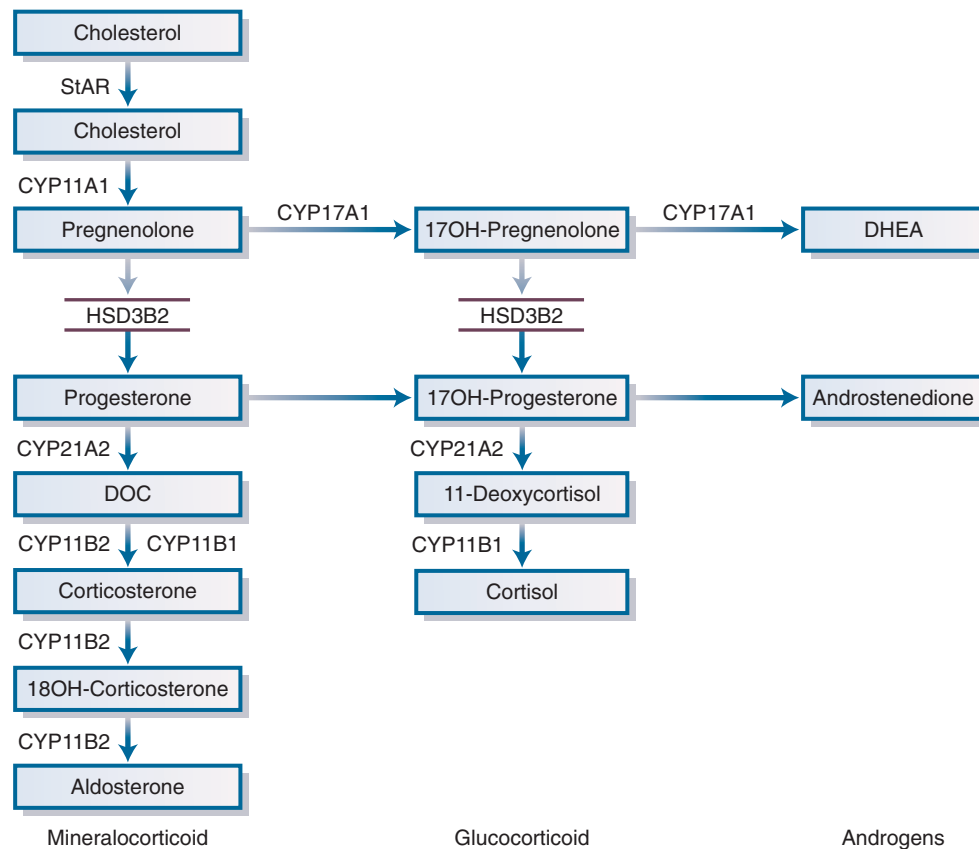

Figure 15-39 Congenital adrenal hyperplasia related to 3 β -hydroxysteroid dehydrogenase (3 β -HSD) type 2 deficiency resulting in cortisol deficiency and variable mineralocorticoid deficiency. Gonadal 3 β -HSD type 2 activity is also absent, resulting in 46,XY DSD and hypogonadism or primary amenorrhea in females. Virilization in females can occur due to 3 β -hydroxysteroid dehydrogenase type 1 activity. DOC, deoxycorticosterone; DHEA, dehydroepiandrosterone; DSD, disorder of sex development; StAR, steroidogenic acute regulatory protein.

HSD3B2 catalyzes three key reactions in adrenal steroidogenesis: the conversion of the Δ^5 -steroids pregnenolone, 17-hydroxypregnenolone, and DHEA to the Δ^4 -steroids progesterone, 17-OHP, and androstenedione, respectively. 3 β -HSDII deficiency affects all three steroid hormone pathways (i.e., mineralocorticoids, glucocorticoids, and sex steroids).

The clinical spectrum shows a wide variety of disease expression. Patients usually present in early infancy with adrenal insufficiency. Loss of mineralocorticoid secretion results in salt wasting, although this is absent in 30% to 40% of cases (Fig. 15-39). As with 21-hydroxylase deficiency, absence of salt wasting may delay the presentation into childhood or puberty, ranging from a severe salt-wasting form with or without ambiguous genitalia in affected male neonates to isolated premature pubarche in infants and children of both sexes and a late-onset variant manifesting with hirsutism and menstrual irregularities. In general, the functional and biochemical data are in close agreement with the expressed phenotype in patients with the non-salt-wasting form of HSD3B2 deficiency. However, some variability exists, and identical mutations have been found in the *HSD3B2* gene in both salt-wasters and non-salt-wasters.^{430,431} The correlation between the impairment in male sexual differentiation and salt wasting is poor. The spectrum of genital development is variable in both sexes. In males, because the HSD3B2 enzyme is also expressed within the gonad, 46,XY DSD may occur resulting in female external genitalia. However, most patients present with hypospadias, and even normal male genitalia may be found. In females, genital development can be normal, but usually there is evidence of mild virilization, presumably because of enhanced adrenal DHEA secretion, which is converted peripherally to testosterone. A late-onset form has been described in patients with premature pubarche⁴³² and a PCOS-like phenotype (i.e., hirsutism, oligorrhea/amenorrhea).⁴³³

Because activity of the HSD3B1 enzyme, present peripherally, is intact, levels of circulating Δ^4 steroids (progesterone, 17-OHP, and androstenedione) may be normal (or even increased). However, a diagnosis is established by demonstration of an increased ratio of Δ^5 steroids (pregnenolone, 17-hydroxypregnenolone, DHEA) to Δ^4 steroids in plasma or urine. Hormonal criteria have been refined for the diagnosis of HSD3B2 deficiency based on genotyping of the *HSD3B2* gene. The 17-hydroxypregnenolone concentrations and the ratios of 17-hydroxypregnenolone to cortisol at baseline and after ACTH stimulation are of the highest discriminatory value in differentiating between patients affected by HSD3B2 deficiency and those with milder biochemical abnormalities, who are commonly negative for *HSD3B2* mutations.^{434,435} Treatment is with replacement glucocorticoids, fludrocortisone (if indicated), and sex steroids from puberty onward.

StAR Deficiency: Congenital Lipoid Adrenal Hyperplasia

Mutations in the gene encoding StAR results in a failure of transport of cholesterol from the outer to the inner mitochondrial membrane in steroidogenic tissues. StAR-independent cholesterol transport occurs only at a low rate. As a result, there is deficiency of all adrenal and gonadal steroid hormones.^{23,436} The adrenal glands are often massively enlarged and full of lipid; before the characterization of StAR, the condition was termed *congenital lipoid adrenal hyperplasia*.⁴³⁶ StAR deficiency severely but incompletely abolishes pregnenolone synthesis. Cholesterol esters accumulate under the increased tone of ACTH

stimulation. Consequently, the lipid accumulation worsens the dysfunction and leads to adrenal cell destruction. Presentation is with acute adrenal insufficiency in the neonatal period, and males exhibit 46,XY DSD due to absent gonadal steroids.

The most severe form of this disorder manifests with 46,XY DSD and combined adrenal insufficiency. Salt wasting typically develops in the neonatal period or after a few weeks of life, but later onset may also occur. Females can show spontaneous pubertal development. A milder form of StAR deficiency has also been described in normally virilized 46,XY individuals who present with adrenal failure during early childhood.⁴³⁷ Treatment consists of glucocorticoid and mineralocorticoid replacement and substitution of sex hormones in later life.

P450 Side-Chain Cleavage Deficiency

Deficiency of P450_{scc} (CYP11A1) enzyme is a rare inborn error of steroidogenesis, with only seven cases reported. It was previously thought that such mutations would not be viable, because the maintenance of human pregnancy relies on placentally produced progesterone. The production is facilitated by the fetal part of the placenta from the second trimester onward. P450_{scc} deficiency manifests clinically and biochemically with similar signs and symptoms as StAR deficiency, but patients do not have enlarged adrenals.⁴³⁸⁻⁴⁴⁰ Depending on the impairment of CYP11A1 function, a spectrum of clinical presentation ranges from 46,XY DSD with severe adrenal insufficiency in the newborn period to hypospadias and cryptorchidism and later manifestation of adrenal insufficiency during childhood.⁴⁴¹ Concentrations of all steroid hormones are decreased, in keeping with impaired conversion of cholesterol to pregnenolone. Treatment with glucocorticoid, mineralocorticoid, and sex steroid replacement is required.

Cortisone Reductase Deficiency

In cortisone reductase deficiency, adrenal glands become "hyperplastic" because of ACTH stimulation due to a defect in cortisol metabolism rather than an inherent defect within the gland itself.^{129,442,443} Patients with this condition have a defect in the conversion of cortisone to cortisol, suggesting inhibition of 11-oxo-reductase activity and, by implication, inhibition of HSD11B1 (see Fig. 15-12). Cortisol clearance is increased and, as a consequence, ACTH secretion is elevated to maintain normal circulating cortisol concentrations but at the expense of adrenal androgen excess. Female patients present with hirsutism, menstrual irregularity, androgenic alopecia, or some combination of these features. Males may present with premature pubarche. Dexamethasone treatment to suppress ACTH has been used with some success to control the hyperandrogenism in these cases. Urinary tetrahydrometabolites of cortisol and cortisone show almost exclusively THE with little or no detectable THF or allo-THF; the ratio THF:allo-THF:THE is less than 0.05 (reference range, 0.8 to 1.3). The molecular bases for cortisone reductase deficiency are inactivating mutations in hexose-6-phosphate dehydrogenase (H6PDH).⁴⁴³ H6PDH, located in the endoplasmic reticulum, catalyzes the conversion of glucose-6-phosphate to glucose-6-phosphogluconate, thereby generating NADPH, which is crucial in conveying oxo-reductase activity on HSD11B1.

Patients with PCOS share many of the same clinical characteristics as those with cortisone reductase deficiency. Whereas there is evidence to support increased cortisol

secretion rates in PCOS, perhaps indicating a defect in the conversion of cortisone to cortisol, a consensus with respect to THF+allo-THF:THE ratios is still lacking.⁴⁴⁴ Association studies using single nucleotide polymorphic markers in the HSD11B1 and H6PDH genes have largely been negative.

Mineralocorticoid Deficiency

The mineralocorticoid deficiency syndromes are listed in Table 15-24. They can be divided into congenital and acquired syndromes. Mineralocorticoid deficiency may occur in some forms of CAH and with other causes of adrenal insufficiency (e.g., Addison's disease, CAH).

Primary Defects in Aldosterone Biosynthesis: Aldosterone Synthase Deficiency

Before the characterization of the *CYP11B2* gene, two diseases were recognized, *corticosterone methyl oxidase type I (CMO I) deficiency* and *corticosterone methyl oxidase type II (CMO II) deficiency*.⁴⁴⁵ Subsequently, both variants were shown to be secondary to mutations in aldosterone synthase (*CYP11B2*), and they are now termed *aldosterone synthase deficiency, types I and II*.⁴⁴⁶ Aldosterone synthase catalyzes the three terminal steps of aldosterone biosynthesis, 11 β -hydroxylation of DOC to corticosterone, 18-hydroxylation to 18-hydroxycorticosterone, and 18-oxidation to aldosterone. Patients with type I aldosterone synthase deficiency have low to normal levels of 18-hydroxycorticosterone but undetectable levels of aldosterone (or urinary tetrahydroaldosterone), whereas patients with the type II variant have high levels of 18-hydroxycorticosterone and only subnormal or even normal levels of aldosterone. This suggests blockade of only the terminal 18-oxidation step, with some residual aldosterone synthase activity remaining. The explanation for the variable biochemical phenotype is unknown, particularly now that the same mutation in aldosterone synthase has been uncovered in both variants. It is possible that the phenotypic variation may reflect polymorphic variants in the residual and normal product of the *CYP11B1* gene, 11 β -hydroxylase.

Both variants are rare and are inherited as autosomal recessive traits.⁴⁴⁶ Patients usually present in neonatal life with a salt-wasting crisis involving severe dehydration, vomiting, and failure to grow and thrive. Hyperkalemia, metabolic acidosis, dehydration, and hyponatremia are found. The plasma renin activity is elevated, and plasma aldosterone levels are low. Plasma 18-hydroxycorticosterone levels, the ratio of plasma 18-hydroxycorticosterone to aldosterone, and the levels of their urinary metabolites are used to differentiate the type I and II variants. In most infants, the disorders become less severe as the child ages; indeed, in older children, adolescents, and adults, the abnormal steroid pattern described may be present

and may persist throughout life without clinical manifestations.

Patients with *CYP11B2* deficiency typically respond well to 9 α -fludrocortisone (starting dose, 150 μ g/m² per day in neonates and infants) and may also benefit from salt supplementation. Patients with failure to grow and thrive usually show a good catch-up growth. Electrolytes often tend to normalize spontaneously between 3 to 4 years of age. However, untreated patients are at significant risk for being growth retarded, although spontaneous normalization of growth can occur. Adults are usually asymptomatic but are more susceptible to salt loss. Rarely, presentation is in adulthood.⁴⁴⁷ Mineralocorticoid treatment in later life has to be established on an individual basis.

Postadrenalectomy Hypoaldosteronism

In a patient with a unilateral aldosteronoma (Conn's syndrome), the contralateral ZG is frequently suppressed. Without reversal of the chronic volume expansion preoperatively, patients may develop severe hyperkalemia and hypotension lasting several days to several weeks after adrenalectomy. This effect may be exacerbated by the use of spironolactone preoperatively. Spironolactone has a long half-life and should be discontinued 2 to 3 days before surgery to minimize the risk of postoperative mineralocorticoid deficiency.

Defects in Aldosterone Action: Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a rare, inherited salt-wasting disorder that was first described by Cheek and Perry in 1958 as a defective renal tubular response to mineralocorticoid in infancy. Patients present in the neonatal period with dehydration, hyponatremia, hypokalemia, metabolic acidosis, and failure to thrive despite normal glomerular filtration and normal renal and adrenal function.⁴⁴⁸ Renin levels and plasma aldosterone are grossly elevated. When patients fail to respond to mineralocorticoid therapy, PHA is suspected as the underlying disorder.

PHA type I can be divided into two distinct disorders based on unique physiologic and genetic characteristics: the renal form of PHA, which is inherited as an autosomal dominant trait, and a generalized autosomal recessive form of PHA. The autosomal dominant form is usually less severe; the patient's condition often improves spontaneously within the first several years of life, allowing discontinuation of therapy. By contrast, the autosomal recessive form produces a multiorgan disorder, with mineralocorticoid resistance seen in the kidney, sweat, and salivary glands and the colonic mucosa. The condition does not spontaneously improve with age and is generally more severe than the autosomal dominant form.

The underlying basis for the autosomal dominant form of PHA is explained on the basis of inactivating mutations in the mineralocorticoid receptor (hMR, NR3C2).^{448,449} By contrast, inactivating mutations in the α -subunit and, to a lesser extent, in the β - and γ -subunits of the epithelial sodium channel (ENaC) account for the generalized autosomal recessive form of mineralocorticoid resistance.^{450,451} (In effect, this represents the opposite of Liddle's syndrome—see Chapter 16.) Generalized loss of ENaC activity leads to renal salt wasting (as seen in the renal form) in addition to recurrent respiratory infections and neonatal respiratory distress, cholelithiasis, and polyhydramnios.

PHA type I is resistant to mineralocorticoid therapy, so standard treatment involves supplementation with salt (2

to 8 g/day) in the form of sodium chloride and sodium bicarbonate as well as cation exchange resins. This usually corrects the patient's biochemical imbalance. However, if a patient shows signs of severe hyperkalemia, peritoneal dialysis may be necessary. Hypercalciuria has been reported in some cases of PHA-I. The recommended course of treatment for these patients usually involves indomethacin or hydrochlorothiazide. Indomethacin is thought to act by causing a reduction in the glomerular filtration rate or an inhibition of the effect of prostaglandin E_2 on renal tubules. Indomethacin has been shown to reduce polyuria, sodium loss, and hypercalciuria. Hydrochlorothiazide has been used to diminish hyperkalemia and reduce hypercalciuria in patients with PHA-I.

In patients with the autosomal dominant or renal form of PHA-I, the signs and symptoms of PHA decrease with age; nevertheless, these patients usually require salt supplementation for the first 2 to 3 years of life. In patients with the autosomal recessive or multiorgan type of PHA-I, resistance to therapy with sodium chloride or drugs that decrease serum potassium concentrations often occurs and may even lead to death in infancy from hyperkalemia. PHA-I patients with multiorgan involvement often require very high amounts of salt in their diet (up to 45 g NaCl per day). Carbenoxolone, a derivative of glycyrrhetic acid in licorice, has been used with moderate success in helping to reduce the high levels of dietary salt needed by renal PHA-I patients. Carbenoxolone acts by inhibiting HSD11B2 activity and allows unmetabolized cortisol to bind to and activate MRs in a manner similar to that of aldosterone.⁴⁵² It was found to be ineffective in patients with multiorgan PHA-I.

Two other variants of PHA have been described—types II and III. Type II PHA, or Gordon's syndrome, is in retrospect a misnomer. Patients with Gordon's syndrome share some of the features of patients with PHA-I, notably hyperkalemia and metabolic acidosis, but they exhibit salt retention with mild hypertension and suppressed plasma renin activity rather than salt wasting. The condition is explained by mutations in a serine threonine kinase family (WNK1 and WNK4) that result in increased expression of these proteins with activation of the thiazide-sensitive sodium-chloride cotransporter in the cortical and medullary collecting ducts.⁴⁵³ The condition represents the exact opposite of Gitelman's syndrome but is not a true form of PHA.

Type III PHA is an acquired and usually transient form of mineralocorticoid resistance seen in patients with underlying renal pathologies including obstruction and infection and in patients with excessive loss of salt through the gut or skin. Reduced glomerular filtration rate is a hallmark of the condition. The cause is unknown, although increased transforming growth factor- β -mediated aldosterone resistance has been suggested to be an underlying factor.

Hyporeninemic Hypoaldosteronism

Angiotensin II is a key stimulus to aldosterone secretion, and damage or blockade of the renin-angiotensin system may result in mineralocorticoid deficiency. Various renal diseases have been associated with damage to the juxtaglomerular apparatus and subsequent renin deficiency. These include systemic lupus erythematosus, myeloma, amyloid, AIDS, and damage related to use of nonsteroidal anti-inflammatory drugs, but the most common (>75% of cases) is diabetic nephropathy.^{454,455}

The usual picture is that of an elderly patient with hyperkalemia, acidosis, and mild to moderate impairment

of renal function. Plasma renin activity and aldosterone levels are low and fail to respond to sodium depletion, erect posture, or furosemide administration. In contrast to adrenal insufficiency, patients have normal or elevated blood pressure and no postural hypotension. Muscle weakness and cardiac arrhythmias may also occur. Other factors may contribute to the hyperkalemia, including the use of potassium-sparing diuretics, potassium supplementation, insulin deficiency, and use of β -adrenoceptor blocking drugs or prostaglandin synthetase inhibitors, which inhibit renin release.

Treatment of primary renin deficiency is with fludrocortisone in the first instance together with dietary potassium restriction. However, these patients are not salt depleted and may become hypertensive with fludrocortisone. In such a scenario, the addition of a loop-acting diuretic such as furosemide is appropriate. This will increase acid excretion and improve the metabolic acidosis.

ADRENAL ADENOMAS, INCIDENTALOMAS, AND CARCINOMAS

Adenomas

Cortisol-secreting adrenal adenomas were discussed earlier, and aldosterone-secreting adenomas (Conn's syndrome) are discussed in Chapter 16.

Pure virilizing benign adrenal adenomas are rare, with approximately 50 cases reported in the literature. Most cases occur in women; in males, the disorder is restricted to childhood, where presentation is with sexual precocity and accelerated bone age. Such tumors have to be considered in the differential diagnosis of CAH in patients presenting during childhood. In females, most patients present before the menopause with marked hirsutism, deepening of the voice, and amenorrhea. Clitoromegaly is found in 80% of cases. Testosterone is usually strikingly elevated, but gonadotropin levels may not be suppressed. By definition, urinary free cortisol is normal. Tumors vary in size and should be treated surgically. Postoperatively, clinical features invariably improve, and normal menses return.⁴⁵⁶

Incidentalomas

Autopsy series had defined the prevalence of adrenal adenomas greater than 1 cm in diameter to be between 1.5% and 7% before the advent of high-resolution imaging procedures such as CT and MRI; since that time, incidentally discovered adrenal masses have become a common clinical problem. An adrenal mass is uncovered in up to 4% of patients imaged for nonadrenal pathology.⁴⁵⁷ Incidentalomas are uncommon in patients younger than 30 years of age but increase in frequency with age; they occur equally in males and females. Clinically, two issues arise: whether the lesion is functional (i.e., secreting hormones) and whether it is malignant. In more than 85% of cases, these lesions are nonfunctioning, benign adenomas. Occasionally they represent myelolipomas, hamartomas, or granulomatous infiltrations of the adrenal and result in a characteristic CT/MRI appearance (Fig. 15-40). Functioning tumors (pheochromocytomas and those secreting cortisol, aldosterone, or sex steroids) and carcinomas comprise the remainder. In addition, it is established that some incidentalomas cause abnormal hormone secretion without obvious clinical manifestations of a hormone excess state. The best example is so-called subclinical Cushing's syndrome, which occurs in up to 20% of all cases.^{457,458} This

Figure 15-40 **A**, Adrenal incidentaloma discovered in a woman undergoing investigation for abdominal pain. **B**, Incidentally discovered right adrenal myelolipoma.

may explain why incidentalomas appear to be more common among patients with obesity and diabetes mellitus.⁴⁵⁹

As a result, all patients with incidentally discovered adrenal masses should undergo appropriate endocrine screening tests. This should comprise 24-hour urinary catecholamine collection or measurement of plasma metanephrines, 24-hour urinary free cortisol (or a midnight salivary cortisol level), and overnight dexamethasone suppression tests. Because of the reported poor sensitivity of serum potassium measurements in detecting primary aldosteronism, circulating levels of plasma renin activity and aldosterone are required in hypertensive patients. DHEAS should be measured as a marker of adrenal androgen secretion. Low levels may occur in patients with suppressed ACTH concentrations due to autonomous cortisol secretion from the adenoma.⁴⁶⁰ Some studies have also documented high levels of 17-OHP after ACTH stimulation tests, suggesting partial defects in 21-hydroxylase in some tumors.

The possibility of malignancy should be considered in each case. In patients with a known extra-adrenal primary, the incidence of malignancy is obviously much higher; for example up to 20% of patients with lung cancer have adrenal metastases on CT scanning. In those with no evidence of malignancy, adrenal carcinoma is rare; in one study, only 26 of 630 incidentalomas were found to be adrenal carcinomas.⁴⁵⁷ Many studies contain a positive bias, and true risk of malignancy may be much lower.⁴⁶¹ In true incidentalomas, size appears to be predictive of malignancy: fewer than 2% of incidentalomas smaller than 4 cm but 25% of those larger than 6 cm in diameter are malignant (Fig. 15-41).⁴⁶² Smooth, homogeneous adenomas on an enhanced adrenal scan with a Hounsfield unit score (a marker of radiodensity) less than 10 HU are invariably benign; malignancy is suspected in irregular, inhomogeneous adenomas with a score greater than 20 HU. On this background, adrenalectomy is indicated for functional tumors and for tumors larger than 4 cm in diameter. Repeat CT scanning in patients with smaller tumors can be used to guide management, but development of functional autonomy is very rare, and patients may be discharged if tumors are static. Laparoscopic adrenalectomy is the treatment of choice, offering shorter hospital stays and reduced operative complications (e.g., blood loss, morbidity) compared with open adrenalectomy. The possible exception is the patient with highly suggestive adrenal carcinoma,

because breach of the tumor capsule is associated with a poorer outcome. Adequate preparation and close endocrine supervision perioperatively and postoperatively is required for functional tumors.

Carcinomas

Primary adrenal carcinoma is very rare, with an annual incidence of 1 per 1 million population. Women are more commonly affected than men, with a ratio of 2.5:1. The

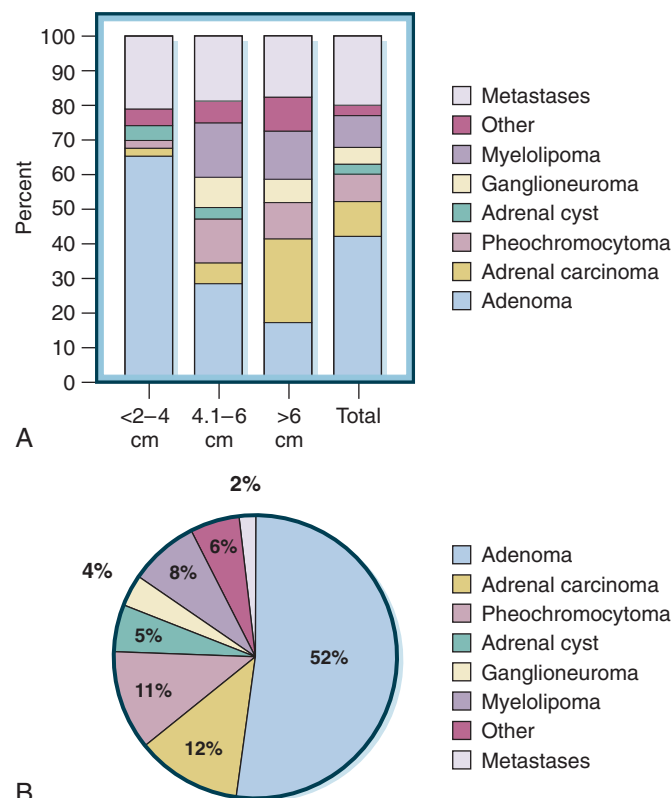

Figure 15-41 Distribution of diagnosis of adrenal incidentalomas. **A**, Data from eight studies with histologically determined diagnoses ($n = 103$) relating to tumor size. **B**, Distribution of 380 incidental adrenal masses by histologic diagnosis. (From Mansmann G, Lau L, Balk E, et al. The clinically inapparent adrenal mass: update in diagnosis and management. *Endocr Rev*. 2004;25:309-340.)

mean age at onset is between 40 and 50 years, although men tend to be older at presentation. Eighty percent of tumors are functional, most commonly secreting glucocorticoids alone (45%), glucocorticoids and androgens (45%), or androgens alone (10%). Fewer than 1% of all tumors secrete aldosterone. Patients present with features of the hormone excess state (glucocorticoid, androgen, or both) but abdominal pain, weight loss, anorexia, and fever occur in 25% of cases. An abdominal mass may be palpable. Current treatment choices for what is often an aggressive tumor are poor. Surgery offers the only chance of cure for patients with local disease, but metastatic spread is evident in 75% of cases at presentation. Radiotherapy is ineffective, as are most chemotherapeutic regimens. Mitotane in high doses offers benefit in reducing tumor growth,²⁷⁶ and in controlling hormonal hypersecretion in 75% of cases.²⁷⁵ Overall, the prognosis is poor, with 5-year survival rates of less than 20%. Newer chemotherapies are being evaluated.²⁷⁷

Etiology of Adrenal Tumors

The underlying basis for adrenal tumorigenesis is unknown. Clonal analysis suggests progression from a normal to an adenomatous to a carcinomatous lesion, but the molecular pathways involved remain obscure. Several factors have been associated with malignant transformation, including the genes encoding p53, p57 cyclin-dependent kinase, menin, IGF2, MC2R, and inhibin- α .⁴⁶³ Mice lacking the inhibin- α gene develop adrenal tumors through a process that is also gonadotropin dependent.⁴⁶⁴

CHAPTER 16

Endocrine Hypertension

WILLIAM F. YOUNG, JR.

An estimated 85 million people in the United States are hypertensive.¹ In most, hypertension is *essential* or *idiopathic*, but a subgroup of approximately 15% have *secondary* hypertension. The secondary causes of hypertension can be divided into renal causes, such as renal parenchymal or renovascular disease, and endocrine causes. There are at least 14 endocrine disorders for which hypertension may be the initial clinical presentation (Table 16-1). An accurate diagnosis of endocrine hypertension provides the clinician with a unique treatment opportunity: to render a surgical cure or to achieve a dramatic response with pharmacologic therapy. The diagnostic and therapeutic approaches to endocrine hypertension—ranging from the classic adrenal causes of hypertension (e.g., pheochromocytoma, primary aldosteronism) to pituitary-dependent hypertension (e.g., Cushing's syndrome, acromegaly)—are reviewed in this chapter.

ADRENAL MEDULLA AND CATECHOLAMINES

The adrenal medulla occupies the central portion of the adrenal gland and accounts for 10% of total adrenal gland volume. There is no clear demarcation between the adrenal cortex and adrenal medulla. The adrenal glands derive

blood supply from the superior, middle, and inferior branches of the inferior phrenic artery, from the renal arteries, and directly from the aorta. The adrenal arteries branch and form a plexus under the capsule. This plexus supplies the cortex. Some of the plexus arteries penetrate the cortex and supply the medulla, as do capillaries draining the cortical cells, forming the corticomedullary portal system. The right adrenal vein is short and drains directly into the inferior vena cava. The left adrenal vein merges with the inferior phrenic vein, and this larger vein (the common phrenic vein) drains into the left renal vein.

Adrenomedullary cells are called *chromaffin cells* (stain brown with chromium salts) or *pheochromocytes*. Cytoplasmic granules turn dark when stained with chromic acid because of the oxidation of epinephrine and norepinephrine to melanin. Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia, collections of chromaffin cells located on both sides of the aorta. The largest cluster of chromaffin cells outside the adrenal medulla is located near the level of the inferior mesenteric artery and is referred to as the *organ of Zuckerkandl*; it is quite prominent in the fetus and is a major source of catecholamines during the first year of life. The preganglionic sympathetic neurons receive synaptic input from neurons within the pons, medulla, and hypothalamus, providing

regulation of sympathetic activity by the brain. Axons from the lower thoracic and lumbar preganglionic neurons, via splanchnic nerves, directly innervate the cells of the adrenal medulla.

The term *catecholamine* refers to substances that contain catechol (ortho-dihydroxybenzene) and a side chain with an amino group—the catechol nucleus (Fig. 16-1).² Epinephrine is synthesized and stored in the adrenal medulla and released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine,

the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves and acts primarily as a neurotransmitter in the central nervous system.

Catecholamines affect many cardiovascular and metabolic processes. They increase the heart rate, blood pressure, myocardial contractility, and cardiac conduction velocity. Specific receptors mediate the biologic actions of catecholamines. The identification of three types of adrenergic receptors (α , β , and dopaminergic receptors), and their subtypes (α_1 , α_2 , β_1 , β_2 , β_3 , D₁, and D₂) have led to understanding of the physiologic responses to endogenous and exogenous administration of catecholamines.³ The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increases blood pressure. The α_2 receptors are located on presynaptic sympathetic nerve endings; when activated, they inhibit release of norepinephrine. Stimulation causes suppression of central sympathetic outflow and decreased blood pressure.

There are three major β -receptor subtypes. The β_1 receptor mediates cardiac effects and is more responsive to isoproterenol than to epinephrine or norepinephrine. Stimulation causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes. The β_2 receptor mediates bronchial, vascular, and uterine smooth muscle relaxation. Stimulation causes bronchodilation, vasodilatation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3 receptor regulates energy expenditure and lipolysis.

D₁ receptors are localized to the cerebral, renal, mesenteric, and coronary vasculatures; stimulation causes vasodilation in these vascular beds. D₂ receptors are presynaptic; they are localized to sympathetic nerve endings, sympathetic ganglia, and brain. Stimulation of D₂ receptors in these locations inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits prolactin release, respectively.

Most cells in the body have adrenergic receptors. The pharmacologic development of selective α - and β -adrenergic agonists and antagonists has advanced pharmacotherapy for various clinical disorders. For example, β_1 antagonists (e.g., atenolol, metoprolol) are now considered standard therapies for angina pectoris, hypertension, and cardiac arrhythmias.⁴ Administration of β_2 agonists (e.g., terbutaline, albuterol) cause bronchial smooth muscle relaxation; these agents are commonly prescribed in inhaled formulations for the treatment of asthma.⁵

Figure 16-1 Biosynthetic pathway for catecholamines. The term *catecholamine* comes from the catechol (ortho-dihydroxybenzene) structure and a side chain with an amino group—the catechol nucleus (shown on left). Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase (TH); this rate-limiting step provides the clinician with the option to treat pheochromocytoma with a TH inhibitor, α -methyl-paratyrosine (metyrosine). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β -hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine N-methyltransferase (PNMT). Cortisol serves as a cofactor for PNMT, which explains why epinephrine-secreting neoplasms are almost exclusively localized to the adrenal medulla. (Modified and redrawn from Dluhy RG, Lawrence JE, Williams GH. Endocrine hypertension. In: Larsen PR, Kronenberg HM, Melmed S, et al., eds. *Williams Textbook of Endocrinology*, 10th ed. Philadelphia, PA: Saunders, 2003:555.)

Catecholamine Synthesis

Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see Fig. 16-1). Tyrosine is derived from ingested food or synthesized from phenylalanine in the liver, and it enters neurons and chromaffin cells by active transport. Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis. Increased intracellular levels of catechols downregulate the activity of tyrosine hydroxylase; as catecholamines are released from secretory granules in response to a stimulus, cytoplasmic catecholamines are depleted and the feedback inhibition of tyrosine hydroxylase is released. Transcription of tyrosine hydroxylase is stimulated by glucocorticoids, cyclic adenosine monophosphate (cAMP)-dependent protein kinases, calcium/phospholipid-dependent protein kinase, and calcium/calmodulin-dependent protein kinase. α -Methyl-paratyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting neoplasms to decrease tumoral synthesis of catecholamines.

Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of dopa to dopamine (see Fig. 16-1). Dopamine is actively transported into granulated vesicles to be hydroxylated to norepinephrine by the copper-containing enzyme dopamine β -hydroxylase. Ascorbic acid is a cofactor and hydrogen donor. The enzyme is structurally similar to tyrosine hydroxylase and may share similar transcriptional regulatory elements, and both are stimulated by glucocorticoids and cAMP-dependent kinases. These reactions occur in the synaptic vesicle of adrenergic neurons in the central nervous system, the peripheral nervous system, and the chromaffin cells of the adrenal medulla. The major constituents of the granulated vesicle are dopamine β -hydroxylase, ascorbic acid, chromogranin A, and adenosine triphosphate (ATP).

In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where the cytosolic enzyme phenylethanolamine N-methyltransferase (PNMT) converts it to epinephrine (see Fig. 16-1). Epinephrine is then transported back into another storage vesicle. The N-methylation reaction by PNMT involves S-adenosylmethionine as the methyl donor as well as oxygen and magnesium. PNMT expression is regulated by the presence of glucocorticoids, which are in high concentration in the adrenal medulla through the corticomedullary portal system. Therefore, catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamines released are epinephrine.

Catecholamine Storage and Secretion

Catecholamines are found in the adrenal medulla and in sympathetically innervated organs. Catecholamines are stored in electron-dense granules that also contain ATP, neuropeptides (e.g., adrenomedullin, corticotropin [ACTH], vasoactive intestinal polypeptide), calcium, magnesium, and chromogranins. Uptake into the storage vesicles is facilitated by active transport by vesicular monoamine transporters (VMAT).⁶ The VMAT ATP-driven pump maintains a steep electrical gradient. For every monoamine transported, ATP is hydrolyzed and two hydrogen ions are transported from the vesicle into the cytosol. Iodine 123 (¹²³I) and ¹³¹I-labeled metaiodobenzylguanidine (MIBG) are imported by VMAT into the storage vesicles in the adrenal medulla, which makes ¹²³I-MIBG useful for

imaging localization of catecholamine-secreting tumors and ¹³¹I-MIBG potentially useful in treating malignant catecholamine-secreting tumors.^{7,8} Catecholamine uptake, as well as that of MIBG, is inhibited by reserpine.⁹ The catecholamine stores are dynamic, with constant leakage and reuptake.¹⁰

Stressful stimuli (e.g., myocardial infarction, anesthesia, hypoglycemia) trigger adrenal medullary catecholamine secretion. Acetylcholine from preganglionic sympathetic fibers stimulates nicotinic cholinergic receptors and causes depolarization of adrenomedullary chromaffin cells. Depolarization leads to activation of voltage-gated calcium channels, which results in exocytosis of secretory vesicle contents. A calcium-sensing receptor appears to be involved in the process of exocytosis. During exocytosis, all the granular contents are released into the extracellular space. Norepinephrine modulates its own release by activating the α_2 -receptors on the presynaptic membrane. Stimulation of the presynaptic α_2 -receptors inhibits norepinephrine release (the mechanism of action of some antihypertensive medications such as clonidine and guanfacine). Catecholamines are among the shortest-lived signaling molecules in plasma; the initial biologic half-life of circulating catecholamines is between 10 to 100 seconds. Approximately one half of the catecholamines circulate in plasma in loose association with albumin. Therefore, plasma concentrations of catecholamines fluctuate widely.

Catecholamine Metabolism and Inactivation

Catecholamines are removed from the circulation either by reuptake in sympathetic nerve terminals or by metabolism through two enzyme pathways (Fig. 16-2), followed by sulfate conjugation and renal excretion. Most of the metabolism of catecholamines occurs in the same cell in which they are synthesized.¹⁰ Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings, termed *uptake-1*. Uptake-1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazines. Extraneuronal tissues also take up catecholamines, and this is termed *uptake-2*. Most of these catecholamines are metabolized by catechol-O-methyltransferase (COMT).

Although COMT is found primarily outside neural tissue, O-methylation in the adrenal medulla is the predominant source of metanephrine (COMT converts epinephrine to metanephrine) and a major source of normetanephrine (COMT converts norepinephrine to normetanephrine) through methylation of the 3-hydroxy group.¹⁰ S-Adenosylmethionine is used as the methyl donor, and calcium is required for this enzymatic step. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by COMT to VMA. MAO is located on the outer membrane of mitochondria. In the storage vesicle, norepinephrine is protected from metabolism by MAO. MAO and COMT metabolize dopamine to homovanillic acid (see Fig. 16-2).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia

Figure 16-2 Catecholamine metabolism. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and converts norepinephrine to normetanephrine through meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by COMT to VMA. Dopamine is also metabolized by MAO and COMT to the final metabolite, homovanillic acid (HVA). (Modified and redrawn from Dluhy RG, Lawrence JE, Williams GH. Endocrine hypertension. In Larsen PR, Kronenberg HM, Melmed S, et al, eds. *Williams Textbook of Endocrinology*, 10th ed. Philadelphia, PA: Saunders, 2003:556.)

are referred to as *pheochromocytomas* and *catecholamine-secreting paragangliomas*, respectively.¹¹ Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both adrenal pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas. However, the distinction between pheochromocytoma and paraganglioma is an important one because of implications for associated neoplasms, risk for malignancy, and genetic testing. Catecholamine-secreting tumors are rare, with an annual incidence of 2 to 8 cases per 1 million people.¹² Based on screening studies for secondary causes of hypertension in outpatients, the prevalence of pheochromocytoma has been estimated at 0.1% to 0.6%.¹³⁻¹⁵ Nevertheless, it is important to suspect, confirm, localize, and resect these tumors, because (1) the associated hypertension is curable with surgical removal of the tumor, (2) a risk of lethal paroxysm exists, (3) at least 10% of the tumors are malignant, and (4) between 10% and 20% of these tumors are familial, and their detection in the proband may result in early diagnosis in other family members.

History

The association between adrenal medullary tumors and symptoms was first recognized by Fränkel in 1886.¹⁶ He described Fraulein Minna Roll, age 18, who had intermittent attacks of palpitation, anxiety, vertigo, headache, chest pain, cold sweats, and vomiting. She had a hard, noncompressible pulse and retinitis. Despite champagne therapy and injections of ether, she died. At autopsy, bilateral adrenal tumors were initially thought to be

angiosarcomas, but later a positive chromaffin reaction confirmed pheochromocytoma. A subsequent study¹⁷ published in 2007 documented the presence of a germline *RET* protooncogene mutation in four living relatives of Fraulein Roll—proving that the original patient and her family had multiple endocrine neoplasia type 2 (MEN2).

The term *pheochromocytoma*, proposed by Pick in 1912,¹⁸ comes from the Greek words *phaios* ("dusky"), *chroma* ("color"), and *cytoma* ("tumor")—words that describe the dark staining reaction that is caused by the oxidation of intracellular catecholamines when they are exposed to dichromate salts. In 1926, César Roux in Lausanne, Switzerland, and Charles Mayo in Rochester, Minnesota, successfully surgically removed abdominal catecholamine-secreting tumors.¹⁹ In 1929, it was discovered that a pheochromocytoma contained an excess amount of a pressor agent.²⁰ Subsequently, epinephrine (in 1936) and norepinephrine (in 1949) were isolated from pheochromocytoma tissue.²⁰ In 1950, it was found that patients with pheochromocytoma excreted increased amounts of epinephrine, norepinephrine, and dopamine in the urine.²¹

Clinical Presentation

Catecholamine-secreting tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades. These tumors are rare in children, and when discovered, they may be multifocal and associated with a hereditary syndrome. The symptoms, listed in Table 16-2, are caused by the pharmacologic effects of excess concentrations of circulating catecholamines.²² The associated hypertension may be sustained or paroxysmal, and patients whose pheochromocytoma is diagnosed in the

TABLE 16-2

Signs and Symptoms Associated with Catecholamine-Secreting Tumors**Spell-Related Signs and Symptoms**

Anxiety and fear of impending death
 Diaphoresis
 Dyspnea
 Epigastric and chest pain
 Headache
 Hypertension
 Nausea and vomiting
 Pallor
 Palpitation (forceful heartbeat)
 Tremor

Chronic Signs and Symptoms

Anxiety and fear of impending death
 Cold hands and feet
 Congestive heart failure—dilated or hypertrophic cardiomyopathy
 Constipation
 Diaphoresis
 Dyspnea
 Ectopic hormone secretion—dependent symptoms (e.g., CRH/ACTH, GHRH, PTHrP, VIP)
 Epigastric and chest pain
 Fatigue
 Fever
 General increase in sweating
 Grade II to IV hypertensive retinopathy
 Headache
 Hyperglycemia
 Hypertension
 Nausea and vomiting
 Orthostatic hypotension
 Painless hematuria (associated with urinary bladder paraganglioma)
 Pallor
 Palpitation (forceful heartbeat)
 Tremor
 Weight loss

Not Typical of Pheochromocytoma

Flushing

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; GHRH, growth hormone-releasing hormone; PTHrP, parathyroid hormone-related peptide; VIP, vasoactive intestinal polypeptide.

(Adapted from Young WF Jr. Pheochromocytoma, 1926-1993. *Trends Endocrinol Metab.* 1993;4:122-127.)

presymptomatic stage may have normal blood pressure. The lability in blood pressure can be attributed to episodic release of catecholamines, chronic volume depletion, and impaired sympathetic reflexes. In addition to volume depletion, altered sympathetic vascular regulation may have a role in orthostasis, which is frequently observed in patients with pheochromocytoma.²³ Symptoms of orthostatic hypotension (e.g., lightheadedness, presyncope, syncope) may dominate the presentation, especially in patients with epinephrine- or dopamine-predominant tumors.^{24,25}

Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation but typically include forceful heartbeat, pallor, tremor, headache, and diaphoresis. The spell may start with a sensation of a “rush” in the chest and a sense of shortness of breath, followed by a forceful heart beat and a throbbing headache. Peripheral vasoconstriction associated with a spell results in cool or cold hands and feet and facial pallor. Increased sense of body heat and sweating are common symptoms that occur

toward the end of the spell. Spells may be either spontaneous or precipitated by postural change, anxiety, medications (e.g., β -adrenergic antagonists, metoclopramide, anesthetic agents), exercise, or maneuvers that increase intra-abdominal pressure (e.g., change in position, lifting, defecation, exercise, colonoscopy, pregnancy, trauma). Although the types of spells experienced across the patient population are highly variable, spells tend to be stereotypical for each patient. Spells may occur multiple times daily or as infrequently as once monthly. The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may be much shorter or last several hours. However, the clinician must recognize that most patients with spells do not have a pheochromocytoma²⁶ (Table 16-3).

Additional clinical signs of pheochromocytoma include hypertensive retinopathy, orthostatic hypotension, angina, nausea, constipation (megacolon may be the presenting

TABLE 16-3

Differential Diagnosis of Pheochromocytoma-Type Spells**Endocrine Causes**

Carbohydrate intolerance
 Hyperadrenergic spells
 Hypoglycemia
 Pancreatic tumors (e.g., insulinoma)
 Pheochromocytoma
 Primary hypogonadism (menopausal syndrome)
 Thyrotoxicosis

Cardiovascular Causes

Angina
 Cardiovascular deconditioning
 Labile essential hypertension
 Orthostatic hypotension
 Paroxysmal cardiac arrhythmia
 Pulmonary edema
 Renovascular disease
 Syncope (e.g., vasovagal reaction)

Psychological Causes

Factitious (e.g., drugs, Valsalva)
 Hyperventilation
 Severe anxiety and panic disorders
 Somatization disorder

Pharmacologic Causes

Chlorpropamide-alcohol flush
 Combination of a monoamine oxidase inhibitor and a decongestant
 Illegal drug ingestion (cocaine, phencyclidine, lysergic acid diethylamide)
 Sympathomimetic drug ingestion
 Vancomycin (“red man syndrome”)
 Withdrawal of adrenergic-inhibitor

Neurologic Causes

Autonomic neuropathy
 Cerebrovascular insufficiency
 Diencephalic epilepsy (autonomic seizures)
 Migraine headache
 Postural orthostatic tachycardia syndrome
 Stroke

Other Causes

Carcinoid syndrome
 Mast cell disease
 Recurrent idiopathic anaphylaxis
 Unexplained flushing spells

Figure 16-3 A computed tomographic (CT) scan of the abdomen with intravenous contrast in a 71-year-old man with an incidentally discovered right adrenal mass. The concentrations of plasma fractionated free metanephrines were abnormal: metanephrine, 0.34 nmol/L (normal, <0.5) and normetanephrine, 8.59 nmol/L (normal, <0.9). The 24-hour urine studies were abnormal: norepinephrine, 455 μ g (normal, <170); epinephrine, 7.2 μ g (normal, <35); dopamine, 160 μ g (normal, <700); metanephrine, 173 μ g (normal, <400); and normetanephrine, 3147 μ g (normal, <900). **A**, The axial CT image shows a typical 3.8-cm heterogeneously enhancing right adrenal mass just lateral to the inferior vena cava and consistent with pheochromocytoma (arrow). **B**, Coronal view shows the location (arrow) of the mass superior to the right kidney and inferior and medial to the liver. After α - and β -adrenergic blockade, a 2.5 \times 1.5 \times 1.5-cm, 20-g pheochromocytoma was removed laparoscopically.

symptom), hyperglycemia, diabetes mellitus, hypercalcemia, Raynaud's phenomenon, livedo reticularis, erythrocytosis, and mass effects from the tumor. Although hypercalcemia may be a sign of MEN2, it is usually isolated and resolves with resection of the catecholamine-secreting tumor. Calcitonin secretion is in part a catecholamine-dependent process; serum calcitonin concentrations are frequently mildly elevated in patients with pheochromocytoma, usually unrelated to MEN2. Fasting hyperglycemia and diabetes mellitus are caused in part by the α -adrenergic inhibition of insulin release. Painless hematuria and paroxysmal attacks induced by micturition and defecation are associated with urinary bladder paragangliomas.

Some of the cosecreted hormones that may dominate the clinical presentation include ACTH (Cushing's syndrome), parathyroid hormone-related peptide (hypercalcemia), vasopressin (syndrome of inappropriate antidiuretic hormone secretion), vasoactive intestinal peptide (watery diarrhea), and growth hormone-releasing hormone (acromegaly).²⁷⁻²⁹ Cardiomyopathy and congestive heart failure are the symptomatic presentations caused by pheochromocytoma that are most frequently unrecognized by clinicians.³⁰ The cardiomyopathy, whether dilated or hypertrophic, may be totally reversible with tumor resection. Myocarditis and myocardial infarction with normal coronary arteries seen on angiography are cardiac-based presentations that may not be recognized as pheochromocytoma.³¹ The myocarditis is characterized by infiltration of inflammatory cells and focal contraction-band necrosis. Many physical examination findings can be associated with genetic syndromes that predispose to pheochromocytoma; these findings include retinal angiomas, iris hamartomas, marfanoid body habitus, café au lait spots, axillary freckling, subcutaneous neurofibromas, and mucosal neuromas on the eyelids and tongue. Some patients with pheochromocytoma are asymptomatic despite high circulating levels of catecholamines; this most likely reflects adrenergic receptor desensitization related to chronic stimulation.

A "rule of 10" has been quoted for describing the characteristics of catecholamine-secreting tumors: 10% are extra-adrenal, 10% occur in children, 10% are multiple or bilateral, 10% recur after surgical removal, 10% are

malignant, 10% are familial, and 10% of benign sporadic adrenal pheochromocytomas are found as adrenal incidentalomas.²⁰ None of these figures is precisely 10%, however. For example, studies have suggested that up to 20% of catecholamine-secreting tumors are familial.³² Also, in one study, 19 (58%) of 33 patients with adrenal pheochromocytoma had their adrenal tumors discovered incidentally on imaging performed for other reasons.³³ Because of the increased use of computed tomography (CT) and magnetic resonance imaging (MRI) and familial testing, pheochromocytoma is diagnosed in many patients before any symptoms develop. Although typically these incidentally discovered tumors in asymptomatic patients are small (<3 cm), they may be up to 10 cm in largest lesional diameter.

At the time of detection, pheochromocytomas have an average diameter of 4.5 cm³⁴ (Fig. 16-3). Paragangliomas are found where there is chromaffin tissue: along the para-aortic sympathetic chain, within the organ of Zuckerkandl (at the origin of the inferior mesenteric artery), in the wall of the urinary bladder, and along the sympathetic chain in the neck or mediastinum.³⁵ During early postnatal life, the extra-adrenal sympathetic paraganglionic tissues are prominent; later they degenerate, leaving residual foci associated with the vagus nerves, carotid vessels, aortic arch, pulmonary vessels, and mesenteric arteries. Odd locations for paragangliomas include the neck, intra-atrial cardiac septum, spermatic cord, vagina, scrotum, and sacrococcygeal region. Paragangliomas in the head and neck region (e.g., carotid body tumors, glomus tumors, chemodectomas) usually arise from parasympathetic tissue and typically do not hypersecrete catecholamines and metanephrines. Paragangliomas in the mediastinum, abdomen, and pelvis usually arise from sympathetic chromaffin tissue and usually do hypersecrete catecholamines and metanephrines.

Genetic and Syndromic Forms of Pheochromocytoma and Paraganglioma

Approximately 15% to 20% of patients with catecholamine-secreting tumors have germline mutations (inherited

TABLE 16-4

Autosomal Dominant Syndromes Associated with Pheochromocytoma and Paranglioma

Syndrome	Gene	Gene Locus	Protein Product	Protein Function	Gene Mechanism	Typical Tumor Location
SDHD (familial paraganglioma type 1)*	SDHD	11q23	SDH D subunit	ATP production	Tumor suppressor	Skull base and neck; occasionally adrenal medulla, mediastinum, abdomen, pelvis
Familial paraganglioma type 2*	SDHAF2	11q13.1	Flavination cofactor	ATP production	Tumor suppressor	Skull base and neck; occasionally abdomen and pelvis
SDHC (familial paraganglioma type 3)	SDHC	1q21	SDH C subunit	ATP production	Tumor suppressor	Skull base and neck
SDHB (familial paraganglioma type 4)	SDHB	1p36.1-35	SDH B subunit	ATP production	Tumor suppressor	Abdomen, pelvis and mediastinum; rarely adrenal medulla, skull base, and neck
MEN1	MEN1	11q13	Menin	Transcription regulation	Tumor suppressor	Adrenal medulla
MEN2A and MEN2B	RET	10q11.2	RET	Tyrosine kinase receptor	Protooncogene	Adrenal medulla, bilaterally
Neurofibromatosis type 1	NF1	17q11.2	Neurofibromin	GTP hydrolysis	Tumor suppressor	Adrenal-periarenal
von Hippel-Lindau disease	VHL	3p25-26	VHL	Transcription elongation suppression	Tumor suppressor	Adrenal medulla, bilaterally; occasionally paraganglioma
Familial pheochromocytoma	PP/TFMEM127	2q11	Transmembrane protein	Regulation of the mTORC1 signaling complex	Tumor suppressor	Adrenal medulla

*Associated with maternal imprinting.

ATP, adenosine triphosphate; GTP, guanosine triphosphate; MEN, multiple endocrine neoplasia; SDH, succinate dehydrogenase.

mutations present in all cells of the body) in genes associated with genetic disease^{36,37} (Table 16-4). Hereditary catecholamine-secreting tumors typically manifest at a younger age than sporadic neoplasms do.³² Sporadic pheochromocytoma typically is diagnosed on the basis of symptoms or as an incidental discovery on CT or MRI, whereas syndromic pheochromocytoma is frequently diagnosed earlier in the course of disease as a result of biochemical surveillance or genetic testing.³⁸

Multiple Endocrine Neoplasia Type 2A

MEN2A (Sipple's syndrome) is an autosomal dominant disorder with age-related penetrance.³⁹ MEN2A is characterized by medullary thyroid cancer (MTC) in all patients, pheochromocytoma in 50% (usually bilateral and frequently asynchronous), primary hyperparathyroidism in 20%, and cutaneous lichen amyloidosis in 5%. Cutaneous lichen amyloidosis is a pruritic, papular, scaly, and pigmented skin lesion that is typically located in the interscapular region or on the extensor surfaces of the extremities.

MTC is usually detected before the pheochromocytoma is diagnosed. The prevalence of MEN2A is approximately 1 in 35,000 people. Numerous activating mutations throughout the *RET* proto-oncogene have been documented in persons with MEN2A. *RET*, located on chromosome 10q11.2, encodes a transmembrane receptor tyrosine kinase that is involved in the regulation of cell proliferation and apoptosis. Most mutations in MEN2A kindreds (>90%) involve one of six cysteine residues in the cysteine-rich region of the *RET* protein's extracellular domain encoded in *RET* exons 10 (codons 609, 611, 618, and 620) or 11 (codons 630 or 634). Eighty-five percent of individuals with MEN2A have a mutation in codon 634, particularly p.Cys634Arg (c.1900C>T).

Multiple Endocrine Neoplasia Type 2B

MEN2B is also an autosomal dominant disorder with age-related penetrance, and it represents approximately 5% of all MEN2 cases.³⁹ MEN2B is characterized by MTC in all patients, pheochromocytoma in 50%, mucocutaneous neuromas (typically involving the tongue, lips, and eyelids) in most patients, skeletal deformities (e.g., kyphoscoliosis, lordosis), joint laxity, myelinated corneal nerves, and intestinal ganglioneuromas (Hirschsprung's disease). Hirschsprung's disease is characterized by the absence of autonomic ganglion cells within the distal colon parasympathetic plexus, which results in chronic obstruction and megacolon.

MEN2B-associated tumors are caused by mutations in the *RET* protein's intracellular domain. A single methionine-to-threonine missense mutation in exon 16 (p.Met918Thr; c.2753T>C) is responsible for more than 95% of MEN2B cases. Another mutation, alanine to phenylalanine at codon 883 in exon 15, has been found in 4% of MEN2B kindreds.

Multiple Endocrine Neoplasia Type 2 Genetic Testing

More than 95% of patients with MEN2A and more than 98% of those with MEN2B have an identifiable mutation in the *RET* proto-oncogene. Genetic testing for mutations in the *RET* proto-oncogene is commercially available and should be considered for patients with bilateral pheochromocytoma, a family history of pheochromocytoma, or co-phenotype disorders. In a family with MEN2, a family member with a clinical diagnosis of MEN2 should be tested first. If a *RET* mutation is found, all family members of unknown status should be offered genotyping. Genetic counseling consultation should be considered before genetic testing is performed. In families with known MEN2, genetic testing shortly after birth facilitates prompt surgical

management of the thyroid gland. Genetic testing shortly after birth is especially important in families with MEN2B, because the thyroid gland should be removed in the first 6 months of life (see Chapter 41 for further discussion of MEN2).

Multiple Endocrine Neoplasia Type 1

MEN1 is an autosomal dominant disorder characterized by pituitary adenomas, primary hyperparathyroidism, pancreatic islet cells tumors, adrenal adenomas, carcinoid tumors, collagenomas, angiofibromas, lipomas, and, very rarely, adrenal pheochromocytoma.^{40,41} Pheochromocytoma has been documented in only a few patients with MEN1.^{42,43} The prevalence of MEN1 is approximately 1 in 30,000 individuals.^{40,41} MEN1 is caused by inactivating mutations in the tumor suppressor gene *MEN1*, which is located on chromosome 11q13. Genetic testing for mutations in *MEN1* is commercially available and should be considered only for patients with adrenal pheochromocytoma and MEN1 co-phenotype disorders.

von Hippel-Lindau Disease

Von Hippel-Lindau (VHL) syndrome is an autosomal dominant disorder that may manifest with a variety of benign and malignant neoplasms: pheochromocytoma (frequently bilateral), paraganglioma (mediastinal, abdominal, pelvic), hemangioblastoma (involving the cerebellum, spinal cord, or brainstem), retinal angioma, clear cell renal cell carcinoma, pancreatic neuroendocrine tumors, endolymphatic sac tumors of the middle ear, serous cystadenomas of the pancreas, and papillary cystadenomas of the epididymis and broad ligament. Patients with VHL syndrome may be divided into two groups: type 1 and type 2. Patients from kindreds with type 1 syndrome do not develop pheochromocytoma, whereas those from kindreds with type 2 syndrome are at high risk for developing pheochromocytoma. In addition, kindreds with type 2 VHL syndrome are subdivided into type 2A (low risk for renal cell carcinoma), type 2B (high risk for renal cell carcinoma), and type 2C (pheochromocytomas only).

The prevalence of VHL syndrome is approximately 1 in 35,000 people. The *VHL* tumor suppressor gene, located on chromosome 3p25-26, encodes a protein that regulates hypoxia-induced proteins.⁴⁴ More than 300 germline *VHL* mutations have been identified that lead to loss of function of the VHL protein. Almost 100% of patients with VHL syndrome have an identifiable gene mutation. Genotype-phenotype correlations have been documented for this disorder, and specific mutations are associated with particular patterns of tumor formation.^{45,46} In up to 98% of cases, pheochromocytoma is associated with missense mutations (rather than truncating or null mutations) in the *VHL* gene. Genetic testing for VHL syndrome is commercially available and should be considered for patients with bilateral pheochromocytoma, a family history of pheochromocytoma, diagnosis of pheochromocytoma at a young age (≤ 30 years), or co-phenotype disorders.

Pheochromocytomas occurring in patients with MEN2 produce predominantly epinephrine and metanephrine, whereas those occurring in patients with VHL syndrome produce predominately norepinephrine and normetanephrine. These biochemical phenotypes result from mutation-specific differential gene expression. PNMT is overexpressed in MEN2-associated tumors (epinephrine and metanephrine profile) and underexpressed in VHL-associated tumors (norepinephrine and normetanephrine profile).⁴⁷ In addition, pheochromocytomas occurring in patients with MEN2 have increased tyrosine hydroxylase activity

compared with those occurring in patients with VHL; this difference accounts for higher levels of catecholamines and metabolites in patients with MEN2.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder characterized by neurofibromas, multiple café-au-lait spots, axillary and inguinal freckling, iris hamartomas (Lisch nodules), bony abnormalities, central nervous system gliomas, pheochromocytoma and paraganglioma, macrocephaly, and cognitive deficits. The expression of these features is variable. Approximately 2% of patients with NF1 develop catecholamine-secreting tumors.⁴⁸ In these patients, the catecholamine-secreting tumor is usually a solitary, benign adrenal pheochromocytoma, occasionally bilateral adrenal pheochromocytomas, and rarely an abdominal perirenal paraganglioma. The prevalence of NF1 is approximately 1 in 3000 people. The *NF1* tumor suppressor gene, located on chromosome 17q11.2, encodes neurofibromin, a guanosine triphosphatase-activating protein that inhibits RAS activity. Inactivating *NF1* mutations cause the disorder. More than 95% of *NF1* mutations can be identified with a multistep testing protocol. However, unless a patient with pheochromocytoma presents with additional clinical characteristics consistent with an NF1 diagnosis, genetic testing of the *NF1* gene is not recommended.

Familial Paraganglioma

Familial paraganglioma is an autosomal dominant disorder characterized by paragangliomas that are located most often in the skull base and neck but also in the mediastinum, abdomen, pelvis, and urinary bladder. The occurrence of catecholamine hypersecretion in a patient with familial paraganglioma depends on tumor location; approximately 5% of skull base and neck paragangliomas and more than 50% of abdominal paragangliomas produce hormones.³⁵ The mean age at diagnosis is 30 to 35 years and can vary greatly within a family (mean difference among individuals \pm standard deviation [SD], 14.3 ± 9.6 years; range, 0 to 37 years).⁴⁹ The prevalence of familial paraganglioma is unknown. Most cases of familial paraganglioma are caused by mutations in the succinate dehydrogenase (SDH; succinate:ubiquinone oxidoreductase) subunit genes (*SDHB*, *SDHC*, *SDHD*, *SHDA*, and *SDHAF2*), which make up portions of mitochondrial complex II.^{50,51} Mitochondrial complex II is a tumor suppressor gene that is involved in the electron transport chain and the tricarboxylic acid (TCA) cycle.

Inactivating germline mutations in *SDHD*, located on chromosome 11q23, have been identified in multigenerational families with skull base and neck parasympathetic paragangliomas that are usually nonfunctional.⁵² However, catecholamine-secreting paragangliomas may occur when mutations are located in the 5' portion of *SDHD*.⁵³ Adrenal pheochromocytomas may also be found in patients with *SDHD* mutations.⁵⁴ Before the gene was characterized, affected families were said to have paraganglioma syndrome type 1. In patients with *SDHD* mutations, penetrance depends on the mutation's parent of origin. The disease is not manifested when the mutation is inherited from the mother but is highly penetrant when inherited from the father.^{52,54} This phenomenon is known as *maternal imprinting*.

Missense mutations in *SDHC*, located on chromosome 1q21, have been reported in families with skull base and neck parasympathetic paragangliomas that are usually nonfunctional.⁵⁵ Before the gene was characterized, affected families were said to have paraganglioma syndrome type

3. Genetic testing for *SDHC* should be considered for families with skull base and neck paragangliomas that are negative for mutations in *SDHD*.

The gene associated with paraganglioma syndrome type 2, called SDH complex assembly factor 2 (*SDHAF2*), has recently been identified.⁵⁶ Multiple cofactors are required for normal activity of the SDH complex, including flavin-adenine dinucleotide (FAD) in Sdh1. FAD is covalently attached to Sdh1, and deletion of *SDHAF2* causes a complete loss of FAD cofactor attachment (flavination) of Sdh1. Germline loss-of-function mutations in the *SDHAF2* gene, located on chromosome 11q13.1, segregated with disease in a family with hereditary paraganglioma. Like families with mutations in *SDHD*, those with paraganglioma syndrome type 2 also exhibit maternal imprinting. This syndrome is associated with parasympathetic paragangliomas that typically occur in the skull base and neck.

Inactivating mutations in the tumor suppressor gene *SDHB*, located on chromosome 1p35-36, are associated with paragangliomas in the abdomen, pelvis, and mediastinum. Adrenal pheochromocytomas may also be found in patients with *SDHB* mutations.⁵⁴ Before the gene was characterized, affected families were said to have paraganglioma syndrome type 4. In families with *SDHB* mutations, imprinting has not been observed. Patients with *SDHB* mutations are at increased risk for malignant paraganglioma.^{54,57,58} In a population-based study, patients with *SDHB* mutations also appeared to be at increased risk for renal cell carcinoma and papillary thyroid cancer,⁵⁴ but a referral center-based study did not find this apparent association.⁵⁹

Genetic testing for *SDHB*, *SDHD*, and *SDHC* is available commercially and, because of the high prevalence among patients with paraganglioma, stepwise testing should be considered for all affected individuals (see later discussion). In addition, large germline deletions of *SDHB* and *SDHD* have been identified in families with paraganglioma⁶⁰; thus, deletion detection testing should be performed if mutations are not found with gene sequencing.

Other Neurocutaneous Syndromes

Additional neurocutaneous syndromes associated with catecholamine-secreting tumors include ataxia-telangiectasia, tuberous sclerosis, and Sturge-Weber syndrome. The Carney triad (gastrointestinal stromal tumor, pulmonary chondroma, and catecholamine-secreting paraganglioma) is another syndrome associated with catecholamine-secreting tumors.⁶¹ This syndrome is a rare, usually sporadic disorder of unknown etiology that primarily affects young women. The gastric stromal tumors are frequently multicentric and associated with early liver metastases. Nevertheless, most affected patients have a very indolent course. The pulmonary chondromas are benign and, if asymptomatic, require no specific therapy. The paragangliomas secrete catecholamines and should be resected when discovered. Additional features of the Carney triad include esophageal leiomyomas and adrenal cortical adenomas. The esophageal leiomyomas, found incidentally at the time of esophagogastroduodenoscopy, are benign and usually asymptomatic. The adrenal cortical adenomas may be nonfunctioning or secrete cortisol autonomously.

Genetic Testing

As previously outlined, genetic testing should be considered if a patient has one or more of the following: (1) paraganglioma, (2) bilateral adrenal pheochromocytoma, (3) unilateral adrenal pheochromocytoma and a family

history of pheochromocytoma/paraganglioma, (4) unilateral adrenal pheochromocytoma with onset at a young age (<30 years), or (5) other clinical findings suggestive of one of the previously discussed syndromic disorders. An asymptomatic person at risk for disease on the basis of family history of pheochromocytoma/paraganglioma should have genetic testing only if an affected family member has a known mutation. Genetic testing can be complex, and testing of one family member has implications for related individuals. Genetic counseling is recommended to help families understand the implications of genetic test results, to coordinate testing of at-risk individuals, and to help families work through the psychosocial issues that may arise before, during, or after the testing process.

The clinician may obtain a list of clinically approved molecular genetic diagnostic laboratories at www.genetests.org (accessed December 2010). Given the considerable cost of genetic testing, use of a stepwise approach based on each patient's clinical scenario is prudent. Some examples follow:

- If a patient has a catecholamine-secreting abdominal, pelvic, or mediastinal paraganglioma, tests for mutations in the following genes should be ordered sequentially: *SDHB*, *SDHD*, *VHL*, *SDHC*. If a mutation is identified at any point in the testing algorithm, no further testing should be performed.
- If a patient presents with bilateral adrenal pheochromocytoma but without a history of MTC or goiter, tests for mutations in the following genes should be ordered sequentially: *VHL*, *RET*. If a *VHL* mutation is identified, genetic testing of the *RET* proto-oncogene should not be ordered. The biochemical phenotype—adrenergic (MEN2) or noradrenergic (VHL)—can also be used to guide genetic testing.
- If a patient who is 30 years of age or younger presents with apparent sporadic unilateral adrenal pheochromocytoma, tests for mutations in the following genes should be considered sequentially: *VHL*, *RET*, *SDHB*, *SDHD*, *SDHC*, and when clinically available, *FP/TMEM127*. If a mutation is identified at any point in the testing algorithm, no further testing should be performed.
- If a patient has a skull-base or neck paraganglioma, tests for mutations in the following genes should be ordered sequentially: *SDHD*, *SDHC*, *SDHAF2* (if clinically available), *SDHB*. If the kindred shows a typical maternal imprinting inheritance pattern, then *SDHD* and *SDHAF2* should be ordered. If a mutation is identified at any point in the testing algorithm, no further testing should be performed.

Evaluation and Monitoring of Carriers of Succinate Dehydrogenase Mutations

If an SDH mutation is identified in a relative of a proband, biochemical and imaging studies are indicated. Prospective studies to guide the clinician in the frequency and type of testing are lacking. Biochemical testing for fractionated metanephrines in plasma or in a 24-hour urine collection should be performed annually in all carriers of SDH mutation. Because paragangliomas may be nonfunctioning or may be detected before catecholamine-secretory autonomy is evident, imaging studies are advised. For example, *SDHB* and at-risk *SDHD* (e.g., paternally inherited) mutation carriers should have CT or MRI of the chest, abdomen, and pelvis every 2 to 3 years; ¹²³I-MIBG scintigraphy should be performed every 5 years. *SDHC* and at-risk *SDHAF2* (e.g., paternally inherited) mutation carriers should have skull-base and neck imaging with ultrasound or MRI every 2 to

3 years; ^{123}I -MIBG scintigraphy should be performed every 5 years; CT or MRI of the abdomen and pelvis every 5 years.

Diagnostic Investigation

Differential Diagnosis

Numerous disorders can cause signs and symptoms that may prompt the clinician to test for pheochromocytoma (see Table 16-3). The disorders span much of medicine and include endocrine disorders (e.g., primary hypogonadism), cardiovascular disorders (e.g., idiopathic orthostatic hypotension), psychologic disorders (e.g., panic disorder), pharmacologic causes (e.g., withdrawal from an adrenergic inhibitor), neurologic disorders (e.g., postural orthostatic tachycardia syndrome), and miscellaneous disorders (e.g., mast cell disease). Indeed, most patients tested for pheochromocytoma do not have it. In addition, levels of fractionated catecholamines and metanephrines may be elevated in several clinical scenarios, including withdrawal from medications or drugs (e.g., clonidine, alcohol), any acute illness (e.g., subarachnoid hemorrhage, migraine headache, preeclampsia), and administration of many drugs and medications (e.g., tricyclic antidepressants, levodopa, buspirone, antipsychotic agents, cocaine, phenylcyclidine, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, isoproterenol) (Table 16-5).

Case Detection

Pheochromocytoma should be suspected in patients who have one or more of the following:

- Hyperadrenergic spells (e.g., self-limited episodes of nonexertional palpitations, diaphoresis, headache, tremor, or pallor)
- Resistant hypertension
- A familial syndrome that predisposes to catecholamine-secreting tumors (e.g., MEN2, NF1, VHL)
- A family history of pheochromocytoma
- An incidentally discovered adrenal mass
- Hypertension and diabetes
- Pressor response during anesthesia, surgery, or angiography
- Onset of hypertension at a young age (<20 years)
- Idiopathic dilated cardiomyopathy
- A history of gastrointestinal stromal tumor or pulmonary chondromas (Carney triad)

Measurement of Fractionated Metanephrines and Catecholamines in Urine and Blood. The diagnosis must be confirmed biochemically by the presence of increased concentrations of fractionated catecholamines and

fractionated metanephrines in urine or plasma (Fig. 16-4).²² The metabolism of catecholamines is primarily intratumoral, with formation of metanephrine from epinephrine and normetanephrine from norepinephrine.¹⁰ Most laboratories now measure fractionated catecholamines (dopamine, norepinephrine, and epinephrine) and fractionated metanephrines (metanephrine and normetanephrine) by high-performance liquid chromatography with electrochemical detection or tandem mass spectrometry.⁶² These techniques have overcome the problems with fluorometric analysis, which include false-positive results caused by α -methyldopa, labetalol, sotalol, and imaging contrast agents.

At Mayo Clinic, the most reliable case-detection strategy is measurement of fractionated metanephrines and catecholamines in a 24-hour urine collection (sensitivity, 98%; specificity, 98%).^{63,64} If clinical suspicion is high, then plasma fractionated metanephrines, which are products of intrapheochromocytoma catecholamine metabolism, should also be measured.⁶⁵ Some groups have advocated that plasma fractionated metanephrines should be a first-line test for pheochromocytoma^{65,66}; the predictive value of a negative test is extremely high, and a normal result excludes pheochromocytoma except in patients with early preclinical disease and those with strictly dopamine-secreting neoplasms.⁶⁴ A plasma test is also attractive because of its simplicity. Although measurement of plasma fractionated metanephrines has a sensitivity of 96% to 100%,^{64,65} the specificity is poor at 85% to 89%,^{64,65,67} and the specificity falls to 77% in patients older than 60 years of age.⁶⁴ It has been estimated that 97% of patients with hypertension seen in a tertiary care clinic who have plasma fractionated metanephrine measurements above the reference range will not have a pheochromocytoma⁶⁷ and this results in excessive health care expenditures because of subsequent imaging and potentially inappropriate surgery.⁶⁸ Therefore, plasma fractionated metanephrines lack the necessary specificity to be recommended as a first-line test, and this measurement should be reserved for cases in which the index of suspicion is high (see Fig. 16-4).

The index of suspicion for pheochromocytoma should be high in the following scenarios: resistant hypertension; spells with associated pallor; a family history of pheochromocytoma; a genetic syndrome that predisposes to pheochromocytoma (e.g., MEN2); a past history of resected pheochromocytoma and present history of recurrent hypertension or spells; and an incidentally discovered adrenal mass that has imaging characteristics consistent with pheochromocytoma (Table 16-6). In addition, measurement of plasma fractionated metanephrines is a good first-line test for children, because obtaining a complete 24-hour urine collection is difficult in pediatric patients. Measurement of urinary dopamine or plasma methoxytyramine can be very useful in detecting the rare tumor with selective dopamine hypersecretion, because plasma metanephrine fractions are not direct metabolites of dopamine and may be normal in the setting of a dopamine-secreting tumor.^{25,64}

The 24-hour urine collection for fractionated metanephrines and catecholamines should include measurement of urinary creatinine to verify an adequate collection. The normal ranges for plasma metanephrine and normetanephrine may be affected by the method used to obtain the blood sample. For example, use of an indwelling cannula for 20 minutes after an overnight fast before the blood draw has resulted in lower diagnostic cutoff points (metanephrine, <0.3 nmol/L; normetanephrine, <0.66 nmol/L)⁶⁹ to exclude pheochromocytoma compared

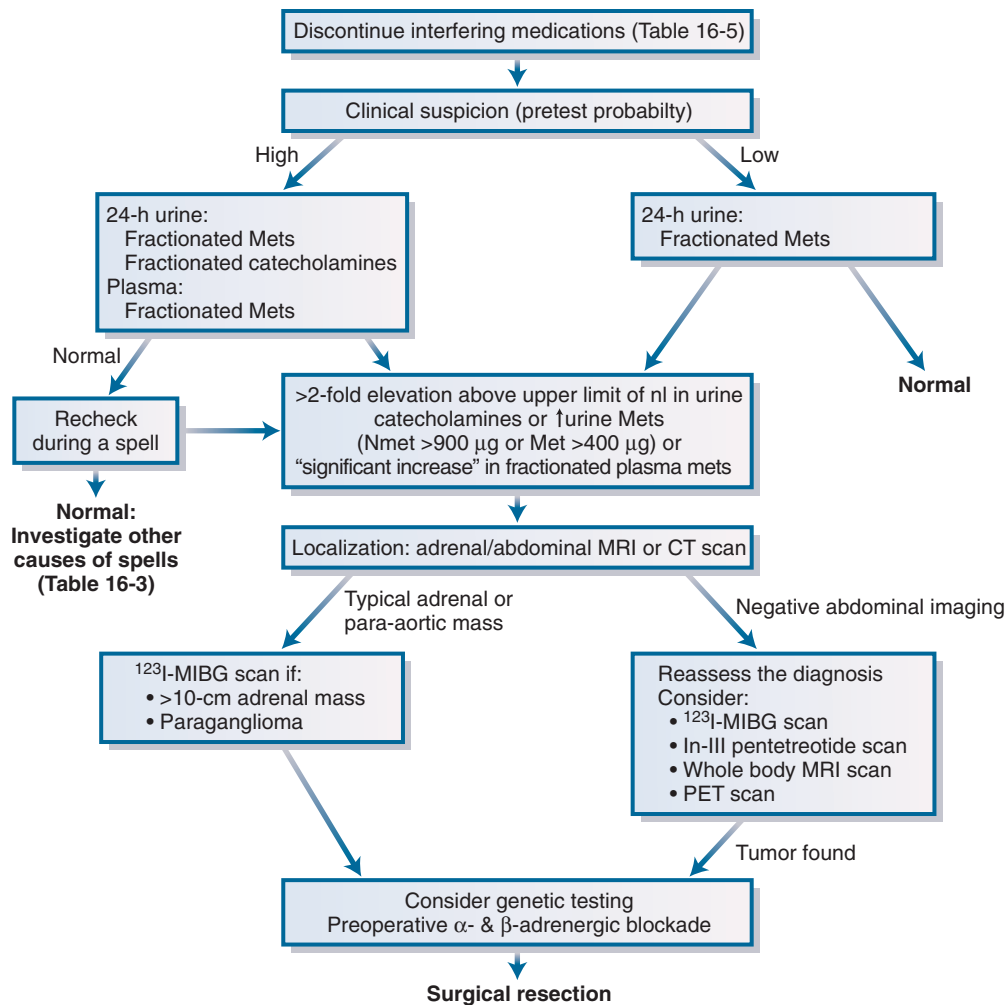

Figure 16-4 Evaluation and treatment of catecholamine-secreting tumors. Clinical suspicion is triggered by paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; a family history of pheochromocytoma or associated conditions; or an incidentally discovered adrenal mass (see text for details). CT, computed tomography; In-III, indium 111; ^{123}I -MIBG, iodine 123-labeled metaiodobenzylguanidine; Mets, metanephrines; MRI, magnetic resonance imaging; nl, normal; Nmet, normetanephrine; PET, positron emission tomography. (Modified from Young WF Jr. Pheochromocytoma, 1926-1993. *Trends Endocrinol Metab.* 1993;4:122, with permission.)

with venipuncture in a seated ambulant nonfasting patient (metanephrine, <0.5 nmol/L; normetanephrine, <0.9 nmol/L).⁶⁴ The diagnostic cutoffs for most 24-hour urinary fractionated metanephrines assays are based on normal ranges derived from normotensive volunteer reference groups, and this can result in excessive false-positive test results. For example, in normotensive laboratory volunteers, the 95th percentiles are 428 μg for normetanephrine and 200 μg for metanephrine, whereas the corresponding values in individuals who are being tested for pheochromocytoma as part of routine clinical practice but who do not have the neoplasm are, respectively, 71% and 51% higher than those of the normal volunteers.⁷⁰

Although it is preferred that patients not receive any medication during the diagnostic evaluation, treatment with most medications may be continued. Tricyclic antidepressants are the drugs that interfere most frequently with the interpretation of 24-hour urinary catecholamines and metabolites. To effectively screen for catecholamine-secreting tumors, treatment with tricyclic antidepressants and other psychoactive agents listed in Table 16-5 should be tapered and discontinued at least 2 weeks before any hormonal assessments. There are clinical situations for

which it is contraindicated to discontinue certain medications (e.g., antipsychotics), and if case-detection testing is positive, then CT or MRI would be needed to exclude a catecholamine-secreting tumor. Furthermore, catecholamine secretion may be appropriately increased in situations of physical stress or illness (e.g., stroke, myocardial infarction, congestive heart failure, obstructive sleep apnea). Therefore, the clinical circumstances under which catecholamines and metanephrines are measured must be assessed in each case.

Other Tests That Have Been Used to Assess for Pheochromocytoma. Because of poor overall accuracy in testing for pheochromocytoma, measurement of plasma catecholamines no longer has a role.⁶⁹ Chromogranin A is stored and released from dense-core secretory granules of neuroendocrine cells and is increased in 80% of patients with pheochromocytoma.⁷¹ Chromogranin A is not specific for pheochromocytoma, and elevations may be seen with other neuroendocrine tumors. Plasma neuropeptide Y levels are increased in 87% of patients with pheochromocytoma,⁷² but they also lack the accuracy of 24-hour urinary fractionated metanephrines and catecholamines. The

TABLE 16-6

Typical Imaging Phenotypes of Adrenal Masses

Tumor Type	Size (cm)	Shape	Texture	Laterality	Contrast Enhancement	CT*	MRI†	Necrosis, Hemorrhage, or Calcifications	Growth
Cortical adenoma	≤3	Round to oval with smooth margins	Homogeneous	Usually unilateral	Limited	<10 HU; >50% washout	Isointense	Rare	Slow
Cortical carcinoma	>4	Irregular with unclear margins	Inhomogeneous	Usually unilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	Rapid
Pheochromocytoma	>3	Round to oval with smooth margins	Inhomogeneous with areas of cystic degeneration	Usually solitary and unilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	1 cm/yr
Metastasis	Variable	Oval to irregular with unclear margins	Inhomogeneous	Often bilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	Variable

CT, computed tomography; HU, Hounsfield unit; MRI, magnetic resonance imaging.

*Precontrast radiodensity (HU) and percentage of contrast medium washout at 10 min.

†Relative intensity compared with liver on T2-weighted images.

24-hour urinary VMA excretion has poor diagnostic sensitivity and specificity compared with fractionated 24-hour urinary metanephrines.

Clonidine Suppression Test. The high false-positive rate for plasma catecholamines and fractionated metanephrines triggered the development of a confirmatory test, the clonidine suppression test. This test is intended to distinguish between pheochromocytoma and false-positive increases in plasma fractionated catecholamines and metanephrines. Clonidine is a centrally acting α_2 -adrenergic receptor agonist that normally suppresses the release of catecholamines from neurons but does not affect the catecholamine secretion from a pheochromocytoma. Clonidine (0.3 mg) is administered orally, and plasma fractionated catecholamines or metanephrines are measured before and 3 hours after the dose.⁷³ In patients with essential hypertension, plasma catecholamine concentrations decrease (norepinephrine + epinephrine <500 pg/mL or >50% decrease in norepinephrine), as do plasma normetanephrine concentrations (into the normal range or >40% decrease). However, these concentrations remain increased in patients with pheochromocytoma.^{73,74}

Provocative Testing and Suppression Testing. Because of advances in the methodology for measuring catecholamines and metanephrines, phentolamine, glucagon, histamine, metoclopramide, and tyramine tests are rarely needed. From 1975 to 1994 at Mayo Clinic, we performed histamine and glucagon stimulation testing in 542 patients in whom pheochromocytoma was highly suspected despite normal 24-hour urinary excretion of total metanephrines or catecholamines; not one patient had a positive stimulation test in this setting.⁷⁵

Renal Failure. Measurements of urinary catecholamines and metabolites may be invalid if the patient has advanced renal insufficiency.⁷⁶ Serum chromogranin A levels have

poor diagnostic specificity in these patients.⁷⁷ In patients without pheochromocytoma who are receiving hemodialysis, plasma norepinephrine and dopamine concentrations are increased, respectively, threefold and twofold above the upper limit of normal.^{78,79} However, standard normal ranges can be used for interpreting plasma epinephrine concentrations.⁸⁰ Therefore, when patients with renal failure have plasma norepinephrine concentrations more than threefold above the upper normal limit or epinephrine concentrations greater than the upper normal limit, pheochromocytoma should be suspected. The findings of one study suggested that plasma concentrations of fractionated metanephrines are increased approximately twofold in patients with renal failure and may be useful in the biochemical evaluation of patients with marked renal insufficiency or renal failure.⁸¹ However, the results of an earlier study suggested that concentrations of plasma fractionated metanephrines could not distinguish between 10 patients with pheochromocytoma and 11 patients with end-stage renal disease who required long-term hemodialysis.⁸²

Factitious Pheochromocytoma. As with other similar disorders, factitious pheochromocytoma can be very difficult to confirm.⁸³ The patient usually has a medical background. The patient may “spike” the 24-hour urine container, or the catecholamines may be administered systemically.⁸⁴

Localization

Localization studies should not be initiated until biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor (see Fig. 16-4). CT or MRI of the adrenal glands and abdomen should be the first localization test (sensitivity, >95%; specificity, >65%).⁸⁵⁻⁸⁸ Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen and pelvis. The most common locations of catecholamine-secreting paragangliomas include superior abdominal para-aortic region, 46%;

inferior abdominal para-aortic region, 29%; urinary bladder, 10%; mediastinum, 10%; head and neck, 3%; and pelvis, 2%.³⁵

Imaging Phenotype. The term *imaging phenotype* refers to the characteristics of the mass on CT or MRI (see Table 16-6). The lipid-rich nature of cortical adenomas is helpful in distinguishing these benign neoplasms from pheochromocytoma. On CT scans, the density of the image (with darker tissues being less dense) is attributed to x-ray attenuation. At the extremes of the CT density spectrum are air (black) and bone (white). The Hounsfield scale is a semi-quantitative method of measuring x-ray attenuation. Typical Hounsfield unit (HU) values are -20 to -150 HU for adipose tissue and 20 to 50 HU for kidney. If an adrenal mass is less than 0 HU on unenhanced CT, it is almost certainly a benign adenoma.^{89,90} Adrenal adenomas show a much earlier washout of contrast enhancement than do nonadenomas.⁹¹ For example, Korobkin and colleagues⁹¹ found that the mean percentage washout for adenomas was 51% at 5 minutes and 70% at 15 minutes, compared with 8% and 20%, respectively, for nonadenomas.

Although CT is still the primary adrenal imaging modality, MRI has advantages in certain clinical situations.⁸⁸ Several different MRI techniques have been used to characterize adrenal masses. Conventional spin-echo MRI was the first and is still the most frequently used technique. Early in the history of abdominal MRI, it became clear that with low- or mid-field-strength magnets, T1- and T2-weighted imaging could be used to differentiate pheochromocytoma and malignancies from benign adenomas. On gadolinium-diethylenetriaminepenta-acetic acid (DPTA)-enhanced MRI, pheochromocytomas and malignant lesions show rapid and marked enhancement and a slower washout pattern, whereas adenomas demonstrate mild enhancement and a rapid washout of contrast.⁹² Similar findings are made with CT.

Chemical shift MRI is a form of lipid-sensitive imaging. Chemical shift MRI is based on the principle that the hydrogen protons in water and lipid molecules resonate at different frequencies. Benign cortical adenomas contain approximately equal amounts of lipid and water, whereas the lipid content of pheochromocytomas is usually low. When the protons of water and lipid are aligned, they are said to be in phase, and when opposite each other, they are out of phase. When fat and water are in phase on MRI, the signal intensity is maximized; when they are out of phase, the signal intensity is reduced. This in-phase and out-of-phase process is the chemical shift technique. Benign adrenal cortical adenomas lose signal on out-of-phase images but appear relatively bright on in-phase images.⁹² A modification of the chemical shift MRI technique uses gradient echo pulse sequences to produce a similar effect.

Imaging characteristics consistent with a benign cortical adenoma include round and homogeneous density, smooth contour with sharp margination, diameter usually less than 3 cm, unilateral location, low unenhanced CT attenuation values (<10 HU) with rapid contrast medium washout at 10 minutes after administration of contrast medium,^{91,93} isointensity with liver on both T1- and T2-weighted MRI sequences, and chemical shift evidence of lipid on MRI (see Table 16-6). The imaging phenotype consistent with pheochromocytoma includes enhancement with intravenous contrast medium on CT (see Fig. 16-3), high signal intensity on T2-weighted MRI (Fig. 16-5), cystic and hemorrhagic changes, and variable size; also, the tumor may be bilateral. Although it has been suggested that patients with apparent simple adrenal cysts do not require hormonal

Figure 16-5 Magnetic resonance images of the abdomen of a 34-year-old woman with a recent onset of palpitations and hypertension. She presented with acute left ventricular failure after a single dose of a β -adrenergic blocker. The 24-hour urine test for total metanephrines and catecholamines showed the following: total metanephrines, 3800 μg (normal, <1000); norepinephrine, 37 μg (normal, <170); epinephrine, 7.7 μg (normal, <35); and dopamine, 147 μg (normal, <700). The images show a 3.3 \times 3.5 \times 4.5-cm, slightly heterogeneous, right adrenal mass consistent with pheochromocytoma (arrows) that has increased signal intensity on T2-weighted images (lower panel). After α -adrenergic blockade and restoration of normal left ventricular function, the patient had a laparoscopic adrenalectomy to remove a 5 \times 4 \times 3 cm, 33-g pheochromocytoma. Postoperatively, the 24-hour urinary excretion of total metanephrines normalized.

evaluation, pheochromocytoma can mimic an adrenal cyst.

¹²³I-MIBG Scintigraphy. If the results of abdominal imaging are negative, scintigraphic localization with ¹²³I-MIBG is indicated (Fig. 16-6). This radiopharmaceutical agent accumulates preferentially in catecholamine-producing tumors; however, this procedure is not as sensitive as was initially hoped (sensitivity, 80%; specificity, 99%).⁸⁶⁻⁸⁸ ¹²³I-MIBG is superior to ¹³¹I-MIBG because the photon energy allows single-photon emission computed tomographic (SPECT) images. Thyroid uptake of ¹²³I should be blocked with the administration of an iodide preparation (e.g., Lugol's solution). In a study of 282 patients with catecholamine-secreting tumors that were surgically confirmed, the overall sensitivity was 89% for CT, 98% for MRI, and 81% for ¹³¹I-MIBG.⁸⁷ If a typical (<10 cm) unilateral

Figure 16-6 Computed tomography (CT) and ^{123}I -metaiodobenzylguanidine (^{123}I -MIBG) imaging from a 44-year-old man. He presented with a 9-year history of hypertension and recent onset of head throbbing, chest pressure, and abdominal pain. The 24-hour urine studies were abnormal: norepinephrine, 900 μg (normal, <170); epinephrine, 28 μg (normal, <35); dopamine, 468 μg (normal, <700); and total metanephrines, 17,958 μg (normal, <1000). **A**, Axial CT image with contrast shows a large, partially vascular and partially necrotic left adrenal tumor (arrow). **B**, ^{123}I -MIBG whole-body scan shows a large focus of increased radiotracer uptake in the left upper abdomen (arrow) that corresponds to the mass seen on the CT image; no other abnormal uptake is seen. **C**, ^{123}I -MIBG and single-photon emission computed tomography (SPECT) fusion CT images correlate with the images seen on CT (anatomic) with those seen on ^{123}I -MIBG (physiologic) in the axial, coronal, and sagittal planes. After α - and β -adrenergic blockade, a 13.5 \times 12 \times 9-cm, 680-g pheochromocytoma was removed.

adrenal pheochromocytoma is found on CT or MRI, ^{123}I -MIBG scintigraphy is superfluous and the results may even confuse the clinician.^{94,95} On the other hand, if the adrenal pheochromocytoma is more than 10 cm in diameter or if a paraganglioma is identified on CT or MRI, then ^{123}I -MIBG scintigraphy is indicated, because the patient has increased

risk of malignant disease and additional paragangliomas. It is important for the clinician to recognize the medications that may interfere with ^{123}I -MIBG uptake (e.g., tricyclic antidepressants, labetalol, calcium channel blockers) and have the patient discontinue them before imaging is performed (Table 16-7).⁹⁶

TABLE 16-7

Drugs That May Interfere with Metaiodobenzylguanidine (MIBG) Uptake***Uptake-I Inhibition****

Antiemetics (e.g., prochlorperazine)
 Antipsychotics (e.g., chlorpromazine, haloperidol)
 Cocaine
 Labetalol
 Phenylpropanolamine
 Tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline)

Depletion of Storage Vesicle Contents†

Amphetamines (e.g., dextroamphetamine, fenfluramine, phentermine)

Inhibition of Vesicular Monoamine Transporters†

Reserpine

Unknown Mechanism*

Calcium channel blockers (e.g., diltiazem, nifedipine, nimodipine, verapamil)

*Should be stopped at least 48 hr before MIBG administration.

†Should be stopped at least 72 hr before MIBG administration.

Other Localizing Procedures. Localizing procedures that also can be used, but are rarely required, include computer-assisted imaging of the chest, neck, and skull base. Other localizing studies, such as somatostatin receptor imaging with ^{111}In -DTPA-pentetreotide, may also be considered. Although somatostatin receptors are usually expressed in pheochromocytomas and paragangliomas,⁹⁷ the sensitivity of somatostatin receptor imaging with ^{111}In -DTPA-pentetreotide is low. Although positron emission tomography (PET) scanning with ^{18}F -fluorodeoxyglucose (FDG) or ^{11}C -hydroxyephedrine or 6- ^{18}F fluorodopamine can identify paragangliomas,^{86,88} these expensive techniques probably should be reserved for identifying sites of metastatic disease in patients with negative ^{123}I -MIBG scintigraphic results. Selective venous sampling for catecholamines is usually misleading and should be avoided.

Treatment

The treatment of choice for pheochromocytoma is complete surgical resection. Surgical survival rates are 98% to 100% and are highly dependent on the skill of the endocrinologist, endocrine surgeon, and anesthesiologist team.^{34,98} The most common adverse event after surgery is sustained hypertension. Careful preoperative pharmacologic preparation is crucial for successful treatment.⁹⁹ Most catecholamine-secreting tumors are benign and can be totally excised. Tumor excision usually cures hypertension.

Preoperative Management

Some form of preoperative pharmacologic preparation is indicated for all patients with catecholamine-secreting neoplasms. However, no randomized, controlled trials have compared the different approaches. Combined α - and β -adrenergic blockade is one approach to control blood

pressure and prevent intraoperative hypertensive crises.²² α -Adrenergic blockade should be started 7 to 10 days preoperatively to normalize blood pressure and expand the contracted blood volume. A longer duration of preoperative α -adrenergic blockade is indicated for patients with recent myocardial infarction, catecholamine cardiomyopathy, or catecholamine-induced vasculitis. Blood pressure should be monitored with the patient in the seated and standing positions twice daily. Target blood pressure is less than 120/80 mm Hg (seated), with systolic blood pressure greater than 90 mm Hg (standing); both targets should be modified on the basis of the patient's age and comorbid disease. On the second or third day of α -adrenergic blockade, patients are encouraged to start a diet high in sodium content (≥ 5000 mg/day) because of the catecholamine-induced volume contraction and the orthostasis associated with α -adrenergic blockade. This degree of volume expansion may be contraindicated in patients with congestive heart failure or renal insufficiency. After adequate α -adrenergic blockade has been achieved, β -adrenergic blockade is initiated, typically 2 to 3 days preoperatively.

α -Adrenergic Blockade. Phenoxybenzamine is the preferred drug for preoperative preparation to control blood pressure and arrhythmia. It is an irreversible, long-acting, nonspecific α -adrenergic blocking agent. The initial dosage is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg in divided doses every 2 to 3 days as needed to control blood pressure and spells (Table 16-8). The final dosage of phenoxybenzamine is typically between 20 and 100 mg daily. The patient should be warned about the orthostasis, nasal congestion, and marked fatigue that occur in almost all patients. With their more favorable side effect profiles, selective α_1 -adrenergic blocking agents (e.g., prazosin, terazosin, doxazosin) are preferable to phenoxybenzamine when long-term pharmacologic treatment is indicated (e.g., for metastatic pheochromocytoma). However, treatment with these agents is not routinely used preoperatively because of incomplete α -adrenergic blockade.

β -Adrenergic Blockade. The β -adrenergic antagonist should be administered only after α -adrenergic blockade is effective because with β -adrenergic blockade alone, hypertension may be more severe due to the unopposed α -adrenergic stimulation. Preoperative β -adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α -adrenergic blockade. The clinician should exercise caution if the patient is asthmatic or has congestive heart failure. Chronic catecholamine excess can produce a myocardiopathy³⁰ that may become evident with the initiation of β -adrenergic blockade, resulting in acute pulmonary edema. Therefore, when the β -adrenergic blocker is administered, it should be used cautiously and at a low dose. For example, a patient is usually given 10 mg of propranolol every 6 hours to start. On the second day of treatment, the β -adrenergic blockade (assuming the patient tolerates the drug) is converted to a single long-acting dose. The dose is then increased as necessary to control the tachycardia (goal heart rate is 60-80 beats per minute).

Catecholamine Synthesis Inhibitor. Metyrosine should be used with caution and only after other agents have been ineffective or in patients in whom tumor manipulation or destruction (e.g., radiofrequency ablation of metastatic sites) will be marked. Although some centers advocate that this agent should be used routinely preoperatively, most reserve it primarily for patients who cannot be treated with

TABLE 16-8

Orally Administered Drugs Used to Treat Pheochromocytoma

Drug	Initial Dosage, mg/day* (Maximum)	Side Effects
α-Adrenergic Blocking Agents		
Phenoxybenzamine	10 [†] (100) [†]	Postural hypotension, tachycardia, miosis, nasal congestion, diarrhea, inhibition of ejaculation, fatigue
Prazosin	1 (20) [‡]	First-dose effect, dizziness, drowsiness, headache, fatigue, palpitations, nausea
Terazosin	1 (20) [†]	First-dose effect, asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations, somnolence
Doxazosin	1 (20)	First-dose effect, orthostasis, peripheral edema, fatigue, somnolence
Combined α- and β-Adrenergic Blocking Agent		
Labetalol	200 [†] (1200) [†]	Dizziness, fatigue, nausea, nasal congestion, impotence
Calcium Channel Blocker		
Nicardipine sustained-release	30 [†] (120) [†]	Edema, dizziness, headache, flushing, nausea, dyspepsia
Catecholamine Synthesis Inhibitor		
α -Methyl-p-L tyrosine (metyrosine)	1000 [‡] (4000) [‡]	Sedation, diarrhea, anxiety, nightmares, crystalluria, galactorrhea, extrapyramidal symptoms

*Given once daily unless otherwise indicated.

[†]Given in two doses daily.[‡]Given in three or four doses daily.

the typical combined α - and β -adrenergic blockade protocol for cardiopulmonary reasons. Metyrosine inhibits catecholamine synthesis by blocking the enzyme tyrosine hydroxylase.¹⁰⁰ The side effects of metyrosine can be disabling; with long-term therapy, they include sedation, depression, diarrhea, anxiety, nightmares, crystalluria and urolithiasis, galactorrhea, and extrapyramidal signs. Metyrosine may be added to α - and β -adrenergic blockade if the resection will be difficult (e.g., malignant paraganglioma) or if destructive therapy is planned (e.g., radiofrequency ablation of hepatic metastases). Our typical protocol with short-term preprocedure preparation is to start with metyrosine 250 mg every 6 hours on day 1, 500 mg every 6 hours on day 2, 750 mg every 6 hours on day 3, and 1000 mg every 6 hours on the day before the procedure, with the last dose (1000 mg) given on the morning of the procedure. With this short-course therapy, the main side effect is hypersomnolence.

Calcium Channel Blockers. Calcium channel blockers, which block norepinephrine-mediated calcium transport into vascular smooth muscle, have been used successfully at several medical centers to preoperatively prepare patients with pheochromocytoma.¹⁰¹⁻¹⁰³ Nicardipine is the most

commonly used calcium channel blocker in this setting; the starting dose is 30 mg twice daily of the sustained-release preparation (see Table 16-8). It is given orally to control blood pressure preoperatively and is given as an intravenous infusion intraoperatively (Table 16-9). Although there is less collective experience with calcium channel blockers than with α - and β -adrenergic blockers, when calcium channel blockers are used as the primary mode of antihypertensive therapy, they may be just as effective.^{101,102} Clearly, the exclusive use of calcium channel blockers for the perioperative management of patients with catecholamine-secreting tumors does not prevent all hemodynamic changes; however, its use has been associated with low morbidity and mortality.¹⁰² The main role for this class of drugs may be either to supplement the combined α - and β -adrenergic blockade protocol when blood pressure control is inadequate or to replace the adrenergic blockade protocol in patients with intolerable side effects.

Acute Hypertensive Crises

Acute hypertensive crises may occur before or during an operation, and they should be treated with intravenously administered sodium nitroprusside, phentolamine, or nicardipine (see Table 16-9). Sodium nitroprusside is an ideal

TABLE 16-9

Intravenously Administered Drugs Used to Treat Pheochromocytoma

Agent	Dosage Range
For Hypertension	
Phentolamine	Administer a 1-mg IV test dose, then 2- to 5-mg IV boluses as needed or continuous infusion.
Nitroprusside	IV infusion rates of 2 μ g/kg of body weight per minute are suggested as safe. Rates >4 μ g/kg per minute may lead to cyanide toxicity within 3 hr. Doses >10 μ g/kg per minute are rarely required, and the maximal dose should not exceed 800 μ g/min.
Nicardipine	Initiate therapy at 5.0 mg/hr; the IV infusion rate may be increased by 2.5 mg/hr q15 min up to a maximum of 15.0 mg/hr.
For Cardiac Arrhythmia	
Lidocaine	Initiate therapy with an IV bolus of 1-1.5 mg/kg (75-100 mg); additional boluses of 0.5-0.75 mg/kg (25-50 mg) can be given q5-10 min if needed up to a maximum of 3 mg/kg. Loading is followed by maintenance IV infusion of 2-4 mg/min (30-50 μ g/kg per minute) adjusted for effect and settings of altered metabolism (e.g., heart failure, liver congestion) and as guided by blood level monitoring.
Esmolol	An initial IV loading dose of 0.5 mg/kg is infused over 1 min, followed by a maintenance infusion of 0.05 mg/kg per minute for the next 4 min. Depending on the desired ventricular response, the maintenance infusion may then be continued at 0.05 mg/kg per minute or increased stepwise (e.g., by 0.1 mg/kg per minute increments to a maximum of 0.2 mg/kg per minute), with each step being maintained for \geq 4 min.

vasodilator for intraoperative management of hypertensive episodes because of its rapid onset of action and short duration of effect. It is administered as an intravenous infusion at 0.5 to 5.0 $\mu\text{g/kg}$ of body weight per minute and adjusted every few minutes for target blood pressure response; to keep the steady-state thiocyanate concentration below 1 mmol/L, the rate of a prolonged infusion should be no more than 3 $\mu\text{g/kg}$ per minute. Phentolamine is a short-acting, nonselective α -adrenergic blocker that is available in lyophilized form in 5-mg vials. An initial test dose of 1 mg is administered and is followed, if necessary, by repeat 5-mg boluses or continuous infusion. The response to phentolamine is maximal 2 to 3 minutes after a bolus injection and lasts 10 to 15 minutes. Nicardipine can be started at an infusion rate of 5 mg/hour and titrated for blood pressure control (the infusion rate may be increased by 2.5 mg/hour every 15 minutes up to a maximum of 15.0 mg/hour) (see Table 16-9).

Anesthesia and Surgery

Surgical resection of a catecholamine-secreting tumor is a high-risk surgical procedure, and an experienced surgeon-anesthesiologist team is required. The last oral doses of α - and β -adrenergic blockers can be administered early in the morning on the day of the operation. Fentanyl, ketamine, and morphine should be avoided, because they potentially can stimulate catecholamine release from a pheochromocytoma.¹⁰³ Also, parasympathetic nervous system blockade with atropine should be avoided because of the associated tachycardia. Anesthesia may be induced with intravenous injection of propofol, etomidate, or barbiturates in combination with synthetic opioids.¹⁰³ Most anesthetic gases can be used, but halothane and desflurane should be avoided. Cardiovascular and hemodynamic variables must be monitored closely. Continuous measurement of intra-arterial pressure and heart rhythm is required. If the patient has congestive heart failure or decreased cardiac reserve, monitoring of pulmonary capillary wedge pressure is indicated. The preoperative and perioperative treatment approach outlined here is the same for adults and children.^{104,105}

In the past, an anterior midline abdominal surgical approach was typically used for resecting adrenal pheochromocytoma. However, the laparoscopic approach to the adrenal gland is currently the procedure of choice for patients with solitary intra-adrenal pheochromocytomas smaller than 8 cm in diameter.¹⁰⁶ In a series of 39 patients with pheochromocytoma who had laparoscopic adrenalectomy, the mean hospitalization was 1.7 days,¹⁰⁷ as opposed to the typical 5 to 7 days for open laparotomy. If the pheochromocytoma is in the adrenal gland, the entire gland should be removed. Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy in cases of difficult dissection, invasion, adhesions, or surgeon inexperience.¹⁰⁸ If the tumor is malignant, as much of the tumor should be removed as possible. If a bilateral adrenalectomy is planned preoperatively, the patient should receive glucocorticoid stress coverage while awaiting transfer to the operating room. In addition, glucocorticoid coverage should be initiated in the operating room if unexpected bilateral adrenalectomy is necessary. Cortical-sparing bilateral adrenalectomies have been used to treat patients with VHL disease.

An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. The midline abdomen should be inspected carefully. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches. "Unresectable" cardiac pheochromocytomas may require cardiac transplantation.

Hypotension may occur during and after surgical resection of the pheochromocytoma, and it should be treated with fluids and colloids and then intravenous pressor agents if necessary. Postoperative hypotension occurs less frequently in patients who have had adequate preoperative α -adrenergic blockade and volume expansion. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered as a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored, and fluid given intravenously should contain 5% dextrose. Blood pressure is usually normal by the time of hospital discharge. Some patients remain hypertensive for up to 4 to 8 weeks postoperatively. Long-standing, persistent hypertension does occur and may be related to accidental ligation of a polar renal artery, resetting of baroreceptors, hemodynamic changes, structural changes of the blood vessels, altered sensitivity of the vessels to pressor substances, functional or structural renal changes, or coincident primary hypertension.

Long-Term Postoperative Follow-Up

Approximately 1 to 2 weeks after surgery, fractionated catecholamines and metanephrines should be measured by collection of a 24-hour urine specimen. If the levels are normal, the resection of the pheochromocytoma should be considered complete. The survival rate after removal of a benign pheochromocytoma is almost equal to that of age- and sex-matched normal controls. Increased levels of catecholamines and metanephrines detected postoperatively are consistent with residual tumor (i.e., a second primary lesion or occult metastases). If bilateral adrenalectomy was performed, lifelong glucocorticoid and mineralocorticoid replacement therapy is prescribed. The 24-hour urinary excretion of fractionated catecholamines and metanephrines or plasma fractionated metanephrines should be checked annually for life. Annual biochemical testing assesses for metastatic disease, tumor recurrence in the adrenal bed, and delayed appearance of multiple primary tumors. Recurrence rates are highest for patients with familial disease, right-sided adrenal pheochromocytoma, or paraganglioma.¹⁰⁹ Follow-up CT or MRI is not needed unless metanephrine or catecholamine levels become elevated or the original tumor was associated with minimal catecholamine excess.

Genetic testing should be considered for patients with one or more of the following: a family history of pheochromocytoma; paraganglioma; and any sign that suggests a genetic cause, such as retinal angiomas, axillary freckling, café au lait spots, cerebellar tumor, MTC, or hyperparathyroidism. In addition, all first-degree relatives of a patient with pheochromocytoma or paraganglioma should have biochemical testing (e.g., 24-hour urine for fractionated metanephrines and catecholamines). If mutation testing in a patient is positive, first-degree relatives (the patient's parents, siblings, and children) should be offered genetic testing.

Malignant Pheochromocytoma and Paraganglioma

Distinguishing between benign and malignant catecholamine-secreting tumors is difficult on the basis of clinical, biochemical, or histopathologic characteristics. Malignancy is rare in patients with MEN2 or VHL syndrome, but it is common in those with familial paraganglioma caused by mutations in *SDHB*. Patients with *SDHB* mutations are more likely to develop malignant disease

and nonparaganglioma neoplasms (e.g., renal cell carcinoma).^{54,57,58} Although the 5-year survival rate for patients with malignant pheochromocytoma is less than 50%, the prognosis is variable: approximately 50% of patients have an indolent form of the disease, with a life expectancy of more than 20 years, and the other half have rapidly progressive disease, with death occurring within 1 to 3 years after diagnosis. The clinician should first assess the pace of the malignant disease and then target the level of therapy to the aggressiveness of tumor behavior. A multimodality, multidisciplinary, individualized approach is indicated to control catecholamine-dependent symptoms, local mass effect symptoms from the tumor, and overall tumor burden. Long-term pharmacologic therapy for the patient with metastatic pheochromocytoma is similar to that outlined for preoperative preparation in a patient with a catecholamine-secreting tumor.

Metastatic sites include local tissue invasion, liver, bone, lung, omentum, and lymph nodes. Metastatic lesions should be resected, if possible, to decrease tumor burden. Skeletal metastatic lesions that are painful or threaten structural function can be treated with external radiotherapy or cryoablation or approached surgically. Thrombotic therapy for large, unresectable liver metastases and radiofrequency ablation for small liver metastases are options to be considered. In selected cases, long-acting octreotide has been beneficial. Because of the risk of massive catecholamine release, ablative therapy should be performed with great caution and only at centers with experience with these techniques; in addition to α - and β -adrenergic blockade, these patients are usually treated with metyrosine before the procedure. External radiotherapy can also be used to treat unresectable soft tissue lesions.

Local tumor irradiation with therapeutic doses of ¹³¹I-MIBG has produced partial and temporary responses in approximately one third of patients.^{7,8,110} If the tumor is considered aggressive and the patient's quality of life is affected, combination chemotherapy may be considered. In a nonrandomized, single-arm trial, the efficacy of chemotherapy with a combination CVD protocol (cyclophosphamide, 750 mg/m² body surface area on day 1; vincristine, 1.4 mg/m² on day 1; and dacarbazine 600 mg/m² on days 1 and 2; repeated every 21 days) was studied in 14 patients with malignant pheochromocytoma.^{111,112} This protocol produced a complete and partial response rate of 57% (median duration, 21 months; range, 7 to >34). Complete and partial biochemical responses were seen in 79% of patients (median duration, >22 months; range, 6 to >35 months). All responding patients had objective improvement in performance status and blood pressure. CVD chemotherapy can be continued until the patient develops new lesions or there is a significant (e.g., >25%) increase in size of known tumor sites. Because CVD chemotherapy may induce massive catecholamine release, it is important that the patient be optimally α - and β -blocked, just as for surgery. In addition, the first cycle of CVD should be completed in the hospital and with close medical observation. Management of malignant pheochromocytoma can be frustrating because curative options are limited. Recent preliminary studies suggest that tyrosine kinase inhibitors (e.g., sunitinib) may have a role in the treatment of metastatic pheochromocytoma.¹¹³

Pheochromocytoma in Pregnancy

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother. The approach to the biochemical diagnosis is the same as for the nonpregnant

patient. MRI (without gadolinium enhancement) is the preferred imaging modality, and ¹²³I-MIBG is contraindicated. The treatment of hypertensive crises is the same as for nonpregnant patients except that use of nitroprusside should be avoided. Although the most appropriate management is debated,¹¹⁴ adrenal pheochromocytomas should be removed promptly if diagnosed during the first or second trimester of pregnancy. The preoperative preparation is the same as for a nonpregnant patient. If the pregnancy is already in the third trimester, a single operation is recommended, to perform a cesarean section and remove the adrenal pheochromocytoma at the same time. Spontaneous labor and delivery should be avoided. The management of catecholamine-secreting paragangliomas in pregnancy may require modification of these guidelines depending on tumor location.

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The components of the renin-angiotensin-aldosterone (RAA) system are shown in Figure 16-7.¹¹⁵ Aldosterone is secreted from the zona glomerulosa under the control of three primary factors: angiotensin II, potassium, and ACTH. The secretion of aldosterone is restricted to the zona glomerulosa because of zone-specific expression of aldosterone synthase (CYP11B2) (see Chapter 15). Dopamine, atrial natriuretic peptide, and heparin inhibit aldosterone secretion.

Renin and Angiotensin

Renin is an enzyme that is produced primarily in the juxtaglomerular apparatus of the kidney; it is stored in granules and released in response to specific secretagogues. The

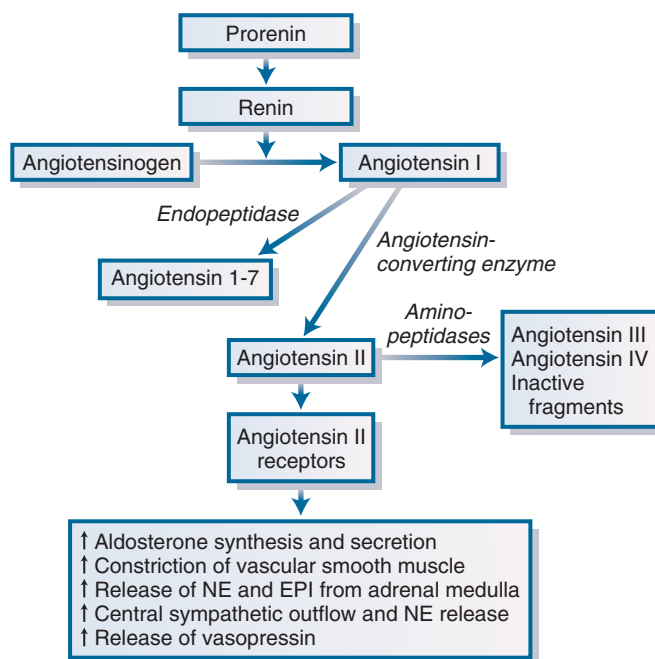

Figure 16-7 Components of the renin-angiotensin system. EPI, epinephrine; NE, norepinephrine. (Adapted and redrawn from Williams GH, Chao J, Chao L. Kidney hormones. In: Conn PM, Melmed S, eds. *Endocrinology: Basic and Clinical Principles*. Totowa, NJ, Humana Press, 1997:393-404.)

protein consists of 340 amino acids, of which the first 43 are a prosegment that is cleaved to produce the active enzyme. The release of renin into the circulation is the rate-limiting step in the RAA system. Renal renin release is controlled by four factors:

1. The macula densa, a specialized group of convoluted distal tubular cells that function as chemoreceptors for monitoring the sodium and chloride loads present in the distal tubule
2. Juxtaglomerular cells acting as pressure transducers that sense stretch of the afferent arteriolar wall and thus renal perfusion pressure
3. The sympathetic nervous system, which modifies the release of renin, particularly in response to upright posture
4. Humoral factors, including potassium, angiotensin II, and atrial natriuretic peptides

Renin release is maximized in conditions of low renal perfusion pressure or low tubular sodium content (e.g., renal artery stenosis, hemorrhage, dehydration). Renin release is suppressed by elevated perfusion pressure at the kidney (e.g., hypertension) and a high-sodium diet. Renin release is increased directly by hypokalemia and decreased by hyperkalemia.

Angiotensinogen, an α_2 -globulin synthesized in the liver, is the only known substrate for renin and is broken down into the angiotensin peptides. The protein consists of 485 amino acids, 33 of which constitute a presegment that is cleaved after secretion. The action of renin on angiotensinogen produces angiotensin I. Angiotensin I comprises the first 10-amino-acid sequence after the presegment and does not appear to have biologic activity. Angiotensin II, the main biologically active angiotensin, is created by cleavage of the two carboxyl-terminal peptides of angiotensin I by angiotensin-converting enzyme (ACE) (see Fig. 16-7). ACE is localized to cell membranes in the lung and intracellular granules in certain tissues that produce angiotensin II. Amino peptidase A can remove the amino-terminal aspartic acid to produce the heptapeptide, angiotensin III. Angiotensin II and angiotensin III have equivalent efficacy in promoting aldosterone secretion and modifying renal blood flow. The half-life in the circulation of angiotensin II is short (<60 seconds). Elements of the RAA system are present in the adrenals, kidneys, heart, and brain. For example, the adrenal glomerulosa cells contain the proteins needed to produce and secrete angiotensin II. Other tissues contain one or more components of the system but require other cells or circulating components, or both, to generate angiotensin II.

Angiotensin II functions through the angiotensin receptor to maintain normal extracellular volume and blood pressure by (1) increasing aldosterone secretion from the zona glomerulosa via increased transcription of CYP11B2; (2) constricting vascular smooth muscle, thereby increasing blood pressure and reducing renal blood flow; (3) releasing norepinephrine and epinephrine from the adrenal medulla; (4) enhancing the activity of the sympathetic nervous system by increasing central sympathetic outflow, thereby increasing norepinephrine discharge from sympathetic nerve terminals; and (5) promoting the release of vasopressin.

Aldosterone

Approximately 50% to 70% of aldosterone circulates bound to albumin or weakly bound to corticosteroid-binding globulin; 30% to 50% of total plasma aldosterone is free.

The half-life is relatively short at 15 to 20 minutes. In the liver, aldosterone is rapidly inactivated to tetrahydroaldosterone. The classic functions of aldosterone are regulation of extracellular volume and control of potassium homeostasis. These effects are mediated by the binding of free aldosterone to the mineralocorticoid receptor in the cytosol of epithelial cells, principally in the kidney.

Mineralocorticoid receptors have tissue-specific expression. For example, the tissues with the highest concentrations of these receptors are the distal nephron, colon, and hippocampus. Lower levels of mineralocorticoid receptors are found in the rest of the gastrointestinal tract and heart. Transport to the nucleus and binding to specific binding domains on targeted genes leads to their increased expression. Aldosterone-regulated kinase appears to be a key intermediary, and its increased expression leads to modification of the apical sodium channel, resulting in increased sodium ion transport across the cell membrane (see Chapter 15). The increased luminal negativity augments tubular secretion of potassium by the tubular cells and of hydrogen ion by the interstitial cells.

Glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor. Specificity of action is provided in many tissues by the presence of a glucocorticoid-inactivating enzyme, 11β -hydroxysteroid dehydrogenase, which prevents glucocorticoids from interacting with the receptor (see Chapter 15). Mineralocorticoid "escape" refers to the counterregulatory mechanisms that are manifested after 3 to 5 days of excessive mineralocorticoid administration. Several mechanisms contribute to this escape, including renal hemodynamic factors and increased levels of atrial natriuretic peptide.

In addition to the classic genomic actions mediated by aldosterone binding to cytosolic receptors, mineralocorticoids have acute, nongenomic actions resulting from activation of an unidentified cell surface receptor. This action involves a G protein signaling pathway and probably a modification of the sodium-hydrogen exchange activity. This effect has been demonstrated in both epithelial and nonepithelial cells.¹¹⁶

Aldosterone has additional, nonclassic effects primarily on nonepithelial cells.¹¹⁷ These actions, although probably genomic and therefore mediated by activation of the cytosolic mineralocorticoid receptor, do not include modification of sodium-potassium balance. Aldosterone-mediated actions include the expression of several collagen genes; genes controlling tissue growth factors (e.g., transforming growth factor- β , plasminogen activator inhibitor type 1); and genes mediating inflammation.¹¹⁸ The resultant actions lead to microangiopathy, necrosis (acutely), and fibrosis in various tissues such as the heart, the vasculature, and the kidney.¹¹⁷ Increased levels of aldosterone are not necessary to cause this damage; an imbalance between the volume or sodium balance state and the level of aldosterone appears to be the critical factor.¹¹⁷

The action of angiotensin II on aldosterone involves a negative feedback loop that also includes extracellular fluid volume (Fig. 16-8).¹¹⁹ The major function of this feedback loop is to modify sodium homeostasis and, secondarily, to regulate blood pressure. Sodium restriction activates the RAA axis. The effects of angiotensin II on both the adrenal cortex and the renal vasculature promote renal sodium conservation. On the other hand, with suppression of renin release and suppression of the level of circulating angiotensin, aldosterone secretion is reduced and renal blood flow is increased, promoting sodium loss. The RAA loop is very sensitive to dietary sodium intake. Sodium excess enhances the responsiveness of the renal and

Figure 16-8 Renin-angiotensin-aldosterone and potassium-aldosterone negative feedback loops. Aldosterone production is determined by input from each loop. ACE, angiotensin-converting enzyme; BP, blood pressure; Na⁺, sodium. (Adapted and redrawn from Williams GH, Dluhy RG. Diseases of the adrenal cortex. In: Braunwald E, Fauci AD, Kasper D, et al., eds. *Harrison's Principles of Internal Medicine*, 15th ed. New York, NY: McGraw-Hill, 2001:2087.)

peripheral vasculature and reduces the adrenal responsiveness to angiotensin II. Sodium restriction has the opposite effect. Therefore, sodium intake modifies target tissue responsiveness to angiotensin II, a fine-tuning mechanism that appears to be critical to maintaining normal sodium homeostasis without a chronic effect on blood pressure.

Excess aldosterone secretion causes hypertension through two main mechanisms: mineralocorticoid-induced expansion of plasma and extracellular fluid volume and increased total peripheral vascular resistance.

PRIMARY ALDOSTERONISM

Hypertension, suppressed plasma renin activity (PRA), and increased aldosterone excretion characterize the syndrome of primary aldosteronism, first described in 1955.¹²⁰ Aldosterone-producing adenoma (APA) and bilateral idiopathic hyperaldosteronism (IHA) are the most common subtypes of primary aldosteronism (Table 16-10). A much less common form, unilateral hyperplasia or primary adrenal hyperplasia (PAH), is caused by micronodular or macronodular hyperplasia of the zona glomerulosa of predominantly one adrenal gland. Familial hyperaldosteronism (FH) is also rare, and two types have been described. FH type I, or glucocorticoid-remediable aldosteronism (GRA), is autosomal dominant in inheritance and is associated with variable degrees of hyperaldosteronism, high levels of hybrid steroids (e.g., 18-hydroxycortisol, 18-oxocortisol), and suppression with exogenous glucocorticoids.¹²¹ FH type II refers to the familial occurrence of APA or IHA or both.¹²²

History

In his presidential address at the annual meeting of the Central Society for Clinical Research, Chicago, Illinois, October, 29, 1954, Dr. Jerome W. Conn stated¹²⁰: "I have prepared no comprehensive review of my personal philosophy of clinical investigation. Instead, I plan to make a scientific report to you about a clinical syndrome, the investigation of which has been most exciting to me since I initiated it in April of this year." Conn, a Professor of Medicine at the University of Michigan, had been active in government-funded research on the mechanisms of

human acclimatization to humid heat. He established that the body's acclimatization response was to rapidly diminish renal salt and water loss and to abruptly curtail the salt content of body sweat and saliva. He suggested that these responses were the result of increased adrenocortical

TABLE 16-10

Adrenocortical Causes of Hypertension

Low Renin and High Aldosterone

Primary Aldosteronism

Aldosterone-producing adenoma (APA)—35% of cases
Bilateral idiopathic hyperplasia (IHA)—60% of cases
Primary (unilateral) adrenal hyperplasia—2% of cases
Aldosterone-producing adrenocortical carcinoma—<1% of cases
Familial hyperaldosteronism (FH)
Glucocorticoid-remediable aldosteronism (FH type I)—<1% of cases
FH type II (APA or IHA)—<2% of cases
Ectopic aldosterone-producing adenoma or carcinoma—<0.1% of cases

Low Renin and Low Aldosterone

Hyperdeoxycorticosteronism

Congenital adrenal hyperplasia
11 β -Hydroxylase deficiency
17 α -Hydroxylase deficiency
Deoxycorticosterone-producing tumor
Primary cortisol resistance
Apparent mineralocorticoid excess (AME)/11 β -HSD deficiency
Genetic
Type I AME
Acquired
Licorice or carbenoxolone ingestion (type I AME)
Cushing's syndrome (type 2 AME)

Cushing's Syndrome

Exogenous glucocorticoid administration—most common cause
Endogenous
ACTH-dependent—85% of cases
Pituitary
Ectopic
ACTH-independent—15% of cases
Unilateral adrenal disease (adenoma or carcinoma)
Bilateral adrenal disease
Massive macronodular hyperplasia (rare)
Primary pigmented nodular adrenal disease (rare)

ACTH, corticotropin; HSD, hydroxysteroid dehydrogenase.

function with elaboration of salt-retaining steroids. He also showed that intramuscular administration of deoxycorticosterone acetate (DOCA) produced similar changes in the electrolyte composition of urine, sweat, and saliva.

In April 1954, Professor Conn was asked to see M.W., a 34-year-old woman with a 7-year history of muscle spasms, temporary paralysis, tetany, and weakness and a 4-year history of hypertension. She was found to have a blood pressure of 176/104 mm Hg, severe hypokalemia (1.6 to 2.5 mEq/L), mild hypernatremia (146 to 151 mEq/L), and alkalosis (serum pH, 7.62). Because there were no signs or symptoms of glucocorticoid or androgen excess, Conn suspected, based on his past research, that M.W.'s clinical presentation could result from excess secretion of the adrenal salt-retaining corticoid. Conn studied M.W. in the Metabolism Research Unit for 227 days. Streeten's bioassay technique developed to measure sodium retention in adrenalectomized rats after intraperitoneal injection of human urine was used, and M.W. averaged 1333 μ g DOCA equivalent per day, compared with normotensive controls at 61.4 μ g/day. In his presidential address, Conn stated: "It is believed that these studies delineate a new clinical syndrome which is designated temporarily as primary aldosteronism." (Note: the word "temporarily" was used because aldosterone was yet to be measured in any human bodily fluid.)¹²⁰

Conn planned for a bilateral adrenalectomy for his patient on December 10, 1954. In 1995, Gittler and Fajans described the surgical scene¹²³: "To the immense delight of Conn and those in the operating room, the surgeon, Dr. William Baum, encountered a right 13-g adrenal tumor which was removed while leaving the contralateral gland intact. The patient's postoperative studies showed an almost total reversal of the preoperative metabolic and clinical abnormalities. Conn had achieved irrefutable proof of the validity of his investigative conclusions and established for the first time the relationship among adrenal aldosterone-producing tumors, hypertension, and hypokalemia. A new era had arrived in the study of hypertension and adrenal mineralocorticoids."

By 1964, Conn had collected 145 cases,¹²⁴ and he suggested that up to 20% of patients with essential hypertension might have primary aldosteronism.¹²⁵ This suggestion was downplayed by most as a gross overestimate.^{126,127} Later, Conn decreased his predicted prevalence of primary aldosteronism to 10% of hypertensives,¹²⁸ a prediction that was substantiated nearly 40 years later.

Prevalence

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuation of antihypertensive medications for at least 2 weeks. This diagnostic approach resulted in predicted prevalence rates of less than 0.5% of hypertensive patients.^{126,127,129-133} However, it is now recognized that most patients with primary aldosteronism are not hypokalemic^{134,135} and that screening can be completed while the patient is taking antihypertensive drugs with a simple blood test that yields the ratio of plasma aldosterone concentration (PAC) to PRA.¹³⁶⁻¹³⁹ Use of the PAC/PRA ratio as a case-detection test, followed by aldosterone suppression for confirmatory testing, has resulted in much higher prevalence estimates for primary aldosteronism—5% to 10% of all patients with hypertension.¹³⁹⁻¹⁴⁵

Clinical Presentation

The diagnosis of primary aldosteronism is usually made in patients who are in the third to sixth decade of life. Few symptoms are specific to the syndrome. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, nocturia, or a combination of these. Periodic paralysis is a very rare presentation in Caucasians, but it is not an infrequent presentation in patients of Asian descent.¹⁴⁶ For example, in a series of 50 patients with APA reported from Hong Kong, 21 (42%) presented with periodic paralysis.¹⁴⁶ Another rare presentation is tetany associated with the decrease in ionized calcium with marked hypokalemic alkalosis. The polyuria and nocturia are a result of hypokalemia-induced renal concentrating defect, and the presentation is frequently mistaken for prostatism in men. There are no specific physical findings. Edema is not a common finding because of the phenomenon of mineralocorticoid escape, described earlier. The degree of hypertension is typically moderate to severe and may be resistant to usual pharmacologic treatments.^{134,147} In the first 262 cases of primary aldosteronism diagnosed at Mayo Clinic (1957-1986), the highest blood pressure was 260/155 mm Hg; the mean (\pm SD) was 184/112 \pm 28/16 mm Hg.¹⁴⁷ Patients with APA tend to have higher blood pressures than those with IHA.¹⁴⁸ Hypokalemia is frequently absent, so all patients with hypertension are candidates for this disorder. In other patients, the hypokalemia becomes evident only with the addition of a potassium-wasting diuretic (e.g., hydrochlorothiazide, furosemide). Deep-seated renal cysts are found in up to 60% of patients with chronic hypokalemia.¹⁴⁹ Because of a reset osmostat, the serum sodium concentration tends to be high-normal or slightly above the upper limit of normal. This clinical clue is very useful in the initial assessment for potential primary aldosteronism.

Several studies have shown that patients with primary aldosteronism are at higher risk than other patients with hypertension for target-organ damage of the heart and kidney.^{150,151} When matched for age, blood pressure, and duration of hypertension, patients with primary aldosteronism have greater left ventricular mass measurements than patients with other types of hypertension (e.g., pheochromocytoma, Cushing's syndrome, essential hypertension).¹⁵² In patients with APA, the left ventricular wall thickness and mass were markedly decreased 1 year after adrenalectomy.¹⁵³ A case-control study of 124 patients with primary aldosteronism and 465 patients with essential hypertension (matched for age, sex, and systolic and diastolic blood pressure) found that patients presenting with either APA or IHA had a significantly higher rate of cardiovascular events (e.g., stroke, atrial fibrillation, myocardial infarction) than the matched patients with essential hypertension.¹⁵¹ A negative effect of circulating aldosterone on cardiac function was found in young nonhypertensive subjects with GRA who had increased left ventricular wall thickness and reduced diastolic function compared with age- and sex-matched controls.¹⁵⁰

Diagnosis

The diagnostic approach to primary aldosteronism can be considered in three phases: case-detection tests, confirmatory tests, and subtype evaluation tests.

Case-Detection Tests

Spontaneous hypokalemia is uncommon in patients with uncomplicated hypertension; when present, it strongly

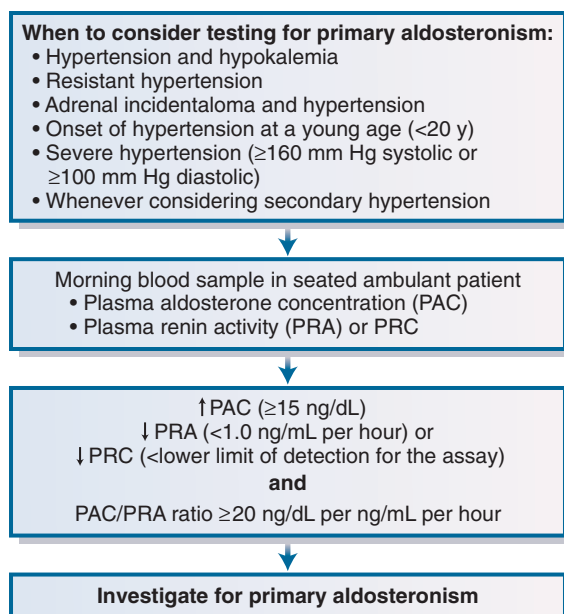

Figure 16-9 Algorithm provides guidance on when to consider testing for primary aldosteronism and use of the ratio of plasma aldosterone concentration (PAC) to plasma renin activity (PRA) as a case-detection tool. PRC, plasma renin concentration.

suggests associated mineralocorticoid excess. However, several studies have shown that most patients with primary aldosteronism have baseline serum levels of potassium in the normal range.^{134,139,154-156} Therefore, hypokalemia should not be the criterion used to trigger case detection testing for primary aldosteronism. Patients with hypertension and hypokalemia (regardless of presumed cause), treatment-resistant hypertension (poor control on three antihypertensive drugs), severe hypertension (≥160 mm Hg systolic or ≥100 mm Hg diastolic), hypertension and an incidental adrenal mass, or onset of hypertension at a young age should undergo screening for primary aldosteronism (Fig. 16-9).^{134,135} In addition, patients should be screened for primary aldosteronism whenever a secondary hypertension evaluation is being considered, such as when a patient lacks a family history of hypertension or is being tested for renovascular disease or pheochromocytoma.

In patients with suspected primary aldosteronism, screening can be accomplished (see Fig. 16-9) by paired measurements of PAC and PRA in a random morning ambulatory blood sample (preferably obtained between 8 and 10 a.m.). This test may be performed while the patient is taking antihypertensive medications (with some exceptions, discussed later) and without posture stimulation.^{134,135,138,139,157,158} Hypokalemia reduces the secretion of aldosterone, and it is optimal to restore the serum level of potassium to normal before performing diagnostic studies. Mineralocorticoid receptor antagonists (e.g., spironolactone, eplerenone) are the only medications that absolutely interfere with interpretation of the ratio and must be discontinued at least 6 weeks before testing. ACE inhibitors and angiotensin receptor blockers (ARBs) have the potential to falsely elevate the PRA. Therefore, the finding of a detectable PRA level or a low PAC/PRA ratio in a patient taking one of these drugs does not exclude the diagnosis of primary aldosteronism. However, an undetectably low PRA level in a patient taking an ACE inhibitor or ARB makes primary aldosteronism likely, and the PRA is

suppressed (<1.0 ng/mL per hour) in almost all patients with primary aldosteronism.

The PAC/PRA ratio, first proposed as a case-detection test for primary aldosteronism in 1981,¹³⁷ is based on the concept of paired hormone measurements. The PAC is measured in nanograms per deciliter, and the PRA in nanograms per milliliter per hour. In a hypertensive hypokalemic patient, secondary hyperaldosteronism should be considered if both PRA and PAC are increased and the PAC/PRA ratio is less than 10 (e.g., renovascular disease). An alternative source of mineralocorticoid receptor agonism should be considered if both PRA and PAC are suppressed (e.g., hypercortisolism). Primary aldosteronism should be suspected if the PRA is suppressed (<1.0 ng/mL per hour) and the PAC is increased. At least 14 prospective studies have been published on the use of the PAC/PRA ratio in detecting primary aldosteronism.¹⁵⁹ Although there is some uncertainty about test characteristics and lack of standardization (see later discussion), the PAC/PRA ratio is widely accepted as the case-detection test of choice for primary aldosteronism.

It is important to understand that the lower limit of detection varies among different PRA assays and can have a dramatic effect on the PAC/PRA ratio. As an example, if the lower limit of detection for PRA is 0.6 ng/mL per hour and the PAC is 16 ng/dL, then the PAC/PRA ratio with an “undetectable” PRA would be 27; however, if the lower limit of detection for PRA is 0.1 ng/mL per hour, the same PAC level would yield a PAC/PRA ratio of 160. Thus, the cutoff for a “high” PAC/PRA ratio is laboratory dependent and, more specifically, PRA assay dependent. In a retrospective study, the combination of a PAC/PRA ratio greater than 30 and a PAC level greater than 20 ng/dL had a sensitivity of 90% and a specificity of 91% for APA.¹⁶⁰ At Mayo Clinic, the combination of a PAC/PRA ratio of 20 or higher, and a PAC level of at least 15 ng/dL is found in more than 90% of patients with surgically confirmed APA. In patients without primary aldosteronism, most of the variation occurs within the normal range.¹⁶¹ A high PAC/PRA ratio is a positive screening test result, a finding that warrants further testing.^{134,135}

It is critical for the clinician to recognize that the PAC/PRA ratio is only a case-detection tool, and all positive results should be followed by a confirmatory aldosterone suppression test to verify autonomous aldosterone production before treatment is initiated.^{134,135} In a systematic review of 16 studies with 3136 participants, the PAC/PRA cutoff levels used varied between 7.2 and 100.¹⁵⁹ The sensitivity for APA varied between 64% and 100%, and the specificity between 87% and 100%. However, the description of the reference standard and the attribution of diagnosis at the end of the studies were incomplete, and there was a lack of standardization concerning the origin of the study cohort, ongoing antihypertensive medications, use of high-salt versus low-salt diet, and circumstances during blood sampling. The authors concluded that none of the studies provided any valid estimates of test characteristics (sensitivity, specificity, and likelihood ratio at various cutoff levels).¹⁵⁹ In a study of 118 subjects with essential hypertension, neither antihypertensive medications nor acute variation of dietary sodium affected the accuracy of the PAC/PRA ratio adversely; the sensitivities on and off therapy were 73% and 87%, respectively, and the specificities were 74% and 75%, respectively.¹³⁹ In a study of African American and Caucasian subjects with resistant hypertension, the PAC/PRA ratio was elevated (>20) in 45 of 58 subjects with primary aldosteronism and in 35 of 207 patients without primary aldosteronism (sensitivity, 78%;

specificity, 83%).¹⁵⁸ Furosemide and upright posture do not improve the post-test probability for APA more than the use of the baseline PAC/PRA ratio.¹⁶²

The measurement of PRA is time-consuming, shows high interlaboratory variability, and requires special pre-analytic prerequisites. To overcome these disadvantages, a monoclonal antibody against active renin is being used by several reference laboratories to measure the plasma renin concentration (PRC) instead of PRA. However, few studies have compared the different methods of testing for primary aldosteronism, and these studies lack confirmatory testing.^{163,164} In one study with 76 normotensive volunteers and 28 patients with confirmed primary aldosteronism, the PAC/PRC ratio performed as well as the PAC/PRA ratio in differentiating the two groups.¹⁶⁵ Before a recommendation to replace PRA with PRC in testing for primary aldosteronism can be made, more studies with larger cohorts are needed. Until then, it is reasonable to consider a positive PAC/PRC test if the PAC is greater than 15 ng/dL and the PRC is lower below the lower limit of detection for the assay (see Fig. 16-9).

Confirmatory Tests

An increased PAC/PRA ratio is not diagnostic by itself, and primary aldosteronism must be confirmed by demonstration of inappropriate aldosterone secretion. The list of drugs and hormones capable of affecting the RAA axis is extensive, and a "medication-contaminated" evaluation is frequently unavoidable in patients with severe hypertension. Calcium channel blockers and α_1 -adrenergic receptor blockers do not affect the diagnostic accuracy in most cases.¹³⁵ It is impossible to interpret data obtained from patients receiving treatment with mineralocorticoid receptor antagonists (e.g., spironolactone, eplerenone) when the PRA is not suppressed. Therefore, treatment with a mineralocorticoid receptor antagonist should not be initiated until the evaluation has been completed and the final decisions about treatment have been made. If primary aldosteronism is suspected in a patient receiving treatment with spironolactone or eplerenone, the treatment should be discontinued for at least 6 weeks before further diagnostic testing is undertaken. Aldosterone suppression testing can be performed with orally administered sodium chloride and measurement of urinary aldosterone or with intravenous sodium chloride loading and measurement of PAC.

Oral Sodium Loading Test. After hypertension and hypokalemia have been controlled, patients should receive a high-sodium diet (supplemented with sodium chloride tablets if needed) for 3 days, with a goal sodium intake of 5000 mg (equivalent to 218 mEq of sodium or 12.8 g sodium chloride).¹⁴⁷ The risk of increasing dietary sodium in patients with severe hypertension must be assessed in each case.¹⁶⁶ Because the high-salt diet can increase kaliuresis and hypokalemia, vigorous replacement of potassium chloride may be needed, and the serum level of potassium should be monitored daily. On the third day of the high-sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and creatinine. To document adequate sodium repletion, the 24-hour urinary sodium excretion should exceed 200 mEq. Urinary aldosterone excretion of more than 12 μ g/24 hours in this setting is consistent with autonomous aldosterone secretion.¹⁶⁷ The sensitivity and specificity of the oral sodium loading test are 96% and 93%, respectively.¹⁶⁸

Intravenous Saline Infusion Test. The intravenous saline infusion test has also been used widely for the diagnosis of

primary aldosteronism.^{135,169-171} Normal subjects show suppression of PAC after volume expansion with isotonic saline; subjects with primary aldosteronism do not show this suppression. The test is done after an overnight fast. Two liters of 0.9% sodium chloride solution is infused intravenously with an infusion pump over 4 hours with the patient recumbent. Blood pressure and heart rate are monitored during the infusion. At the completion of the infusion, blood is drawn for measurement of PAC. PAC levels in normal subjects decrease to less than 5 ng/dL, whereas most patients with primary aldosteronism do not suppress to less than 10 ng/dL. Post-infusion PAC values between 5 and 10 ng/dL are indeterminate and may be seen in patients with IHA.^{131,169,170,172}

Fludrocortisone Suppression Test. In the fludrocortisone suppression test, fludrocortisone acetate is administered for 4 days (0.1 mg every 6 hours) in combination with sodium chloride tablets (2 g three times daily with food). Blood pressure and serum potassium levels must be monitored daily. In the setting of low PRA, failure to suppress the upright 10 a.m. PAC to less than 6 ng/dL on day 4 is diagnostic of primary aldosteronism.¹⁷³ Increased QT dispersion and deterioration of left ventricular function have been reported during fludrocortisone suppression tests.¹⁶⁶ Most centers no longer use this test.

Subtype Studies

After case-detection and confirmatory testing, the third management issue guides the therapeutic approach by distinguishing APA and PAH from IHA and GRA. Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all cases; hypertension is improved in all cases and is cured in 30% to 60%.¹⁷⁴⁻¹⁷⁶ In IHA and GRA, unilateral or bilateral adrenalectomy seldom corrects the hypertension.¹⁴⁷ IHA and GRA should be treated medically. APA is found in approximately 35% of cases and bilateral IHA in approximately 60% (see Table 16-10). APAs are usually hypodense nodules (<2 cm in diameter) on CT and are golden yellow in color when resected. IHA adrenal glands may be normal on CT or may show nodular changes. Aldosterone-producing adrenal carcinomas are almost always larger than 4 cm in diameter and have an inhomogeneous phenotype on CT (see Table 16-6).

Computed Tomography of the Adrenal. Primary aldosteronism subtype evaluation may require one or more tests, the first of which is imaging of the adrenal glands with CT (Fig. 16-10). If a solitary unilateral hypodense (HU < 10) macroadenoma (>1 cm) and normal contralateral adrenal morphology are found on CT in a young patient (<40 years) with severe primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option (see Fig. 16-10). However, in many cases, CT shows normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (\leq 1 cm), or bilateral macroadenomas (Fig. 16-11). In these cases, additional testing is required to determine the source of excess aldosterone secretion.

Small APAs may be labeled incorrectly as IHA on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may actually represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, non-functioning unilateral adrenal macroadenomas are not uncommon, especially in older patients (>40 years).¹⁷⁷ Unilateral PAH may be visible on CT, or the PAH adrenal may appear normal on CT. In general, patients with APAs have more severe hypertension, more frequent hypokalemia,

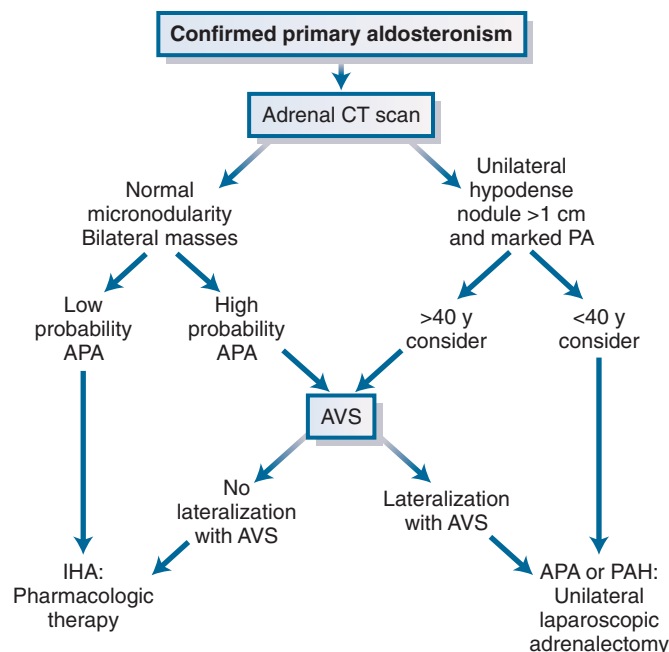

Figure 16-10 Subtype evaluation of primary aldosteronism. For patients who want to pursue a surgical treatment for their hypertension, adrenal venous sampling is frequently a key diagnostic step (see text for details). APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; CT, computed tomography; IHA, idiopathic hyperaldosteronism; PA, primary aldosteronism; PAH, primary adrenal hyperplasia. (Modified from Young WF Jr, Hogan MJ: Renin-independent hypermineralocorticoidism. *Trends Endocrinol Metab.* 1994;5:97-106.)

and higher levels of plasma aldosterone (>25 ng/dL) and urinary aldosterone (>30 μ g/24 hours), and are younger (<50 years), compared with those who have IHA.^{147,148} Patients fitting these descriptors are considered to have a “high probability of APA” regardless of the CT findings (see Fig. 16-10), and 41% of patients with a “high probability of APA” and a normal adrenal CT scan prove to have unilateral aldosterone hypersecretion.¹⁷⁸

Adrenal CT is not accurate in distinguishing between APA and IHA.^{178,179} In one study of 203 patients with primary aldosteronism who were evaluated with both CT and adrenal venous sampling, CT was accurate in only 53% of patients¹⁷⁸; based on the CT findings, 42 patients (22%) would have been incorrectly excluded as candidates for adrenalectomy, and 48 (25%) might have had unnecessary or inappropriate surgery.¹⁷⁸ In a systematic review of 38 studies involving 950 patients with primary aldosteronism, adrenal CT/MRI results did not agree with the findings from adrenal venous sampling in 359 patients (38%)¹⁷⁹; based on CT/MRI, 19% of the 950 patients would have undergone noncurative surgery, and 19% would have been offered medical therapy instead of curative adrenalectomy.¹⁷⁹ Therefore, adrenal venous sampling is essential to direct appropriate therapy in patients with primary aldosteronism who have a high probability of APA and are seeking a potential surgical cure.

Adrenal Venous Sampling. Adrenal venous sampling is the criterion standard test to distinguish between unilateral and bilateral disease in patients with primary aldosteronism.^{178,179} Adrenal venous sampling is an intricate procedure because the right adrenal vein is small and may be difficult to locate and cannulate; the success rate depends on the proficiency of the angiographer. A review of 47

reports found that the success rate for cannulation of the right adrenal vein in 384 patients was 74%.¹⁴⁷ With experience and focusing the expertise to one or two radiologists at a referral center, the AVS success rate can be as high as 96%.^{178,180,181}

The five keys to a successful adrenal venous sampling program are: (1) appropriate patient selection, (2) careful patient preparation, (3) focused technical expertise, (4) defined protocol, and (5) accurate data interpretation.¹⁸² A center-specific, written protocol is mandatory. The protocol should be developed by an interested group of endocrinologists, hypertension specialists, internists, radiologists, and laboratory personnel. Safeguards should be in place to prevent mislabeling of the blood tubes in the radiology suite and to prevent sample mixup in the laboratory.

At Mayo Clinic, we use continuous cosyntropin infusion during AVS (50 μ g/hour starting 30 minutes before sampling and continuing throughout the procedure) for the following reasons: (1) to minimize stress-induced fluctuations in aldosterone secretion during nonsimultaneous AVS; (2) to maximize the gradient in cortisol from adrenal vein to inferior vena cava (IVC) and thus confirm successful sampling of the adrenal veins; and (3) to maximize the secretion of aldosterone from an APA.^{171,178,181,182} The

Results of bilateral adrenal venous sampling

Vein	Aldosterone (A), ng/dL	Cortisol (C), μ g/dL	A/C ratio	Aldosterone ratio*

Figure 16-11 A 43-year-old woman had a 2-year history of hypertension and hypokalemia. The screening test for primary aldosteronism was positive, with a plasma aldosterone concentration (PAC) of 37 ng/dL and low plasma renin activity (PRA) at less than 0.6 ng/mL per hour (PAC/PRA ratio >61). The confirmatory test for primary aldosteronism was also positive, with the 24-hour urinary excretion of aldosterone measured at 53 μ g on a high-sodium diet (urinary sodium, 196 mEq/24 hours). **A**, Adrenal CT shows a 12-mm, low-density mass (arrow, right panel) in the medial limb of the left adrenal and two low-density, 10-mm nodules (arrows, left panel) within the right adrenal gland. **B**, Adrenal venous sampling lateralized aldosterone secretion to the right, and two cortical adenomas ($1.8 \times 1.2 \times 0.8$ cm and $2.5 \times 1.5 \times 1.2$ cm) were found at laparoscopic right adrenalectomy. The postoperative plasma aldosterone concentration was less than 1.0 ng/dL. Hypokalemia was cured and blood pressure was normal without the aid of antihypertensive medications.

Figure 16-12 Adrenal vein aldosterone lateralization ratios for patients with unilateral aldosterone-producing adenomas (APA), bilateral idiopathic hyperplasia (IHA), and unilateral primary adrenal hyperplasia (PAH). Shaded symbols indicate that the diagnosis was confirmed surgically. The sensitivity and specificity of a cortisol-corrected plasma aldosterone concentration lateralization ratio greater than 4.0 for unilateral disease are 95.2% and 100%, respectively. (Reproduced with permission from Young WF Jr, Stanson AV, Thompson GB, et al. Role for adrenal venous sampling in primary aldosteronism. *Surgery*. 2004;136:1227-1235.)

adrenal veins are catheterized through the percutaneous femoral vein approach, and the position of the catheter tip is verified by gentle injection of a small amount of non-ionic contrast medium and radiographic documentation. Blood is obtained from both adrenal veins and from the IVC below the renal veins and assayed for aldosterone and cortisol concentrations. To be sure that there is no cross-contamination, the "IVC" sample should be obtained from the external iliac vein. The venous sample from the left side typically is obtained from the common phrenic vein immediately adjacent to the entrance of the adrenal vein. The cortisol concentrations from the adrenal veins and IVC are used to confirm successful catheterization; the adrenal vein/IVC cortisol ratio is typically greater than 10:1.

Dividing the right and left adrenal vein PAC values by their respective cortisol concentrations corrects for the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; these are termed *cortisol-corrected ratios* (Fig. 16-12). In patients with APA, the mean cortisol-corrected aldosterone ratio (i.e., the ratio of PAC/cortisol from the APA side to that from the normal side) is 18:1.¹⁷⁸ A cutoff point of 4:1 for this ratio is used to indicate unilateral aldosterone excess (see Fig. 16-12).¹⁷⁸ In patients with IHA, the mean cortisol-corrected aldosterone ratio is 1.8:1 (high side to low side), and a ratio of less than 3.0:1 suggests bilateral aldosterone hypersecretion (see Fig. 16-12).¹⁷⁸ Therefore, most patients with a unilateral source of aldosterone have cortisol-corrected aldosterone lateralization ratios greater than 4.0, and ratios greater than 3.0 but less than 4.0 represent a zone of overlap. Ratios no higher than 3.0 are consistent with bilateral aldosterone secretion. The test characteristics of adrenal vein sampling for detection of unilateral aldosterone hypersecretion (APA or PAH) are 95% sensitivity and 100% specificity.¹⁷⁸ At centers with experience with adrenal vein sampling, the complication rate is 2.5% or less.^{178,180} Complications can include symptomatic groin hematoma, adrenal hemorrhage, and dissection of an adrenal vein.

Some centers and clinical practice guidelines recommend that adrenal venous sampling should be performed in all patients who have the diagnosis of primary

aldosteronism.^{135,179} The use of adrenal venous sampling should be based on patient preference, patient age, clinical comorbidities, and the clinical probability of finding an APA.¹³⁴ A more practical approach is the selective use of adrenal venous sampling outlined in Figure 16-10.

Glucocorticoid-Remediable Aldosteronism: Familial Hyperaldosteronism Type I. GRA (FH type I) is inherited in an autosomal dominant fashion and is responsible for fewer than 1% of cases of primary aldosteronism (see Table 16-10).¹²¹ GRA is characterized by early-onset hypertension that is usually severe and refractory to conventional anti-hypertensive therapies, aldosterone excess, suppressed PRA, and excess production of 18-hydroxycortisol and 18-oxycortisol. GRA is caused by a chimeric gene duplication that results from unequal crossover between the promoter sequence of the *CYP11B1* gene (which encodes 11 β -hydroxylase) and the coding sequence of *CYP11B2* (which encodes aldosterone synthase).¹²¹ This chimeric gene contains the 3' corticotropin-responsive portion of the promoter from the 11 β -hydroxylase gene fused to the 5' coding sequence of the aldosterone synthase gene. The result is ectopic expression of aldosterone synthase activity in the cortisol-producing zona fasciculata. Mineralocorticoid production is regulated by corticotropin instead of by the normal secretagogue, angiotensin II. Therefore, aldosterone secretion can be suppressed by glucocorticoid therapy. In the absence of glucocorticoid therapy, this mutation results in overproduction of aldosterone and the hybrid steroids 18-hydroxycortisol and 18-oxycortisol, which can be measured in the urine to make the diagnosis.

Genetic testing is a sensitive and specific means of diagnosing GRA and obviates the need to measure the urinary levels of 18-oxycortisol and 18-hydroxycortisol or to perform dexamethasone suppression testing. Genetic testing for GRA should be considered for patients with primary aldosteronism who have a family history of primary aldosteronism, onset of primary aldosteronism at a young age (<20 years), or a family history of strokes at a young age.¹⁸²

Familial Hyperaldosteronism Type II. FH type II is autosomal dominant and may be monogenic.¹²² The hyperaldosteronism in FH type II does not suppress with dexamethasone, and GRA mutation testing is negative. FH type II is more common than FH type I, but it still accounts for fewer than 2% of all patients with primary aldosteronism. The molecular basis for FH type II is unclear, although a recent linkage analysis study showed an association with chromosomal region 7p22.¹²²

Historical Perspectives. One of the first methods used to differentiate unilateral from bilateral adrenal disease in patients with primary aldosteronism was adrenal venous sampling.¹⁸³ However, other diagnostic methods were sought because of the suboptimal catheter technology in the 1960s and 1970s and the difficulty in successfully sampling from both adrenal veins. [¹³¹I]-19-iodocholesterol scintigraphy¹⁸⁴ was first used in the early 1970s, and an improved agent, [¹³¹I]-6 β -iodomethyl-19-norcholesterol (NP-59), was introduced in 1977.¹⁸⁵ The sensitivity of this test depended heavily on the size of the adenoma.^{186,187} In addition to its poor sensitivity, NP-59 is no longer available for use in the United States.

The posture stimulation test, also developed in the 1970s, was based on the finding that PAC in patients with APA shows diurnal variation and is relatively unaffected by

changes in angiotensin II levels, whereas IHA is characterized by enhanced sensitivity to a small change in angiotensin II that occurs with standing.¹⁸⁸ In a review of 16 published reports, the accuracy of the posture stimulation test was found to be 85% in 246 patients with surgically verified APA.¹⁴⁷ However, it became clear that some APAs are sensitive to angiotensin II and some patients with IHA have diurnal variation in aldosterone secretion. Also, although the posture stimulation test may have predicted which patient had APA, it did not assist in localization.

18-Hydroxycorticosterone (18-OHB) is considered to be either the immediate precursor of aldosterone or a separate end product formed after 18-hydroxylation of corticosterone. Patients with APA typically have recumbent plasma 18-OHB levels greater than 100 ng/dL at 8 a.m., whereas patients with IHA usually have levels less than 100 ng/dL.¹⁸⁹ 18-OHB has actually proved to be a surrogate for PAC, which also tends to be higher in patients with APA than in those with IHA. However, the accuracy of supine morning 18-OHB and PAC levels in distinguishing between patients with APA and those with IHA is less than 80%.¹⁴⁷

Principles of Treatment

The treatment goal is to prevent the morbidity and mortality associated with hypertension, hypokalemia, and cardiovascular damage.¹⁹⁰ Knowing the cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal. In addition to the kidney and colon, mineralocorticoid receptors are present in the heart, brain, and blood vessels. Excessive secretion of aldosterone is associated with increased risk of cardiovascular disease and morbidity. Therefore, normalization of circulating aldosterone or mineralocorticoid receptor blockade should be part of the management plan for all patients with primary aldosteronism.¹⁵⁴ However, clinicians must understand that most patients with long-standing primary aldosteronism have some degree of renal insufficiency that is masked by the glomerular hyperfiltration associated with aldosterone excess.^{190,191} The true degree of renal insufficiency may become evident only after effective pharmacologic or surgical therapy.^{190,191}

Surgical Treatment of Aldosterone-Producing Adenoma and Unilateral Hyperplasia

Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or unilateral hyperplasia.¹⁰⁶ Although blood pressure control improves in almost 100% of patients postoperatively, average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 60%.^{174,176} Persistent hypertension after adrenalectomy is correlated directly with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, increased serum creatinine level, and duration of hypertension and is most likely caused by coexistent primary hypertension.^{174,176}

Laparoscopic adrenalectomy is the preferred surgical approach and is associated with shorter hospital stays and less long-term morbidity than the open approach.^{192,193} Because APAs are small and may be multiple, the entire adrenal gland should be removed.¹⁹⁴ To decrease the surgical risk, hypokalemia should be corrected with potassium supplements or a mineralocorticoid receptor antagonist, or both, preoperatively. These medications should be discontinued postoperatively. PAC should be measured 1 to 2 days after the operation to confirm a biochemical cure.

Serum potassium levels should be monitored weekly for 4 weeks after surgery, and a generous sodium diet should be followed to avoid the hyperkalemia of hypoaldosteronism that may occur because of the chronic suppression of the RAA axis. Clinically significant hyperkalemia develops after surgery in approximately 5% of APA patients, and short-term fludrocortisone supplementation may be required. Typically, the hypertension that was associated with aldosterone excess resolves in 1 to 3 months after the surgery. It has been found that adrenalectomy for APA is significantly less expensive than long-term medical therapy.¹⁹⁵

Pharmacologic Treatment

IHA and GRA should be treated medically. In addition, APA may be treated medically if the medical treatment includes mineralocorticoid receptor blockade.¹⁹⁶ A sodium-restricted diet (<100 mEq of sodium per day), maintenance of ideal body weight, tobacco avoidance, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. No placebo-controlled, randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism.¹⁹⁷

Spirolactone has been the drug of choice to treat primary aldosteronism for more than 4 decades.¹⁹⁸ It is available as 25-, 50-, and 100-mg tablets. The dosage is 12.5 to 25 mg per day initially and can be increased to 400 mg/day if necessary to achieve a high-normal serum potassium concentration without the aid of oral potassium chloride supplementation. Hypokalemia responds promptly, but hypertension can take as long as 4 to 8 weeks to be corrected. After several months of therapy, the dosage of spironolactone often can be decreased to as little as 25 to 50 mg/day; dosage titration is based on a goal serum potassium level in the high-normal range. Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of therapy (especially in patients with renal insufficiency or diabetes mellitus). Spirolactone increases the half-life of digoxin, and the digoxin dosage may need to be adjusted when treatment with spironolactone is started. Concomitant therapy with salicylates should be avoided because they interfere with the tubular secretion of an active metabolite and decrease the effectiveness of spironolactone. However, spironolactone is not selective for the mineralocorticoid receptor. For example, antagonism at the testosterone receptor may result in painful gynecomastia, erectile dysfunction, and decreased libido in men, and agonist activity at the progesterone receptor results in menstrual irregularity in women.¹⁹⁹

Eplerenone is a steroid-based antimineralocorticoid that acts as a competitive and selective mineralocorticoid receptor antagonist and was approved by the U.S. Food and Drug Administration (FDA) for the treatment of uncomplicated essential hypertension in 2003.¹⁹⁸ The 9,11-epoxide group in eplerenone results in a marked reduction of the molecule's progestational and antiandrogenic actions; compared with spironolactone, eplerenone has 0.1% of the binding affinity to androgen receptors and less than 1% of the binding affinity to progesterone receptors. Treatment trials comparing the efficacy of eplerenone versus spironolactone for the treatment of primary aldosteronism have not been published. Presumably, eplerenone will be the superior drug if it is shown to be as effective as spironolactone for the treatment of mineralocorticoid-dependent hypertension, because it lacks the limiting antiandrogen side effects of spironolactone. Eplerenone is available as 25- and 50-mg tablets. For primary aldosteronism, it is reasonable to start with a dose of 25 mg twice daily (twice daily because of the shorter half-life of eplerenone

compared with spironolactone) and titrated upward; the target is a high-normal serum potassium concentration without the aid of potassium supplements. The maximum dose approved by the FDA for hypertension is 100 mg/day. Potency studies with eplerenone show 25% to 50% less milligram-per-milligram potency compared with spironolactone. As with spironolactone, it is important to monitor blood pressure, serum potassium, and serum creatinine levels closely. Side effects include dizziness, headache, fatigue, diarrhea, hypertriglyceridemia, and elevated liver enzymes.

Patients with IHA frequently require a second antihypertensive agent to achieve good blood pressure control. Hypervolemia is a major reason for resistance to drug therapy, and low doses of a thiazide (e.g., 12.5 to 50 mg of hydrochlorothiazide daily) or a related sulfonamide diuretic are effective in combination with the mineralocorticoid receptor antagonist. Because these agents often lead to further hypokalemia, serum potassium levels should be monitored.

Before treatment is initiated, the diagnosis of GRA should be confirmed with genetic testing. In the GRA patient, chronic treatment with physiologic doses of a glucocorticoid normalizes blood pressure and corrects hypokalemia. The clinician should be cautious about iatrogenic Cushing's syndrome with excessive doses of glucocorticoids, especially when dexamethasone is used in children. Shorter-acting agents such as prednisone or hydrocortisone should be prescribed, using the smallest effective dose in relation to body surface area (e.g., hydrocortisone, 10 to 12 mg/m² per day). Target blood pressure in children should be guided by age-specific blood pressure percentiles.²⁰⁰ Children should be monitored by pediatricians with expertise in glucocorticoid therapy, with careful attention paid to preventing retardation of linear growth due to overtreatment. Treatment with mineralocorticoid receptor antagonists in these patients may be just as effective as glucocorticoids and avoids the potential disruption of the hypothalamic-pituitary-adrenal axis and risk of iatrogenic side effects. In addition, glucocorticoid therapy or mineralocorticoid receptor blockade may even have a role in normotensive GRA patients.¹⁵⁰

OTHER FORMS OF MINERALOCORTICOID EXCESS OR EFFECT

The medical disorders associated with excess mineralocorticoid effect from 11-deoxycorticosterone (DOC) and cortisol are listed in Table 16-10. These diagnoses should be considered if PAC and PRA are low in a patient with hypertension and hypokalemia.

Hyperdeoxycorticosteronism

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol (see Chapter 15).²⁰¹ The lack of inhibitory feedback by cortisol on the hypothalamus and pituitary produces an ACTH-driven buildup of cortisol precursors proximal to the enzymatic deficiency. A deficiency of 11 β -hydroxylase (CYP11B) or 17 α -hydroxylase (CYP17) causes hypertension and hypokalemia because of hypersecretion of the mineralocorticoid DOC. The

mineralocorticoid effect of increased circulating levels of DOC also decreases PRA and aldosterone secretion. These defects are autosomal recessive in inheritance and typically are diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.

11 β -Hydroxylase Deficiency. Approximately 5% of all cases of CAH are caused by 11 β -hydroxylase deficiency; the prevalence in Caucasians is 1 in 100,000.²⁰¹ More than 40 mutations have been described in *CYP11B1*, the gene encoding 11 β -hydroxylase.²⁰² There is an increased prevalence among Sephardic Jews from Morocco, suggestive of a founder effect. The impaired conversion of DOC to corticosterone results in high levels of DOC and 11-deoxycortisol; the substrate mass effect results in increased levels of adrenal androgens. Girls present in infancy or childhood with hypertension, hypokalemia, acne, hirsutism, and virilization, and boys present with pseudoprecocious puberty. Approximately two thirds of patients have mild to moderate hypertension. Markedly increased levels of DOC, 11-deoxycortisol, and adrenal androgens confirm the diagnosis. Glucocorticoid replacement normalizes the steroid abnormalities and hypertension.

17 α -Hydroxylase Deficiency. 17 α -Hydroxylase deficiency is a rare cause of CAH. 17 α -Hydroxylase is essential for the synthesis of cortisol and gonadal hormones, and deficiency results in decreased production of cortisol and sex hormones. Genetic 46,XY males present with either pseudohermaphroditism or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore, a person with this form of CAH may not come to medical attention until puberty. The biochemical findings include low concentrations of plasma adrenal androgens, 17 α -hydroxyprogesterone, aldosterone, and cortisol. The plasma concentrations of DOC, corticosterone, and 18-OHB are increased and PRA is suppressed. Although it is still rare, there is an increased prevalence of 17 α -hydroxylase deficiency among Dutch Mennonites. As with 11 β -hydroxylase deficiency, glucocorticoid replacement normalizes the steroid abnormalities and the hypertension.

Deoxycorticosterone-Producing Tumor

DOC-producing adrenal tumors are usually large and malignant.²⁰³ Some of them secrete androgens and estrogens in addition to DOC, which may cause virilization in women or feminization in men. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen on CT confirm the diagnosis. Aldosterone secretion in these patients is typically suppressed. Optimal treatment is complete surgical resection.

Primary Cortisol Resistance

Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing's syndrome are found in patients with primary cortisol resistance (or glucocorticoid resistance), a rare familial syndrome.²⁰⁴ The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, and increased adrenal androgen secretion. The hypertension and hypokalemia probably result from the combined effects of excess DOC and increased cortisol access to the mineralocorticoid receptor, resulting in high rates of cortisol production that overwhelm 11 β -hydroxysteroid dehydrogenase type 2 (HSD11B2) activity (see discussion in next section). Primary cortisol resistance is caused by defects in the glucocorticoid receptor and the steroid-receptor complex. The treatment

for the mineralocorticoid-dependent hypertension is blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of ACTH secretion with dexamethasone.

Apparent Mineralocorticoid Excess Syndrome

Apparent mineralocorticoid excess is the result of impaired activity of the microsomal enzyme HSD11B2, which normally inactivates cortisol in the kidney by converting it to cortisone. Cortisol can be a potent mineralocorticoid, and because of the enzyme deficiency, high levels of cortisol accumulate in the kidney.²⁰⁵ HSD11B2 normally excludes physiologic glucocorticoids from the nonselective mineralocorticoid receptor by converting them to the inactive 11-keto compound, cortisone. The characteristic abnormal urinary cortisol-cortisone metabolite profile seen in apparent mineralocorticoid excess reflects decreased HSD11B2 activity; the ratio of cortisol to cortisone is increased 10-fold above the normal value.²⁰⁵

Decreased HSD11B2 activity may be hereditary, or it may be secondary to pharmacologic inhibition of enzyme activity by glycyrrhizic acid, the active principle of licorice root (*Glycyrrhiza glabra*) and some chewing tobaccos. The congenital forms are rare autosomal recessive disorders; fewer than 50 patients have been identified worldwide. Children present with low birth weight, failure to thrive, hypertension, polyuria and polydipsia, and poor growth.²⁰² The clinical phenotype of patients with apparent mineralocorticoid excess includes hypertension, hypokalemia, metabolic alkalosis, low PRA, low PAC, and normal plasma cortisol levels. The diagnosis is confirmed by demonstration of an abnormal ratio of cortisol to cortisone in a 24-hour urine collection. Treatment includes blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of endogenous cortisol secretion with dexamethasone.

The mineralocorticoid excess state caused by ectopic ACTH secretion, commonly seen in patients with Cushing's syndrome, is related to the high rates of cortisol production that overwhelm HSD11B2 activity. DOC levels may also be increased in severe ACTH-dependent Cushing's syndrome and contribute to the hypertension and hypokalemia in this disorder.

Liddle's Syndrome: Abnormal Renal Tubular Ionic Transport

In 1963, Liddle described an autosomal dominant renal disorder that appeared to be primary aldosteronism with hypertension, hypokalemia, and inappropriate kaliuresis.²⁰⁶ However, PAC and PRA were very low in patients with Liddle's syndrome, so the disorder was termed *pseudaldosteronism*. Liddle's syndrome is caused by mutations in the β or γ subunit of the amiloride-sensitive epithelial sodium channel.²⁰² This results in enhanced activity of the epithelial sodium channel, increased sodium reabsorption, potassium wasting, hypertension, and hypokalemia. Clinical genetic testing is available (see www.genetests.org). As would be predicted, amiloride and triamterene are very effective agents to treat the hypertension and hypokalemia of pseudaldosteronism. However, spironolactone is ineffective in these patients. Liddle's syndrome can easily be distinguished from apparent mineralocorticoid excess based on the good clinical response to amiloride and triamterene, lack of efficacy of spironolactone and dexamethasone, and normal 24-hour urine cortisone/cortisol ratio.

Hypertension Exacerbated by Pregnancy

Hypertension exacerbated by pregnancy is a rare autosomal dominant disorder found in women who have early-onset hypertension with suppressed levels of aldosterone and renin. During pregnancy, both the hypertension and the hypokalemia are severely exacerbated. These patients have an activating mutation in the gene encoding the mineralocorticoid receptor that allows progesterone and other mineralocorticoid antagonists to become agonists.²⁰⁷

OTHER ENDOCRINE DISORDERS ASSOCIATED WITH HYPERTENSION

Cushing's Syndrome

Hypertension occurs in 75% to 80% of patients with Cushing's syndrome (see Chapter 15).^{208,209} The mechanisms of hypertension include increased production of DOC, enhanced pressor sensitivity to endogenous vasoconstrictors (e.g., epinephrine, angiotensin II), increased cardiac output, activation of the RAA system by increased hepatic production of angiotensinogen, and cortisol inactivation overload with stimulation of the mineralocorticoid receptor. The source of excess glucocorticoids may be exogenous (iatrogenic) or endogenous. Mineralocorticoid production is usually normal in endogenous Cushing's syndrome; aldosterone and renin levels are usually normal, and DOC levels are normal or mildly increased. In adrenal carcinomas, DOC and aldosterone may be elevated.

The case-detection studies for endogenous cortisol excess include a midnight salivary cortisol measurement, the 1-mg overnight dexamethasone suppression test, and measurement of free cortisol in a 24-hour urine collection. Further studies to confirm Cushing's syndrome and to determine the cause of the cortisol excess state are outlined in Chapter 15.

The hypertension associated with Cushing's syndrome should be treated until a surgical cure is obtained. Mineralocorticoid receptor antagonists, at dosages used to treat primary aldosteronism, are effective in reversing the hypokalemia. Second-step agents (e.g., thiazide diuretics) may be added for optimal control of blood pressure. The hypertension associated with the hypercortisolism usually resolves over several weeks after a surgical cure, and anti-hypertensive agents may be tapered and withdrawn.

Thyroid Dysfunction

Hyperthyroidism

When excessive amounts of circulating thyroid hormones interact with thyroid hormone receptors on peripheral tissues, both metabolic activity and sensitivity to circulating catecholamines increase. Thyrotoxic patients usually have tachycardia, high cardiac output, increased stroke volume, decreased peripheral vascular resistance, and increased systolic blood pressure.²¹⁰ The initial management in patients with hypertension and hyperthyroidism includes use of a β -adrenergic blocker to treat hypertension, tachycardia, and tremor. The definitive treatment of hyperthyroidism is cause-specific (see Chapter 12).

Hypothyroidism

The frequency of hypertension (usually diastolic) is increased threefold in hypothyroid patients and may account for as many as 1% of cases of diastolic hypertension

in the general population.²¹¹ The mechanisms for the elevation in blood pressure include increased systemic vascular resistance and extracellular volume expansion. Treatment of thyroid hormone deficiency decreases blood pressure in most patients with hypertension and normalizes blood pressure in one third of them. Synthetic levothyroxine is the treatment of choice for hypothyroidism (see Chapter 13).

Primary Hyperparathyroidism

Hypercalcemia is associated with an increased frequency of hypertension. The most common cause of hypercalcemia is primary hyperparathyroidism. The frequency of hypertension in patients with primary hyperparathyroidism varies from 10% to 60%.²¹² Most patients with primary hyperparathyroidism are asymptomatic, and the focus of the presentation may be the side effects of chronic hypercalcemia: polyuria and polydipsia, constipation, osteoporosis, renal lithiasis, peptic ulcer disease, and hypertension (see Chapter 28). The mechanisms of hypertension are unclear because there is no direct correlation with the elevated parathyroid hormone or calcium levels. The hypertension associated with hyperparathyroidism can also occur as a complication of hypercalcemia-induced renal impairment or when this disorder is part of MEN2 (pheochromocytoma). The treatment of hyperparathyroidism is surgical; hypertension may or may not remit after successful parathyroidectomy.²¹³

Acromegaly

Chronic growth hormone excess from a growth hormone-producing pituitary tumor results in the clinical syndrome of acromegaly. The effects of chronic excess of growth hormone include acral and soft tissue overgrowth, progressive dental malocclusion, degenerative arthritis related to chondral and synovial tissue overgrowth within joints, low-pitched sonorous voice, excessive sweating and oily skin, perineural hypertrophy leading to nerve entrapment (e.g., carpal tunnel syndrome), cardiac dysfunction, and hypertension (see Chapter 9). Hypertension occurs in 20% to 40% of the patients and is associated with sodium retention and extracellular volume expansion.²¹⁴ Pituitary surgery is the treatment of choice; if necessary, it is supplemented with medical therapy or irradiation or both. The hypertension of acromegaly is treated most effectively by curing the excess of growth hormone. If a surgical cure is not possible, the hypertension usually responds well to diuretic therapy.

CHAPTER 17

Physiology and Pathology of the Female Reproductive Axis

SERDAR E. BULUN

REPRODUCTIVE PHYSIOLOGY

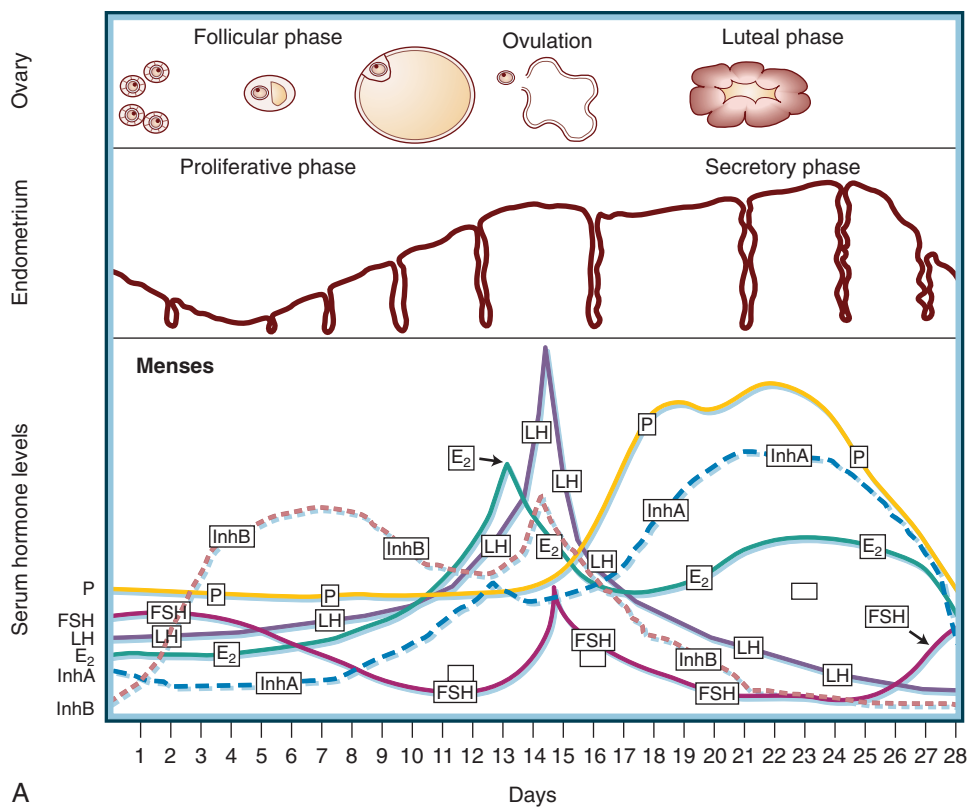

Tightly coordinated functions of the hypothalamus, pituitary, ovaries, and endometrium give rise to cyclic, predictable menses that indicate regular ovulation. Regular ovulation requires normal functioning of other endocrine glands, such as the thyroid and adrenals, and patients with hypothyroidism, hyperthyroidism, Cushing's syndrome, or glucocorticoid resistance may present with anovulation. Clinicians need a thorough knowledge of the functions and interactions of the hypothalamus, pituitary, ovaries, and uterus with other systems to correctly diagnose reproductive disorders and design treatment strategies.

A prominent reproductive function of the hypothalamus is pulsatile secretion of gonadotropin-releasing hormone (GnRH). Negative feedback effects of several factors, including ovarian steroids, regulate hypothalamic GnRH secretion into the portal vessels. Dopamine, norepinephrine, serotonin, and opioids produced in the brain may mediate the regulation of GnRH secretion by ovarian hormones or other stimuli. In response to GnRH, the anterior pituitary cells secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Steroids (e.g., estradiol, progesterone) and

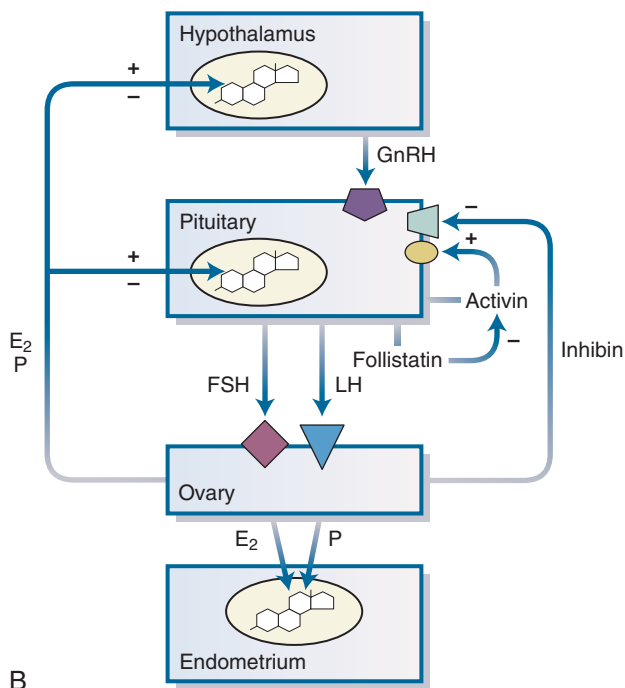

peptides (e.g., inhibin) of ovarian origin and activin and follistatin of pituitary origin modify secretion of FSH and LH. LH stimulates androstenedione production in theca cells of the ovary; FSH regulates estradiol and inhibin B production in the granulosa cells and follicular growth. Release of an egg from the mature follicle depends on a sudden rise in LH levels in midcycle. After ovulation, the follicle transforms into a corpus luteum that secretes estradiol and progesterone under the control of FSH and LH. LH also stimulates granulosa-lutein cells of the corpus luteum to secrete inhibin A (Fig. 17-1A).

The endocrine effects of FSH, LH, estradiol, progesterone, inhibin A, and inhibin B have been deduced from changes in their serum levels throughout the menstrual cycle (see Fig. 17-1A). The postulated endocrine effects were then demonstrated in cell-based and in vivo studies (see Fig. 17-1B). Activin and follistatin are produced in the ovary and the pituitary. They appear to act on FSH in the pituitary by autocrine or paracrine but not endocrine pathways. Activin stimulates FSH production, whereas follistatin suppresses this action of activin.

Endometrium, the mucosal lining of the uterine cavity, has extremely high concentrations of nuclear receptors for estrogen and progesterone and is extremely sensitive to

A

B

Figure 17-1 **A**, Changes in the ovarian follicle, endometrial thickness, and serum hormone levels during a 28-day menstrual cycle. Menses occur during the first few days of the cycle. **B**, Endocrine interactions in the female reproductive axis. Some of the well-characterized endocrine interactions among the hypothalamus, pituitary, ovary, and endometrium for regulation of the menstrual cycle are depicted. E₂, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; Inh, inhibin; LH, luteinizing hormone; P, progesterone.

these hormones. The biologically active estrogen, estradiol, induces the growth of endometrium; progesterone limits this estrogenic effect and enhances differentiation. Sloughing off the functional portion (functionalis) of the endometrium follows withdrawal of estrogen or progesterone. The remaining basal layer (basalis) is capable of full regeneration in response to estrogen.

Ovaries remain quiescent until puberty because the hypothalamus is immature in prepubertal children, and FSH and LH do not stimulate the ovaries. The entire reproductive function and most of the endocrine function of the ovaries cease after menopause because ovaries have lost all oocytes and surrounding steroidogenic cells by this time. These prepubertal and postmenopausal states,

characterized by the absence of ovarian function, are associated with the lack of menses.

In summary, the female reproductive function from puberty to menopause can be viewed as an extremely delicate ticking clock. The normal function of this apparatus depends on coordinated actions of the hypothalamus, pituitary, ovaries, and endometrium. The result is regular menses every 24 to 35 days. Any disorder of these tissues or disorders of other systems that affect these reproductive units secondarily may result in anovulation and consequent irregular uterine bleeding.

REPRODUCTIVE FUNCTIONS OF THE HYPOTHALAMUS

Gonadotropin-Releasing Hormone

GnRH and its analogs are used for the treatment of hormone-dependent disorders and assisted reproductive technologies such as in vitro fertilization (IVF).¹ In a number of vertebrates, three GnRHs and three cognate receptors with distinct distributions and functions have been identified. In humans, the hypothalamic GnRH is primarily encoded by the GnRH type I (GnRH-I) gene (*GNRH1*) and regulates gonadotropin secretion through the pituitary GnRH type I receptor, which functions as a G protein-coupled receptor. Binding of GnRH-I to its type I receptor leads primarily to activation of G_q . A second form of GnRH, called GnRH-II is conserved in all higher vertebrates, including humans, and is present in extrahypothalamic brain and many reproductive tissues. Its cognate receptor has been cloned from various vertebrate species, including primates. The human gene homolog of this receptor has a frameshift and stop codon, and it appears that GnRH-II signaling occurs through the type I GnRH receptor. There is considerable plasticity in the use of different GnRHs, receptors, and signaling pathways for diverse functions.¹ For practical purposes, GnRH-I is referred to as GnRH in this chapter.

GnRH is a 10-amino-acid peptide that is synthesized primarily in specialized neuronal bodies of the arcuate nucleus of the medial basal hypothalamus.² Axons from GnRH neurons project to the median eminence and terminate in the capillaries that drain into the portal vessels.

The portal vein is a low-flow transport system that descends along the pituitary stalk and connects the hypothalamus to the anterior pituitary. The direction of the blood flow in this hypophyseal portal circulation is from the hypothalamus to the pituitary. GnRH originating in the neurons of the arcuate nucleus is secreted at the median eminence into the portal circulation, which delivers this hormone to the anterior pituitary (Fig. 17-2).

The mature decapeptide GnRH is derived from the post-translational processing of a large precursor molecule, pre-pro-GnRH (see Fig. 17-2).³ This precursor peptide is the product of a gene located in the short arm of chromosome 8.⁴ The pre-pro-GnRH consists of 92 amino acids and contains four parts (from amino-terminal to carboxyl-terminal): a 23-amino-acid signal domain, the GnRH decapeptide, a 3-amino-acid proteolytic processing site, and a 56-amino-acid domain called GnRH-associated peptide.^{5,6} The cleavage products of this precursor, GnRH and gonadotropin-releasing hormone-associated peptide (GAP), are transported to the nerve terminals and secreted into the portal circulation (see Fig. 17-2).^{3,7,8} A physiologic role for GAP has not been established.⁷

B

Figure 17-2 Gonadotropin-releasing hormone (GnRH) production. **A**, The GnRH gene encodes a precursor protein, pre-pro-GnRH, in the neuronal body. GnRH is released from this protein by proteolytic processing, which gives rise to GnRH and GnRH-associated protein (GAP) within the neuronal body. Both GnRH and GAP are transported in an axon to the nerve terminal and secreted into the portal circulation. **B**, Pre-pro-GnRH is a 92-amino-acid (aa) protein. The biologically active decapeptide (amino acids 1 through 10) is sandwiched between the 23-amino-acid signal peptide and the Gly-Lys-Arg sequence. The arrow indicates the site of proteolytic processing. The C-terminal 56-amino-acid peptide is cleaved to produce GAP. LHRH, luteinizing hormone-releasing hormone (gonadotropin-releasing hormone I). (From Yen SSC. Endocrine regulation of the reproductive system. In: Yen SSC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology*, 4th ed. Philadelphia, PA: Saunders; 1999:44.)

In humans, GnRH neurons are located primarily in the arcuate nucleus of the medial basal hypothalamus and the preoptic area of the anterior hypothalamus. The population of GnRH-producing neurons is relatively limited and is in the range of 1000 to 2000. The neurons that produce GnRH originate from the olfactory area during embryogenesis. GnRH and olfactory neurons migrate together along cranial nerves connecting the nose and forebrain to the hypothalamus during embryologic development, and disruption of this process causes idiopathic hypogonadotropic

Figure 17-3 Effect of pulsatile or continuous administration of gonadotropin-releasing hormone (GnRH) to ovariectomized monkeys previously rendered GnRH deficient by placement of a lesion in the hypothalamus. Release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) was restored by hourly GnRH infusion, inhibited during a continuous infusion, and again restored after reinstitution of pulsatile GnRH administration. (Adapted from Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. *Science*. 1978;202:631-633. Copyright © 1978, by American Association for the Advancement of Science.)

hypogonadism with anosmia, or Kallmann's syndrome. Individuals with Kallmann's syndrome usually have irreversible pubertal delay and subsequent infertility due to deficient GnRH and pituitary gonadotropins. The neuronal proteins anosmin 1 (encoded by the *KAL1* gene) and fibroblast growth factor receptor type 1 (encoded by the *FGFR1* gene) affect olfactory and GnRH neuron migration. Mutations in these genes cause Kallmann's syndrome. Data suggest that mutations of the genes for nasal embryonic luteinizing hormone-releasing hormone factor (*NELF*) and chromodomain helicase DNA-binding protein 7 (*CHD7*) may cause Kallmann's syndrome, but this correlation is not as conclusively established as it is for *KAL1* and *FGFR1*. Kallmann's syndrome associated with reproductive and olfactory dysfunction illustrates the important embryologic event of GnRH and olfactory neuron migration.⁹

Knobil and coworkers demonstrated in a pioneering series of experiments that normal gonadotropin secretion requires pulsatile GnRH discharge within a critical frequency and amplitude.¹⁰ The periodicity and amplitude of the pulsatile rhythm of GnRH and gonadotropin secretion are crucial in regulating gonadal activities and therefore the entire reproductive axis (Fig. 17-3). The self-priming effect of GnRH in upregulating its receptors on pituitary gonadotropin-producing cells manifests only at the physiologic periodicity of 60 to 90 minutes.^{11,12} Slower frequency causes anovulation and amenorrhea because of inadequate stimulation. Higher frequency or constant exposure to GnRH also gives rise to anovulation by downregulating expression of the GnRH receptor, thereby abolishing gonadotropin responses.

The activation of gene expression for gonadotropin subunits, including the common α -subunit and specific β -subunits for LH and FSH, dimerization of $\alpha\beta$ subunits, and glycosylation appear to be governed by intermittency of GnRH inputs to pituitary gonadotrophs.¹³ In humans, measurement of LH pulses is commonly used as an indication of GnRH pulsatile secretion.¹⁴ The LH pulse frequency is approximately 90 minutes during the early follicular phase, 60 to 70 minutes during the late follicular phase,

100 minutes during the early luteal phase, and 200 minutes during the late luteal phase.¹⁵ This variation is responsible for changes in FSH and LH levels and ovarian steroid release during these phases of the menstrual cycle. The relationship of gonadotropin secretion to GnRH pulse pattern has been studied in hypophysectomized animals receiving exogenous GnRH and in numerous in vitro systems. More rapid pulse frequencies favor LH secretion, whereas slower pulse frequencies favor FSH. It appears that variations in GnRH pulse frequency markedly influence both the absolute levels and the ratio of LH and FSH release.

Regulation of Gonadotropin-Releasing Hormone Secretion

Cyclic, predictable menses require the pulsatile release of GnRH within a critical range of frequencies. Pulsatile, rhythmic activity is an intrinsic property of GnRH neurons, and various hormones and neurotransmitters modulate this rhythm (Fig. 17-4).

The variations in GnRH pulse frequency are achieved, in part, by gonadal steroid feedback. Estradiol increases GnRH pulse frequency, and elevated progesterone levels decrease GnRH pulsatility.¹³ Increased progesterone levels may decrease GnRH pulse frequency and thereby lead to preferential biosynthesis and secretion of FSH, as observed in the late luteal phase.¹³

GnRH pulsatility is also modulated by the actions of locally released neurotransmitters. Norepinephrine stimulates GnRH release, whereas dopamine exerts an inhibitory effect (see Fig. 17-4).¹⁶ β -Endorphin and other opioids may suppress the hypothalamic release of GnRH.^{17,18} The gonadal steroids modify endogenous opioid activity, and

Figure 17-4 Regulation of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) secretion. Locally synthesized and systemic hormones regulate the pulsatile secretion of GnRH from the hypothalamus into the portal circulation. GnRH and a number of steroid and peptide hormones regulate the synthesis of α and β gonadotropin subunits and the formation and secretion of FSH and LH. CRH, corticotropin-releasing hormone; E₂, estradiol; P, progesterone.

the negative feedback of steroids on gonadotropins appears to be mediated in part by endogenous opioids.¹⁹ It has been proposed that sex steroids enhance the activity of endogenous opioids that exert an inhibitory effect on GnRH secretion.²⁰ The negative effect of opioids on GnRH secretion is clinically explicable because the reduced GnRH secretion associated with hypothalamic amenorrhea may be mediated by an increase in endogenous opioid inhibitory tone.²¹

Estrogen signaling to GnRH neurons appears to be critical for suppressing FSH and LH and for coordinating the preovulatory surge release of LH. The precise roles of estrogen receptors α and β (ER α and ER β , respectively) within the GnRH neurons or estradiol-sensitive afferent neurons in these negative and positive feedback effects of estrogen are not well understood.²² Results of stimulation of FSH release after treatment of a premenopausal woman with an aromatase inhibitor and of in vitro studies suggest that estrogen locally produced by hypothalamic neurons may regulate gonadotropin secretion.^{23,24}

Binding of the peptide kisspeptin to its G protein-coupled receptor KISS1R (previously known as GPR54), which is expressed in GnRH neurons, stimulates GnRH release in the hypothalamus.^{25,26} Kisspeptin neurons contact GnRH neurons and act at the cell body and the nerve terminals. Kisspeptin can act directly on GnRH neurons or indirectly through synaptic input from other neurons to inhibit inwardly rectifying potassium channels and activate nonspecific cation channels, producing long-lasting depolarization and an increased action potential firing rate.²⁷ Mutations or targeted knockout of KISS1R produces isolated hypogonadotropic hypogonadism in humans and mice, indicating that signaling through this receptor is essential for sexual development and function.^{25,26} Moreover, kisspeptin- and KISS1R-expressing

neurons may be critical targets for the negative and positive feedback actions of estrogen and progesterone.²⁸

Gonadotropin-Releasing Hormone Analogs

The half-life of GnRH is short (2 to 4 minutes) because it is degraded rapidly by peptidases in the hypothalamus and pituitary gland.²⁹ These peptidases cleave the bonds between amino acids 5 and 6, 6 and 7, and 9 and 10. Analogs of GnRH with different properties have been synthesized by alteration of amino acids at these positions. Many agonistic and antagonistic GnRH analogs with various biologic effects have been produced.

Peptide Gonadotropin-Releasing Hormone Agonists

Several GnRH agonist peptides are generated by substitution of amino acids at the 6 or 10 position (Fig. 17-5). The increased biologic activity of agonistic peptides has been attributed to their high binding affinity to GnRH receptors and their reduced susceptibility to enzymatic degradation. An amino acid substitution at position 6 gives rise to metabolic stability, whereas replacement of the C-terminal glycine residue by an ethylamide group increases strikingly the affinity for the receptors.²⁹⁻³¹ Peptide GnRH agonists are administered subcutaneously, intranasally, or intramuscularly. An initial agonistic action (i.e., flare effect) is associated with an increase in the circulating levels of LH and FSH.

The most prominent agonistic response is observed during the early follicular phase, when the combined effects of GnRH agonist and elevated levels of estradiol create a large reserve pool of gonadotropins.³² Desensitization and downregulation of the pituitary produce hypogonadotropic hypogonadism. Administration of a long-acting

Figure 17-5 Gonadotropin-releasing hormone (GnRH) agonist and antagonist analogs in clinical practice. Purple circles indicate amino acids in the wild-type GnRH decapeptide, and white circles are labeled with the changes made to the analogs. (Modified from Millar RP, Lu Z, Pawson AJ, et al. Gonadotropin-releasing hormone receptors. *Endocr Rev.* 2004;25:235-275. Copyright © 2004 by the Endocrine Society.)

depot formulation of a GnRH agonist gives rise to downregulation of the gonadotropin-gonadal axis within 1 to 3 weeks. The initial downregulation effect is caused by desensitization, whereas the sustained response results from loss of receptors and the uncoupling of the receptor from its effector system. GnRH agonists may cause ovarian quiescence by the secretion of biologically inactive gonadotropins.

The U.S. Food and Drug Administration (FDA) has approved the use of these agonists for the treatment of GnRH-dependent precocious puberty, endometriosis, and prostate cancer. Another indication is preoperative hematologic improvement of patients with anemia caused by uterine leiomyomas. Off-label indications for GnRH agonists include downregulation of the pituitary during ovulation induction, induction of endometrial atrophy before endometrial ablation surgery, and prevention of menstrual bleeding in patients with coagulation defects. GnRH agonists have also been used to suppress ovarian steroidogenesis in hirsute patients.³³

The most prominent side effects of long-term use of depot GnRH agonist formulations are caused by estrogen deficiency. Depot GnRH agonists induce a menopause-like state characterized by hot flashes, vaginal dryness, bone resorption, and osteopenia. Osteopenia is reversible in young women if treatment is maintained for no more than 6 months.^{34,35} The risk/benefit ratio must be considered carefully before GnRH agonist treatment is extended for longer periods. Add-back regimens employing low-dose estrogens or progestins, or both, administered along with GnRH agonists have provided a means to overcome these side effects and to extend the length of agonist therapy.³⁶

Peptide Gonadotropin-Releasing Hormone Antagonists

Inhibition of a premature LH rise by GnRH agonists requires at least 7 days, because it is accompanied by an initial stimulation of GnRH receptors before gonadotroph desensitization is achieved. In contrast, GnRH antagonists compete directly with endogenous GnRH for receptor binding and therefore rapidly inhibit secretion of gonadotropin and steroid hormones (see Fig. 17-5). This property conveys a potential advantage over GnRH agonists in the management of ovarian stimulation. However, because of the constant need to block endogenous GnRH, much higher doses of antagonists are required. The GnRH antagonists incorporate a number of amino acid substitutions in the N-terminal domain (involved in receptor activation) combined with a D-amino acid substitution for Gly6, which enhances the β II-type bend necessary for receptor binding.¹ GnRH antagonists have the advantage of inducing an immediate decrease in circulating gonadotropin levels with rapid reversal.³⁷⁻⁴⁰ GnRH antagonists are alternative drugs to GnRH agonists for the prevention of a natural LH surge during ovulation induction by injectable FSH.⁴¹ Use of GnRH antagonists has become popular in ovulation induction protocols for IVF (see Fig. 17-5).⁴¹

Nonpeptide Gonadotropin-Releasing Hormone Antagonists

Small molecular compound collections have been screened in mammalian cells that ectopically expressed human GnRH type I receptor. These studies led to the identification of synthetic compounds that bind to the GnRH type I receptor and block it. Several companies have manufactured orally administered GnRH antagonists intended for various indications, including endometriosis. None of these medications has yet reached the market.¹

REPRODUCTIVE FUNCTIONS OF THE ANTERIOR PITUITARY

Gonadotrophs

Gonadotrophs are specialized cell types of the anterior pituitary that synthesize and secrete LH and FSH. These cells constitute 7% to 15% of the total number of anterior pituitary cells and are detected in this location from early fetal life.⁴² Most gonadotrophs are capable of synthesizing both LH and FSH.^{42,43} LH and FSH are each composed of two distinct, noncovalently associated protein subunits called α and β (see Fig. 17-4). In the gonadotroph, the subunit genes are transcribed into messenger ribonucleic acids (mRNAs), which are translated into the subunit precursors. Gonadotrophs contain cell surface GnRH type I receptors that mediate the action of GnRH. These receptors belong to the seven-transmembrane domain and G protein-coupled receptor family.

Gonadotropin-Releasing Hormone Receptor

In humans, hypothalamic GnRH regulates gonadotropin secretion through the pituitary GnRH type I receptor by activation of $G_{q/11}$.⁴⁴ Although the predominant coupling of the type I GnRH receptor in the gonadotroph is through $G_{q/11}$ stimulation, signal transduction can occur through other G proteins and potentially by G protein-independent means.^{1,44} A number of downstream cascades are activated by GnRH. These include protein kinase C (PKC)-, Ca^{2+} -, and tyrosine kinase-dependent pathways.¹ In mouse pituitary gonadotrophs, the GnRH receptor activates several mitogen-activated protein (MAP) kinase cascades, including the ERK1/2, the JUN N-terminal kinase (JNK), the p38 MAP kinase, and the big MAP kinase (BMK1/ERK5).¹ The cross-talk between these pathways remains to be clarified.

Activation of G protein-coupled receptors is typically followed by their desensitization and internalization, and these processes involve rapid agonist-induced receptor phosphorylation by second messenger-dependent protein kinases and G protein-coupled receptor kinases. Because the serine and threonine residues that are phosphorylated by G protein-coupled receptor kinases are often located in the C-terminal tail, which is uniquely absent in the mammalian GnRH receptor, several studies have revealed that the tailless GnRH receptor neither undergoes rapid homologous desensitization nor exhibits agonist-induced receptor phosphorylation. The receptor internalizes slowly by means of clathrin-coated vesicles, and this process occurs independently of β -arrestin and dynamin.¹

Luteinizing Hormone and Follicle-Stimulating Hormone

Each gonadotropin is a heterodimer. LH and FSH are made of two peptide subunits called α and β , which are associated with noncovalent bonds. The α -subunits of human LH, FSH, thyroid-stimulating hormone (TSH), and human chorionic gonadotropin (hCG) have an identical polypeptide structure. In contrast, the β -subunit of each hormone has a unique amino acid sequence and confers the specific activity of the $\alpha\beta$ -heterodimer. Each subunit is rich in cysteine and contains multiple disulfide linkages. Each subunit also contains multiple carbohydrate moieties that play important roles in the biologic activity and metabolism of these hormones. The common α -subunit contains 92

TABLE 17-1

Properties of Gonadotropins

Gonadotropins	Location of β -Subunit Gene	Size of β -Subunit (No. of Amino Acids)	Half-Life in Serum
FSH	Chromosome 11p13	117	3-4 hr
LH	Chromosome 19q13.3	121	20 min
hCG	Chromosome 19q13.3	145	24 hr

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

amino acids. The β -subunits of human FSH, LH, and hCG contain 117, 121, and 145 amino acids, respectively (Table 17-1).⁴⁵⁻⁴⁸ On binding of GnRH to its receptor, the biosynthesis of the gonadotropins proceeds by transcription of the subunit genes, translation of the subunit mRNAs, post-translational modifications of the precursor subunits and subunit folding and combination, mature hormone packaging, and hormone secretion (see Fig. 17-4).

The human α -subunit gene is located on the short arm of chromosome 6. The encoded precursor polypeptide contains a 24-amino-acid leader sequence that is cleaved post-translationally to produce the mature 92-amino-acid α -subunit.

The human LH and hCG β -subunit genes are located on chromosome 19q13.3, which contains a cluster of seven β -subunit-like genes.⁴⁶ Five of these sequences are noncoding pseudogenes arranged in groups of tandem and inverted pairs. Only LH and hCG β -subunit genes give rise to two distinct and functional mRNA species. The LH β -subunit mRNA encodes a 145-amino-acid precursor protein that is later cleaved to produce a 24-amino-acid leader peptide and an 121-amino-acid, biologically active, mature peptide. The hCG β -subunit mRNA also encodes a 145-amino-acid protein. This protein, however, is not processed post-translationally and functions as the biologically active hCG β -subunit. The amino acid sequences of the human LH and hCG β -subunits are 82% homologous. These two β -subunits confer identical biologic activities when associated with the α -subunit.⁴⁶⁻⁴⁸

A single gene located on the short arm of chromosome 11 encodes the FSH β -subunit, which is 117 amino acids long.⁴⁹ Complementary DNA encoding human FSH- β , LH- β , or hCG- β in combination with the complementary DNA of the α -subunit is expressed in mammalian cells in culture. These cells can synthesize these proteins, modify them after translation, glycosylate and combine the subunits, and secrete them as intact FSH, LH, or hCG.⁵⁰ Recombinant gonadotropins produced through recombinant technology in mammalian cells are used clinically to stimulate gonadal function.⁵¹

Regulation of Circulating Levels of Follicle-Stimulating Hormone and Luteinizing Hormone

The molecular mechanisms responsible for formation and combination of the α - and β -subunits of FSH and LH are not completely understood. Production rates of α - and β -subunits are regulated in part by negative feedback by

estrogen, which regulates the pulsatile release of GnRH from the hypothalamus.^{50,52} The pituitary contains more α -subunit than β -subunit mRNA, and readily detectable levels of free α -subunit are present in serum. The free β -subunit is present at relatively low levels in the pituitary and is rarely found in serum or urine. The specific β -subunit may be the rate-limiting factor in the synthesis of these glycoprotein hormones.

Inhibin, activin, and follistatin were first identified as gonadal hormones that exerted selective effects on FSH secretion. Although the primary source of inhibin remains the ovary, activin and follistatin are produced in extragonadal tissues and can exert effects on FSH through an autocrine-paracrine mechanism. Inhibin B is secreted by ovarian granulosa cells during the follicular phase (under the control of FSH) and inhibin A by the corpus luteum in the luteal phase (under the control of LH). Inhibins act synergistically with estradiol to inhibit FSH secretion. Activin can directly stimulate FSH biosynthesis and release from the gonadotroph cells of the pituitary gland.⁵³ Follistatin can negatively regulate these effects by binding activin and preventing it from interacting with the activin receptor at the cell membrane.⁵⁴

Serum levels of gonadotropins are proportional to their secretion rates and serum half-lives, which are regulated by the number of carbohydrate residues. The higher the content of carbohydrate residues, especially the sialic acid residues, the lower the rate of metabolism and the higher the serum half-life.⁵⁵ The sialic acid content of gonadotropic hormones and other glycoproteins has a marked effect on their rate of clearance and influences their apparent molecular size. The higher content of sialic acid in FSH compared with LH is responsible for slower clearance of FSH from the circulation; LH has the most rapid clearance rate. The hCG is highly sialylated and has the longest half-life (see Table 17-1).

OVARY

The ovary is essential for periodic release of oocytes and production of the steroid hormones, estradiol and progesterone. These activities are integrated into the cyclic repetitive process of follicular maturation, ovulation, and formation and regression of the corpus luteum. The ovary fulfills two major objectives: generation of a fertilizable ovum and preparation of the endometrium for implantation through the sequential secretion of estradiol and progesterone.⁵¹ The ovarian follicle comprising the egg and surrounding granulosa and theca cells constitutes the fundamental functional unit of the ovary.

Adult human ovaries are oval bodies with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. The combined weight of normal ovaries during the reproductive years is 10 to 20 g (average, 14 g). The ovaries lie near the posterior and lateral pelvic wall and are attached to the posterior surface of the broad ligament by the peritoneal fold, called the *mesovarium*. Blood vessels, nerves, and lymphatic vessels traverse the mesovarium and enter the ovary at the hilum.⁵⁶

The ovary consists of three structurally distinct regions: an outer cortex containing the surface germinal epithelium and the follicles; a central medulla consisting of stroma; and a hilum around the area of attachment of the ovary to the mesovarium. The functional anatomy of the adult ovary is illustrated in Figure 17-6. The hilum is the point of attachment of the ovary to the mesovarium. It contains nerves, blood vessels, and hilus cells, which have the

Figure 17-6 Functional anatomy and changes in the adult ovary during an ovarian cycle. (From Carr BR, Wilson JD. Disorders of the ovary and female reproductive tract. In: Braunwald E, Isselbacher KJ, Petersdorf RG, et al, eds. *Harrison's Principles of Internal Medicine*, 11th ed. New York, NY: McGraw-Hill; 1987:1818-1837.)

potential to become active in steroidogenesis or to form androgen-secreting tumors. These cells are similar to the testosterone-producing Leydig cells of the testes. The outermost portion of the cortex, called the *tunica albuginea*, is covered by a single layer of surface cuboidal epithelium called the *germinal epithelium*. The oocytes, enclosed in complexes called *follicles*, are in the inner part of the cortex, embedded in stromal tissue. One dominant follicle is recruited for ovulation during each cycle. The preovulatory follicle transforms into a corpus luteum after ovulation. In the absence of pregnancy, the corpus luteum regresses to become the corpus albicans. The stromal tissue is composed of connective tissue and interstitial cells, which are derived from mesenchymal cells and are presumed to have the ability to respond to LH or hCG with the production of androstenedione. The central medullary area of the ovary is derived largely from mesonephric cells.

Genetic Determinants of Ovarian Differentiation and Folliculogenesis

Nascent components of the human ovary develop long before a distinct ovary-like organ can be discerned. The female germ cells are created during embryogenesis when the precursors of primordial germ cells differentiate from somatic lineages of the embryo and take a unique route from the base of the yolk sac along the hindgut to reach the genital ridge. This starts the differentiation of female gonads (ovaries) at the genital ridge. The originally undifferentiated gonad differentiates along a female pathway, and the newly formed oocytes proliferate and subsequently enter meiosis.⁵¹

Ovarian differentiation and folliculogenesis depend on coordinated expression and interaction of a multitude of

genes.⁵⁷ Targeted gene disruption or insertion in mice has made it possible to inquire about the function of specific genes in ovarian differentiation and folliculogenesis. Figure 17-7 summarizes the biologic roles of some of these genes.⁵⁷ Genetically altered mice represent a first step in attempts to understand in vivo the various gene interactions that result in a functional ovary. Ovarian pathologic conditions in transgenic mice closely resemble disorders observed in mutant human homologs, as exemplified in cases involving the FSH β -subunit and FSH receptor. Many mouse models of ovarian pathologic conditions are available. They can be divided into mice that have prenatal ovarian insufficiency with disordered gonad formation and diminished number of germ cells or absent germ cells and mice that have postnatal ovarian insufficiency as a result of defects at various stages of folliculogenesis (see Fig. 17-7).⁵⁷ These models should lead to the identification of genetic and molecular mechanisms responsible for the development and function of the human ovary.

In humans, certain gene defects give rise to specific defects in folliculogenesis. This was demonstrated by the discovery of a heterozygous mutation in the bone morphogenetic protein 15 gene (*BMP15*) that caused ovarian dysgenesis. BMP15 is an oocyte-specific growth and differentiation factor that stimulates folliculogenesis and granulosa cell growth. In vitro, mutant BMP15 reduced granulosa cell growth and antagonized the stimulatory activity of wild-type protein on granulosa cell proliferation. In vivo, this mutation was associated with familial ovarian dysgenesis, indicating that the action of BMP15 is required for progression of human folliculogenesis.⁵⁸ A comprehensive discussion of genes responsible for ovarian development, folliculogenesis, and ovulation is provided in an excellent review article by Edson and colleagues.⁵¹

Figure 17-7 Developmental stages at which certain murine genes affect oogenesis. Data from transgenic mice with disruption of various genes have delineated critical roles of several genes during various phases of the follicular development. Prenatal follicular growth is thought to be gonadotropin independent, whereas antrum formation and follicular maturation require the action of follicle-stimulating hormone (FSH). *Acvr2*, activin type II receptor; *Amh*, anti-Müllerian hormone; *Bmp15*, bone morphogenetic protein-15; *Ccnd2*, cyclin d2; *Esr1*, estrogen receptor- α ; *Esr2*, estrogen receptor- β ; *Figla*, factor in the germline- α ; *Foxl2*, forkhead box L2; *Fshb*, FSH β -subunit; *Fshr*, FSH receptor; *Gdf9*, growth differentiation factor 9; *Gja4*, gap junction protein connexin 37; *Igf1*, insulin-like growth factor I; *Inha*, inhibin α -subunit; *Inhba*, activin β_A -subunit; *Kit*, kit receptor; *Kitl*, kit-ligand; *Nobox*, newborn oogenesis homeobox gene; *Smad3*, Smad3, Smad family member 3; *Taf4b*, TATA-box-binding protein-associated factor-4b. Oocytes

The fertilization of an oocyte by a spermatozoon gives rise to a zygote that starts to divide rapidly. An eight-cell embryo is formed usually on the third day after fertilization. Up to that point, all embryonic cells are morphologically identical, truly totipotent, and capable of starting a new individual or any lineage. The formation of a 16-cell morula marks the beginning of the process of differentiation, with cells being allocated to the inside or outside of the embryo. At the next stage, the blastocyst, three lineages are defined: trophoblast, which is the precursor of placenta; epiblast, which gives rise to the somatic cells of the embryo; and primitive endoderm, which eventually forms the yolk sac. After the embryo implants, a group of cells within the epiblast form the precursors of the primordial germ cells, the first cells of the future ovary to be defined.⁵¹ The extraembryonic trophoblast and primitive endoderm, which surround the epiblast cells of the postimplantation egg cylinder, are the sources of signals that instruct this small number of epiblast cells to become primordial germ cells; the rest of the cells commence differentiation into somatic tissues. The first primordial germ cell precursors express a key protein named PRDM1 (PRDI-BF1-RIZ domain containing 1, formerly called BLIMP1); these precursor cells represent the first cells of the mammalian embryo with committed cell fates.⁵¹

The primordial germ cells first become recognizable as a cluster of cells that stain intensely for alkaline phosphatase activity; these epiblast cells are observed at the base of the yolk sac before formation of the allantois.⁵¹ Studies have confirmed that these cells are the only primordial germ cells, because their ablation results in embryos

without germ cells, whereas transplantation of these cells leads to their proliferation followed by migration to the genital ridge.⁵¹

With the use of alkaline phosphatase as a marker, migration of these primordial germ cells from the yolk sac-epiblast junction to the indifferent gonad can be tracked; eventually, the ovary forms and permits the primordial germ cells to differentiate into oocytes. The oocytes enter meiosis and subsequently arrest. Entry into meiosis marks the developmental stage at which any progenitor cells that are capable of differentiating to oocytes disappear. The meiotically arrested oocytes eventually become surrounded by pre-granulosa cells and form individual primordial follicles, the resting pool of oocytes that have the potential to be recruited into the growing follicle pool during the postpubertal stage to be fertilized and to contribute to the next generation. These phenomena have been primarily observed in mice and are thought to be applicable to humans.⁵¹

Primordial germ cells of epiblast origin migrate to cross a remarkably long distance from the base of the yolk sac to the genital ridge in the fetus by amoeboid movements with the aid of pseudopodia.⁵⁹ This long route of migration along the dorsal mesentery of the hindgut is interrupted only by the required lateral crossing of the celomic angle at the level of the genital ridge (Fig. 17-8). The exact trigger that initiates primordial germ cell migration and the chemoattractants that are required for directional movement toward the genital ridge are slowly beginning to be understood. The trigger may be expression of a key receptor on the primordial germ cell and expression of the secreted chemoattractants from the genital ridge. For example, suppression of transforming growth factor- β (TGF- β) signaling

Figure 17-8 Transverse section of the caudal region of a 5-week embryo shows the location of gonadal ridges, the primordium of the adrenal glands, and the migration path of primordial germ cells. From the third week on, germ cells of epiblast origin located at the base of the yolk sac cross the dorsal mesentery of the hindgut and migrate to the gonadal ridges. By the end of the fifth week, rapid division of primordial germ cells, gonadal epithelium, and mesenchyme starts the early gonad that differentiates subsequently into the ovary in a 46,XX fetus. CC, celomic cavity. (Modified from Moore K. *The Developing Human*. Philadelphia, PA: WB Saunders; 1983.)

leads to enhanced migration due to reduction in the levels of TGF- β -induced collagen type 1 in the extracellular matrix.⁶⁰ An extracellular matrix gradient along the path of migration is important, and if too much matrix is laid down, germ cells show reduced migration. The KIT ligand (KITLG) may function as an effective chemoattractant for the primordial germ cells. The phosphatidylinositol 3 kinase (PI3K)/AKT and SRC kinase pathways are involved downstream of KIT in the primordial germ cell.⁶¹

Germ cells appear to be unable to persist outside the genital ridge, which may be viewed as the only region competent to sustain gonadal development. By the same token, germ cells play an indispensable role in the induction of gonadal development. No functional gonad can form in the absence of germ cells.

On arrival at the genital ridge by the fifth week of gestation, the premeiotic germ cells are referred to as *oogonia*.⁶² During the subsequent 2 weeks of intrauterine life (weeks 5 to 7 of gestation, or the *indifferent stage*), the primordial gonadal structure constitutes no more than a bulge on the medial aspect of the urogenital ridge (see Fig. 17-8). This protuberance is created by proliferation of surface (celomic) germinal epithelium, by growth of the underlying mesenchyme, and by oogonial multiplication. The oogonia total 10,000 by about 6 to 7 weeks of intrauterine life. Because meiosis and oogonial atresia are not occurring, the actual number of germ cells is dictated by mitotic division at this time.

During the indifferent phase, the gonadal cortex and medulla are first delineated. However, short of cytogenetic evidence, the precise sexual identity of the gonadal ridge cannot be ascertained at this point. Nevertheless, the absence of testicular development beyond 7 weeks' gestation is considered presumptive evidence of formation of the ovary. Additional clues to the sexual identity of the gonad can be derived from the detection of oogonial meiosis at about 8 weeks' gestation, because no comparable

process is observed in the testis until puberty. The sexual identity of the gonadal ridge is histologically clear by 16 weeks' gestation, when the first primordial follicles can be visualized.

By about 8 weeks of intrauterine life, persistent mitosis increases the total number of oogonia to 600,000 (Fig. 17-9). From this point on, the oogonial endowment is subject to three simultaneous processes: mitosis, meiosis, and oogonial atresia. Stated differently, the onset of oogonial meiosis and oogonial atresia is superimposed on oogonial mitosis. As a result of the combined impact of these processes, the number of germ cells peaks at 6 to 7×10^6 by 20 weeks' gestation (see Fig. 17-9). At this time, two thirds of the total germ cells are intrameiotic primary oocytes; the remaining third can still be viewed as oogonial. The midgestational peak and the postpeak decline are accounted for in part by the progressively decreasing rate of oogonial mitosis, a process destined to end entirely by about the seventh month of intrauterine life. Equally relevant is the increasing rate of oogonial atresia, which peaks at 5 months' gestation. During this period, regulation of the ovarian developmental process is complex and probably involves a diverse group of genes (see Fig. 17-7).^{63,64}

From midgestation onward, relentless and irreversible attrition progressively diminishes the germ cell endowment of the gonad. About 50 years later, it is exhausted. For the most part, this is accomplished through follicular atresia rather than oogonial atresia, begins at about month

Figure 17-9 Age-dependent changes in germ cell number in the human ovary. The highest number of oocytes is found in the ovaries of a human fetus at midgestation. This number decreases sharply during the third trimester. After birth, the progressive decline in the number of ovarian follicles containing oocytes continues until complete depletion at menopause. (From Baker TG. A quantitative and cytological study of germ cells in the human ovaries. *Proc R Soc Biol Sci*. 1963;158:417-433.)

6 of gestation, and continues throughout life (see Fig. 17-9). In contrast, oogonial atresia is destined to end at 7 months of intrauterine life as follicular atresia sets in. Follicular atresia has a profound effect on germ cell endowment, because only 1 to 2×10^6 germ cells are present at birth (see Fig. 17-9).⁶⁵ Remarkably, this dramatic depletion of the germ cell mass occurs during a period as short as 20 weeks. No similar rate of depletion occurs earlier or subsequently. Consequently, newborn girls enter life still far from realizing their reproductive potential but having lost as much as 80% of their germ cell endowment. The germ cell mass decreases further to approximately 300,000 by the onset of puberty. Of these follicles, only 400 to 500 (<1% of the total) are recruited for ovulation in the course of a reproductive life span.

Between weeks 8 and 13 of fetal life, some of the oogonia depart from the mitotic cycle to enter the prophase of the first meiotic division. This change marks the conversion of these cells to primary oocytes well before actual follicle formation. Meiosis (beginning at about 8 weeks' gestation) provides temporary protection from oogonial atresia, allowing the germ cells to invest themselves with granulosa cells and to form primordial follicles. Oogonia that persist beyond the seventh month of gestation and have not entered meiosis are subject to oogonial atresia; consequently, no oogonia are usually present at birth.

Once formed, the primary oocyte persists in prophase of the first meiotic division until the time of ovulation, when meiosis is resumed and the first polar body is formed and extruded (Fig. 17-10). Although the exact cellular

Figure 17-10 Meiotic cell division. During meiosis, the chromosomes that were inherited from the parents of the individual and stored in gonads are processed to prepare their genetic material for transmission to the offspring. Meiosis occurs exclusively in germ cells and serves two critical purposes: generation of germ cells genetically distinct from the somatic cells and generation of a mature egg (or sperm) with a reduction in the number of chromosomes from 46 to 23. Genetic recombination through crossover of genes between homologous chromosomes and random assortment of (grand-) maternal and (grand-) paternal chromosomes into daughter cells during the first meiotic division are responsible for the first function of meiosis, maintenance of genetic diversity. The second function is provided by a reduction in the number of chromosomes so that each daughter cell, or ovum, receives randomly one chromosome from each of the 23 pairs. During fertilization, the fusion of ovum and sperm, each of which contributes 23 chromosomes, produces a genetically novel individual with 46 chromosomes. The chromosome marked as white in the oogonium (upper left corner) originates from the father of the female fetus, whereas the blue chromosome comes from the mother of the fetus. The random exchange of genes (alleles) between homologous chromosomes (crossover) takes place before the meiotic arrest in the prophase I stage before birth. After birth, the oocytes of this child remain in meiotic arrest until puberty. In the developing oocyte in the graafian follicle, meiosis I is resumed immediately after the preovulatory luteinizing hormone (LH) surge during each ovulatory cycle. Meiotic maturation is defined as the period from the breakdown of the oocyte's nucleus (germinal vesicle [GV]) until the oocyte reaches metaphase II (i.e., transition from oocyte to egg). A second and short meiotic arrest occurs at metaphase II until the oocyte is fertilized by a sperm. DNA, deoxyribonucleic acid; GVBD, germinal vesicle breakdown; mat, maternal; n, amount of DNA material in the haploid number (23) of chromosomes; pat, paternal.

Figure 17-11 Developmental stages of the ovarian follicle. The primordial follicle is composed of a single layer of granulosa cells and a single immature oocyte arrested in the diplotene stage of the first meiotic division. The primordial follicle is separated from the surrounding stroma by a thin basal lamina (i.e., basement membrane). The oocyte and granulosa cells do not have a direct blood supply. The first sign of follicular recruitment is cuboidal differentiation in the spindle-shaped cells inside the basal lamina, which thereafter undergo successive mitotic divisions to form a multilayered granulosa cell zone. The oocyte enlarges and secretes a glycoprotein-containing mucoid substance called the zona pellucida, which surrounds the oocyte and separates the granulosa cells from the oocyte. This structure is a primary follicle. The secondary follicle is formed by further proliferation of granulosa cells and by the final phase of oocyte growth, in which the oocyte reaches 120 μm in diameter, coincident with proliferation of layers of cells immediately outside the basal lamina to constitute the theca. The portion of the theca adjacent to the basal lamina is called the theca interna. Theca cells that merge with the surrounding stroma are designated the theca externa. The secondary follicle acquires an independent blood supply consisting of one or more arterioles that terminate in a capillary bed at the basal lamina. Capillaries do not penetrate the basement membrane, and the granulosa and oocyte remain avascular. The tertiary follicle is characterized by further hypertrophy of the theca and the appearance of a fluid-filled space among the granulosa cells, called the antrum. The fluid in the antrum consists of a plasma transudate and secretory products of granulosa cells, some of which (estrogens) are found there in strikingly higher concentrations than in peripheral blood. The follicle rapidly increases in size under the influence of gonadotropins to form the mature or graafian follicle. In the graafian follicle, the granulosa and oocyte remain encased by the basal lamina and are devoid of direct vascularization. The antral fluid increases in volume, and the oocyte, surrounded by an accumulation of granulosa cells (i.e., cumulus oophorus), occupies a polar, eccentric position within the follicle. The mature graafian follicle is then ready to release the ovum by the process of ovulation. (Adapted from Erickson GF, Magoffin DA, Dyer CA. The ovarian androgen producing cells: a review of structure-function relations. *Endocr Rev.* 1985;6:371-379. Copyright © 1985 by The Endocrine Society.)

mechanisms responsible for this meiotic arrest remain uncertain, it is presumed that a granulosa cell-derived meiosis inhibitor is in play. This hypothesis is based on the observation that denuded (granulosa-free) oocytes are capable of spontaneously completing meiotic maturation in vitro.

The primary oocyte is converted into a secondary oocyte by completion of the first meiotic metaphase and formation of the first polar body, which occurs before ovulation but after the LH surge. At ovulation, the secondary oocyte and the surrounding granulosa cells (cumulus oophorus) are extruded and enter the fallopian tube. If sperm penetration occurs, the secondary oocyte undergoes a second meiotic division, after which the second polar body is eliminated (see Fig. 17-10).

Granulosa Cell Layer

In the developing ovaries of a human female fetus, oocytes initially exist as germ cell clusters before an ovarian follicle is formed. During the second half of in utero life, these germ cell clusters break down, and the surviving oocytes

become individually surrounded with squamous pre-granulosa cells to give rise to primordial follicles. The transition from primordial to primary follicle is marked histologically by a morphologic change in granulosa cells from squamous to cuboidal. By the secondary stage, there are at least two layers of cuboidal granulosa cells and an additional layer of somatic cells, the theca, which forms outside the basement membrane of the follicle (Fig. 17-11).⁵¹ At puberty, FSH secreted by the pituitary promotes further granulosa cell proliferation and survival.

A basement lamina separates the oocyte and granulosa cells from the surrounding stromal cells.⁶⁶ The granulosa cells do not have direct access to the circulation before ovulation (Fig. 17-12).

The avascular nature of the granulosa cell compartment necessitates contact between neighboring cells. The granulosa cells are interconnected by extensive intercellular gap junctions, which result in their coupling to yield an expanded, integrated, and functional syncytium (Fig. 17-13).^{67,68} Gap junctions are composed of proteins called *connexins*. Connexin-37 and other connexins have been demonstrated in gap junctions in follicles. Gap junction

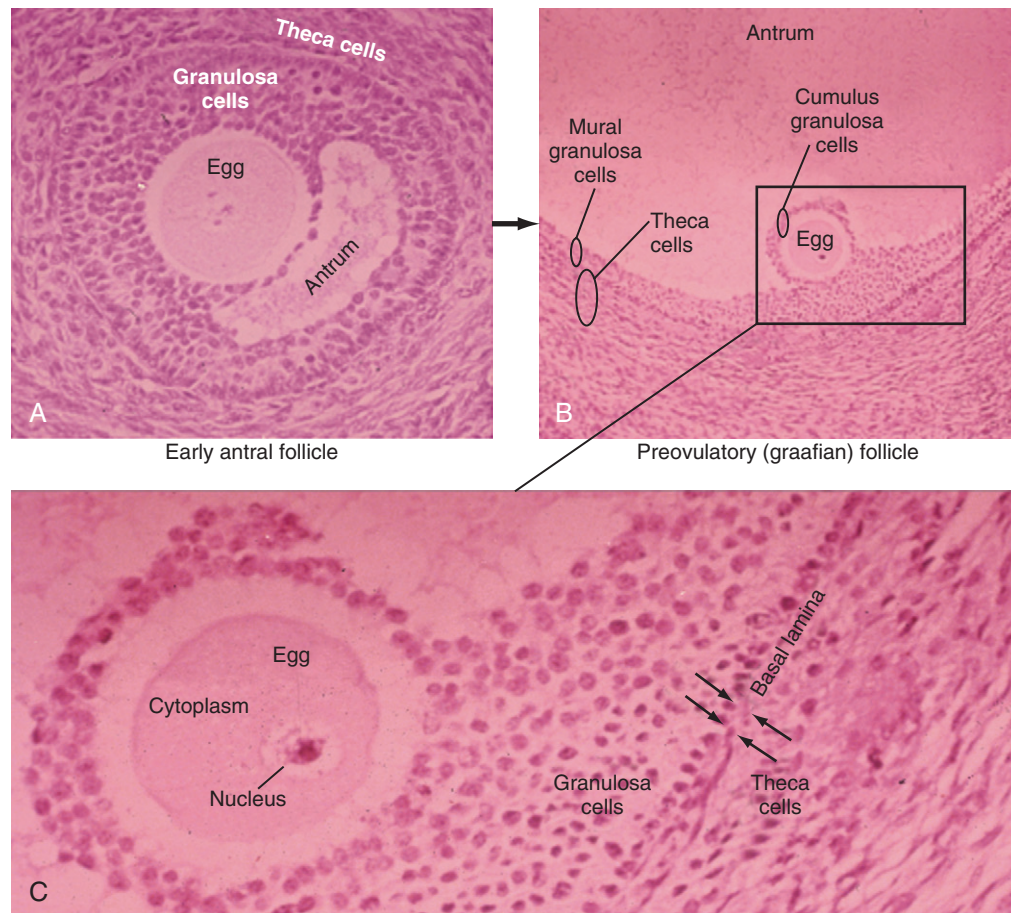

Figure 17-12 Histology of gonadotropin-dependent ovarian follicle development. **A**, Development of an antrum marks gonadotropin dependency. Multiple layers of granulosa and theca cells are present. **B**, The follicle destined to ovulate distinguishes itself from the rest of the cohort through accumulation of large quantities of antral fluid. The granulosa cells, which accumulate around the oocyte, are called *cumulus granulosa cells* and primarily function to support egg development. The mural granulosa cells in the periphery primarily serve as steroidogenic cells. **C**, A membrane called the *basal lamina* (arrows), which has been formed at the primary stage, separates the granulosa cells from the theca component of the follicle.

protein connexin 37 (GJA4)-deficient mice lack graafian follicles, fail to ovulate, and develop inappropriate corpora lutea.⁶⁹ These specialized cell junctions may be important in metabolic exchange and in the transport of small molecules between neighboring granulosa cells. Moreover, the granulosa cells extend cytoplasmic processes that penetrate the zona pellucida to form gap junctions with the plasma membrane of the oocyte (see Fig. 17-13). In the GJA4-deficient mice, oocyte development is arrested before meiotic competence.⁶⁹ Gap junctions represent a crucial communication system that is needed for the tight control exerted by the cumulus granulosa cells on the resumption of meiosis by the enclosed primary oocyte.

Several gene products regulate the transition from primordial to primary follicle, which is marked by a change in the morphology of granulosa cells from squamous to cuboidal, followed by an increase in granulosa cell layers in the secondary follicle.⁵¹ These genes are expressed in the oocyte or granulosa cells, emphasizing the active role of the oocyte in granulosa cell differentiation. Newborn oogenesis homeobox (NOBOX), spermatogenesis and oogenesis helix-loop-helix 1 (SOHLH1), and SOHLH2 are critical transcription factors during the transition from primordial to primary follicles.⁵¹ Interactions between KITLG expressed in granulosa cells and the KIT tyrosine kinase receptor expressed in oocytes also appear to be critical in

early folliculogenesis. The KITLG/KIT pathway induces the PI3K/AKT pathway, leading to phosphorylation and inactivation of forkhead box O3 (FOXO3), an inhibitor of primordial follicle activation.⁵¹ These genetic studies supported a critical role of the PI3K/AKT/FOXO3 pathway in early follicle development and granulosa cell differentiation. Whereas FOXO3 is the key oocyte factor critical for suppressing primordial follicle activation, another forkhead domain transcription factor, forkhead box L2 (FOXO2), is crucial in the transition from squamous to cuboidal granulosa cells.⁵¹

Anti-müllerian hormone (AMH) produced by the granulosa cells of growing follicles appears to inhibit the growth of primordial follicles, and in its absence, there is a faster depletion of growing follicles, although it is unknown whether this is a direct or indirect effect of AMH. Clinically, serum AMH may be a useful biomarker of ovarian reserve. In women and mice, serum AMH declines with increasing age. Although it is difficult to establish a direct link between serum AMH and the primordial follicle pool in humans, antral follicle number is positively correlated with AMH levels.⁵¹ More detailed information has been reviewed by Edson and colleagues.⁵¹

The granulosa cells in the fully developed graafian follicle shortly before ovulation are stratified in a manner that allows the distinction of a number of populations of

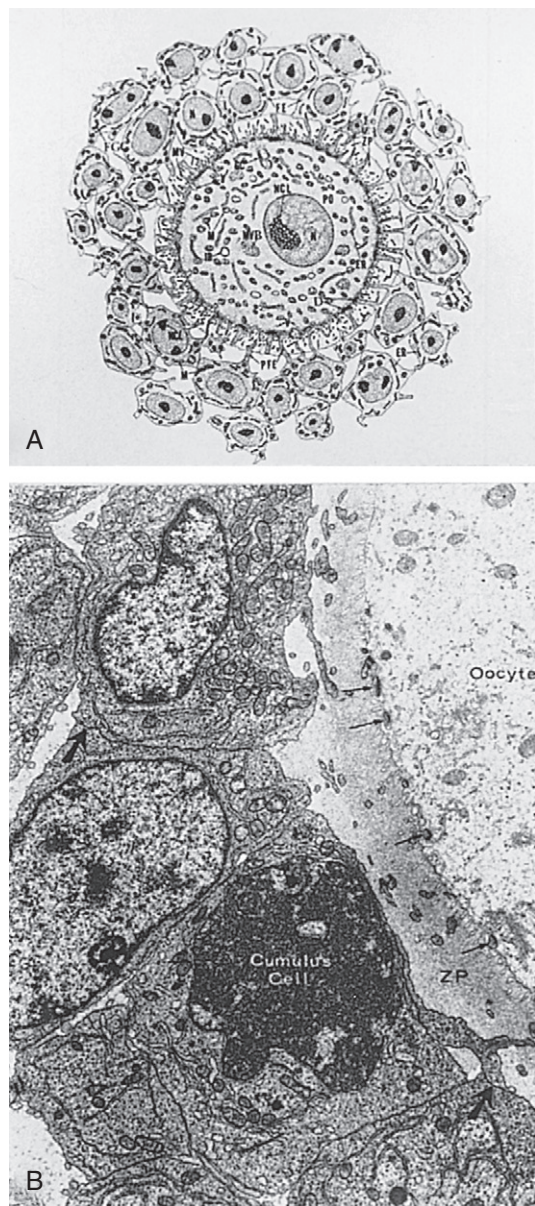

Figure 17-13 Structural relationship between the cumulus granulosa cell and the oocyte. **A**, Microvilli of an oocyte interdigitate with cytoplasmic extensions of granulosa cells, penetrating the zona pellucida. **B**, Notice the penetration of the zona pellucida by cytoplasmic processes of the granulosa cells. Small gap junctions (thin arrows) are observed between processes of the granulosa cell and the oocyte membrane. The thick arrow indicates a gap junction between granulosa cells. (From Erickson GF. An analysis of follicle development and ovum maturation. *Semin Reprod Endocrinol.* 1986;4:233, with permission of Thieme Medical Publishers, New York.)

cells.^{70,71} Distinct populations of granulosa cells exhibit specific, specialized functions.⁷²⁻⁷⁴ Mural granulosa cells within the outermost layer adjacent to the basement layer contain high levels of gonadotropin hormone receptors and steroidogenic enzymes and account for most of the steroidogenesis in the follicle.^{70,71} The *cumulus oophorus* contains the egg and a surrounding mass of granulosa cells that have cell-cell interactions with the egg and seem to have critical roles in oocyte development (see Figs. 17-12 and 17-13).⁷²⁻⁷⁴

Mural and cumulus granulosa cells also exhibit distinct patterns of gene expression. For example, the tumor

suppressor BRCA1 is highly expressed in ovarian granulosa cells of developing follicles.⁷⁵ However, in large antral or preovulatory follicles, BRCA1 expression significantly decreases in mural granulosa cells and becomes restricted to cumulus granulosa cells; these cells, unlike the mural ones, do not contain abundant aromatase, so this development gives rise to an intriguing inverse correlation of BRCA1 with aromatase mRNA and protein levels.⁷⁵ Stimulation of an FSH-dependent signaling pathway greatly induces aromatase but suppresses BRCA1 expression in granulosa cells. Moreover, BRCA1 binds to the aromatase promoter and inhibits its activity.⁷⁶ Therefore, BRCA1 may exert its tumor suppressor activity, in part, by limiting excessive estrogen formation in the ovary. A summary of ovarian follicle development is presented in Figure 17-11.

Theca Cell Layer

After the follicle achieves two layers of granulosa cells, another morphologically distinct layer of somatic cells, the theca, differentiates from ovarian stroma (see Figs. 17-11, 17-12, and 17-13).⁵¹ The cells making up the theca-interstitial compartment are heterogeneous in nature.⁷⁷ Cells of the theca interna layer, which forms just outside the basement membrane surrounding the granulosa cells, show typical steroidogenic features, including mitochondria with tubular cristae, smooth endoplasmic reticulum, and abundant lipid vesicles (see Figs. 17-11 and 17-12). Theca interna cells are responsible for producing the C19 steroids that diffuse into the neighboring granulosa cells and serve as substrates for estrogen production. Theca externa is the outermost layer of the follicle and is composed of fibroblasts, smooth muscle-like cells, and macrophages (see Figs. 17-11 and 17-12). The theca externa is thought to have an important function during ovulation. Cells that contribute to the theca differentiate from mesenchymal precursor cells present in the ovarian stroma, adjacent to developing follicles. Like preantral folliculogenesis, theca formation is gonadotropin independent. Thecal precursor cells lack LH receptors, and the theca layer still forms in the ovaries of FSH-deficient mice.⁵¹ After a discernible theca interna layer has developed, theca cell C19 steroid production is regulated primarily by LH.

The differentiated state of theca interna cells is marked by expression of a number of steroidogenic genes, including those of the LH receptor (*LHCGR*); steroidogenic acute regulatory protein (*STAR*); side-chain cleavage enzyme (*CYP11A1*); 3β -hydroxysteroid dehydrogenase- $\Delta^5,4$ isomerase type 2 (*HSD3B2*); and 17-hydroxylase/17,20-lyase (*CYP17A1*) in the human. Granulosa cells of the developing follicles appear to secrete factors that regulate theca cell differentiation. Candidate factors that may contribute to theca cell differentiation include insulin-like growth factor (IGF), KITLG, and growth differentiation factor 9 (GDF9). IGF1 induces expression of *LHCGR*, *CYP11A1*, and *HSD3B* type 1 (counterpart of human *HSD3B* type 2), whereas KITLG stimulates *StAR* protein and *CYP17A1* expression in rat theca cells. In mice lacking the *GDF9* gene, a theca layer fails to form in the ovary. Whether GDF9 regulates theca cell recruitment or differentiation directly or indirectly through regulation of preantral granulosa cell development is unknown.

Follicles

The follicle represents the key functional unit in the ovary with respect to germ cell development and steroid production. The follicles are embedded in loose connective tissue

of the ovarian cortex and can be subdivided into two functional types: nongrowing (primordial) and growing. Between 90% and 95% of follicles are nongrowing throughout reproductive life. Recruitment of a primordial follicle initiates dramatic changes in growth, structure, and function. The growing follicles are divided into four stages: primary, secondary, tertiary, and graafian (see Figs. 17-7 and 17-11). The first three stages of growth can occur in the absence of the pituitary and therefore appear to be controlled by intraovarian mechanisms (see Figs. 17-7 and 17-11). The follicle destined to ovulate is recruited during the first few days of the current cycle.⁷⁸

The early growth of follicles occurs over several menstrual cycles, but the ovulatory follicle is one of a cohort recruited at the time of transition from the previous cycle's luteal phase to the current cycle's follicular phase.^{79,80} The total time to achieve preovulatory status is approximately 85 days.^{79,80} Most of this developmental period is FSH independent. Eventually, this cohort of follicles reaches a stage at which, unless recruited by FSH, the next step is atresia. A cohort of follicles measuring 2 to 5 mm in diameter is continuously available for a response to FSH. The late luteal increase in FSH is the critical feature in rescuing this cohort of follicles from atresia; it allows a dominant follicle to emerge and pursue a path to ovulation. The increase in the FSH level must be maintained for a critical period (see Fig. 17-1).⁸¹

Recruited primordial follicles either develop into dominant, mature graafian follicles destined to ovulate or degenerate as a result of atresia.⁸² The average time for development of a selected follicle to the point of ovulation is 10 to 14 days. If a follicle is not recruited, it goes through a process called *atresia*, during which the oocyte and granulosa cells within the basal lamina die and are replaced by fibrous tissue. The theca cells outside the basal lamina do not seem to die but are thought to dedifferentiate and return to the pool of cells consisting of ovarian interstitial or stromal cells.⁵⁶ The process of atresia is thought to result from lack of the hormones or growth factors that are formed by the mature dominant follicle through intrinsic intraovarian mechanisms. There is general agreement that atresia of follicles occurs through apoptosis.⁸³ Apoptosis is an active and regulated process that is triggered by a cascade of caspase proteases that lead to characteristic fragmentation of DNA and eventual cell death.

Ovulation

There is a dramatic rise in circulating estradiol level as midcycle approaches. This is followed by a striking LH surge and, to a lesser extent, an FSH surge, which trigger the dominant follicle to ovulate. During each menstrual cycle, usually one follicle ovulates and gives rise to a corpus luteum. In women, LH or its surrogate hCG is essential to stimulate rupture of the mature follicle. It has been proposed that increased local prostaglandin biosynthesis in the follicle mediates the ovulatory effect of LH.^{84,85}

Ovulation consists of rapid follicular enlargement followed by protrusion of the follicle from the surface of the ovarian cortex. This is followed by the rupture of the follicle and extrusion of an egg-cumulus complex into the peritoneal cavity (Fig. 17-14). Follicular rupture or ovulation occurs predictably 34 to 36 hours after the start of the LH surge. Elevation of a conical *stigma* on the surface of the protruding follicle precedes rupture (see Fig. 17-14). Rupture of this stigma is accompanied by a gentle rather than explosive expulsion of the ovum and antral fluid. A number of transcriptional regulators downstream of the LH

Figure 17-14 Ovulation of the cumulus-oocyte complex through the stigma. (From Erickson GF. An analysis of follicle development and ovum maturation. *Semin Reprod Endocrinol.* 1986; 4:233, Thieme Medical Publishers, New York, with permission.)

receptor are required for ovulation. After the LH surge, progesterone receptor (PR) levels rapidly increase in the mural granulosa cells of the preovulatory follicle.⁵¹ LH- or PR-dependent production of proteases acting locally on protein substrates in the basal lamina may play an important role in stigma formation and follicular rupture.^{86,87} In particular, levels of plasminogen activator increase in the follicle before rupture.⁸⁸ Plasminogen activator-mediated conversion of plasminogen to plasmin may contribute to the proteolytic digestion of the follicular wall, which is a prerequisite for follicular rupture. Gene knockout studies in mice suggest that other factors important for ovulation or follicular rupture include endothelin 2, peroxisome proliferator-activated receptor- γ (PPAR γ), CCAAT/enhancer-binding protein- β , liver receptor homolog 1, steroidogenic factor 1, and nuclear receptor interacting protein 1.⁵¹

Corpus Luteum

After ovulation, the dominant follicle reorganizes to become the corpus luteum (Fig. 17-15). After rupture of the follicle, capillaries and fibroblasts from the surrounding stroma proliferate and penetrate the basal lamina (see Fig. 17-11). This rapid vascularization of the corpus luteum may be guided by angiogenic factors, some of which are detected in the follicular fluid.⁸⁹ Vascular endothelial growth factor has been isolated from corpora lutea and has been postulated, along with basic fibroblast growth factor, to be a potential angiogenic agent in corpora lutea.⁹⁰ Concurrently, the granulosa and theca cells undergo morphologic changes collectively referred to as *luteinization*. The granulosa cells become granulosa-lutein cells (large cells), and the theca cells are transformed into theca-lutein cells (small cells) (see Fig. 17-15).⁹¹ The so-called K cells, scattered throughout the corpus luteum, are believed to be macrophages.

The corpus luteum is the endocrine gland that serves as the major source of sex steroid hormones secreted by the ovary during the postovulatory phase of the cycle. The human corpus luteum secretes as much as 40 mg of

Figure 17-15 Corpus luteum. **A**, Hematoxylin and eosin stain shows the large granulosa-lutein cells occupying the center and smaller theca-lutein cells in the periphery. **B**, Immunoreactive aromatase, a product of the *CYP19A1* gene (brown stain), is the hallmark of granulosa-lutein cells, whereas immunoreactive 17-hydroxylase/17,20-lyase, a product of the *CYP17A1* gene (purple stain), is selectively localized to theca-lutein cells. (Courtesy of Dr. Hironobu Sasansendai, Japan.)

progesterone per day during the midluteal phase of the ovarian cycle.⁹² In view of the small size of the corpus luteum, it is the most active steroidogenic tissue in humans. An important aspect of corpus luteum formation is the penetration of the follicle basement membrane by blood vessels, which provides the granulosa-lutein cells with low-density lipoprotein (LDL)-cholesterol.⁸⁹ LDL-cholesterol serves as the substrate for corpus luteum progesterone production.

A key regulator of steroidogenesis in the corpus luteum is LH. In humans, the LH receptor is maintained throughout the functional life span of the corpus luteum and not downregulated during the maternal recognition of pregnancy.⁹³ The rate-limiting step in LH-mediated progesterone formation in luteinized granulosa cells is the entry of cholesterol into the mitochondria, which is regulated by the StAR protein.⁹⁴ The availability of LDL-cholesterol and the StAR-mediated mitochondrial entry of cholesterol into the mitochondria seem to be the two critical factors that account for the production of large amounts of progesterone in the corpus luteum.

The functional life span of the corpus luteum is normally 14 ± 2 days, after which it spontaneously regresses. Unless pregnancy occurs, the corpus luteum is replaced by an avascular scar referred to as the *corpus albicans*.

Factors that may regulate luteal life span include hormones such as hCG, maintenance of luteal vascularization, and immune cells.⁹⁵ There is little doubt about the central role of LH in the maintenance of corpus luteum function. Withdrawal of LH support in a variety of experimental circumstances has almost invariably resulted in luteal regression.⁹⁵ In pregnancy, however, the LH surrogate hCG, secreted by the gestational trophoblast, maintains the ability of the corpus luteum to elaborate progesterone; this stimulus helps to maintain the early gestation until the luteoplacental shift.⁹⁶ The corpus luteum doubles in size (compared with the prepregnancy size) during the first 6 weeks of gestation (see Fig. 17-15). This increase results from proliferation of connective tissues and blood vessels, along with hypertrophy of the luteinized granulosa and theca cells. This early hypertrophy is followed by regression. The corpus luteum at term is only one half of its size during the menstrual cycle.

Hormones such as estrogens and prostaglandins have been suggested to be important factors in the promotion

of luteal demise.^{97,98} Immune factors may influence luteal life span because corpus luteal regression is associated with a progressive infiltration of lymphocytes and macrophages.⁹⁵

Apoptosis is a critical end-point mechanism by which human corpora lutea are deleted. Corpora lutea during the early luteal phase of the menstrual cycle and the corpora lutea of early pregnancy show no evidence of apoptotic DNA fragmentation.⁹⁹ DNA fragmentation is detected in midluteal and late luteal corpora.⁹⁹ LH or hCG inhibits apoptosis in the corpus luteum. In the absence of these trophic factors, apoptosis ensues. The remaining corpus luteum, the corpus albicans, is composed of dense connective tissue.

Ovarian Follicle-Stimulating Hormone and Luteinizing Hormone Receptors

The FSH receptor is expressed exclusively by granulosa cells. The LH or hCG receptor (LHCGR) is expressed primarily by the theca-interstitial cells of all follicles and by granulosa cells of large preovulatory follicles.

Granulosa cells in primary or secondary follicles that are in the early developmental stages before antrum formation primarily bind FSH but not LH. In these preantral follicles, the binding of LH or hCG is confined to theca-interstitial cells.¹⁰⁰ Granulosa cells in more mature tertiary follicles with an antrum appear capable of binding both LH and FSH. The FSH receptors are found in granulosa cells from follicles of all sizes, but LH receptors are found only in granulosa cells of large preovulatory follicles.¹⁰¹⁻¹⁰³ These observations are consistent with the concept that the acquisition of LH receptors on granulosa cells is under the influence of FSH.^{104,105}

The receptors for the glycoprotein hormones have related structures (Fig. 17-16). The receptors belong to the large family of G protein-coupled receptors, whose members all have a transmembrane domain that consists of seven membrane-traversing α -helices connected by three extracellular and three intracellular loops (see Fig. 17-16). The glycoprotein hormone receptors form a separate subgroup within this large family by virtue of their large extracellular hormone-binding domain at the N-terminus. FSH binds to the FSH receptor, and LH and hCG bind to the same LH receptor. The LH and FSH

Figure 17-16 Gonadotropin receptor. The seven-transmembrane domain, G protein-coupled receptors for luteinizing hormone and follicle-stimulating hormone that are located in the membranes of ovarian granulosa and theca cells typically have large extracellular domains. (From Bulun SE, Simpson ER, Mendelson CR. The molecular basis of hormone action. In: Carr BR, Blackwell RE, eds. *Textbook of Reproductive Medicine*, 2nd ed. Stamford, CN: Appleton & Lange; 1998:137-156.)

receptor genes are located on chromosome 2 in the p21 region.⁴⁹ The relation of the glycoprotein hormone receptors to the other G protein-coupled receptors is indicated by their sequence homology in the C-terminal half of the receptor. This domain, encoded by a single, last exon, contains the seven-transmembrane segments and the G protein-coupling domain. The unusually large extracellular domain of the glycoprotein hormone receptors is encoded by the first 9 or 10 exons (Fig. 17-17).

Role of Follicle-Stimulating Hormone in Ovarian Function. FSH is the main promoter of follicular maturation. Given that FSH receptors have been exclusively localized to granulosa cells, it is presumed that FSH action in the ovary involves the granulosa cells. The ability of FSH to orchestrate follicular growth and differentiation depends on its ability to exert multiple actions concurrently.

Phenotypes of women with mutations that disrupt the function of the FSH β -subunit gene are in good agreement and demonstrate that FSH is necessary for normal follicular development, ovulation, and fertility.⁴⁹ Pubertal development is hampered in the absence of sufficient numbers of later-stage follicles with the granulosa cells needed for adequate estrogen production. Treatment of affected patients with exogenous FSH has resulted in follicular maturation, ovulation, and normal pregnancy.⁴⁹ The presenting phenotype of FSH β -subunit deficiency is practically identical to that caused by inactivating mutations of the FSH receptor.⁴⁹

Women with FSH receptor mutations are clinically similar to patients with gonadal dysgenesis; they have absent or poorly developed secondary sexual characteristics and high serum levels of FSH and LH. The notable difference is the presence of ovarian follicles in women with mutated FSH receptors, consistent with the FSH independence of primordial follicle recruitment and early follicular growth and development. Total absence of any follicles, including those in the primordial stage, occurs in people in whom the FSH receptor mutation cannot be

demonstrated.⁴⁹ The ovarian phenotype of FSH receptor deficiency is distinct from the common form of gonadal dysgenesis (Turner's syndrome), which is characterized by streak gonads and an absence of growing follicles.⁴⁹

In vivo rodent studies suggest that FSH is capable of increasing the number of its own receptors in the granulosa cell. Whereas estradiol by itself may be without effect on the distribution, number, or affinity of granulosa cell FSH receptors, estrogens synergize with FSH to enhance the overall number of granulosa cell FSH receptors.¹⁰⁶ Changes in the production of estradiol by preantral follicles can increase their response to FSH through regulation of granulosa cell surface FSH receptors. This interaction between FSH and estradiol in follicular development has been well established in rodents. It appears that ER α and ER β mediate the estrogenic effect on ovarian development and follicular maturation in mice.¹⁰⁷ However, it is not clear whether a similar relationship exists in the human ovary. ER α is not detected in the human ovary in significant quantities. Nevertheless, the demonstration of ER β in the human ovary suggests an interaction between FSH and estrogen in the regulation of normal follicle development and ovulation in women.¹⁰⁸

One of the major actions of FSH is induction of granulosa cell aromatase activity.^{109,110} Little or no estrogen can be produced by FSH-unprimed granulosa cells even if they are supplied with aromatizable androgen precursors. Treatment with FSH enhances the aromatization capability of granulosa cells, an effect related to enhancement of the granulosa cell aromatase content.^{111,112}

Treatment with FSH has also been shown to induce LH receptors in granulosa cells. The ability of FSH to induce LH receptors is augmented by the concomitant presence of estrogens.¹¹³ Progestins, androgens, and LH itself may also induce LH receptors. After induction, the granulosa cell LH receptor requires the continued presence of FSH for its maintenance.

Circumstantial evidence, deduced from studies of women with disrupting mutations of the genes that encode FSH and LH receptors and aromatase (CYP19A1), indicates that FSH action, but not estrogen or LH action, is essential for follicular growth in humans.^{49,114} Follicular growth and development up to the antral stage was observed in women with deficient LH action or estrogen biosynthesis, although these individuals were anovulatory.^{49,114} Women with mutations of the FSH β -subunit or FSH receptor have only primordial follicles in their ovaries.⁴⁹ These data indicate that estrogen or LH is not critical for follicular development at least until the tertiary stage (see Figs. 17-11 and 17-12). However, FSH by itself is not sufficient to achieve normal follicular development and ovulation.

Role of Luteinizing Hormone in Ovarian Function. LH is essential for ovulation (follicular rupture) and the sustenance of corpus luteum function; in addition, it plays other important roles in follicular function. First, LH probably plays a major role in the promotion of theca-interstitial cell androgen production. Second, LH may well synergize with FSH in the more advanced phases of follicular development. Third, small and sustained increments in the circulating levels of LH are necessary and sufficient to cause small antral follicles to grow and develop to the preovulatory stage.^{115,116}

It is presumed that LH acts on the theca-interstitial cells of small follicles, where it promotes the biosynthesis of C19 steroids.¹¹⁷ The consequent increase in estrogen production is presumed to contribute to the growth and development of the follicles. Treatment with small doses of LH

Figure 17-17 Human gonadotropin receptor genes. **A** and **B**, The structure of the genes is depicted at the top of the drawings. The open bars indicate sections of the exons that encode untranslated regions of the messenger ribonucleic acid; the closed bars indicate the sequences that encode the protein. Both genes are at least 80 kb long. The relation between the intron-exon structure of the gene and the domains on the protein is indicated by the lines connecting the gene to the protein. The horizontally hatched part of the protein indicates the signal peptide, and the cross-hatched bars signify the seven segments of the transmembrane domain. The numbers below the protein indicate the start and end of the signal peptide and the length of the total protein product, including the signal peptide. The receptor genes are similar in structure, with the exception of an additional exon in the luteinizing hormone (LH) receptor gene. Exon 1 encodes the signal peptide and a small part of the extracellular domain; the next eight or nine exons encode the rest of the extracellular domain, including the leucine-rich repeat motifs. In both receptor genes, the final exon is the largest and contains the information for the transmembrane signal transduction domain. FSH, follicle-stimulating hormone. (From Themmen APN, Huhtaniemi IT. Mutations of gonadotropins and gonadotropin receptors: elucidating the physiology and pathophysiology of pituitary-gonadal function. *Endocr Rev.* 2000;21:4551-583. Copyright © 2000 by The Endocrine Society.)

also presumably results in an increase in LH receptor content and in induction of the key steroidogenic proteins such as StAR, CYP11A1, HSD3B2, and CYP17A1.

The role of LH action in human ovarian physiology was exemplified by the phenotype of a woman with a disrupting mutation of the LH receptor gene.⁴⁹ She presented with amenorrhea, normally developed secondary sexual characteristics, increased circulating FSH and LH levels, and low levels of estradiol and progesterone that were unresponsive to hCG treatment.⁴⁹ The ovary contained follicles that developed up to antral stage with a well-developed theca layer but no preovulatory follicles or corpora lutea. These observations collectively support the view that LH is essential for ovulation and sufficient estrogen production, whereas follicular development is initially autonomous but at later stages depends on intact FSH action.

Ovarian Steroidogenesis

The steroid hormone contents of the ovarian vein effluents and peripheral venous blood were compared to distinguish steroids secreted by the ovary from those secreted by the adrenal or produced by peripheral conversion of precursors.¹¹⁸ These studies revealed that the ovaries secrete pregnenolone, progesterone, 17 α -hydroxyprogesterone, dehydroepiandrosterone (DHEA), androstenedione, testosterone, estrone, and estradiol.¹¹⁹ Although such measurements provide insights into the steroidogenic pathways

under study, they do not identify the specific ovarian cells involved. Studies using microdissected preovulatory follicles identified estrone and estradiol as the major steroid products (Fig. 17-18). Progesterone and 17 α -hydroxyprogesterone proved to be the major products of the corpus luteum (see Fig. 17-18).

The general steroidogenic pathway for the production of estrogens and androgens is depicted in Figure 17-18. The biologically active ovarian steroids are estradiol and progesterone. The major C19 steroid product of the ovary, androstenedione, is not biologically active. However, it acts as a dual precursor and contributes to circulating levels of estrone and testosterone through conversion in extraglandular tissues such as adipose tissue and skin (discussed later).¹²⁰⁻¹²² It is likely that estrogenically weak estrone is further converted to the potent estrogen estradiol and androgenically weak testosterone is converted to the potent androgen dihydrotestosterone (DHT) locally in target tissues such as brain, breast, prostate, and genital skin and subsequently exert potent biologic effects.¹²² This notion is supported by the presence in many human tissues of multiple proteins with overlapping enzymatic activities that catalyze these conversions (e.g., reductive 17 β -HSD and 5 α -reductase).¹²³

The preovulatory follicle secretes estradiol during the first half of the menstrual cycle, and the corpus luteum secretes estradiol and progesterone during the second half of the cycle. The production of these two biologically

Figure 17-18 Steroidogenic pathway in the human ovary. The biologically active steroids progesterone and estradiol are produced primarily in the ovary of a woman of reproductive age. Estradiol production requires the activity of six steroidogenic proteins, including StAR, and six enzymatic steps. 17-Hydroxylase/17,20-lyase, the product of the *CYP17A1* gene, catalyzes two enzymatic reactions. The four rings of the cholesterol molecule and its derivative steroids are identified by the first four letters in the alphabet, and the carbons are numbered in the sequence shown in the insert. CYP17A1, 17-hydroxylase/17,20-lyase; CYP19A1, aromatase; HSD17B1, 17 β -hydroxysteroid dehydrogenase type I; HSD3B2, 3 β -hydroxysteroid dehydrogenase- Δ^5 isomerase type 2; StAR, steroidogenic acute regulatory protein.

active steroids is orchestrated in the follicle and corpus luteum in a cell-specific manner that is under the control of LH and FSH.

Steroids formed by the ovary and other steroid-producing organs are derived from cholesterol (see Fig. 17-18). Several sources of cholesterol can provide the ovary with substrate for steroidogenesis, including plasma lipoprotein cholesterol, cholesterol synthesized de novo within the ovary, and cholesterol from intracellular stores of cholesterol esters within lipid droplets. In the human ovary, LDL-cholesterol is an important source of cholesterol used for steroidogenesis.⁹² LH stimulates the activity of adenylate cyclase, increasing production of cyclic adenosine monophosphate (cAMP), which serves as a second messenger to increase LDL receptor mRNA, binding and uptake of LDL-cholesterol, and the formation of cholesterol esters.^{91,92} LDL-derived cholesterol is particularly essential for normal levels of progesterone production in the granulosa-lutein cells of the corpus luteum.⁹²

Steroidogenic Genes and Their Functions in the Ovary

The first and rate-limiting step in the synthesis of all ovarian steroid hormones is the movement of cholesterol

into the mitochondrion, which is regulated by the StAR protein encoded by the *STAR* gene (see Fig. 17-18).¹²⁴ This movement is followed by conversion of cholesterol to pregnenolone, which is catalyzed by the mitochondrial side-chain cleavage enzyme complex consisting of CYP11A1, adrenodoxin, and flavoprotein. LH induces steroidogenesis by increasing intracellular cAMP, which increases the conversion of cholesterol to pregnenolone in two distinct ways: acute regulation, which occurs over minutes through phosphorylation of preexisting StAR and rapid synthesis of new StAR, and chronic stimulation, which occurs within hours to days through the induction of CYP11A1 expression and consequent increased steroidogenesis (Fig. 17-19). StAR increases the flow of cholesterol to mitochondria, regulating substrate availability to CYP11A1 on the inner mitochondrial membrane.¹²⁴ In the absence of StAR, only 14% of the maximal StAR-induced level of steroidogenesis persists as StAR-independent steroidogenesis.¹²⁴

StAR expression in the preovulatory graafian follicle is limited primarily to the theca cells (see Fig. 17-19).¹²⁵ The most important product of the theca cell during the follicular phase is the estrogen precursor androstenedione, and its production is thought to be controlled primarily by StAR. The biologically active steroid product of the ovary

Figure 17-19 Two-cell hypothesis for ovarian steroidogenesis. **A**, The preovulatory follicle produces estradiol through a paracrine interaction between theca and granulosa cells. In response to stimulation with a gonadotropin, steroidogenic factor 1 (SF-1, a member of the nuclear receptor family) acts as a master switch to initiate transcription of a series of steroidogenic genes in theca cells. In follicular granulosa cells, another nuclear receptor, liver homolog receptor 1 (LRH-1), seems to primarily mediate the downstream effects of follicle-stimulating hormone (FSH) in the rodent ovary.^{133,134} In humans, the roles of SF-1 and LRH-1 in steroidogenesis in preovulatory granulosa cells are not well understood. Because granulosa cells do not have a direct connection to the circulation, CYP19A1 (aromatase) in granulosa cells depends for substrate on androstenedione that diffuses from theca cells. Two critical steps in estradiol formation are the entry of cholesterol into mitochondria facilitated by steroidogenic acute regulatory protein (STAR) in theca cells and the conversion of androstenedione to estrone catalyzed by CYP19A1 in granulosa cells. **B**, In the corpus luteum, granulosa-lutein cells are heavily vascularized, a condition that is critical for entry of abundant quantities of cholesterol into this cell type through primarily low-density lipoprotein (LDL)-cholesterol receptors and for secretion of large amounts of progesterone into the circulation. The entry of cholesterol into mitochondria (mediated by STAR) is probably the most critical steroidogenic step for progesterone formation in granulosa-lutein cells. Androstenedione produced in theca-lutein cells serves as a substrate for estrone, which is further converted to estradiol in granulosa-lutein cells. Human data suggest that LRH-1 may mediate at least a portion of gonadotropin-dependent steroidogenesis in the corpus luteum.¹³⁶ Gonadotropins, SF-1, and possibly LRH-1 play key roles for important steroidogenic steps in the ovary. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FSHR, FSH receptor; HSD, hydroxysteroid dehydrogenase; LHCGR, LH receptor.

during the follicular phase is estradiol, which arises from the granulosa cells located adjacent to theca cells. The rate-limiting step for granulosa cell estradiol production is regulated by the FSH-dependent activity of the aromatase enzyme in a cyclic fashion.¹¹⁰ During the luteal phase, cells of the corpus luteum, including granulosa-lutein cells, also show intense StAR immunoreactivity with a patchy distribution.^{94,125} The delivery of cholesterol to the mitochondrial side-chain cleavage enzyme system in the corpus luteum is the rate-limiting step for progesterone biosynthesis and is regulated by StAR.⁹⁴ Estradiol production seems to be regulated primarily by StAR and CYP19A1, whereas progesterone biosynthesis may be primarily under the control of StAR.

The ovarian granulosa, theca, and corpus luteum cells possess StAR plus five distinct proteins with specific enzyme activities for steroid hormone formation. These steroidogenic enzymes are CYP11A1 (side-chain cleavage of P450), HSD3B2 (3 β -hydroxysteroid dehydrogenase- $\Delta^{5,4}$ isomerase type 2), CYP17A1 (17-hydroxylase/17,20-lyase), CYP19A1 (aromatase P450), and HSD17B1 (17 β -hydroxysteroid dehydrogenase type 1).¹²⁶ These enzymes are responsible for the conversion of cholesterol to the two major biologically active products: estradiol and progesterone.¹²⁷

Steroidogenesis that depends on LH and FSH in theca and granulosa cells is mediated by common signaling molecules, including cAMP and the specific transcription factors steroidogenic factor 1 (SF1), product of the *NR5A1* gene, and liver receptor homolog 1 (LRH1), product of the *NR5A2* gene, which belong to the nuclear receptor family (see Fig. 17-19).^{128,129} SF1 and LRH1 regulate the expression of genes that encode StAR, CYP11A1, HSD3B2, CYP17A1, and CYP19A1 (see Fig. 17-19). SF1 and possibly LRH1 can be regarded as downstream master switches that orchestrate ovarian steroidogenesis.¹²⁹

All steroid hormones are derived from cholesterol. C27 cholesterol is converted to the 18-, 19-, and 21-carbon steroid hormones that are secreted by the ovary.

C21 Steroids. The principal progestogens are C21 steroids and include pregnenolone, progesterone, and 17-hydroxyprogesterone (see Fig. 17-18). Pregnenolone is of primary importance in the ovary because of its key position as a precursor of all steroid hormones. Progesterone, the principal secretory product of the corpus luteum, is responsible for the progestational effects (i.e., cell differentiation and induction of secretory activity in the endometrium of the estrogen-primed uterus). Progesterone is essential for implantation of the fertilized ovum and maintenance of pregnancy. It also induces decidualization of the endometrium, inhibits uterine contractions, increases the viscosity of cervical mucus, promotes lateral (alveolar) development of the breast glands, and increases basal body temperature. However, 17-hydroxyprogesterone, also secreted by the corpus luteum, is thought to have little or no biologic activity.

C19 Steroids. The ovary secretes a variety of C19 steroids, including DHEA, androstenedione, and testosterone (see Fig. 17-18). They are produced by the theca cells and, possibly, to a lesser degree by the ovarian stroma. The major C19 steroid is androstenedione, part of which is secreted directly into plasma, with the remainder converted to estrogen by the granulosa cells. DHEA and androstenedione do not appear to have major androgenic actions. In the ovary and in peripheral tissues, DHEA is converted to androstenedione, which can be converted to estrone or testosterone. Testosterone is converted locally to DHT at target tissues for full androgenic action.

C18 Steroids. The naturally occurring estrogens are C18 steroids characterized by the presence of an aromatic A ring, a phenolic hydroxyl group at C3, and a hydroxyl group (estradiol) or a ketone group (estrone) at C17. Aromatase is the key enzyme for estrogen production in the ovary (see Fig. 17-18). The protein aromatase P450, encoded by the *CYP19A1* gene, confers the specific activity of the aromatase enzyme complex. CYP19A1 production in the ovarian granulosa cell is regulated primarily by FSH.¹²⁶ The principal and most potent estrogen secreted by the ovary is estradiol. Although estrone is also secreted by the ovary, another important source of estrone is extraglandular conversion of androstenedione in peripheral tissues.¹³⁰ Estriol (16-hydroxyestradiol) is the most abundant estrogen in urine and is produced by metabolism of estrone and estradiol in extraovarian tissues. All C18 steroids, including estrone, estradiol, and estriol, are commonly referred to as estrogens. However, estrone and estriol are only weakly estrogenic and must be converted to estradiol to show full estrogenic action. At least seven enzymes with overlapping activities are capable of converting estrone to estradiol in the ovary and extraovarian tissues.¹³¹

Catechol estrogens are formed by hydroxylation of estrogens at the C2 or C4 position. The physiologic role of catechol estrogen, if any, is unclear. Low body weight and hyperthyroidism are associated with increased formation of catechol estrogens.¹³² Estrone sulfate, formed by peripheral conversion of estradiol and estrone, is the most abundant estrogen in blood, but it is not physiologically active. Estrone sulfate is presumed to serve as a reservoir for estrone formation in a number of tissues, including those that are targets of estrogen. Estradiol regulates gonadotropin secretion, development of the secondary sexual characteristics of women, uterine growth, thickening of the vaginal mucosa, thinning of the cervical mucus, linear growth of the ductal system of the breast, growth spurt, epiphyseal closure, and bone mineralization.

Two-Cell Theory for Ovarian Steroidogenesis

The classic two-cell theory is supported by molecular findings. Ovarian steroidogenesis in the preovulatory follicle takes place through LH receptors on theca cells and FSH (possibly also LH) receptors on granulosa cells (see Fig. 17-19). cAMP production and increased SF1 binding to multiple steroidogenic promoters mediate LH action in theca cells. The StAR protein is the primary regulator of production of androstenedione, which subsequently diffuses into granulosa cells to serve as the estrogen precursor. In the preovulatory follicle, cholesterol in theca cells arises from circulating lipoproteins and de novo biosynthesis. FSH is responsible for follicular growth and estrogen formation. FSH induces cAMP formation, activation of protein kinase A and certain mitogen-activated protein kinases, and increased binding activity of LRH1 or SF1 to the *CYP19A1* promoter in preovulatory granulosa cells to form estradiol primarily through aromatization of androstenedione (see Fig. 17-19). The relative roles of SF1 and LRH1 in estrogen formation in human ovarian granulosa cells are not well understood.¹³³⁻¹³⁵

In the corpus luteum, large deposits of cholesterol (which provides the yellow color) arise primarily from circulating lipoproteins to support the production of extremely high quantities of progesterone. Other key anatomic events in formation of the corpus luteum are the disruption of the basement membrane between the granulosa and theca cells and strikingly increased vascularization of granulosa-lutein cells (see Fig. 17-15). Theca-lutein cells possess LH receptors and produce androstenedione. Cyclic

AMP, SF1, and StAR induced by LH remain as the key regulators for biosynthesis of androstenedione, which serves as the estrogen precursor in neighboring granulosa-lutein cells (see Fig. 17-19).

The granulosa-lutein cell of the corpus luteum is anatomically and functionally different from its counterpart in the preovulatory follicle in several ways. First, these cells are luteinized and heavily vascularized and contain large quantities of cholesterol. Second, granulosa-lutein cells contain high levels of LH receptors in addition to FSH receptors. Third, they produce large quantities of progesterone that is regulated primarily by LH and StAR. Granulosa-lutein cells also aromatize androstenedione of thecal origin and eventually give rise to estradiol formation through FSH action and CYP19A1. The known mediators of LH and FSH in human granulosa-lutein cells are cAMP and increased LRH1 levels.¹³⁶ The relative roles of LRH1 and SF1 for progesterone and estradiol production in granulosa-lutein cells are not clear. Specific functions of the two gonadotropins (i.e., differentiation, growth, and progesterone formation versus estradiol formation) are probably determined by as yet unidentified modifying factors (see Fig. 17-19).

Peptide Hormones Produced by the Ovary

The ovary produces a large number of peptides that can act in an intracrine, autocrine, paracrine, or endocrine fashion. They include numerous growth factors (e.g., insulin-like growth factors [IGFs]) and cytokines (e.g., interleukin-1 β). IGFs cross-talk with the FSH-dependent signaling cascade to augment the effects of FSH in granulosa cells.

These peptides, including inhibin, activin, and follistatin, are produced in ovarian granulosa cells under the control of FSH and LH (Fig. 17-20). Production of inhibin and activin is not limited to the ovary; a number of other tissues, including adrenal, pituitary, and placenta, synthesize these peptides. Two isoforms of inhibin have been

isolated: inhibin A and inhibin B. They contain an identical α -subunit but distinct β -subunits (β_A and β_B), encoded by separate genes. The heterodimers of inhibin, $\alpha\beta_A$ and $\alpha\beta_B$, are called inhibin A and inhibin B, respectively (see Fig. 17-20). Although inhibin is produced by a number of tissues in the body, most of it is derived from the gonads. In the ovary, the source of inhibin is granulosa cells. The main role of inhibin is to suppress FSH production in the pituitary.

Although both inhibin isoforms seem to have similar biologic properties, their synthesis is regulated differently during the follicular and luteal phases (see Fig. 17-1A). Under the influence of FSH, inhibin B is secreted mainly during the early follicular phase, with levels decreasing in midfollicular phase and becoming undetectable after the LH surge.¹³⁵ LH-induced inhibin A levels are low during the first half of the follicular phase but increase gradually during midfollicular phase and peak during the luteal phase. All three subunits are detected in small antral follicles by immunohistochemistry and in situ hybridization.^{137,138} The α - and β_A -subunits are found in the dominant follicle and in the corpus luteum. All three subunits are expressed in response to gonadotropins or factors that increase intracellular cAMP.¹³⁹

Activin is structurally related to inhibin but exerts opposite actions. Activin contains two subunits that are identical to the β -subunits of inhibins A and B. The three activin isoforms are activin A ($\beta_A\beta_A$), activin B ($\beta_B\beta_B$), and activin AB ($\beta_A\beta_B$). In the pituitary, activin stimulates the release of FSH. In the ovarian follicle, activin enhances FSH action (see Fig. 17-20). As in the case of inhibin, activins are also produced in ovarian granulosa cells and pituitary gonadotrophs. Unlike inhibin, locally synthesized activin in the pituitary, rather than the ovarian-derived activin, is responsible for regulating FSH (see Fig. 17-4).

Follistatin is a single-unit peptide that is produced in several human tissues, including the pituitary and ovary (see Fig. 17-20). It binds and neutralizes the biologic

Figure 17-20 Structures of inhibin subunit precursors and processed forms in serum, the activins and the follistatins. The precise contribution of each molecular-weight form of inhibin to the biologic activity in serum is not known, but it has been established that the 55-kd and 32-kd forms are biologically active. (Modified from Burger H. Inhibin, activin and neoplasia. In: Yen SC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology*, 4th ed. Philadelphia, PA: Saunders; 1999:669-675.)

functions of activin. It appears that local follistatin levels in tissues modulate the effects of activin. This explains the inhibitory effect of follistatin on pituitary FSH secretion (see Fig. 17-4).

Overview of the Hormonal Changes during the Ovarian Cycle

FSH secretion is suppressed by negative feedback of the ovarian hormones estradiol, inhibin, and progesterone during the early and midluteal phase. The sharp decline of these hormones on regression of the corpus luteum during the late luteal phase abolishes this negative feedback (see Fig. 17-1A). This permits increased secretion of FSH just before and during menses. This initial increase in FSH is essential for follicle recruitment and growth and steroidogenesis. With continued growth of the follicle, autocrine and paracrine factors produced within the follicle maintain follicular sensitivity to FSH. Continuing and combined action of FSH and activin leads to the appearance of LH receptors on the granulosa cells, a prerequisite for ovulation and luteinization.

Ovulation is triggered by the rapid rise in circulating levels of estradiol. A positive feedback response at the level of the anterior pituitary and possibly at the hypothalamus results in the midcycle surge of LH that is necessary for expulsion of the egg and formation of the corpus luteum (see Fig. 17-1A). A rise in the progesterone level follows ovulation, along with a second rise in the estradiol level, producing the 14-day-long luteal phase characterized by low FSH and LH levels. Demise of the corpus luteum concomitant with a fall in hormone (progesterone, estradiol, and inhibin A) levels allows FSH to increase again toward the end of the luteal phase, initiating a new cycle. If pregnancy is established by implantation of a blastocyst, the structural integrity and function (i.e., progesterone and estradiol production) of the corpus luteum are maintained by hCG secreted from the trophoblast. The hCG acts as a surrogate for LH on the corpus luteum.

In addition to FSH and LH, local factors (e.g., activin, inhibin) regulate follicular development and steroidogenesis. In the early follicular phase, activin produced by granulosa cells in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation while simultaneously suppressing C19-steroid formation in theca cells. In the late follicular phase, increased production of inhibin by the granulosa cells and decreased activin levels promote the synthesis of C19 steroids in the theca layer in response to LH and local growth factors and cytokines; this provides larger amounts of the precursor androstenedione for production of estrone and ultimately of estradiol in the granulosa cells.¹⁴⁰

LH-mediated androstenedione production in theca cells and FSH-mediated estradiol production in granulosa cells are potentiated by IGFs.¹⁴¹ The major endogenous IGF produced in the human ovarian follicle is IGF2 (rather than IGF1), which is produced by granulosa and theca cells. The actions of IGF1 and IGF2 are mediated by IGF receptor type 1 in both cells. IGF receptor type 1 is structurally similar to the insulin receptor. It appears that gonadotropin-related IGF action in the ovary is regulated primarily by IGF2 and IGF receptor type 1.¹⁴¹

In summary, ovulation is under the control of substances functioning as classic hormones (i.e., FSH, LH, estradiol, and inhibin), which transmit messages between the ovary and the hypothalamic-pituitary axis and of paracrine and autocrine factors such as IGF2, inhibin, and activin, which coordinate sequential activities within the

follicle destined to ovulate. The negative feedback relationship between corpus luteum products (i.e., estradiol, progesterone, and inhibin) and FSH results in the critical initial rise in FSH immediately before and during menses, and the positive feedback relationship between estradiol and LH is responsible for the ovulatory stimulus (see Fig. 17-1). Within the ovary, IGF2, inhibin, and activin modify follicular responses necessary for growth and function. These endocrine, paracrine, and autocrine factors undoubtedly represent only a portion of the complete picture. The causes of anovulation are diverse and may be related to defects in cell surface receptors, intracellular elements of signal transduction, or cell-cell interactions.^{142,143}

Extraovarian Steroidogenesis

Estradiol formation takes place in several tissues in the woman of reproductive age, including the ovary, peripheral tissues such as subcutaneous fat and skin, and physiologic and pathologic target sites such as the hypothalamus, breast cancer cells, and the cells of endometriosis (Fig. 17-21).¹²² The latter two sources of estrogen are particularly critical in anovulatory premenopausal and postmenopausal women. Although only small quantities of estrogen are produced by an individual adipocyte or skin fibroblast in a continuous fashion, these cell types contribute to circulating estradiol levels because of their relative

Figure 17-21 Estrogen biosynthesis in women. The biologically active estrogen, estradiol (E_2), is produced in at least three major sites: (1) by direct secretion from the ovary in reproductive-age women; (2) by conversion of circulating androstenedione (A), originating from the adrenal or ovary or both, to estrone (E_1) in peripheral tissues; and (3) by conversion of A to E_1 in estrogen target tissues. In the latter two instances, estrogenically weak estrone (E_1) is converted to E_2 within the same tissue. The expression of genes that encode the enzymes aromatase and reductive 17 β -hydroxysteroid dehydrogenases (17 β -HSD) is critical for E_2 formation at these sites. Reductive 17 β -HSD activity in peripheral tissues may be conferred by protein products of several genes with overlapping functions. HSD17B1 is a distinct reductive 17 β -HSD enzyme that is encoded by a specific gene expressed primarily in the ovary. Aromatase is encoded by a single gene (*CYP19A1*). E_2 formation by peripheral and local conversion is particularly important in postmenopausal women and in those with estrogen-dependent diseases such as breast cancer, endometriosis, or endometrial cancer.

abundance.¹²² This effect is more pronounced in obese women because of increased mass of the adipose tissue and skin.¹²⁰

Aromatase (CYP19A1) in adipocytes and skin fibroblasts is responsible for peripheral aromatization of androstenedione that arises from the ovary and the adrenal in premenopausal women and primarily from the adrenal in postmenopausal women (see Fig. 17-21).¹²² However, the product of this reaction, estrone, is only weakly estrogenic. Estrone is further converted to estrone sulfate, which serves as a reservoir for estrone in blood and other tissues. Estrone (arising from androstenedione and estrone sulfate) is further converted to the biologically active estradiol in target tissues such as the endometrium and breast by a number of enzymatic proteins with overlapping reductive 17 β -HSD activity (see Fig. 17-21).^{131,144,145} It is likely that local CYP19A1 expression in hypothalamus is critical for the regulation of gonadotropin secretion.¹⁴⁶ Estrogen-dependent pathologic tissues such as those in breast cancer and endometriosis contain extremely high levels of CYP19A1 that enhances tissue growth by increasing local estradiol concentrations (see Fig. 17-21).¹²² Circulating androstenedione is the major substrate for aromatase activity in these physiologic and pathologic target tissues.^{144,147}

Significant quantities of circulating androstenedione can also be converted to testosterone in peripheral tissues (discussed later). This is probably accomplished by the presence of multiple 17 β -HSDs with overlapping reductive activities in peripheral tissues.¹³¹ Androgenic action of testosterone is strikingly amplified by its conversion to DHT in peripheral and target tissues (e.g., skin, prostate). At least two distinct proteins encoded by two separate genes, 5 α -reductase type 1 and type 2, catalyze the conversion of testosterone to DHT in liver, prostate, and skin.¹²³ Local production of DHT in genital skin fibroblasts is critical for normal masculinization of external genitalia of male fetuses in utero.¹²³ DHT formation in the skin is an important cause of hirsutism.¹⁴⁸

ENDOMETRIUM

The endometrium is the mucosal lining of the uterine cavity. The decidua is the highly modified and specialized endometrium of pregnancy. From an evolutionary perspective, the human endometrium is highly developed to accommodate the hemochorioendothelial type of placentation, which requires the presence of spiral arteries (Fig. 17-22). Trophoblasts of the blastocyst invade spiral arteries during implantation and placentation in the establishment of uteroplacental vessels.

Spiral arteries of the human endometrium confer another unique process, *menstruation*. Menstruation is shedding of endometrial tissue with hemorrhage that depends on sex steroid hormone-directed changes in blood flow in the spiral arteries. Spiral arteries are essential for menstruation; only humans and a few other primates that have endometrial spiral arteries experience menstruation. With nonfertile but ovulatory ovarian cycles, menstruation affects desquamation of the endometrium. New endometrial growth and development must be initiated with each ovarian cycle, so endometrial maturation corresponds with the next opportunity for pregnancy. There seems to be a narrow window of endometrial receptivity to blastocyst implantation, comprising the period between days 20 and 24 during a 28-day menstrual cycle.¹⁴⁹

Figure 17-22 Functional anatomy of the endometrium. Endometrium is a multilayered mucosa specialized for implantation and support of pregnancy. A single, continuous layer of epithelial cells lines the surface of the stroma and penetrates the stroma with deep invaginations almost all the way down to the myometrium-endometrium junction. The entire thickness of the endometrium is penetrated by the spiral arteries and their capillaries. Spiral arteries originate from the radial branches of arcuate arteries, which arise from uterine arteries. The superficial layer (functionalis) is shed during menstruation, whereas the permanent bottom layer (basalis) gives rise to the regeneration of endometrium after each menstruation. The striking changes in the spiral arteries (i.e., coiling, stasis, and vasodilatation followed by intense vasoconstriction) are consistently observed before the onset of every menstruation episode. (Courtesy of Dr. Kristof Chwalisz, North Chicago, Illinois.)

Functional Anatomy of the Endometrium

The endometrium can be divided morphologically into an upper two-thirds *functionalis* layer and a lower one-third *basalis* layer (see Fig. 17-22). The purpose of the functionalis layer is to prepare for the implantation of the blastocyst; it is the site of proliferation, secretion, and degeneration. The purpose of the basalis layer is to provide the regenerative endometrium after menstrual loss of the functionalis.¹⁵⁰ Major histologic components of the endometrium include stromal cells, which constitute the skeleton of the tissue; a single layer of epithelial cells, which lines the lumen of the endometrial cavity and invaginations of the stroma; blood vessels; and resident immune cells. The epithelial cells that line the rather deep invaginations of the stroma are also referred to as *glandular cells*. However, these deep crypts represent extensions of the intracavitary lumen and are not true glands. These invaginations lined by epithelial cells extend from the surface of the functionalis layer (i.e., luminal epithelium) deep into the basalis level (i.e., glandular epithelium). After the functionalis layer is shed at the time of menstruation, the basalis, which contains epithelial and stromal cells, can give rise to a new functionalis layer for the upcoming cycle (Fig. 17-23).

The cellular components of the functionalis layer undergo a striking progression during the menstrual cycle, whereas the basalis shows only modest alterations. The sequence of endometrial changes associated with an ovulatory cycle has been carefully studied by Noyes and colleagues in humans and by Markee^{151,152} and Bartelmez¹⁵³ in subhuman primates.

Figure 17-23 Cyclic changes in thickness and morphology of endometrium and the relation of these changes to those of the ovarian cycle. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In: Cunningham FG, ed. *Williams Obstetrics*, 19th ed. Stamford, CN: Appleton & Lange, 1993:81-109.)

Hormone-Induced Morphologic Changes of the Endometrium

The cyclic changes in endometrial histology are faithfully reproduced during each ovulatory ovarian cycle. These sex steroid hormone-induced modifications can be summarized in several steps. First, during the preovulatory, or follicular, phase of the cycle, estradiol is secreted (principally by a single dominant follicle of one ovary) in increasing quantities until just before ovulation. Second, during the postovulatory, or luteal, phase of the cycle, progesterone is secreted by the corpus luteum in increasing amounts (up to 40 to 50 mg/day) until the midluteal phase. Third, beginning about 7 to 8 days after ovulation, the rates of progesterone and estradiol secretion by the corpus luteum begin to decline and then diminish progressively before menstruation (see Fig. 17-1).

In response to these cyclic changes in the rates of ovarian sex steroid hormone secretion, there are five main stages of the corresponding endometrial cycle: (1) menstrual-postmenstrual *reepithelialization*; (2) *endometrial proliferation* in response to stimulation by estradiol; (3) abundant *epithelial secretion*, occurring in response to the combined action of estradiol and progesterone; (4) *premenstrual ischemia*, the result of endometrial tissue volume involution, which causes stasis of blood in the spiral arteries; and (5) *menstruation*, which is preceded and accompanied by severe vasoconstriction of the endometrial spiral arteries and collapse and desquamation of all but the deepest layer of the endometrium. In the final analysis, menstruation is the consequence of the withdrawal of factors that maintain endometrial growth and differentiation (see Fig. 17-23).

Commonly, the initiation of menstruation is attributed to progesterone withdrawal. This concept was developed because the administration of estrogen to postmenopausal women and treatment with and then withdrawal of a progestin causes menstruation, even with continued estrogen treatment. Moreover, progesterone

facilitates decidualization of the endometrium and the maintenance of pregnancy, whereas progesterone withdrawal favors the initiation of menstruation, lactation, and parturition. There are probably many additional coordinated and interactive processes other than progesterone withdrawal that are operative and essential for the success of each of these events.

The preovulatory (follicular or proliferative) phase and the postovulatory (luteal or secretory) phase of the ovarian-endometrial cycles are customarily divided into early and late stages (see Fig. 17-23). The normal secretory phase of the endometrial (menstrual) cycle can be subdivided almost daily by histologic criteria, from shortly after ovulation until the onset of menstruation. Noyes and other investigators have provided an extremely detailed description of the histologic features of the secretory phase endometrium, which permit accurate dating during the luteal phase.¹⁵⁴ Some gynecologists use histologic dating of endometrial biopsies obtained during the luteal phase to evaluate ovulation, progesterone production, or the degree of biologic response of the endometrium to progesterone. Normal endometrial development is assumed when the histologic and chronologic endometrial dating agree within 2 days. If they differ by more than 2 days, the endometrium is considered to be out of phase. Out-of-phase endometrial tissue may be a cause of implantation failure, producing infertility. However, the sensitivity and specificity of the dating of endometrial biopsy specimens for evaluation of infertility are unknown. It is important to understand this and other limitations of the test with respect to its routine clinical use as a basis for infertility treatments. For example, one important disadvantage of this test is interobserver variation in histologic interpretation of biopsies.

Effects of Ovarian Steroids on Endometrium

Estradiol or synthetic estrogens such as ethinyl estradiol cause a striking thickening of endometrial tissue. Stromal

Figure 17-24 Critical epithelial effects of estrogen (i.e., deoxyribonucleic acid [DNA] synthesis, proliferation, and gene expression) are mediated primarily by estrogen receptor- α (ER) in stromal cells in a paracrine manner in the endometrium. This was demonstrated in mice.¹⁵⁶ It was also shown in mice and humans that the antiestrogenic effects of progesterone on epithelial cells (e.g., decreased proliferation, enhanced differentiation) are mediated primarily by progesterone receptors (PRs) in stromal cells.¹⁵⁷

and epithelial cells of the endometrium proliferate rapidly under the influence of estradiol. Estradiol greatly increases mitotic activity and DNA synthesis in both cell types (Fig. 17-24). While promoting growth, estradiol also renders endometrial tissue responsive to progesterone by inducing the expression of progesterone receptors (PRs) in this tissue; progesterone action depends on previous or concurrent estrogen exposure of the endometrium.¹⁵⁵

In contrast to the proliferative effects of estrogen, progesterone action primarily enables differentiation of the endometrium. For example, progesterone can inhibit and even reverse the proliferative action of estrogen on the functionalis layer (see Fig. 17-24). Moreover, progesterone action prepares the endometrium for implantation of the embryo through differentiation of epithelial and stromal cells. Progesterone induces the production and secretion of a glycogen-rich substance from the epithelial cells. Progesterone also causes an increase in stromal cell cytoplasm, a process called *pseudodecidualization*. The term *decidualization* is reserved for stroma differentiated under the combined influence of progesterone and hCG of placental origin during pregnancy.

Estrogen Action

Estradiol, the biologically potent, naturally occurring estrogen that is secreted by the granulosa cells of the dominant ovarian follicle, promotes responses of the endometrium through mechanisms similar to those used by other steroid hormones. Estradiol enters cells from blood by simple diffusion, but in estrogen-responsive cells, binding to the ER sequesters estradiol. ERs are proteins with a high affinity for estradiol and other biologically active estrogens (i.e., synthetic estrogens). Although ER α and ER β are present in the endometrium, ER α seems to be the primary mediator of the estrogenic action in that tissue.^{158,159} After transformational changes, the estradiol-receptor complex is a transcriptional factor that becomes associated with chromatin.¹⁶⁰ Estradiol-ER α complexes bind thousands of DNA sites across the entire genome and regulate the transcription of hundreds of genes at one time.^{160,161} Contrary to a previous

notion, most ER α binding sites are outside classically defined basal promoters, interact with the transcriptional start sites through DNA bending, and do not contain classically defined estrogen response elements.^{160,161} This interaction brings about ER-specific initiation of gene transcription, which promotes the synthesis of specific mRNAs and, thereafter, specific proteins.¹⁶² Among the many proteins synthesized in most estrogen-responsive cells are additional ERs and PRs. Estradiol acts in the endometrium and in other estrogen-responsive tissues to promote the perpetuation of estrogen action and the responsiveness of that tissue to progesterone.

The endometrial epithelial cells are estrogen responsive but probably do not replicate as a result of direct action of estradiol on them. Replication of human endometrial epithelial cells in culture is not increased appreciably, if at all, when estrogen is added to the medium. Estrogen acts on mouse uterine stromal cells to promote the synthesis of growth factors that act on epithelial cells (see Fig. 17-24).¹⁵⁶ These growth factors operate in a paracrine manner to cause increased DNA synthesis and replication in the adjacent epithelial cells. This type of paracrine arrangement may be a common mechanism that mediates estrogen action in hormone-responsive tissues.

Progesterone Action

Progesterone enters cells by diffusion, and in responsive tissues, it becomes associated with PRs that have a high affinity for progesterone. Two PR isoforms, PR-A and PR-B, are present in the human endometrium.¹⁶³ Because PR-B but not PR-A levels in the endometrium are tightly regulated during the human menstrual cycle, PR-B is presumed to play a more important biologic role.¹⁶³ The cellular content of PRs typically depends on previous estrogen action.

The progesterone-PR complex also promotes gene transcription, but the response to progesterone is strikingly different from that evoked by the estradiol-ER complex. Similar to ER α , PR binding sites are also widely distributed across the genome, lie frequently outside of basal promoters, and do

not involve classically defined progesterone response elements.¹⁶⁴ Interaction of PR binding sites with basal promoters possibly requires DNA coiling.¹⁶⁴

Progesterone actions include a decrease in the expression of ERs.¹⁶⁵ This is one means by which progesterone (and synthetic progestins) attenuates estrogen action. Progesterone also acts to increase the rate of enzymatic inactivation of estradiol to estrone through an increase in the activity of an oxidative-type 17 β -HSD enzyme. Progesterone-dependent transcription of the *HSD17B2* gene is responsible for this enzyme activity.¹⁶⁶ Progesterone also acts to increase sulfation of estrogens (i.e., by estrogen sulfotransferase), another means of estrogen inactivation.¹⁶⁷ Progesterone acts as an antiestrogen in at least three ways: by reducing ER expression, by decreasing the tissue levels of estradiol through conversion to estrone, and by enhancing estrogen inactivation through sulfation. As in the case of estrogen action in the uterus, tissue recombination experiments using uteri of PR knockout and normal mice have demonstrated that many effects of progesterone on epithelial cells are also mediated in a paracrine fashion by PRs in stromal cells but not by those in epithelial cells (see Fig. 17-24).¹⁵⁷ Progesterone-dependent *HSD17B2* enzyme induction and consequent estradiol inactivation are mediated primarily by stromal PRs in human endometrium.¹⁶⁸

The most striking consequence of progesterone action is the differentiation of the endometrium. The histologic correlates of differentiation—stromal predecidualization and epithelial secretion—parallel increased levels of circulating progesterone during the luteal phase. The PR content of human endometrial tissue peaks during the late proliferative phase, just before ovulation, and declines sharply before circulating progesterone levels increase during the luteal phase.¹⁶³ This dyssynchrony between endometrial PR expression and circulating progesterone is not well understood. Molecular correlates of progesterone action with respect to differentiation include increased production of lactoferrin and glycodein in epithelial cells and of prolactin and IGF-binding protein 1 in stromal cells of the endometrium.

The Receptive Phase of the Endometrium for Implantation

Unless the ovum is fertilized within 24 hours after ovulation, it does not survive. Fertilization takes place in the ampullary, the distal one third of the oviduct. Over the next 2 days, the fertilized ovum remains unattached within the tubal lumen; tubal fluids and residual attached cumulus granulosa cells sustain nutrition and energy for early cellular cleavage. After this stage, the embryo (which consists of a solid ball of cells called the morula) leaves the oviduct and enters the uterine cavity. By this time, endometrial secretions under the influence of luteal progesterone have filled the cavity and bathe the embryo in nutrients. This is the first of many neatly synchronized events that mark the conceptus-endometrial relationship. By 6 days after ovulation, the embryo (now a blastocyst) is ready to attach and implant. It finds an endometrial lining of sufficient depth, vascularity, and nutritional richness to sustain the important events of early placentation that are to follow. Just below the epithelial lining, a rich capillary plexus has been formed and is available for creation of the trophoblast-maternal blood interface. Later, the surrounding superficial portion of the functionalis zone, now occupying more and more of the endometrial cavity, provides a sturdy splint to retain endometrial architecture despite the invasive inroads of the burgeoning trophoblast.

Progesterone is essential for the maintenance of pregnancy. The blastocyst depends on progesterone produced by the corpus luteum at this time. The hCG secreted by the trophoblast prevents regression of the corpus luteum by acting as a surrogate LH. It maintains a continuous supply of progesterone to maintain the pregnancy until the placental tissue starts to produce sufficient quantities of progesterone (6 to 7 weeks after fertilization).

Studies in experimental and domestic animals have demonstrated that there must be synchronous development of the embryo and endometrium for normal implantation and development to occur. In laboratory animals, there is a discrete window for implantation, which in some species lasts only a matter of hours.

The receptive phase of the endometrium is the temporal window of endometrial maturation during which the trophectoderm of the blastocyst can attach to the endometrial epithelial cells and proceed to invade the endometrial stroma. In the study of human endometrial receptivity, a key question is the determination of the temporal window of implantation. Only factors expressed during this temporal window can be considered markers or functional mediators of the receptive state.

The window of uterine receptivity can be inferred from what has been learned from transfer of embryos to uteri of women primed with exogenous estrogen and progesterone preparations (Fig. 17-25). There is a distinct window for embryo transfer leading to implantation, which spans endometrial cycle days 16 to 20. Presumably, the actual window of implantation follows this window of transfer, because embryos need to develop further, from the four-cell to eight-cell stage to the blastocyst stage, before initiation of attachment and frank invasion can occur.

Based on serial measurements of serum hCG as a marker of initial embryonic-maternal interaction, the window of implantation in humans is estimated to be between days 20 and 24 of the cycle.¹⁶⁹ This relatively wide window agrees with the earlier morphologic data developed by Adams and colleagues.¹⁷⁰

Mechanism of Menstruation

In the absence of pregnancy, failure of the appearance of hCG despite otherwise appropriate tissue reactions leads to the vasomotor changes associated with estrogen-progesterone withdrawal and menstrual desquamation. A program of endometrial remodeling is initiated; alterations in the extracellular matrix and infiltration of leukocytes lead to hypoxia-reperfusion injury and sloughing of the functionalis, followed by activation of hemostatic and regenerative processes. The main histologic features of the premenstrual phase are degradation of the stromal reticular network, stromal infiltration by polymorphonuclear and mononuclear leukocytes, and secretory exhaustion of the endometrial glands, whose epithelial cells now have basal nuclei. The endometrium shrinks preceding menstruation in part as a result of diminished secretory activity and the catabolism of extracellular matrix.

The most prominent and final effect of progesterone and estrogen withdrawal is menstruation. The classic studies of Markee suggested that an ischemic phase caused by vasoconstriction of the arterioles and coiled arteries precedes the onset of menstrual bleeding by 4 to 24 hours.¹⁵¹ Bleeding occurs after the arterioles and arteries relax, leading to hypoxia-reperfusion injury. The superficial endometrial layers are distended by the formation of hematomas, and fissures develop, leading to the detachment of tissue fragments. Lysis and fragmentation of cells

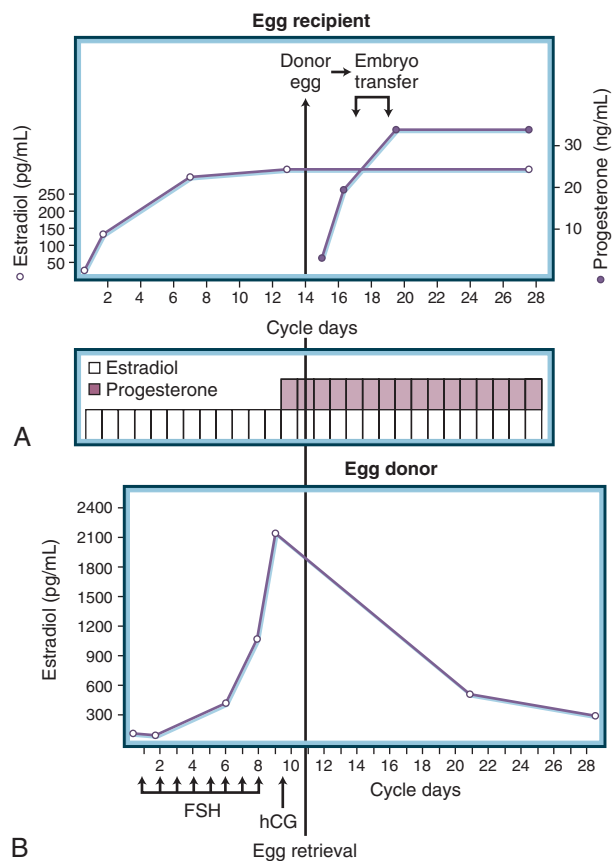

Figure 17-25 Donation of oocytes by a woman undergoing egg retrieval to a woman with ovarian insufficiency treated with exogenous estrogen and progesterone. The window of implantation in both women is synchronized by different but comparable hormonal treatments **A**, Woman with ovarian insufficiency is initially treated with oral micronized estradiol during days 1 through 14 of the cycle. Exogenous intramuscular progesterone is added to the estradiol treatment on days 15 through 28 and continued if pregnancy is diagnosed. Several donor eggs are fertilized with sperm from the recipient's husband, and one or two embryos are transferred to the uterus on day 16 to 19, depending on the stage of embryo development. These embryos are expected to implant between days 20 and 24. **B**, The egg donor is simultaneously treated with human recombinant follicle-stimulating hormone (FSH) with or without menopausal gonadotropin until cycle day 8 to 12, when human chorionic gonadotropin (hCG) is given to induce ovulation, and oocytes are harvested 32 to 36 hours later. One or two fertilized eggs are transferred to the uterus of the recipient. Progesterone supplement to the recipient is started before the embryo transfer. Serum levels of estradiol (E_2) or progesterone (P_4) in both women are shown. To convert estradiol values to picomoles per liter, multiply by 3.671. To convert progesterone values to nanomoles per liter, multiply by 3.180.

and apoptosis are evident. The menstrual efflux is composed of shed fragments of endometrium mixed with blood and liquefied by the fibrinolytic activity of the cellular debris (see Fig. 17-23). Clots of various sizes may be present if blood flow is excessive.

Control of Endometrial Function with the Use of Exogenous Hormones

The fertility potential of a woman is primarily determined by the biologic quality of her oocytes, reflected in part by the capacity of the fertilized ovum to divide at an optimal rate and contain a normal chromosomal complement. This biologic quality declines sharply after the age of 35 years. However, the biologic potential of the endometrium for

successful implantation remains intact even at advanced ages.¹⁷¹ Oocyte donation from a fertile woman and fertilization of the donor eggs in vitro with the recipient's male partner's sperm, followed by embryo transfer into the uterine cavity of the recipient woman with nonfunctioning ovaries (e.g., premature ovarian insufficiency), have been used successfully as a therapeutic strategy to treat infertility (see Fig. 17-25).^{171,172} This clinical application has provided unique opportunities to examine the hormonal therapy for endometrial maturation. Several hormone replacement protocols have been proposed, and many pregnancies have resulted from donor oocytes in women with ovarian insufficiency (see Fig. 17-25). The success of these procedures (i.e., pregnancy rate) has averaged about 50% per embryo transfer.

The degree of endometrial differentiation in response to exogenous hormones has been evaluated by histologic analysis of endometrial biopsy specimens. The epithelial elements exhibit delayed maturation early during progesterone administration on days 20 to 22, but they catch up by day 26. Despite this apparent dyssynchrony, the pregnancy rate in these patients with donor oocytes is higher than in conventional IVF.¹⁷²

The follicular phase is mimicked by administration of oral micronized estradiol in daily doses of up to 8 mg for about 10 days. Serum estradiol in these subjects during the replacement follicular phase reaches sufficiently high levels to stimulate endometrial growth. This is followed by up to 8 mg/day of oral estradiol combined with daily intramuscular progesterone (50 mg) to promote the secretory transformation. Intramuscular injection of 50 mg/day of progesterone in oil generates serum levels of progesterone usually greater than 20 ng/mL. The length of exposure to progesterone, but not the absolute plasma progesterone concentration achieved after adequate priming of the endometrium with estrogen, is a key factor for the development of uterine receptivity. The exogenous administration of only estradiol and progesterone is sufficient to prepare the endometrium for implantation in the absence of ovarian function. This observation further underscores the essential roles of these steroids in uterine physiology.

APPROACH TO THE WOMAN WITH REPRODUCTIVE DYSFUNCTION

Reproductive dysfunction in an adult woman is most often manifested by disruption of cyclic, predictable menses. Efficient diagnosis of the underlying disorder requires a thorough understanding of female reproductive physiology and pathology and an accurate history and physical examination. Without a critical analysis of clinical findings based on thorough knowledge of normal and abnormal reproductive function, the application of predetermined algorithms of laboratory testing causes unnecessary use of hormone measurements or imaging studies and delays diagnosis.

History

An essential tool for the evaluation of a woman with a reproductive disorder is a carefully recorded history. The history should be obtained from the patient with the aim of assessing the biologic effects of each of the various hormones. Recording the details of pubertal development as a reference for the onset of particular symptoms provides critical clues to the cause of certain reproductive disorders. For example, anovulation manifested by irregular uterine

bleeding associated with the polycystic ovary syndrome (PCOS) most often begins during the pubertal years. The onset of gradually progressing hirsutism at about the time of puberty suggests nonclassic adrenal hyperplasia or PCOS. In these cases, measurement of serum 17-hydroxyprogesterone may help to differentiate nonclassic adrenal hyperplasia from PCOS. The appearance of hirsutism before puberty or several years after normal pubertal development should alert the clinician to the possibility of ovarian or adrenal neoplasms. Sudden onset of hirsutism at any age or the presence of virilization should prompt the physician to rule out steroid-secreting ovarian or adrenal tumors. Most women with symptomatic endometriosis suffer from severe episodes of painful menses (i.e., dysmenorrhea) that start during pubertal years.

Evaluation of female reproductive function depends on a detailed history of the menses. For example, PCOS is unlikely without a long-standing history of irregular periods since the menarche. A history of a period of cyclic, predictable menses before the onset of menstrual irregularities should draw attention to hypothalamic or other causes of anovulation. The current frequency, regularity, length, and quantity of uterine bleeding should be carefully recorded for several reasons. First, this information reflects tightly regulated interactions of several tissues, including the hypothalamus, pituitary, ovaries, and endometrium. Second, regular, predictable menses imply ovulation. Third, defining the type of menstrual irregularity may help with diagnosis of the underlying cause. For example, prolonged amenorrhea in a thin and estrogen-deficient woman suggests anovulation of hypothalamic origin. Infrequent periods of varying duration and with a varying amount of blood loss in a well-estrogenized, overweight woman suggest a primary ovarian dysfunction such as PCOS. Anovulation in a thin but well-estrogenized woman may also be caused by PCOS. Regular but heavy and prolonged menses with intermittent spotting may result from uterine anatomic disorders such as adenomyosis or leiomyomas. Fourth, neoplastic disorders of the endometrium, including endometrial polyps, hyperplasia, or malignancies, may be manifested by any pattern of irregular bleeding. The combination of vaginal ultrasonography and endometrial biopsy is extremely sensitive for the diagnosis of endometrial neoplasia.¹⁷³

Disruption of cyclic and predictable menses is a common and alarming symptom that initially brings the patient to the clinician. After a careful evaluation of the menstrual symptoms, the clinician should identify other obvious symptoms of the endocrine disorder underlying the irregular periods. Pregnancy is the most common cause of amenorrhea (and other menstrual irregularities) in a woman of reproductive age. In a woman presenting with amenorrhea or any other menstrual irregularity, normal pregnancy, ectopic pregnancy, or gestational trophoblastic disease must be excluded at the onset. Careful evaluation of past reproductive history and the patient's sexual activity and contraceptive practices can provide useful indications of the likelihood of pregnancy. The reproductive history may suggest the possibility of Sheehan's syndrome of postpartum pituitary necrosis if menses did not resume after a delivery complicated by significant hemorrhage.¹⁷⁴ In such instances, evidence of adrenal and thyroid insufficiency should be sought. A classic symptom of Sheehan's syndrome is the absence of postpartum lactation, which is related to prolactin deficiency.

Amenorrhea is traditionally categorized as primary (no history of menstruation) or secondary (cessation of menses after a variable time). The diverse causes of primary

amenorrhea are discussed extensively in Chapters 23 and 25. Although the distinction between primary and secondary amenorrhea may be useful for identifying the mechanism of disease and the differential diagnosis, the clinician should be aware that a disorder can initially manifest with either primary or secondary amenorrhea. For example, most women with gonadal dysgenesis have primary amenorrhea, but some patients have residual follicles and ovulate, and in these women with partial gonadal dysgenesis, some menstruation and rare pregnancies may occur before the cessation of ovarian function.^{175,176} Patients with PCOS usually have secondary amenorrhea but occasionally have primary amenorrhea. Rarely, pregnancy may manifest as primary amenorrhea.

After pregnancy is ruled out, secondary amenorrhea is most often caused by chronic anovulation, which can be broadly categorized as hypothalamic dysfunction, galactorrhea-associated anovulation, ovarian insufficiency, androgen excess, or chronic illness or primary uterine disease (e.g., intrauterine adhesion formation after a postpartum curettage). Establishing any association of secondary amenorrhea with life events is extremely useful. Strenuous exercise is often associated with amenorrhea. Weight loss often precedes or accompanies secondary amenorrhea and has been suggested as evidence of hypothalamic dysfunction. An unusual dietary history may suggest bulimia or anorexia nervosa. A history of dilatation and curettage, postpartum endometritis, or disseminated tuberculosis with absent to scant menses suggests the possibility of intrauterine adhesion.¹⁷⁷ The presence of any signs or symptoms of estrogen deficiency, including painful intercourse, atrophic vagina, emotional lability, and vasomotor instability, suggests anovulation of a central nature with low concentrations of circulating gonadotropins (i.e., hypogonadotropic hypogonadism) or ovarian insufficiency with elevated gonadotropins (i.e., hypergonadotropic hypogonadism).

Galactorrhea in the absence of a recent history of pregnancy suggests a host of diagnostic possibilities and is frequently a manifestation of excessive prolactin secretion, although it may result from increased sensitivity of breast tissue to the hormones necessary for milk production. This history frequently reveals drug ingestion as the cause. Various drugs, including several psychotropic agents, antihypertensive agents, and oral contraceptives, have been implicated. Primary hypothyroidism may be associated with precocious puberty with galactorrhea in the child and with amenorrhea or galactorrhea, or both, in the adult woman. A history of excessive nipple manipulation or chest wall disease should be elicited because it may be the cause of galactorrhea. Prolactinomas, the prolactin-secreting adenomas of the pituitary, are a common cause of galactorrhea related to abnormally high serum levels of prolactin.

Physical Examination

The quantity and distribution of excessive hair growth should be considered in light of the familial history. Hypertrichosis—excessive growth of hair on the extremities, the head, and the back—must be distinguished from true hirsutism, which is the development of facial hair, chest hair, and a male escutcheon with or without signs of virilization in response to increased production of or sensitivity to biologically active androgens. Some degree of hypertrichosis is not uncommon in women of Mediterranean descent, whereas the occurrence of any facial hirsutism in the relatively hairless Asian woman may require

thorough investigation. Hirsutism is best documented and quantified with the help of photographs. Virilization is characterized as thickening of the voice, severe cystic acne, hair loss, increased muscle mass, and clitoromegaly and implies a more severe degree of androgen excess than that found with hirsutism. The syndrome of complete androgen insensitivity is characterized by sparse to absent pubic and axillary hair due to resistance to androgen.

A careful inspection of the breasts is essential for a thorough physical examination. Classification of the stage of breast development according to the method of Marshall and Tanner¹⁷⁸ is a convenient and valuable adjunct. The physician should assess whether the breasts appear to have decreased in size recently (e.g., severe androgen excess), whether the areolae are well formed and pigmented (as they are in pregnancy), and whether a discharge (e.g., galactorrhea) can be expressed.

A woman with PCOS who has never ovulated or taken a progestin-containing medication may have Tanner stage 4 breast development related to adequate estrogen production, whereas the progression to Tanner stage 5 requires exposure to progesterone through ovulation or ingestion of a progestin (e.g., administration of oral contraceptives). Chapter 25 discusses Tanner staging of breast development.

The vulva, vagina, and cervix also represent sensitive indicators of gonadal steroid action. Because sensitivity of the genital skin and mucosa to androgen decreases with time from the early stages of fetal development to adulthood, the extent of any virilization can be helpful in suggesting the timing of androgen exposure. The most profound androgenic effects, such as posterior labial fusion with or without formation of a penile urethra, usually are observed in 46,XX fetuses exposed to androgens during the first 10 weeks of pregnancy. Similar findings have been described in patients with virilizing congenital adrenal hyperplasia, true hermaphroditism, and drug-induced virilization. Significant postnatal clitoromegaly, on the other hand, requires marked hormonal stimulation and, in the absence of significant exogenous steroids, strongly implicates an androgen-secreting tumor. The size of the glans clitoris can be quantitated by determining the clitoral index, which is the product of the sagittal and transverse diameters of the glans. Ninety-five percent of normal women have a clitoral index less than 35 mm².

The vagina and uterine cervix are the most sensitive indicators of estrogen action. Under the influence of estrogen, the vaginal mucosa progresses during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a tissue with a dull, gray-pink, rugated surface with copious, thick secretions. Well-estrogenized vaginal mucosa with stretchable cervical mucus (i.e., *spinnbarkeit*) may indicate the proliferative phase of the menstrual cycle in an ovulatory woman or extraovarian estrogen formation in an anovulatory woman with PCOS. The biologic activity of estrogen can also be quantified by vaginal cytology.

To summarize, irregular uterine bleeding is a common symptom that brings the woman with reproductive dysfunction to the physician's office. Various disorders of the hypothalamus, pituitary, ovaries, or uterus or other issues that affect reproductive function may be responsible for this alarming symptom. After pregnancy is ruled out, a detailed history and results of the physical examination should be carefully recorded. In particular, the physician should pay attention to the salient features in the history and the biologic indicators of hormone action at target tissues during the physical examination. An analysis of

these findings most often leads to a tentative diagnosis, which should be confirmed by laboratory testing.

DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

Chronic Anovulation

Chronic anovulation is one of the most common gynecologic problems encountered by the practitioner. Patients may present with secondary amenorrhea, infrequent uterine bleeding (i.e., oligomenorrhea), or irregular episodes of excessive uterine bleeding. Infertility is an obvious consequence of chronic anovulation. Pregnancy or any cause related to end-organ insufficiency (e.g., intrauterine adhesions, müllerian agenesis), amenorrhea associated with genital ambiguity at birth (e.g., male or female pseudohermaphroditism, true hermaphroditism), or sexual infantilism due to gonadal dysgenesis should initially be ruled out.

For practical purposes, most of the etiologic factors giving rise to chronic anovulation in a woman of reproductive age fall into five broad categories: hypothalamic anovulation, hyperprolactinemia, androgen excess, premature ovarian insufficiency, and chronic illness (e.g., hepatic or renal insufficiency, acquired immunodeficiency syndrome [AIDS]). Salient features of the history and physical examination help to place a woman with anovulation in one or more of these categories.

One group of anovulatory patients is estrogen deficient. Common disorders in this group include hypothalamic anovulation, galactorrhea-hyperprolactinemia (e.g., hypothyroidism, prolactinoma, nonfunctioning pituitary tumor), and premature ovarian insufficiency in a woman of reproductive age. These patients are usually amenorrheic. All patients present with signs of estrogen deficiency (e.g., vaginal atrophy). Patients with hypothalamic anovulation or galactorrhea-hyperprolactinemia usually do not complain of hot flashes, whereas women with premature ovarian insufficiency present with vasomotor symptoms. One serious consequence of estrogen deficiency is bone loss giving rise to osteopenia and osteoporosis. If possible, the underlying cause should be corrected. Hormone therapy should be provided if ovulation cannot be restored.

Women with androgen excess constitute the second major group of anovulatory patients. A serious consequence of anovulation in this group is the greater risk for carcinoma of the endometrium because of unopposed action of estrogen formed continuously in extraovarian tissues. The most common disorder of the ovary associated with androgen excess and anovulation is PCOS. Insulin resistance plays a significant role in this condition and, along with hyperandrogenism, increases the risk of developing cardiovascular disease (CVD) or diabetes mellitus or both.¹⁴² The clinician must recognize the long-term impact of PCOS and undertake therapeutic management of these anovulatory patients to avoid unwanted consequences. The clinician should also develop a plan with the patient to address long-term complications of unopposed estrogen formation associated with PCOS (e.g., endometrial neoplasia). Oral contraceptives or periodic progestin supplementation may be provided to prevent endometrial hyperplasia and cancer.

Many mechanisms may be responsible for anovulation in chronic illness. Effective treatment of the primary illness may restore normal menses. Alternatively, anovulatory

bleeding may be managed with the use of exogenous hormones in these chronically ill patients (discussed later).

Measurements of FSH and prolactin help to categorize anovulatory patients. An undetectable or low-normal FSH level is consistent with hypothalamic amenorrhea, PCOS, or hyperprolactinemia, whereas high FSH levels suggest ovarian insufficiency. High prolactin levels may indicate a pituitary prolactinoma or hypothyroidism. The following sections describe specific disorders that cause chronic anovulation in women of reproductive age.

Hypothalamic Anovulation

Anovulation of hypothalamic origin usually manifests as amenorrhea. The terms *hypothalamic anovulation* and *hypothalamic amenorrhea* are used interchangeably in this chapter. A reduction in GnRH pulse frequency from the characteristic 60 to 120 minutes to intervals longer than 180 minutes leads to lower levels of LH and FSH secretion by the pituitary gland.^{13,15} This functional gonadotropin deficiency fails to provide adequate stimulation to the ovarian follicles, and the normal sequence of follicular growth, maturation, follicular selection, and ovulation becomes attenuated. Downstream ovarian estradiol production remains low, and endometrial growth is reduced or arrested, resulting in a prolonged interval of amenorrhea. The transition from normal menstrual cyclicity to anovulation and amenorrhea can take place gradually and may be characterized by inadequate luteal phases, irregular menstrual bleeding, and amenorrhea. Patients with hypothalamic amenorrhea do not complain of hot flashes, even though circulating levels of estradiol are within the menopausal range. This suggests a significant role for GnRH or gonadotropins in the cause of hot flashes.

Any disorder of the central nervous system that interferes with normal GnRH pulse frequency can cause anovulation. Some of these disorders may be defined genetic or anatomic evidence such as isolated gonadotropin deficiency (with or without anosmia), infection, suprasellar tumors (e.g., pituitary adenomas, craniopharyngioma), and head trauma.¹⁰ These genetic and anatomic disorders affect the function of the hypothalamus, and some of them may be ruled out by the medical history, physical examination, and imaging of the head (Table 17-2).

The most commonly observed form of hypothalamic anovulation is not associated with a demonstrable neuroanatomic finding.¹⁸⁰ This common form is called *functional hypothalamic amenorrhea* because it is presumed to involve aberrant but reversible regulation of otherwise normal neuroendocrine pathways. Changes in lifestyle may result in the return of normal ovulatory cycles. Functional hypothalamic amenorrhea may be associated with excessive exercise, abrupt weight loss, and emotional distress. It is hypothesized that these stress factors cause anovulation by affecting brain function and the GnRH pulse generator. Other causes of hypothalamic anovulation demonstrable by neuroanatomic or genetic evidence are uncommon (see Table 17-2).

Functional Hypothalamic Amenorrhea

Anovulation resulting from stress-associated changes is viewed as a functional disorder in which no anatomic or organic abnormalities of the hypothalamic-pituitary-ovarian axis can be identified. This condition typically manifests as amenorrhea of 6 months' duration and has also been called *functional hypothalamic amenorrhea*. The overall prevalence of functional hypothalamic amenorrhea among all amenorrhea disorders ranges from 15% to 48%.¹⁸⁰

TABLE 17-2

Classification of Anovulation Caused by Disorders of the Hypothalamic-Pituitary Unit

Functional Hypothalamic Anovulation (Amenorrhea)

Stress (psychogenic or physical)
Dieting
Vigorous exercise
Chronic illness (e.g., chronic liver or renal insufficiency, AIDS)

Psychiatric-Medical Emergencies

Anorexia nervosa

Medications

Antipsychotics (e.g., olanzapine, risperidone, amisulpride, clozapine)¹⁷⁹
Opiates

Hypothyroidism

Anatomically or Genetically Defined Pathologies of the Hypothalamic-Pituitary Unit

Pituitary tumors
Prolactinoma
Clinically nonfunctioning adenoma
GH-secreting adenoma (acromegaly)
ACTH-secreting adenoma (Cushing's disease)
Other pituitary tumors (e.g., metastasis, meningioma)
Pituitary stalk section
Hemorrhagic pituitary destruction, including pituitary apoplexy and Sheehan's syndrome
Pituitary aneurysm
Infiltrative disease of the pituitary (e.g., lymphocytic hypophysitis, sarcoidosis, histiocytosis X, tuberculosis)
Empty sella syndrome
Tumors that affect hypothalamic function (e.g., metastasis, craniopharyngioma)
Infiltrative granulomatous disease of the hypothalamus (e.g., sarcoidosis, histiocytosis X, tuberculosis)
Head trauma
Irradiation to the head
CNS infection
Isolated gonadotropin deficiency (including Kallmann's syndrome)
Other

ACTH, adrenocorticotropic hormone; AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; GH, growth hormone.

Anovulation of hypothalamic origin is characterized by estrogen deficiency and low levels of gonadotropins. No genetic or anatomic disorders are identified in most patients. The concept of functional hypothalamic anovulation (i.e., amenorrhea) was first postulated in the 1940s as the failure of the hypothalamic-pituitary pathways to release LH from the anterior pituitary.¹⁸¹ Since then, many clinical studies have confirmed this idea.¹⁴ Accumulated data suggest that the common underlying defect is an alteration in the pulsatile secretion of GnRH. In patients with this disorder, diverse etiologic factors such as malnutrition or caloric restriction, depression, psychogenic stress, excessive energy expenditure related to exercise, or combinations of these disorders precede the onset of functional hypothalamic anovulation. Heightened awareness of diet or exercise and unrealistic expectations with respect to body image have most likely contributed to the epidemic of this anovulatory disorder.

Diagnosis of Functional Hypothalamic Amenorrhea

Patients with functional hypothalamic amenorrhea most commonly present with secondary amenorrhea characterized by absence of menstrual cycles for longer than 6

months without evidence of an organic disorder. The diagnosis of hypothalamic amenorrhea is one of exclusion. There are many neuroanatomic or genetic disorders that can mimic functional hypothalamic anovulation (see Table 17-2), and a careful and complete evaluation is essential to make this diagnosis.

Women with functional hypothalamic amenorrhea usually present with a history of regular menses for some time after menarche. This period of normal ovulatory function (determined by history) is interrupted by anovulation that usually manifests as secondary amenorrhea. Women with functional hypothalamic anovulation may occasionally present with primary amenorrhea.

Women with functional hypothalamic amenorrhea typically have a normal body weight or are thin. They are driven and involved in high-stress occupations. The occupation of the patient (e.g., ballerina, competitive athlete) may be an important clue. A detailed interview may reveal a variety of emotional crises or stressful events (e.g., divorce, death of a friend) preceding the onset of amenorrhea. During the interview, additional environmental and interpersonal factors may become evident, such as academic pressure, social maladjustment, or psychosexual problems. When evaluating the patient, the physician should take note of the current diet regimen, the use of any sedatives or hypnotics, and the nature and extent of the patient's exercise habits. Despite a careful interview, a history of stress, excessive physical exercise, or an eating disorder may not be readily revealed by some women with functional hypothalamic anovulation. These women usually do not complain of hot flashes, in contrast to women with ovarian insufficiency.

The physician should exclude a possible hyperprolactinemic cause (e.g., prolactinoma, hypothyroidism) and evidence of androgen excess (e.g., PCOS) during the physical examination. These women usually have normal secondary sexual characteristics. The pelvic examination usually shows a thinning vaginal mucosa accompanied by scant to absent cervical mucus with a normal to small uterus, which are all evidence of estrogen deficiency. Signs of a well-estrogenized vagina and cervix observed during the physical examination make the diagnosis of hypothalamic amenorrhea unlikely.

Laboratory tests are obtained to exclude other causes of anovulation and secondary amenorrhea. LH and FSH levels should be measured. Gonadotropin levels are usually lower than the normal values ordinarily found in the early follicular phase. TSH and prolactin levels are obtained to rule out hypothyroidism and hyperprolactinemia. The progestin challenge test (medroxyprogesterone acetate [MPA] at 5 mg/day for 10 days) elicits either a small spotting episode or an absence of withdrawal uterine bleeding in most patients. The administration of combined estrogen (2 mg/day of oral micronized estradiol) with progestin (5 mg/day of MPA for 10 days) will result in endometrial growth followed by vaginal bleeding because the uterine compartment remains functionally normal.

These results confirm that there is a scant or absent estrogenic effect on the endometrium, because circulating estradiol levels are typically in the low or early follicular phase range. Measurement of the serum estradiol level is not necessary. Because a suprasellar or large pituitary tumor is in the differential diagnosis, magnetic resonance imaging (MRI) of the head is necessary to rule out these possibilities. Imaging of the head is especially important if amenorrhea develops suddenly or is associated with a neurologic sign, both of which make the presence of a tumor more likely.

Pathophysiology of Functional Hypothalamic Anovulation

A critical defect in hypothalamic amenorrhea is the reduction in GnRH release from the medial basal hypothalamus, which leads to a reduction in GnRH pulse frequency. In humans, it is challenging and sometimes impossible to directly examine GnRH pulse frequency. LH pulse frequency is used as a surrogate measure to evaluate GnRH secretion because each GnRH pulse is accompanied by a concomitant LH pulse. It is possible to determine the temporal secretion of LH using frequent sampling of the peripheral blood at 10- to 15-minute intervals. Most clinical studies that focus on defining the GnRH pulse frequency use rapid, frequent blood sampling to measure the LH pulse frequency.¹⁸⁰

A key observation in functional hypothalamic anovulation is the absence of increased gonadotropin secretion despite the lack of inhibitory factors of ovarian origin, such as estradiol and inhibin. The secretory pattern of LH is abnormal. A mechanistic factor in women with this type of anovulation is a slowdown in the frequency of pulsatile GnRH secretion.^{14,182,183}

There is considerable variability in the amplitude and frequency of the pulsatile LH secretion in women with functional hypothalamic amenorrhea. When the LH secretory patterns are compared with that of the follicular phase of the menstrual cycle, a characteristic abnormality in LH pulse frequency and amplitude is seen, and occasionally, regression to a pronounced variability similar to what is seen in the prepubertal pattern is observed.^{14,182,183} In severe cases, the frequency and amplitude of LH pulses are markedly reduced. These LH patterns also suggest that GnRH pulsatile secretion is not altered to the same degree in every patient. During the recovery phase of hypothalamic amenorrhea, reversal to a pattern of LH secretion seen early in puberty often occurs, and it is characterized by a sleep-associated increase in LH amplitude.¹⁸⁰

The response of the pituitary gland to GnRH with respect to production and release of gonadotropins is not impaired in functional hypothalamic anovulation. Intravenous pulsatile GnRH administration can restore normal levels of LH and FSH.^{184,185}

Norepinephrine, dopamine, and serotonin produced in the brain have been shown to modulate GnRH or LH release in animal studies. Patients receiving medication that alters these neurotransmitters (e.g., sedatives, antidepressants, stimulants, antipsychotics) have presented with abnormalities in their menstrual cycles. These responses to medications provide circumstantial evidence that disruptions of neural pathways can alter GnRH release in humans. From these observations, it appears that activation of the noradrenergic neurons principally stimulates release of GnRH, whereas dopaminergic and serotonergic neurons can stimulate or inhibit GnRH-LH secretion.¹⁸⁶

Another group of substances that have inhibitory influences on GnRH secretion are endogenous opioid peptides.^{187,188} Blockade of endogenous opiate receptors by the administration of naloxone, an opiate antagonist, to women with this disorder causes an increase in the frequency and amplitude of pulsatile LH release.¹⁸⁹ Gonadotropin secretion resumes if the activity of the opiate receptor is blocked by long-term naloxone use in these anovulatory patients, and ovulatory function may be regained in some cases.¹⁹⁰ These studies suggest that there is an overall increase in endogenous opiate activity, which can reduce pulsatile GnRH secretion in functional hypothalamic amenorrhea.

The hypothalamic-pituitary-adrenal axis is hyperactive in many women with functional hypothalamic amenorrhea, with increased secretion of corticotropin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), and cortisol. Studies have demonstrated an increase in pulsatile ACTH secretion, increased adrenal sensitivity to ACTH, and increased cortisol secretion with a normal diurnal rhythm.¹⁸⁰ Reproductive function may be disrupted by chronic exposure to stress.¹⁸¹ Activation of the pituitary-adrenocortical system is a common response in patients with chronic stress.¹⁹¹ In functional hypothalamic amenorrhea, stressors such as exercise or emotional distress can chronically activate the hypothalamic-pituitary-adrenal axis.

The association between emotional or physical stress and disruption of the reproductive function of the hypothalamus is complex and involves several mechanisms. Daytime cortisol levels are markedly elevated, and the pituitary response to CRH is blunted.^{185,192} In an animal model, CRH seems to be an important factor in the inhibition of GnRH pulsatility.^{193,194} This inhibitory effect can be prevented by coadministration of a CRH antagonist or reversed by the opiate antagonist naloxone, suggesting that cross-talk occurs between the action of CRH and activation of the opioidergic system. Moreover, ACTH administration blocks the pituitary response to GnRH at the pituitary level.^{195,196} Another stress hormone, oxytocin, can inhibit hypothalamic GnRH secretion.¹⁸⁸ In summary, overproduction of CRH and other stress-related hormones in the brain and activation of the pituitary-adrenocortical system by chronic stress seem to play causative roles in the inhibition of gonadotropin secretion in functional hypothalamic anovulation.

Leptin administration to correct the relative leptin deficiency in women with hypothalamic amenorrhea improves reproductive, thyroid, and growth hormone axes and markers of bone formation. This suggests that leptin, a peripheral signal reflecting the adequacy of energy stores, is required for normal reproductive and neuroendocrine function.¹⁹⁷

The roles of energy balance-regulating peptides such as leptin and ghrelin were investigated in the mechanism of hypothalamic amenorrhea.¹⁸⁰ Leptin is a cytokine produced by the adipocytes and is considered to be an appetite-suppressor peptide. Leptin is secreted in a pulsatile manner with a diurnal rhythm. A decrease in total circulating leptin with loss of the normal diurnal rhythm was reported in women with hypothalamic amenorrhea.¹⁹⁷ This relative hypoleptinemia is a common characteristic of several energy-deficient conditions and is associated with slowing of the LH pulse frequency.¹⁹⁷ Leptin administration to correct the relative leptin deficiency in women with hypothalamic amenorrhea was shown to improve reproductive, thyroid, and growth hormone axes and markers of bone formation, suggesting that leptin, a peripheral signal reflecting the adequacy of energy stores, is required for normal reproductive and neuroendocrine function.¹⁹⁷ In contrast to leptin, ghrelin is an appetite-inducing peptide secreted from the stomach. During the fasting state, ghrelin serves as the hunger signal from the periphery to the hypothalamic arcuate nucleus, a region that is known to control food intake. Ghrelin levels are reported to be elevated in women with hypothalamic amenorrhea.¹⁹⁸

Hypothalamic Anovulation and Exercise

Regular vigorous exercise can lead to menstrual disturbances, a delay in menarche, luteal phase dysfunction, and secondary amenorrhea. Thirty percent of adolescent ballet

dancers have problems with the progression of puberty. The mean age at menarche is delayed until the age of 15 years. Advancement of pubertal stages seems to coincide with times of prolonged rest or after recovery from an injury.¹⁹⁹⁻²⁰⁴ The intensity, length, and type of the sport determine the severity of the disease. Activities associated with an increased frequency of reproductive dysfunction are those that favor a lower body weight and include middle-distance and long-distance running, competitive swimming, gymnastics, and ballet dancing.

Competitive athletes show endocrine abnormalities in the central nervous system consistent with those in other forms of functional hypothalamic anovulation. Abnormalities include elevations of central CRH and β -endorphin levels.

The management of exercise-related anovulation depends on the patient's choices and expectations. Side effects such as osteoporosis and delay of puberty must be discussed thoroughly with the patient.²⁰⁵ Decrease in exercise level and behavioral modification may be sufficient for the return of ovulatory function. Hormone therapy should be provided if sufficient results are not achieved. A low-dose oral contraceptive is a suitable option for women younger than 35 years of age.

Hypothalamic Anovulation Associated with Eating Disorders

Two common eating disorders associated with hypothalamic dysfunction are anorexia nervosa and bulimia. Patients with anorexia nervosa have extreme weight loss (>25% of original body weight) and a distorted body image accompanied by a striking fear of obesity. Bulimia is a related disorder characterized by alternating episodes of binge eating followed by periods of food restriction, self-induced vomiting, or excessive use of laxatives or diuretics. About 90% to 95% of these patients are women. The incidence of classic anorexia nervosa is about 1 case per 100,000 people in the general population.²⁰⁶ Among female high school and college students, bulimia is fairly common. The incidence of anorexia nervosa peaks twice during the teen years, at ages 13 and 17. Bulimia usually begins at a later age, between 17 and 25 years. Anorexia nervosa has an extremely high mortality rate of 9% and is a true medical emergency. Death may result from cardiac arrhythmia, which may be precipitated by diminished heart muscle mass and associated electrolyte abnormalities.²⁰⁷ These patients are also at increased risk for suicide.²⁰⁸

Gonadotropin secretion in anorexic women exhibits a prepubertal pattern that is similar to that observed in other forms of hypothalamic anovulation. Transitional patterns of LH secretion are seen with moderate degrees of weight recovery, and there is a normal or supranormal response to GnRH. Anovulation can persist in up to 50% of anorexic patients, even after normal weight is achieved. Anorexic and bulimic patients exhibit hyperactivation of the hypothalamus-pituitary system. Although the diurnal variation is maintained, persistent hypersecretion of cortisol occurs throughout the day.²⁰⁹ Cushingoid features are not present, in part because of mild hypercortisolemia and a reduction of peripheral glucocorticoid receptors. Levels of CRH and β -endorphin are increased in the central nervous system.^{210,211}

In anorexia nervosa, basal metabolism is decreased because peripheral conversion of thyroxine (T_4) to biologically potent triiodothyronine (T_3) is decreased. Instead, T_4 is converted to reverse T_3 , an inactive isoform. This alteration is also observed in severely ill patients and during starvation.²¹² Anorexics have partial diabetes insipidus and

are unable to concentrate urine appropriately because of the impaired secretion of vasopressin.²¹³

Anorexia nervosa and bulimia are extremely difficult to treat. The most accepted approaches include individual psychotherapy, group therapy, and behavior modification. Patients with eating disorders should have psychiatric consultation and follow-up. This helps with the diagnosis and treatment. For patients who weigh less than 75% of their ideal body weight, immediate hospitalization and aggressive treatment are recommended. Complications of anorexia nervosa include osteoporosis, estrogen deficiency, and generalized effects of malnutrition.²⁰² Hormone therapy in the form of a low-dose oral contraceptive should be provided until ovulatory function is achieved.

Treatment and Management of Functional Hypothalamic Anovulation

Treatment of chronic anovulation resulting from central nervous system–hypothalamic disorders should be directed at reversal of the primary cause (e.g., stress management, reduction of exercise, correction of weight loss). The importance of successful treatment of this disease state is underscored because these women are prone to the development of osteoporosis. For a considerable number of patients, spontaneous recovery of menstrual function takes place after a modification of lifestyle, psychological guidance, or accommodation to environmental stress. The initial treatment should be directed to a change in lifestyle and tailored to the individual patient. For individuals who remain amenorrheic, periodic assessment of reproductive status (every 4 to 6 months) is prudent.

Modification of the stress response through cognitive-behavioral therapy is a logical approach to lowering the endogenous stress levels in women with hypothalamic amenorrhea. This approach was explored in 16 subjects with hypothalamic amenorrhea randomized to cognitive-behavioral therapy or observation for a 20-week period.²¹⁴ The therapy design focused on attitudes and habits concerning eating, exercise, body image, problem-solving skills, and stress reduction. The results were encouraging. About 88% of those who underwent cognitive-behavioral therapy had evidence of ovulation, compared with only 25% of those who were observed.²¹⁴ These results suggest that endogenous stress is a major factor in the development and maintenance of hypothalamic amenorrhea and that modification of this stress response can restore normal menses.

If anovulation persists for longer than 6 months or if reversal of the primary cause is not practical (e.g., professional athletes, ballerinas), a major concern is the long-term effect of hypoestrogenism, especially on bone metabolism. In addition to estrogen deficiency, IGF1 deficiency, hypercortisolism, and nutritional factors may contribute to bone loss in this disorder.²¹⁵ However, epidemiologic data on the risk of fractures and the benefits of hormone therapy are scant.^{205,215} On the basis of studies of reproductive-age women who were ovariectomized or underwent treatment with GnRH agonist for endometriosis, bone density is expected to decrease significantly, even within the first 6 months of amenorrhea. Because these patients are often reluctant to take medications, serial bone density studies of the lumbar spine and femur may be necessary to convince them of the necessity to begin estrogen replacement therapy. If the patient is not at risk for thromboembolism and does not smoke cigarettes, a low-dose combination oral contraceptive is a reasonable replacement option. Alternatively, a combination of conjugated estrogens (0.625 mg) and MPA (2.5 mg) daily may

be administered to provide estrogenic support. The progestin (MPA) is added solely to prevent endometrial hyperplasia.

If the patient desires ovulation to achieve pregnancy, the most physiologic approach is ovulation induction with pulsatile GnRH. This is the best physiologic means of induction because the cause of the anovulatory state is decreased endogenous GnRH secretion. Pulsatile intravenous GnRH (5 µg every 90 minutes) was shown to be effective.²¹⁶ Monitoring of serum estradiol levels or follicular development can be minimized because the ovarian follicular response and gonadotropin output mimic the natural menstrual cycle. In these patients, continuation of pulsatile GnRH or hCG (1500 units administered intramuscularly every 3 days for a total of four doses) can support the function of the corpus luteum. Intravenous GnRH treatment results in ovulation rates of approximately 90%, pregnancy rates of up to 30%, and hyperstimulation rates of less than 1% per treatment cycle. Because the intravenous GnRH pump is not a practical choice for many women, an alternative strategy is the use of subcutaneous recombinant FSH for the development of one to three follicles and the induction of ovulation with intramuscular hCG followed by luteal support using intramuscular hCG or progesterone in oil.

The long-term prognosis for women with hypothalamic anovulation is encouraging. A group of investigators followed 93 women affected by functional hypothalamic amenorrhea for an average of 8.1 years.²¹⁷ At the end of the follow-up, 70.7% patients had recovered. Factors that predicted recovery included lowered mean cortisol levels, higher androstenedione levels, and an increase in body mass index. In recovered women, the body mass index increased or remained stable, whereas in nonrecovered women, it decreased or remained stable. At the end of the follow-up, 74.3% of patients treated with hormone therapy and 80% of those with no therapy recovered, but only 41.7% of those taking oral contraceptive pills recovered.²¹⁷

Chronic Anovulation Associated with Pituitary Disorders

The most common pituitary-related causes of anovulation are associated with hyperprolactinemia caused by prolactinomas or other functional or anatomic disorders of the pituitary. These disorders are frequently associated with dysregulation of gonadotropin secretion. Hyperprolactinemia and other pituitary disorders and their relation to reproduction are discussed in Chapter 9.

Chronic Anovulation Associated with Androgen Excess

The most common ovary-related disorder of chronic anovulation is PCOS. Irregular periods or amenorrhea and androgen excess are the most commonly observed features of PCOS. Other causes of ovary-related anovulation include steroid-secreting ovarian tumors and premature ovarian insufficiency. Androgen excess arising from extraovarian sources (e.g., adrenal disorders) is also associated with anovulation.

Approach to the Patient with Androgen Excess

Two natural androgens are testosterone, which is transported to target tissue by the circulation, and DHT, which is produced primarily by target tissues. Increased levels of these androgens can lead to hirsutism, which is excessive

Figure 17-26 Hirsutism. **A**, Mild facial hirsutism. **B**, Severe facial hirsutism (chin), which requires regular shaving. **C**, Severe hirsutism on chest. (**B** and **C**, From Dunaif A, Hoffman AR, Scully RE, et al. The clinical, biochemical and ovarian morphologic features in women with acanthosis nigricans and masculinization. *Obstet Gynecol.* 1985;66:545-552.)

androgenic hair growth, or to virilization, a more severe form of androgen excess. Hirsutism is defined as the presence of terminal (coarse) hair in locations at which hair is not commonly found in women, including facial hair on the cheek, above the upper lip, and on the chin (Fig. 17-26A and B). The presence of midline chest hair is also significant (see Fig. 17-26 C). A male escutcheon, hair on the inner aspects of the thighs, and midline lower back hair entering the intergluteal area are hair growth patterns compatible with androgen excess. A moderate amount of hair on the forearms and lower legs by itself may not be abnormal, although it may be viewed by the patient as undesirable and may be mistaken for hirsutism. Numerous scoring systems are available for quantifying hirsutism. One of the most detailed scales was proposed by Ferriman and Gallwey.²¹⁸ A practical and clinically useful means of quantifying hirsutism is recording the hair growth in detail using simple drawings and photographs. In particular, photographs are invaluable for documenting hirsutism accurately.

Compared with hirsutism, virilization is a more severe form of androgen excess and implies significantly higher rates of testosterone production. Its manifestations include temporal balding, deepening of voice, decreased breast

size, increased muscle mass, loss of female body contours, and clitoral enlargement (Fig. 17-27). Even if testosterone levels are moderately increased (<1.5 ng/mL), temporal balding and clitoromegaly may be observed after a long period (>1 year) in the presence of persistent androgen excess. A marked increase in androgen secretion, such as may occur from production by neoplasms, leads to a more full-blown picture of virilization in less than a few months.

Measurements of an enlarged clitoris may be used for the quantification of virilization. A clitoral length greater than 10 mm is considered abnormal (see Fig. 17-27). Clitoral length is quite variable, however. An increase in clitoral diameter is a much more sensitive indicator of androgen action. Normal values for clitoral diameter are less than 7 mm at the base of the glans (see Fig. 17-27). The most accurate definition of clitoromegaly involves use of the clitoral index (the product of the sagittal and transverse diameters of the glans clitoris). A clitoral index greater than 35 mm² is abnormal and correlates statistically with androgen excess.²¹⁹

Origins of Androgens

Among the natural C19 steroids, DHT is a biologically potent androgen that is capable of acting through

Figure 17-27 Severe clitoromegaly resulting from a testosterone-secreting ovarian tumor. **A**, The entire length of the clitoris is approximately 4 cm (normal, <1 cm). **B**, The transverse diameter of the clitoris measures 1.5 cm (normal, <0.7 cm).

androgen receptors on target cells. Testosterone is also thought to be a biologically active androgen, even though the direct androgenic effects of testosterone have not been clearly demonstrated *in vivo*. Almost all testosterone target tissues contain 5α -reductase activity, which converts testosterone to DHT, or aromatase activity, which produces estradiol in an intracrine fashion. It is not clear whether testosterone has any direct biologic effects independent of DHT or estradiol produced locally. There is no convincing evidence that the other C19 steroids, including androstenedione, DHEA, and dehydroepiandrosterone sulfate (DHEAS), are biologically active.

Testosterone in reproductive-age women is produced by two major mechanisms: direct secretion by the ovary, which accounts for roughly one third of testosterone production, and conversion of the precursor androstenedione to testosterone in the peripheral (extragonadal) tissues, which accounts for two thirds of testosterone production (Fig. 17-28).²²⁰ These peripheral tissues include the skin and adipose tissue. Androstenedione, the direct precursor of testosterone, is produced in the ovary and the adrenal. The C19 steroids DHEAS and DHEA of adrenal origin and DHEA of ovarian origin indirectly contribute to testosterone formation by first being converted to androstenedione, which is subsequently converted to testosterone (see Fig. 17-28).

DHEA, DHEAS, and androstenedione are biologically inert steroids that serve as precursors for testosterone or estrone production. Up to 20 mg of DHEAS is produced daily, compared with only 3 mg of androstenedione and 8 mg of DHEA per day. These C19 steroids of adrenal origin (DHEAS and DHEA) exert their effects after conversion to testosterone (see Fig. 17-28). Only androstenedione can be converted directly to testosterone. The conversion rate of circulating androstenedione to testosterone in extragonadal tissues is about 5% in both men and women.

Testosterone binds nuclear androgen receptors but is converted to a more potent steroid, DHT, to exert full androgenic effects on certain target tissues such as hair follicles and external genitalia.^{123,148} For example, intense androgen action in sex skin fibroblasts requires receptor occupancy by DHT. This conversion is catalyzed by the enzyme 5α -reductase and takes place in the liver and within androgen target cells such as sex skin fibroblasts (i.e., intracrine effect). The protein products of two genes (5α -reductase type 1 and type 2) exhibit this enzymatic activity.¹²³ DHT is necessary for hair growth and virilization

of external genitalia, whereas a direct role of testosterone in these processes is questionable.

Androgen action in target tissues is determined at least in part by the level of local 5α -reductase activity and the androgen receptor content (see Fig. 17-28). Androgen receptors mediate androgenic action in critical target

Figure 17-28 Androgen biosynthesis in women. Depending on the menstrual cycle phase or postmenopausal status, 20% to 30% of testosterone (T) is secreted by the ovary. The rest is accounted for by the conversion of circulating androstenedione (A) to T in various peripheral tissues. Both the adrenal and the ovary contribute to circulating A directly or indirectly, depending on the cycle phase or postmenopausal status and chronologic age. T may also be formed locally in androgen target tissues. T is converted to the biologically potent androgen dihydrotestosterone (DHT) within the target tissues and cells. For example, local conversion of T to DHT by 5α -reductase activity, which is conferred by products of at least two genes, in sex skin fibroblasts and hair follicles plays a key role in clitoral enlargement and hirsutism. The enzyme activity of 17β -HSD in peripheral tissues may be conferred by protein products of several genes with overlapping functions; HSD17B1, a distinct reductive 17β -HSD enzyme, is encoded by a specific gene expressed primarily in the ovary. DHEAS, dehydroepiandrosterone sulfate; 17β -HSD, reductive 17β -hydroxysteroid dehydrogenase.

tissues.^{148,221} Local enzymes at target tissues other than 5 α -reductase (e.g., aromatase, oxidative 17 β -HSD) also regulate androgen action by metabolizing testosterone to the androgenically inactive androstenedione or to estradiol, a potent estrogen. There appears to be a balance between potent androgen action when DHT is formed and reduction of androgenicity when inactive C19 steroids or estradiol is formed from testosterone in target tissues and other extragonadal tissues. In particular, the metabolism of testosterone to DHT versus androstenedione or estradiol in these tissues is relevant for androgen-dependent disorders (e.g., hirsutism, virilization) and estrogen-dependent disorders such as malignancies of breast and endometrium (see Figs. 17-21 and 17-28).

Laboratory Evaluation of Androgen Action

Testosterone circulates in three forms: that which is bound to sex hormone-binding globulin (SHBG), the portion not bound to SHBG but loosely associated with albumin, and the fraction not bound by SHBG or albumin (i.e., free or dialyzable testosterone). The blood testosterone that is available to diffuse into target tissues includes the free and albumin-bound fractions and is referred to as bioavailable or non-SHBG-bound testosterone. The remainder is tightly bound to the protein SHBG.

SHBG is one of the primary regulators that determine the amounts of circulating bound and bioavailable testosterone available to act on target tissues. Conditions that decrease SHBG binding (e.g., androgen excess, obesity, acromegaly, hypothyroidism, liver disease) also increase bioavailable testosterone, augmenting the effect of testosterone. SHBG also regulates the circulating amounts of bioavailable estradiol by binding a significant fraction of circulating estradiol. Conditions that decrease SHBG levels give rise to increased bioavailable (non-SHBG-bound) estradiol.

The measurement of non-SHBG-bound (bioavailable) forms of testosterone has been advocated for states of androgen excess to detect more accurately subtle forms of hirsutism. Although the diagnostic yield of this measurement is superior to that of total serum testosterone, the correlation between total and non-SHBG-bound testosterone is excellent, so that bioavailable testosterone can usually be predicted from the total testosterone level.²²² The purpose of measuring serum testosterone is to establish the presence of circulating androgen excess and to detect extremely high values that may originate from an androgen-secreting neoplasm.

The normal serum levels of androgens, especially free testosterone determined by radioimmunoassay (RIA), vary from laboratory to laboratory. A group of investigators compared serum free testosterone levels measured by equilibrium dialysis with those measured by direct RIA and with those calculated from the free androgen index ($100 \times$ testosterone/SHBG), a simple index that correlates with the free testosterone level.²²³ Calculated values for free testosterone using the free androgen index correlated well with those obtained from equilibrium dialysis. In contrast, the direct RIA method had unacceptably high systematic bias and random variability and did not correlate as well with equilibrium dialysis values. Moreover, the lower limit of detection was higher for the direct RIA than for equilibrium dialysis or calculated free testosterone.²²³ The clinician should be aware of the limitations of RIAs performed without rigorous quality control.

Measuring the levels of all C19 steroids is not clinically necessary for most patients presenting with androgen excess. The most useful initial test is a serum total

testosterone level. An abnormal level in the presence of hirsutism or virilization may be associated with PCOS, hyperthecosis, nonclassic adrenal hyperplasia, or an androgen-secreting neoplasm. Most androgen-secreting tumors are of ovarian origin. The likelihood of a neoplasm correlates roughly with increasing testosterone levels. The following tests may be added on the basis of the clinical presentation: serum 17-hydroxyprogesterone (i.e., nonclassic adrenal hyperplasia), serum prolactin and TSH (i.e., mild androgen excess associated with hyperprolactinemia), serum FSH and LH (i.e., elevated LH/FSH ratio in PCOS), serum DHEAS (i.e., adrenal tumors), and imaging of ovaries and adrenals (i.e., PCOS and steroid-secreting tumors).

Causes of Androgen Excess

Several disorders give rise to androgen excess. They include unusual causes such as iatrogenic or drug-induced androgen excess, congenital genital ambiguity (e.g., excessive in utero androgen formation in female pseudohermaphroditism), and conditions unique to pregnancy (e.g., luteoma of pregnancy, hyperreactio luteinalis). These uncommon causes and relatively more prevalent disorders associated with androgen excess are listed in Table 17-3. The term *extraovarian steroid formation* is used synonymously with *extraglandular, extragonadal, or peripheral steroid formation* in this text.

Overall, the prevalence of androgen-excess disorders was found to be as follows: 72.1% for PCOS (anovulatory patients, 56.6%; mildly affected ovulatory patients, 15.5%); 15.8% for idiopathic hyperandrogenism; 7.6% for idiopathic hirsutism; 4.3% for 21-hydroxylase-deficient nonclassic adrenal hyperplasia; and 0.2% for androgen-secreting tumors.²²⁴

In most hyperandrogenic disorders, androgen originates from more than one source (see Fig. 17-28). For example, testosterone secretion is somewhat increased from the ovary in PCOS, but the bulk of testosterone comes from extraovarian conversion of significantly elevated circulating androstenedione of ovarian origin to testosterone. Patients with PCOS also show increased adrenal output of

Idiopathic hyperandrogenism (patients who do not fall into any of the other categories listed)

DHEAS, which (after peripheral conversion to DHEA that is further converted to androstenedione) contributes indirectly to extraovarian testosterone formation.

If androgen excess is associated with primary amenorrhea, abnormal in utero sexual differentiation should be strongly suspected. These disorders are discussed in Chapter 23. Before embarking on a major workup for hirsutism or virilization, the physician is well advised to rule out exogenous androgen use. It is best to ask the patient to list all prescriptions and over-the-counter medications that she takes on her own, including injections. This is usually more rewarding than asking the patient whether she takes any androgens. Medications that can cause hirsutism or virilization are related to testosterone and include anabolic steroids and similar compounds.

The most common identifiable cause of androgen excess is PCOS, which is discussed elsewhere in this chapter. In this section, we first define some of the other disorders associated with hirsutism or virilization. This is followed by a simplified treatment strategy that may be applied to most hirsute patients within the categories of PCOS, non-classic adrenal hyperplasia, and idiopathic hirsutism.

Idiopathic Hirsutism

Hirsutism is defined subjectively as the presence in a woman of terminal hair growth in a male-distribution pattern that affects quality of life sufficiently to prompt her to seek medical advice. Hirsutism should be distinguished from hypertrichosis, in which the excessive hair growth is not restricted to androgen-dependent areas and comprises vellus or lanugo-type hair. Hypertrichosis is considered to be a phenotype not associated with male pattern hair growth and is unlikely to be modified by the known treatments of hirsutism.

Idiopathic (constitutional) hirsutism is characterized by excessive hair growth in the absence of excessive circulating androgen levels in ovulatory women, and it occurs more frequently in certain ethnic populations, particularly in women of Mediterranean ancestry.¹⁴⁸ It is defined as hirsutism in conjunction with regular menstrual cycles and normal levels of serum testosterone. Idiopathic hirsutism is not associated with any signs of virilization. Its cause is not understood completely. It has been proposed that women with idiopathic hirsutism have significantly increased cutaneous 5 α -reductase activity,²²⁵ but this association has not been confirmed. It is also unclear whether either of the 5 α -reductase isoenzymes (type 1 or 2) is predominant in the development of idiopathic hirsutism.¹⁴⁸

Idiopathic hirsutism is diagnosed in women who have hirsutism,¹⁴⁸ normal ovulatory function, and normal total or free testosterone levels. More than 80% of all women with cyclic predictable menses are ovulatory. Ovulatory function may be verified by a luteal phase day 7 progesterone level, which should be at least 5 ng/mL. Luteal phase day 7 corresponds to cycle day 17 for 24-day intervals, cycle day 21 for 28-day intervals, and cycle day 28 for 35-day intervals. The presence of oligo-ovulation or anovulation in hirsute women after exclusion of related disorders (e.g., hypothyroidism, hyperprolactinemia, nonclassic adrenal hyperplasia) is consistent with the diagnosis of PCOS.¹⁴⁸ Thyroid dysfunction and hyperprolactinemia should be excluded by the measurements of TSH and prolactin. The follicular-phase basal 17-hydroxyprogesterone level should be measured to exclude 21-hydroxylase-deficient, nonclassic adrenal hyperplasia. The use of exogenous androgens should also be excluded. In summary, the diagnosis of idiopathic hirsutism is one of exclusion in which ovulatory dysfunction, elevated circulating

testosterone levels, and other causes of androgen excess are ruled out.

Androgen-Secreting Tumors of the Ovary and Adrenal

Most androgen-secreting tumors arise from the ovary. These ovarian tumors secrete large quantities of testosterone or its precursor, androstenedione. They include Sertoli-Leydig cell tumors, hilus cell tumors, lipoid cell tumors, and infrequently, granulosa-theca tumors. Steroidogenically inert ovarian neoplasms such as epithelial cystadenomas or cystadenocarcinomas may produce factors that stimulate steroidogenesis in adjacent non-neoplastic ovarian stroma and induce production of sufficient amounts of androgen precursors such as androstenedione to give rise to clinically detectable androgen excess. Approximately 5% of androstenedione is converted to testosterone in extraovarian tissues, ultimately producing androgen excess (see Fig. 17-28).

Sertoli-Leydig cell tumors, which account for fewer than 1% of all solid ovarian tumors, tend to occur during the second to fourth decades of life, whereas hilus cell tumors occur more frequently in postmenopausal women. By the time the signs and symptoms of androgen excess cause the patient to seek medical assistance, Sertoli-Leydig cell tumors are usually so large that they are readily palpable on pelvic examination, whereas hilus cell tumors are still small. In women with either type of tumor, the serum testosterone level is markedly elevated. Granulosa-theca tumors primarily produce estradiol but may occasionally produce testosterone.

Rapidly progressing symptoms of androgen excess suggest the presence of an androgen-producing tumor unless proved otherwise. This rapid progression is typical of both ovarian and adrenal androgen-producing tumors. Progression is usually associated with defeminizing signs, such as loss of female body contour and decreased breast size. As the tumor continues to grow, more and more testosterone is produced, resulting in rapidly worsening hirsutism and progressive virilization. Elevated serum testosterone levels are characteristically associated with ovarian tumors. This change may be mediated by production and secretion of testosterone directly by the tumor or by secretion of large quantities of androstenedione that are converted to testosterone in extragonadal tissues. The testosterone levels produced by certain ovarian tumors (e.g., Sertoli-Leydig cell tumors) may be suppressed by GnRH agonists,²²⁶ so use of a GnRH agonist cannot be relied on to differentiate a neoplasm from another functional state.

In interpreting testosterone levels, the clinician should be familiar with the normal ranges of the clinical laboratory used. A value of three times the upper-normal range (or >2 ng/mL) suggests a neoplasm, particularly if the clinical history supports this diagnosis. Lower serum testosterone levels occasionally may be associated with virilizing ovarian tumors. If an androgen-secreting tumor is suspected, measurement of androstenedione is clinically useful. A severely elevated level of androstenedione is consistent with an ovarian or adrenal tumor. When an elevated level of testosterone is found and confirmed by clinical history, meticulously performed transvaginal ultrasonography should be able to detect the ovarian tumor. Transvaginal ultrasonography is the most sensitive method for the detection of an ovarian tumor.

In contrast to testosterone-secreting tumors of the ovary, testosterone-secreting tumors of the adrenal are rare. The cells of some testosterone-producing adrenal tumors may

resemble ovarian hilus cells, which are analogous to Leydig cells. These tumor cells produce testosterone and may be stimulated by LH or hCG. In patients with testosterone-producing adrenal adenomas, testosterone secretion usually decreases after LH suppression and increases after hCG stimulation. Testosterone-secreting adrenal carcinomas also have been reported.²²⁷

Virilizing adrenal tumors commonly secrete large quantities of DHEAS, DHEA, and androstenedione, and testosterone is usually produced by extraovarian conversion of these precursors. Levels of serum DHEAS are highly elevated in most patients with virilizing adrenal tumors.²²⁸ If DHEAS levels exceed 8 µg/mL, adrenal imaging by computed tomography (CT) or MRI should be ordered. Occasionally, such high levels of DHEAS are associated with a functional abnormality such as congenital adrenal hyperplasia caused by an enzymatic defect or an unexplained hyperfunctional adrenal state that is commonly associated with PCOS. These circumstances may explain a negative CT or MRI result, which warrants further investigation.

Levels of a variety of adrenal steroids, including corticosteroids, may be elevated in various combinations in the presence of an adrenal tumor. It is not possible to describe a particular pattern of hormones that defines an adrenal tumor.²²⁸ Very high levels of serum DHEAS (>8 µg/mL) suggest an adrenal tumor. Testosterone-secreting adrenal tumors are rare. Virilizing ovarian tumors are encountered much more frequently than those of adrenal origin. If the presentation is compatible with an androgen-secreting tumor and the ovaries are normal by transvaginal ultrasonography, the adrenals should be evaluated next by imaging.

Testosterone levels three times the upper-normal range (i.e., >2 ng/mL) and DHEAS levels higher than 8 µg/mL have been used traditionally as guidelines to investigate further whether neoplasms of the ovary or adrenal are the sources of androgen excess. These numbers are provided only as guidelines, not as rules, and there are exceptions. First, because tumors secrete androgens episodically, more than one measurement may be required to detect a significantly elevated level.²²⁹ Second, other precursor steroids are often elevated as well (particularly androstenedione), and their measurement should be considered. Third, some tumors may give rise to milder elevations of DHEAS and testosterone levels. Even mild elevations in a postmenopausal woman are highly suspicious for an androgen-secreting tumor. By the same token, greatly elevated serum testosterone levels may be observed in women with severe ovarian hyperthecosis (a severe variant of PCOS) in the absence of a tumor.

Virilization of recent onset and short duration warrants immediate investigation, even if testosterone and DHEAS levels are mildly elevated. With improvements in scanning techniques—vaginal ultrasonography for the ovary; abdominal ultrasonography, CT, and MRI for the adrenal—the diagnosis of even a small ovarian or adrenal tumor may be made. If no neoplasm can be localized, imaging of the ovary or adrenal after intravenous administration of radiolabeled iodomethylnorcholesterol (NP-59), which detects active steroid-producing tumors, has proved useful.²³⁰ These diagnostic studies should be pursued aggressively before surgical exploration of a suspected tumor.

The clinician should question whether an ovarian or adrenal tumor detected by imaging is the actual source of androgen excess before resorting to its surgical resection. Occasionally, a hemorrhagic corpus luteum cyst of the ovary may mimic an androgen-secreting tumor, or a

woman with androgen excess may have an adrenal “incidentaloma,” which does not secrete androgen. Intraoperative selective ovarian or adrenal vein catheterization may be considered as a last resort to demonstrate significant steroid gradients before surgical exploration of an adrenal or ovary for a small tumor is undertaken, especially if the clinical picture is not certain.²³¹

Non-Neoplastic Adrenal Disorders and Androgen Excess

Adrenal disorders such as classic congenital adrenal hyperplasia, Cushing's syndrome, and glucocorticoid resistance give rise to androgen excess related to overproduction of testosterone precursors from the adrenal. These disorders are discussed elsewhere in this text. In this chapter, we discuss nonclassic adrenal hyperplasia.

The diagnosis and prevalence of nonclassic adrenal hyperplasia continues to be debated, although the disorder clearly exists. Other terms that have been used to describe this syndrome include late-onset, adult-onset, attenuated, incomplete, and cryptic adrenal hyperplasia. This form of adrenal hyperplasia is caused by a partial deficiency in 21-hydroxylase activity. Although deficiencies in 11β-hydroxylase and 3β-HSD may result in the disorder, defects in 21-hydroxylase account for more than 90% of cases.²³²

The clinical presentation is almost identical to that of patients with PCOS. The prevalence of this disorder varies according to ethnic background, and the prevalence reported by different investigators has varied widely. The characteristic presentation consists of anovulatory uterine bleeding and progressive hirsutism of pubertal onset. These individuals are born with normal genitalia, do not exhibit salt wasting, and are symptom free until puberty. Patients of northern European ancestry have a low frequency of this disorder, whereas Ashkenazi Jews, Hispanics, and patients of central European ancestry have a much higher prevalence.²³³ High-risk ethnic groups should be screened.

Screening may first be carried out by obtaining an 8:00 a.m. serum level of 17-hydroxyprogesterone in an anovulatory patient on any day. Although most women with nonclassic adrenal hyperplasia are anovulatory, some women with this disorder present with regular periods and hirsutism of pubertal onset or with only unexplained infertility.²³² If nonclassic adrenal hyperplasia is suspected in an ovulatory patient on the basis of clinical presentation, an 8:00 a.m. serum level of 17-hydroxyprogesterone should be obtained during the follicular phase, because 17-hydroxyprogesterone levels are higher in the luteal phase than in the proliferative phase in affected or disease-free ovulatory women.²³² A level of less than 2 ng/mL effectively rules out this diagnosis.²³²

The diagnosis of nonclassic adrenal hyperplasia can be made if the basal 17-hydroxyprogesterone level is higher than 8 ng/mL. No further testing is required in these cases. Values between 2 and 8 ng/mL are considered increased but not diagnostic of nonclassic adrenal hyperplasia. For example, disease-free women and patients with PCOS may also have basal levels of 17-hydroxyprogesterone in this indeterminate range.²³² In these circumstances, an ACTH stimulation test should be used to distinguish nonclassic adrenal hyperplasia from PCOS.²³² A rise of the 17-hydroxyprogesterone level to at least 10 ng/mL 60 minutes after intravenous injection of ACTH has been considered diagnostic of nonclassic adrenal hyperplasia.²³⁴ A higher basal level of 17-hydroxyprogesterone within the 2 to 8 ng/mL range is associated with a higher likelihood of nonclassic adrenal hyperplasia. For example, an 8:00 a.m.

17-hydroxyprogesterone level higher than 4 ng/mL had a sensitivity of 90% for the diagnosis of nonclassic adrenal hyperplasia.²³²

In a patient with androgen excess who belongs to an ethnic group in which there is a high prevalence of nonclassic adrenal hyperplasia, a baseline level of 17-hydroxyprogesterone should be measured at 8:00 a.m. A screening baseline level of 17-hydroxyprogesterone should be obtained for patients with premature pubarche, those with androgen excess of early pubertal onset, women with progressive hirsutism or virilization, and patients with strong family histories of severe androgen excess.

Laboratory Testing to Aid the Differential Diagnosis of Androgen Excess

Algorithms exist for the differential diagnosis of anovulation associated with hirsutism or virilization or both. Salient clinical features are of paramount importance to guide laboratory testing. The most important features are the onset and severity of the signs and the rapidity with which they progress. Rapidly progressing severe androgen excess implies an androgen-secreting tumor until proved otherwise. The possibility of a tumor is further underscored in a postmenopausal woman or in a reproductive-age woman with a recent history of cyclic, predictable periods. Ovarian hyperthecosis, a severe variant of PCOS, also gives rise to severe androgen excess that may progress rapidly, especially at the time of expected puberty. Androgen excess emerging at the time of puberty may be indicative of PCOS or nonclassic adrenal hyperplasia.

The most useful initial test to evaluate androgen excess is the serum level of total testosterone (Table 17-4). Testosterone levels in most normal ovulatory women are lower than 0.6 ng/mL, although the value may vary from laboratory to laboratory. Women with idiopathic hirsutism have cyclic menses and normal testosterone levels. No further testing for androgen excess is required in this group.

If the testosterone level is elevated in an anovulatory woman, serum levels of TSH and prolactin should be obtained to rule out anovulation associated with hyperprolactinemia. Ultrasonography of the ovaries also can help to identify an ovarian tumor or polycystic ovaries. If the ethnic background of the patient (i.e., Ashkenazi Jews,

Hispanics, and those of central European ancestry), onset of hirsutism (i.e., puberty), or family history suggests nonclassic adrenal hyperplasia, a baseline serum level of 17-hydroxyprogesterone should be obtained at 8:00 a.m. Rare causes of androgen excess include an adrenal tumor, Cushing's syndrome, and glucocorticoid resistance. A serum level of DHEAS and adrenal imaging are required to assess the presence or absence of an adrenal tumor. CT, MRI, or abdominal ultrasonography may be used to assess the adrenals, depending on the expertise of the local radiology laboratory. A screening test for Cushing's syndrome and glucocorticoid resistance may be performed to explore rare adrenal causes of androgen excess (see Chapter 15).²³⁵

Most women with chronic anovulation and mild to moderate hirsutism of pubertal onset fall into the category of PCOS. These women have high normal or elevated testosterone levels and no other laboratory abnormalities. After other diagnoses are ruled out by laboratory testing or on clinical grounds, a diagnosis of PCOS can be made.

Treatment of Hirsutism

Therapy for androgen excess should be directed toward its specific cause and suppression of abnormal androgen secretion. Specific treatments for hirsutism and virilization are indicated for ovarian and adrenal tumors, hyperthecosis, Cushing's syndrome, and adrenal hyperplasia. Neoplasms warrant surgical intervention and are not discussed in greater detail here. Suppression with a GnRH analogue may be tried initially for ovarian hyperthecosis. However, bilateral oophorectomy is ultimately necessary to control androgen excess arising from hyperthecosis in most patients (see later discussion). Patients with adrenal disease are treated specifically. For Cushing's syndrome, treatment correlates with the source of hypercortisolism. For nonclassic adrenal hyperplasia, glucocorticoid replacement should be implemented, as it is for adrenal insufficiency. When treating androgen excess associated with nonclassic adrenal hyperplasia, an antiandrogen (e.g., spironolactone) in combination with an oral contraceptive or a glucocorticoid may be used. The doses of glucocorticoids needed to suppress the adrenal can often cause symptoms and signs of glucocorticoid excess during long-term treatment. A combination oral contraceptive plus spironolactone is favored to treat androgen excess if the patient responds to this treatment with decreased hirsutism. More details of glucocorticoid therapy may be found in Chapter 15.

The general treatment of androgen excess is directed toward the prevention of abnormal hair growth and virilization. For practical purposes, the same approach is used for androgen excess associated with idiopathic hirsutism, PCOS, and nonclassic adrenal hyperplasia. The existing hair follicles and manifestations of virilization (e.g., thickening of voice, clitoromegaly, temporal balding) remain even after elimination of excessive androgen production. Terminal hair should be removed by mechanical methods (e.g., electrolysis) at least 3 months after androgen suppression is achieved. Patients with clitoromegaly may be referred to a urologist for clitoral reduction surgery after the source of virilization has been effectively eliminated. Several medications are available for the treatment of androgen excess and hirsutism.

Oral Contraceptives. Oral contraceptives reduce circulating testosterone and androgen precursors by suppression of LH and stimulation of SHBG levels, thereby reducing hirsutism in hyperandrogenic patients.¹⁴⁸ Oral contraceptives decrease circulating androgen in patients with PCOS and synergize with the effects of antiandrogens. Oral

contraceptives may further improve the results of antiandrogen therapy in patients with idiopathic hirsutism or nonclassic adrenal hyperplasia. It is advisable to use an oral contraceptive containing 30 or 35 μg of ethinyl estradiol to achieve effective suppression of LH.¹⁴⁸ A meta-analysis showed that treatment with oral contraceptives for 6 months reduced Ferriman-Gallwey scores of hirsutism by an average of 27%.²³⁶

Spironolactone. The most common androgen blocker used for the treatment of hirsutism in the United States is spironolactone, an aldosterone antagonist structurally related to progestins. Spironolactone is effective for abnormal hair growth associated with PCOS or idiopathic hirsutism. Treatment with spironolactone for 6 months reduces Ferriman-Gallwey scores of hirsutism by an average of 38.4%.

Because spironolactone acts through mechanisms different from those of oral contraceptives, overall effectiveness is improved by combining these two medications in patients with hirsutism, including those with PCOS, idiopathic hirsutism, or nonclassic adrenal hyperplasia. Apart from inhibiting steroidogenesis and acting as an androgen antagonist, spironolactone has a significant effect in inhibiting 5α -reductase activity.^{148,237} Basic experimental and several clinical studies have confirmed the efficacy of spironolactone for hyperandrogenism and suggest that the principal effect is related to its ability to block peripheral androgen production and action.¹⁴⁸

Doses of spironolactone used in clinical studies have varied from 50 to 400 mg daily. Although doses of 100 mg/day usually are effective for the treatment of hirsutism, higher doses (200 to 300 mg/day) may be preferable in extremely hirsute or markedly obese women.^{148,237} The initial recommended dosage is 100 mg/day, gradually increasing it by increments of 25 mg/day every 3 months up to 200 mg/day on the basis of the response. This approach may be helpful to minimize side effects such as gastritis, dry skin, and anovulation. In patients with normal renal function, hyperkalemia is almost never seen. Hypotension is rare except in older women. Monitoring for electrolytes and blood pressure is imperative within the first 2 weeks at each dose level. Adjustments in dose should be made only after 3 to 6 months, as with other antiandrogens, to account for the slow changes in the hair cycle.

Patients usually notice an initial transient diuretic effect. Some women with normal cycles complain of menstrual irregularity with spironolactone; this is remedied by a downward dose adjustment or the addition of an oral contraceptive. The mechanism for abnormal bleeding is unclear. In women with oligomenorrhea, such as those with PCOS, resumption of normal menses may occur. This change may be caused in part by an alteration in levels of circulating androgens; LH levels have only occasionally been reported to decrease.²³⁸ Another important consideration is the potential in utero feminizing effect of this antiandrogen on the genitalia of a 46,XY fetus. Effective contraception should always be provided in women taking spironolactone.

Cyproterone Acetate. Cyproterone acetate is a 17-hydroxyprogesterone acetate derivative with strong progestagenic properties. Cyproterone acetate acts as an antiandrogen by competing with DHT and testosterone for binding to the androgen receptor. There is also some evidence that cyproterone acetate and ethinyl estradiol in combination can inhibit 5α -reductase activity in skin.²³⁹ Cyproterone acetate is not available in the United States but has been used in other countries. The drug usually is administered daily in doses of 50 to 100 mg on days 5 through 15 of the

treatment cycle. Because of its slow metabolism, it is administered early in the treatment cycle; when ethinyl estradiol is added, it is usually administered in 50- μg doses on days 5 through 26. This regimen is needed for menstrual control and is usually referred to as the *reverse sequential regimen*. Cyproterone acetate in doses of 50 to 100 mg/day, combined with ethinyl estradiol at 30 to 35 μg /day, is as effective as the combination of spironolactone (100 mg/day) and an oral contraceptive in the treatment of hirsutism.¹⁴⁸ In smaller doses (2 mg), cyproterone acetate has been administered as an oral contraceptive in daily combination with 50 or 35 μg of ethinyl estradiol. This regimen is primarily suited for individuals with a milder form of hyperandrogenism.¹⁴⁸

Finasteride. Finasteride inhibits 5α -reductase activity and has been used primarily for the treatment of prostatic hyperplasia. It can also be used in the treatment of hirsutism.^{240,241} At a dose of 5 mg/day, a significant improvement of hirsutism is observed after 6 months of therapy, without significant side effects. In hirsute women, the decline in circulating DHT levels is small and cannot be used to monitor therapy. Although this treatment regimen increases testosterone levels, SHBG levels remain unaffected.²⁴⁰ A meta-analysis showed that finasteride treatment for 6 months reduced Ferriman-Gallwey scores of hirsutism by an average of 20.3%.²³⁶

Finasteride primarily inhibits 5α -reductase type 2. Because hirsutism results from the combined effects of type 1 and type 2, this agent is only partially effective. Although prolonged experience with finasteride is lacking, one of the potential advantages of this agent is its benign side effect profile. One study showed efficacy with 1 year of hirsutism treatment.²⁴² It was also reported that finasteride is less effective than spironolactone with respect to the reduction of hirsutism in women.¹⁴⁸ Nevertheless, finasteride at a dose of 5 mg/day for prolonged periods represents a useful option because of its benign side effect profile and good tolerance by patients. Like spironolactone, finasteride may cause congenital genital ambiguity in a 46,XY fetus, and effective contraception should be provided during its use.

Flutamide. Flutamide is a potent antiandrogen used in the treatment of prostate cancer. It has been shown to be effective in the treatment of hirsutism.^{243,244} The mean Ferriman-Gallwey score is reduced by 41.3%.²³⁶ Nevertheless, occasional severe hepatotoxicity makes this drug unsuitable for the indication of hirsutism.²⁴⁵

Metformin and Thiazolidinediones. Most studies conducted during the past decade have suggested that treatment with metformin (1500 to 2700 mg/day) for 6 months significantly reduces hirsutism as assessed by the Ferriman-Gallwey scoring system.²³⁶ Most studies showed modest reductions in hirsutism scores (average, 19.1%).²³⁶ In obese adolescent women with PCOS, metformin in combination with lifestyle modification (i.e., diet with a 500 kcal/day deficit and exercise 30 min/day) and oral contraceptives reduced the total testosterone level and waist circumference.²⁴⁶ The thiazolidinediones (4 mg/day of rosiglitazone or 30 mg/day of pioglitazone), reduced Ferriman-Gallwey scores significantly.²³⁶ These studies suggested that insulin-sensitizing agents may be used in the treatment of hirsutism, especially for women who do not wish to use other oral agents.

Lifestyle Modification. In obese adolescent women with PCOS, lifestyle modification (i.e., diet with a 500 kcal/day deficit and exercise 30 min/day) alone resulted in a 59% reduction in the testosterone/SHBG ratio, with a 122% increase in SHBG.²⁴⁶ A moderate diet and exercise

program should be recommended as part of hirsutism management, particularly for obese women.

Comprehensive Treatment Strategy for Hirsutism. The medications described in the previous paragraphs may be effective when administered as individual treatments. Patients with the most common form of hirsutism (i.e., PCOS) are often initially treated with a combination of two agents, one that suppresses the ovary (e.g., an oral contraceptive) and another that suppresses the extraovarian (peripheral) action of androgens (e.g., spironolactone). An oral contraceptive containing 30 to 35 µg of ethinyl estradiol combined with spironolactone (100 mg/day) is the initial treatment of choice. Even in women with idiopathic hirsutism, the addition of an oral contraceptive to the antiandrogen spironolactone can improve efficacy and prevent abnormal bleeding. For women with only minor complaints of hirsutism, the use of an oral contraceptive alone may be an appropriate first approach. Moderate lifestyle modification (i.e., diet with a 500 kcal/day deficit and 30 min/day of exercise) should be a part of hirsutism management in obese patients.

Because the growth phase of body hairs lasts 3 to 6 months, a response should not be expected before 6 months after onset of treatment. Objective means should be used to assess changes in hair growth. Scoring systems and evaluation of anagen hair shafts are difficult; taking photographs is the simplest and most objective tool. Patients are often unaware that change is taking place unless there is some objective measurement. Pictures of the face and selected midline body areas before and during therapy are especially useful for the encouragement of the patient and compliance with the treatment.

Suppression of androgen production and action inhibits only new hair growth. Existing coarse hair should be removed mechanically. Plucking, waxing, and shaving are ineffective for hair removal and cause irritation, folliculitis, and ingrown hairs. Electrolysis is still the method of choice. Laser epilation is relatively new and needs further evaluation.¹⁴⁸

Most patients with PCOS and idiopathic hirsutism respond to this strategy within 1 year. Patients should be encouraged to continue treatment for at least 2 years. Then, depending on the wishes and clinical responses of patients, therapy can be stopped and the patient reevaluated. Many patients require continuous treatment for suppression of hirsutism.

Polycystic Ovary Syndrome

PCOS is the most common form of chronic anovulation associated with androgen excess; it occurs in perhaps 5% to 10% of reproductive-age women.¹⁴² The diagnosis of PCOS is made by excluding other hyperandrogenic disorders (e.g., nonclassic adrenal hyperplasia, androgen-secreting tumors, hyperprolactinemia) in women with chronic anovulation and androgen excess.

During the reproductive years, PCOS is associated with important reproductive morbidity, including infertility, irregular uterine bleeding, and increased pregnancy loss. The endometrium of the patient with PCOS must be evaluated by biopsy, because long-term unopposed estrogen stimulation leaves these patients at increased risk for endometrial cancer. PCOS is also associated with increased metabolic and cardiovascular risk factors.²⁴⁷ These risks are linked to insulin resistance and are compounded by the common occurrence of obesity, although insulin resistance also occurs in nonobese women with PCOS.¹⁴²

PCOS is considered to be a heterogeneous disorder with multifactorial causes. PCOS risk is significantly increased with a positive family history of chronic anovulation and androgen excess, and this complex disorder may be inherited in a polygenic fashion.^{248,249}

Historical Perspective

In their pioneering studies, Stein and Leventhal described an association between the presence of bilateral polycystic ovaries and signs of amenorrhea, oligomenorrhea, hirsutism, and obesity (Fig. 17-29).²⁵⁰ At the time, these signs were strictly adhered to in the diagnosis of what was then known as *Stein-Leventhal syndrome*. These investigators also reported the results of bilateral wedge resection of the ovaries, in which at least half of each ovary was removed as a therapy for PCOS. Most of their patients resumed menses and achieved pregnancy after ovarian wedge resection. They postulated that removal of the thickened capsule of the ovary would restore normal ovulation by allowing the follicles to reach the surface of the ovary. The exact mechanism responsible for the therapeutic effect of removal or destruction of part of the ovarian tissue is still not well understood.

On the basis of Stein and Leventhal's work, a primary ovarian defect was inferred, and the disorder was commonly referred to as *polycystic ovarian disease*. Subsequent clinical, morphologic, hormonal, and metabolic studies uncovered multiple underlying pathologies, and the term *polycystic ovary syndrome* was introduced to reflect the heterogeneity of this disorder.

One of the most significant discoveries regarding the pathophysiology of PCOS was the demonstration of a unique form of insulin resistance and associated hyperinsulinemia.¹⁴² Burghen and coworkers first reported this finding in 1980.²⁵¹ The presence of insulin resistance in PCOS has since been confirmed by a number of groups worldwide.¹⁴²

Diagnosis of Polycystic Ovary Syndrome and Laboratory Testing

One of the most prominent features of PCOS is the history of ovulatory dysfunction (i.e., amenorrhea, oligomenorrhea, or other forms of irregular uterine bleeding) of pubertal onset. A clear history of cyclic predictable menses of menarchal onset makes the diagnosis of PCOS unlikely. Acquired insulin resistance associated with significant weight gain or an unknown cause may induce the clinical picture of PCOS in a woman with a history of previously normal ovulatory function. Hirsutism may develop prepubertally or during adolescence, or it may be absent until the third decade of life. Seborrhea, acne, and alopecia are other common clinical signs of androgen excess. In extreme cases of ovarian hyperthecosis (a severe variant of PCOS), clitoromegaly may be observed. Nonetheless, rapid progression of androgenic symptoms and virilization are rare in PCOS. Some women may never have signs of androgen excess because of hereditary differences in target tissue sensitivity to androgens.¹⁴⁸ Infertility related to the anovulation may be the only presenting symptom.

During the physical examination, it is essential to search for and document signs of androgen excess (hirsutism, virilization, or both), insulin resistance (acanthosis nigricans, Fig. 17-30), and the presence of unopposed estrogen action (well-rugated vagina and stretchable, clear cervical mucus) to support the diagnosis of PCOS. None of these signs is specific for PCOS, and each may be associated with any of the conditions listed in the differential diagnosis of PCOS (Table 17-5).

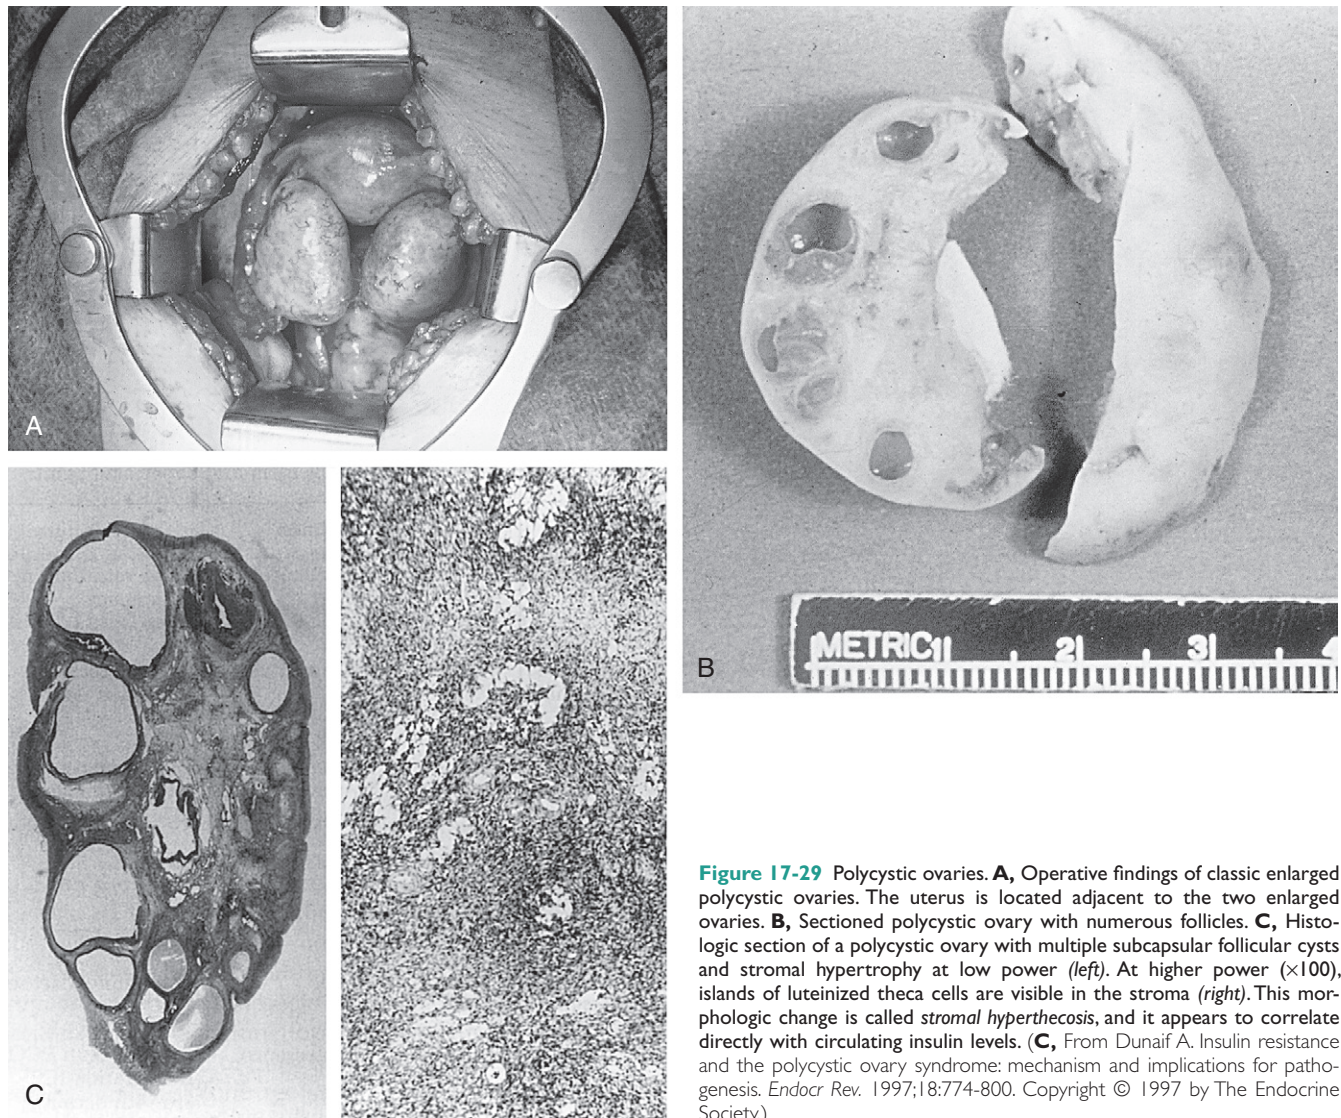

Figure 17-29 Polycystic ovaries. **A**, Operative findings of classic enlarged polycystic ovaries. The uterus is located adjacent to the two enlarged ovaries. **B**, Sectioned polycystic ovary with numerous follicles. **C**, Histologic section of a polycystic ovary with multiple subcapsular follicular cysts and stromal hypertrophy at low power (left). At higher power ($\times 100$), islands of luteinized theca cells are visible in the stroma (right). This morphologic change is called *stromal hyperthecosis*, and it appears to correlate directly with circulating insulin levels. (C, From Dunaif A. Insulin resistance and the polycystic ovary syndrome: mechanism and implications for pathogenesis. *Endocr Rev.* 1997;18:774-800. Copyright © 1997 by The Endocrine Society.)

PCOS was previously defined according to the proceedings of an expert conference sponsored by the National Institutes of Health (NIH) in 1990, which described the disorder as including hyperandrogenism or hyperandrogenemia (or both), oligo-ovulation, and exclusion of

known disorders of androgen excess and anovulation.^{252,253} Another expert conference held in Rotterdam in 2003 defined PCOS, after the exclusion of related disorders, by the presence of two of the following three features: oligo-ovulation or anovulation, clinical or biochemical signs of hyperandrogenism (or both), and polycystic ovaries (Fig. 17-31).²⁵⁴ In essence, the Rotterdam 2003 criteria expanded the NIH 1990 definition by creating two new phenotypes: ovulatory women with polycystic ovaries plus hyperandrogenism and oligo-anovulatory women with polycystic ovaries but without hyperandrogenism. The clinical usefulness of including these new groups with respect to increased risk of infertility, insulin resistance, and long-term metabolic complications is not clear at this time.²⁵⁵ More recently, the Androgen Excess Society published a broad consensus statement that included discussions of the merits and disadvantages of the NIH and Rotterdam criteria and suggested a practical definition that integrates both sets of diagnostic criteria (Table 17-6).²⁵⁵

Figure 17-30 Acanthosis nigricans. **A**, Moderate acanthosis nigricans (i.e., darkening and thickening of skin) at the lateral lower fold of the neck. Notice facial hirsutism (sideburns) in the same patient. **B**, Severe acanthosis nigricans in another patient with severe insulin resistance. (**B**, Courtesy of Dr. R. Ann Word, Dallas, Texas.)

The exclusion of hyperprolactinemia, hypothyroidism, nonclassic adrenal hyperplasia, and tumors requires a careful history, physical examination, and laboratory testing, as detailed previously (see Table 17-4). Cushing's syndrome and glucocorticoid resistance may give rise to androgen excess and anovulation after a period of normal ovulatory function in teens. An 8:00 a.m. cortisol level after dexamethasone (1 mg) administration at midnight is a useful screening test for both conditions. Cushing's syndrome may be recognized by its typical signs, whereas 8:00 a.m. and 4:00 p.m. cortisol levels are essential to confirm the diagnosis of glucocorticoid resistance.²⁵⁶ Glucocorticoid

resistance is characterized by preserved diurnal rhythm despite significantly elevated cortisol, ACTH, and adrenal C19 steroid levels and absence of cushingoid symptoms and signs.²⁵⁶

Elevated total testosterone is the most direct evidence for androgen excess. Various levels of testosterone are found in women with PCOS. Rarely, serum testosterone levels higher than 2 ng/mL may be encountered in association with the most severe form of PCOS, ovarian hyperthecosis. Overall, it is much more common to observe

Figure 17-31 Transvaginal ultrasound image of a polycystic ovary. Notice the multiple, mid-sized follicles in the periphery and the increased solid area in the middle. (From Franks S. Medical progress: polycystic ovary syndrome. *N Engl J Med.* 1995;333:853-861.)

TABLE 17-6

Criteria for the Definition of PCOS

NIH Statement (1990)²⁵³

- To include all of the following:
1. Hyperandrogenism and/or hyperandrogenemia
 2. Oligo-ovulation
 3. Exclusion of related disorders*

ESHRE/ASRM Statement (Rotterdam, 2003)²⁵⁴

- To include two of the following, in addition to exclusion of related disorders*:
1. Oligo-ovulation or anovulation (e.g., amenorrhea, irregular uterine bleeding)
 2. Clinical and/or biochemical signs of hyperandrogenism (e.g., hirsutism, elevated serum total or free testosterone)
 3. Polycystic ovaries (by ultrasonography)

AES Suggested Criteria for the Diagnosis of PCOS (2006)²⁵⁵

- To include all of the following:
1. Hyperandrogenism: hirsutism and/or hyperandrogenemia
 2. Ovarian dysfunction: oligo-anovulation and/or polycystic ovaries
 3. Exclusion of other androgen excess or related disorders*

*Including but not limited to 21-hydroxylase-deficient nonclassic adrenal hyperplasia, thyroid dysfunction, hyperprolactinemia, neoplastic androgen secretion, drug-induced androgen excess, the syndromes of severe insulin resistance, Cushing's syndrome, and glucocorticoid resistance.

high-normal levels or borderline elevations of testosterone in women with PCOS.

Prolactin and TSH concentrations should be measured routinely to rule out mild androgen excess and anovulation that may be associated with hyperprolactinemia. If basal LH levels are used as a marker for PCOS, a significant number of patients will slip through the cracks because they do not manifest elevated LH levels or increased LH/FSH ratios. The NIH-sponsored consensus conference on diagnostic criteria for PCOS in 1990 recommended that LH and the LH/FSH ratio are not required for the diagnosis of PCOS.^{253,257} The heterogeneity of LH values in PCOS may be caused by the pulsatile nature of LH secretion and negative effects of obesity on LH levels. An elevated LH/FSH ratio supports the diagnosis of PCOS and may be useful in differentiating mild cases of nonobese PCOS without prominent androgen excess from hypothalamic anovulation. However, failure to exhibit an elevated LH level is of no diagnostic value. By definition, nonclassic adrenal hyperplasia does not manifest as congenital virilization of external genitalia. Hyperandrogenic symptoms most commonly appear peripubertally or postpubertally. The clinical evaluation and laboratory-based diagnosis of nonclassic adrenal hyperplasia was discussed earlier. Chapter 15 describes the ACTH stimulation test. A screening test for Cushing's syndrome or glucocorticoid resistance should be performed as clinically indicated (see Chapter 15).

Serum DHEAS levels may be increased (up to 8 $\mu\text{g/mL}$) in about 50% of anovulatory women with PCOS. DHEAS originates almost exclusively from the adrenal.²⁵⁸ The cause of adrenal hyperactivity in PCOS is unknown. Obtaining a DHEAS level routinely in a patient with PCOS is not recommended because it does not change the diagnosis or management. If an adrenal tumor is suspected, a DHEAS level should be obtained. DHEAS levels higher than 8 $\mu\text{g/mL}$ may be associated with steroidogenically active adrenal tumors, and imaging is then indicated.

The Rotterdam 2003 criteria include the use of ultrasound as a diagnostic tool. The use of ultrasonography in the diagnosis of PCOS must be tempered by an awareness of the broad spectrum of women with ultrasonographic findings characteristic of polycystic ovaries. The typical polycystic-appearing ovary emerges in a nonspecific fashion when a state of anovulation persists for any length of time (see Fig. 17-31). About 75% of a cross-section of all anovulatory women will have polycystic-appearing ovaries as determined by ultrasonography.²⁵⁹ There are numerous causes of anovulation, and there are numerous reasons for polycystic ovaries. A similar clinical picture and ovarian condition can reflect any of the dysfunctional states discussed previously. The polycystic-appearing ovary is the result of a functional derangement but not a specific central or local defect.

Biochemical evidence of insulin resistance or glucose intolerance is not necessary for the diagnosis of PCOS. Nonetheless, glucose intolerance should be investigated. Plasma glucose levels should be measured after a 75-g glucose load as a screen for glucose intolerance.

Women with PCOS commonly present with irregular uterine bleeding in the form of infrequent periods (i.e., oligomenorrhea) or amenorrhea. It is not necessary to document anovulation by ultrasonography, progesterone levels, or otherwise, especially if menstrual cycles are irregular with periods of amenorrhea. To confirm the diagnosis of chronic anovulation and unopposed estrogen exposure, most clinicians perform a progestin challenge test after a negative urine pregnancy test. Because endometrium is exposed to estradiol chronically in PCOS, these women

respond to a challenge with a progestin (e.g., 5 mg/day of MPA given orally for 10 days) by uterine bleeding within a few days after the last pill of progestin. Reasons for lack of uterine bleeding after a progestin challenge include pregnancy, insufficient prior estrogen exposure of the endometrium, or an anatomic defect. If uterine bleeding does not follow progestin challenge, pregnancy should be ruled out again, along with other causes of chronic anovulation, as described in this chapter. An anatomic defect such as intrauterine adhesions may be ruled out with a hysterosalpingogram or hysteroscopy.

During the initial workup, an endometrial biopsy specimen should be obtained with the use of a plastic minisuction cannula (e.g., Pipelle) in the physician's office. If chronic anovulation persists, endometrial biopsies should be repeated periodically. Pregnancy should be ruled out by a urine or serum pregnancy test before each biopsy. Response to oral contraceptives or periodic progestin treatment with predictable withdrawal bleeding episodes is reassuring, and patients with predictable bleeding patterns do not need endometrial sampling during these treatments. In untreated patients, the risk of endometrial hyperplasia and malignancy is significantly increased even in young women with PCOS because of unopposed estrogen exposure.

Gonadotropin Production in Polycystic Ovary Syndrome

Women with PCOS have higher mean concentrations of LH but low or low-normal levels of FSH compared with levels found in normal women in the early follicular phase.²⁶⁰ The elevated LH levels partly reflect increased sensitivity of the pituitary to GnRH stimulation, manifested by increases in LH pulse frequency and LH pulse amplitude.²⁶¹⁻²⁶³ An increased level of LH bioactivity accompanies high levels of LH in women with PCOS.²⁶²

The elevated LH levels in PCOS are presumed to be primarily caused by accelerated GnRH-LH pulsatile activity.²⁶³ Central opioid tone appears to be suppressed because the pattern of LH secretion does not change in response to naloxone.²⁶⁴ The enhanced pulsatile secretion of GnRH has been attributed to a reduction in hypothalamic opioid inhibition caused by the chronic absence of progesterone.¹⁸³ An increase in amplitude and frequency of LH secretion also correlates with steady-state levels of circulating estrogen.

In obese women with PCOS, LH levels may not be increased. The increase in LH pulse frequency is characteristic of the anovulatory state regardless of body fat content.²⁶⁵ LH pulse amplitude, however, is comparatively normal in overweight women with PCOS, whereas it is increased in nonobese women with PCOS.²⁶⁶ The overall LH reduction in obese women with PCOS may result from factors other than changes in LH pulse amplitude.²⁶⁷ A low LH value does not rule out the diagnosis of PCOS, whereas a high LH/FSH ratio supports this diagnosis in an anovulatory woman.

Insulin has been implicated as a potential regulator of LH secretion in PCOS. Insulin enhances the transcription of the LH- β gene (*LHB*).^{268,269} This laboratory observation was supported by an in vivo human study showing that insulin infusion suppresses pituitary response to GnRH in normal women and in women with PCOS.²⁷⁰ These studies support the concept that insulin resistance or hyperinsulinemia may be responsible for abnormal gonadotropin release.

Figure 17-32 Pathologic mechanisms in polycystic ovary syndrome (PCOS). A deficient in vivo response of the ovarian follicle to physiologic quantities of follicle-stimulating hormone (FSH), possibly because of an impaired interaction between signaling pathways associated with FSH and insulin-like growth factors (IGFs) or insulin, may be an important defect responsible for anovulation in PCOS. Insulin resistance associated with increased circulating and tissue levels of insulin and bioavailable estradiol (E₂), testosterone (T), and IGF1 gives rise to abnormal hormone production in a number of tissues. Oversecretion of luteinizing hormone (LH) and decreased output of FSH by the pituitary, decreased production of sex hormone-binding globulin (SHBG) and IGF-binding protein I (IGFBP-I) in the liver, increased adrenal secretion of dehydroepiandrosterone sulfate (DHEAS), and increased ovarian secretion of androstenedione (A) all contribute to the feed-forward cycle that maintains anovulation and androgen excess in PCOS. Excessive amounts of E₂ and T arise primarily from the conversion of A in peripheral and target tissues. T is converted to the potent steroids estradiol or DHT (dihydrotestosterone). Reductive 17β-hydroxysteroid dehydrogenase (17β-HSD) enzyme activity may be conferred by protein products of several genes with overlapping functions; 5α-reductase (5α-red) is encoded by at least two genes, and aromatase is encoded by a single gene. GnRH, gonadotropin-releasing hormone.

Steroid Production in Polycystic Ovary Syndrome

Ovulatory cycles are characterized by cyclic fluctuating hormone levels that regulate ovulation and menses (see Fig. 17-1A). Anovulation in women with PCOS is associated with steady-state levels of gonadotropins and ovarian steroids. In patients with persistent anovulation, the average daily production of estrogen and androgens is increased and depends on LH stimulation (Fig. 17-32).²⁷¹ This is reflected in higher circulating levels of testosterone, androstenedione, DHEA, DHEAS, 17-hydroxyprogesterone, and estrone.²⁷² Testosterone, androstenedione, and DHEA are secreted directly by the ovary, whereas DHEAS, which is elevated in about 50% of anovulatory women with PCOS, is almost exclusively an adrenal contribution.²⁵⁸ Circulating levels of androstenedione, secreted by polycystic ovaries, are particularly high.

Estrone arises primarily from peripheral aromatization of androstenedione and in part from ovarian secretion (Fig. 17-33).²⁷² Estrone is not a potent estrogen but can be viewed as a precursor that must be converted to estradiol to exert full estrogenic action. The presence of a number of reductive 17β-HSD isoenzymes with overlapping activities that catalyze the conversion of estrone to estradiol in peripheral (extraovarian) tissues is in part responsible for maintaining estradiol production in women with PCOS.^{131,272} Increased androstenedione leads to a detectable increase in circulating levels of estradiol in women with PCOS compared with the levels measured during the first few days of an ovulatory cycle. This occurs through aromatase and 17β-HSD activities in extraovarian tissues such

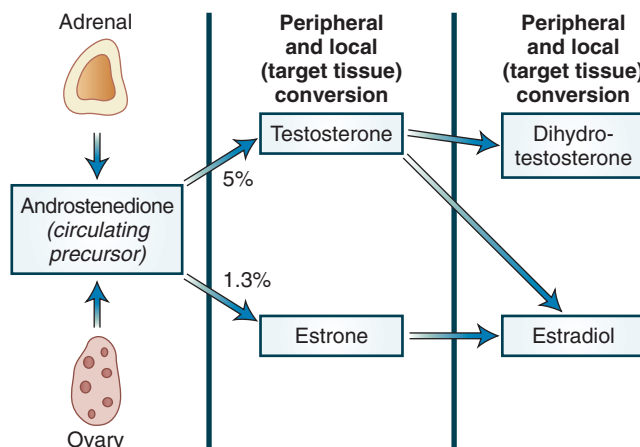

Figure 17-33 Extraovarian conversion of androstenedione to androgen and estrogen. Androstenedione of adrenal or ovarian origin, or both, acts as a dual precursor for androgen and estrogen. Approximately 5% of circulating androstenedione is converted to circulating testosterone, and approximately 1.3% of circulating androstenedione is converted to circulating estrone in peripheral tissues. Testosterone and estrone are further converted to biologically potent steroids, dihydrotestosterone and estradiol, in peripheral and target tissues. Biologically active amounts of estradiol in serum are measured in picograms per milliliter (pg/mL, or pmol/L), whereas biologically active levels of testosterone in serum are measured in nanograms per milliliter (ng/mL, or nmol/L). The 1.3% conversion of normal quantities of androstenedione to estrone may have a critical biologic impact in settings such as postmenopausal endometrial or breast cancer. Significant androgen excess is observed in conditions with abnormally increased androstenedione formation (e.g., polycystic ovary syndrome).

as skin and subcutaneous adipose tissue. Local conversion of estrone to estradiol is an important physiologic process for certain estrogen target tissues, such as disease-free breast and genital skin. Local conversion also can promote the growth of pathologic estrogen-dependent tissues, such as breast cancer and endometriosis (see Fig. 17-33).^{122,131,273-275}

Androstenedione of ovarian origin is the most strikingly elevated steroid in PCOS. Androstenedione is not biologically active but serves as a dual precursor for androgen (i.e., testosterone that is further converted to the biologically far stronger androgen DHT) and estrogen (i.e., estrone that is further converted to biologically active estradiol in target tissues).¹²⁰ Estradiol is an extremely potent steroid. Biologically effective circulating levels of estradiol are measured in units of picograms per milliliter (pg/mL) or picomoles per liter (pmol/L); biologically effective levels of testosterone are measured in units of nanograms per milliliter (ng/mL) or nanomoles per liter (nmol/L) and circulate at 10 to 100 times the physiologic levels of estradiol. Even small rates of conversion of androstenedione to estrone may have a significant biologic impact, whereas markedly elevated production of androstenedione is required to produce significant amounts of testosterone and manifestations of androgen excess (see Fig. 17-33). Because elevated production of androstenedione does occur in PCOS, extraovarian production of testosterone is biologically significant in this disease. In postmenopausal women, who have much lower levels of androstenedione, extraovarian production of testosterone is less important. Relatively small quantities of estrone (and estradiol) produced primarily by peripheral aromatization of androstenedione have a biologic impact in men and postmenopausal women.¹²⁰

Production of Sex Hormone–Binding Globulin in Polycystic Ovary Syndrome

SHBG binds testosterone and estradiol and decreases the biologic activities of these critical steroids. In PCOS, the net production of androgen and estrogen is increased. Amplified estrogenic and androgenic effects in PCOS also are caused by a decreased SHBG concentration, giving rise to increased free or biologically active quantities of estradiol and testosterone (see Fig. 17-32). The levels of SHBG are controlled by a balance of hormonal influences on its synthesis in the liver. Testosterone and insulin inhibit, whereas estrogen and T_4 stimulate SHBG formation.²⁷⁶ In anovulatory women with PCOS, circulating levels of SHBG are reduced by approximately 50%; this may be a hepatic response to increased circulating levels of testosterone and insulin (see Fig. 17-32).²⁷⁶ Circulating free estradiol and testosterone levels are increased because of the significant decrease in SHBG in patients with PCOS.

Three mechanisms contribute to the increased quantities of biologically available estradiol in PCOS: increased production of estradiol from estrone in peripheral (extraovarian) tissues, which gives rise to increased levels of circulating estradiol; increased, biologically available circulating estradiol levels due to decreased SHBG concentrations; and local conversion of estrone to estradiol at target tissues.²⁷⁴ The local conversion mechanism is likely to be physiologically significant in estrogen targets such as the breast that proliferate in response to estrogen and in the central nervous system, which produces GnRH and gonadotropins under feedback regulation by estrogen (see Fig. 17-32).

In addition to giving rise to increased biologically available estradiol, decreased serum levels of SHBG cause

elevations in biologically available free testosterone levels. Testosterone decreases serum SHBG levels, giving rise to a vicious feedback circle favoring low SHBG and high bioavailable testosterone levels (see Fig. 17-32). Insulin directly decreases serum SHBG concentrations in women with PCOS independent of any action of sex steroids.²⁷⁶ Insulin increases free testosterone levels in PCOS by two mechanisms: increasing ovarian secretion of testosterone precursors (e.g., androstenedione) and suppressing SHBG.²⁷⁶

Follicular Fate in Polycystic Ovary Syndrome

Under the influence of relatively low but constant levels of FSH, follicular growth is continuously stimulated, although not to the point of full maturation and ovulation.²⁷⁷ Despite the fact that full growth potential is not realized, the follicular life span may be extended by several months in the form of multiple follicular cysts. Most of these follicles in polycystic ovaries are 2 to 10 mm in diameter, and some can be as large as 15 mm. Hyperplastic theca cells, often luteinized in response to the high LH levels, surround these follicles (see Fig. 17-29). The accumulation of follicles arrested at various stages of development allows increased and relatively constant production of steroids in response to steady-state levels of gonadotropins.

These follicles are subject to atresia and are replaced by new follicles of similar limited growth potential. Steady-state turnover of stromal cells contributes to the stromal compartment of the ovary, and it is sustained by tissue derived from follicular atresia. A degenerating granulosa compartment, leaving the theca cells to contribute to the stromal compartment of the ovary, accompanies atresia (see Fig. 17-29). This functioning stromal tissue secretes significant amounts of androstenedione under the influence of increased LH. Androstenedione, by the mechanisms discussed previously, leads to increases in free testosterone and free estradiol levels and decreases in SHBG concentrations (see Fig. 17-32). From the point of view of steroidogenesis and steroid action, PCOS is the result of a complex vicious circle that includes a number of positive and negative feedback mechanisms.

Figure 17-32 summarizes the postulated mechanisms underlying PCOS. Because FSH and insulin or IGFs can synergize, it was postulated that this synergy does not occur in the presence of insulin resistance and might lead to relative resistance of the ovarian follicle to FSH. However, *in vitro* studies do not support this view. Cultured granulosa cells obtained from the small follicles of polycystic ovaries produce negligible amounts of estradiol but show a dramatic increase in estrogen production when FSH or IGF1 is added to the culture medium. When FSH and IGF1 were added together *in vitro*, they synergized to increase estrogen biosynthesis in granulosa cells from polycystic ovaries.²⁷⁸

Induction of ovulation in PCOS is achieved by increasing FSH levels that are hypothesized to overcome this postulated *in vivo* block to FSH at the granulosa cell level. Two popular treatments, oral clomiphene citrate and injectable recombinant FSH, can provide increased levels of endogenous or exogenous FSH that may lead to ovulation at various doses. Some PCOS patients require large doses of clomiphene citrate or FSH to achieve ovulation. Paradoxically, the polycystic ovary may overreact to pharmacologic levels of FSH by recruiting a large number of developing follicles at once; this occasionally gives rise to the ovarian hyperstimulation syndrome (discussed later).²⁷⁹ The therapeutic window between ovarian nonresponsiveness and hyperreactivity is usually narrow. There are significant gaps

of knowledge that do not permit reconciliation of clinical postulates with in vitro and in vivo findings related to the pathophysiology of PCOS.

Ovarian Hyperthecosis

Ovarian hyperthecosis is a severe variant of PCOS. The term refers to significantly increased stromal tissue with luteinized theca-like cells scattered throughout large sheets of fibroblast-like cells. The clinical and histologic findings represent an exaggerated version of PCOS.²⁸⁰ This diagnosis can be made on clinical grounds; an ovarian biopsy is not necessary except to rule out an ovarian tumor.

Increased androgen production leads to the clinical picture of more intense androgenization. The higher testosterone levels may also lower LH levels by blocking estrogen action at the hypothalamic-pituitary level.²⁶⁷ Hyperthecosis seems to be an exaggerated version of the same process that gives rise to chronic anovulation in PCOS. The severity of hyperthecosis correlates with the degree of insulin resistance.²⁶⁷ Because insulin and IGF1 stimulate proliferation of thecal interstitial cells, hyperinsulinemia may be an important pathophysiologic factor in the cause of hyperthecosis.

It is not uncommon to encounter markedly high levels of testosterone, even above 2 ng/mL, in patients with ovarian hyperthecosis. Virilization is common. These patients usually do not ovulate in response to clomiphene or recombinant FSH. It is usually difficult to suppress testosterone production, even using a GnRH agonist. Bilateral oophorectomy should be a last resort, but it may be necessary to control testosterone production in some of these patients.

Genetics of Polycystic Ovary Syndrome

The strong trend of PCOS to aggregate in families suggests an underlying genetic basis.^{281,282} Some key clinical features of PCOS are genetically transmitted. In particular, there is familial aggregation of hyperandrogenemia (with or without oligomenorrhea) in PCOS kindreds, suggesting that it is a genetic trait.²⁴⁹ Another study showed that hyperinsulinism may be a familial characteristic in daughters of women with PCOS.²⁸³

The PCOS phenotype is a consequence of genes and environment. For example, obesity associated with unhealthy lifestyle choices aggravates the PCOS phenotype in genetically susceptible women. The lack of a clearcut phenotype adds further challenge to genetic studies of PCOS. Several genomic loci have been proposed to account for the PCOS phenotype. These include *CYP11A1*, the insulin gene, and the follistatin gene; however, no convincing evidence regarding any of these loci has been published.²⁸⁴ Although independent studies identified a dinucleotide repeat marker near the insulin receptor gene that maps to chromosome 19p13.2, the particular PCOS gene in this locus has not been isolated.²⁸⁵

Insulin Resistance and Polycystic Ovary Syndrome

Insulin resistance is a major factor in the pathogenesis of non-insulin-dependent diabetes mellitus (NIDDM). The term *insulin resistance* can be defined as impaired whole-body insulin-mediated glucose disposal, as determined with the use of techniques such as the hyperinsulinemic glucose clamp technique.¹⁴² Insulin resistance is defined clinically as the inability of a known quantity of exogenous or endogenous insulin to increase glucose uptake and use in an affected individual as much as it does in a normal person. Insulin resistance is frequently observed in lean and obese women with PCOS. More severe degrees of

insulin resistance or impaired glucose tolerance are more common in obese women with PCOS.¹⁴²

The association between a disorder of carbohydrate metabolism and androgen excess was first described in 1921 by Archard and Thiers and was called the "diabetes of bearded women." Since then, the association between PCOS and insulin resistance or impaired glucose tolerance has been well recognized.¹⁴² This clinical association of insulin resistance and anovulatory hyperandrogenism is commonly found throughout the world and among different ethnic groups.²⁸⁶ Androgen excess and insulin resistance are often associated with acanthosis nigricans. Acanthosis nigricans is a gray-brown, velvety discoloration and increased thickness of the skin, usually seen at the neck, groin, and axillae and under the breasts; it is a marker for insulin resistance (see Fig. 17-30). Hyperkeratosis and papillomatosis are the histologic characteristics of acanthosis nigricans. Acanthosis nigricans in hyperandrogenic women depends on the presence and severity of hyperinsulinemia and insulin resistance.²⁸⁷ The mechanism responsible for the development of acanthosis nigricans is uncertain. This abnormal growth response of the skin may be mediated through receptors for various growth factors, including those for insulin and IGF1. Acanthosis nigricans is not specific for insulin resistance because it can be observed in the absence of insulin resistance or androgen excess.

Insulin resistance is characterized by an impaired glucose response to a specific amount of insulin. In many of these patients, normal glucose levels are maintained at the expense of increased circulating insulin to overcome the underlying defect. More severe forms of insulin resistance in PCOS range from impaired glucose tolerance to frank NIDDM. Resistance to insulin-stimulated glucose uptake is a relatively common phenomenon in the general population and is sometimes referred to as *syndrome X* or *dysmetabolic syndrome*. The fundamental abnormality leading to the manifestations that make up the metabolic syndrome is resistance to insulin-mediated glucose uptake in muscle and increased lipolysis, which produces elevated levels of circulating free fatty acids.²⁸⁸ These individuals also have dyslipidemia, hypertension, and increased risk of developing CVD. Not surprisingly, the incidences of dyslipidemia and cardiovascular risk are increased significantly in women with PCOS.^{289,290} The incidence of hypertension increases significantly after menopause in women with a history of PCOS.¹⁴² There is a significant clinical and pathologic overlap between the metabolic syndrome and PCOS.²⁹¹

The clinical presentation of patients with insulin resistance depends on the ability of the pancreas to compensate for the target tissue resistance to insulin. During the first stages of this condition, compensation is effective, and the only metabolic abnormality is hyperinsulinemia. In many patients, the beta cells of the pancreas eventually fail to meet the challenge, and declining insulin levels lead to impaired glucose tolerance and eventually to frank diabetes mellitus. Beta cell dysfunction is demonstrable in women with PCOS before the onset of glucose intolerance.²⁹²

Studies of well-characterized causes of hyperinsulinemia and androgen excess have illuminated various mechanisms of insulin resistance. Factors such as a decrease in insulin binding related to autoantibodies to insulin receptors, postreceptor defects, and a decrease in insulin receptor sites in target tissues are all involved in insulin resistance.²⁹³ These rare syndromes are found in an extremely small portion of women with anovulation, androgen excess, and insulin resistance, leaving most PCOS patients without any

demonstrable abnormalities in the number or quality of receptors or in antibody formation. The exact nature of insulin resistance in most women with PCOS is not well understood.

To understand the molecular defect underlying insulin resistance in PCOS, Dunaif and coworkers studied the differences between skin fibroblasts from women with and without PCOS with respect to insulin-dependent signal transduction.¹⁴² The fibroblasts of women with PCOS showed no change in insulin binding or receptor affinity, but a postreceptor defect was observed in one half of the women with PCOS.¹⁴² This defect is characterized by increased basal insulin receptor serine phosphorylation and a decreased in insulin-dependent tyrosine phosphorylation of the insulin receptor.¹⁴² At about the same time, Miller and coworkers evaluated whether post-translational modification of the product of the *CYP17A1* gene alters the ratio of its hydroxylase to lyase activity; they found that serine phosphorylation of CYP17A1 dramatically increases the enzyme's 17,20-lyase but not its 17 α -hydroxylase activity. These observations led the investigators to hypothesize that a dominantly inherited kinase (or kinases) phosphorylates serine residues at the insulin receptor- β and CYP17A1 product, leading to insulin resistance and increased androgen production, respectively. The cause of this abnormal phosphorylation pattern and consequences for insulin action and androgen production are important topics for further study.²⁹⁴

Within the context of a unified hypothesis, insulin resistance seems to be a critical defect that explains most of the endocrine abnormalities observed in PCOS (see Fig. 17-32). Insulin resistance is associated with abnormal responses of the ovarian follicle to FSH, which lead to anovulation and androgen secretion. This results in noncyclic formation of estrogen from androgens in peripheral tissues. Estradiol together with elevated androgen and insulin levels gives rise to abnormal gonadotropin secretion. This creates an anovulatory state favoring continuous formation of LH, steroid precursors, androgen, and estrogen (see Fig. 17-32).

Role of Obesity in Insulin Resistance and Anovulation. Increased waist-to-hip ratio compounded by significantly increased body mass index is called *android obesity* because this type of adipose tissue distribution is observed more commonly in men. Overweight women with anovulatory androgen excess commonly have this particular body fat distribution.²⁹⁵ Android obesity is the result of fat deposition in the abdominal wall and in visceral mesenteric locations. This fat is more sensitive to catecholamines, less sensitive to insulin, and more active metabolically. Android obesity is associated with insulin resistance, glucose intolerance, diabetes mellitus, and an increase in androgen production rate and results in decreased levels of SHBG and increased levels of free testosterone and estradiol.²⁹⁵ Android obesity is associated significantly with cardiovascular risk factors, including hypertension and dyslipidemia, and it has been tied to a notable increase in the risk of poor-prognosis breast cancer.^{296,297} However, no direct association has been reported between PCOS and breast cancer risk.²⁹⁸

Although the combination of insulin resistance and androgen excess is often observed in obese women overall, women with android-type obesity appear to be at a significantly higher risk for insulin resistance and androgen excess. However, insulin resistance and androgen excess are not confined to obese anovulatory women but also occur in nonobese anovulatory women.²⁶⁵ Although obesity by itself causes insulin resistance, the combination

of insulin resistance and androgen excess is a specific feature of PCOS. Not surprisingly, the combination of obesity and PCOS is associated with more severe degrees of insulin resistance than those found in nonobese women with PCOS.^{265,299} Android-type obesity, in contrast to general obesity, is a more specific risk factor for PCOS.

Diagnosis of Insulin Resistance. In everyday clinical practice, the criteria for diagnosing insulin resistance in an individual patient have not been standardized and present extremely complex issues. One fourth of the normal population has fasting and glucose-stimulated insulin levels that overlap with those of insulin-resistant individuals because of the great variability of insulin sensitivity in normal subjects.¹⁴² Clinically available measures of insulin action, such as fasting or glucose-stimulated insulin levels, do not correlate well with more detailed measurements of insulin sensitivity in research settings.

In view of these constraints, it is reasonable to consider all women with PCOS at risk for insulin resistance and the associated abnormalities of the metabolic syndrome—dyslipidemia, hypertension, and CVD.²⁹¹ A lipid profile should be obtained in all cases of PCOS. Especially for obese women with PCOS, fasting glucose levels and glucose levels 2 hours after a 75-g glucose load should be obtained as a screen for glucose intolerance. The clinician should encourage the patient to take every possible measure (e.g., weight reduction, exercise) to reduce insulin resistance.

Use of Antidiabetic Drugs to Treat Anovulation and Androgen Excess. A logical approach to the management of PCOS includes using medications that improve insulin sensitivity in target tissues, achieving reductions in insulin secretion, and stabilizing glucose tolerance. The antidiabetic medication metformin (a biguanide) and the thiazolidinediones pioglitazone and rosiglitazone have been used to reduce insulin resistance. Although metformin appears to influence ovarian steroidogenesis directly, this effect does not appear to be primarily responsible for the attenuation of ovarian androgen production in women with PCOS. Rather, metformin inhibits the output of hepatic glucose, necessitating a lower insulin concentration and thereby probably reducing androgen production by theca cells.³⁰⁰

Metformin at a dose of 500 mg three times daily reduced hyperinsulinemia, basal and stimulated levels of LH, and free testosterone concentrations in overweight women with PCOS.^{301,302} Some anovulatory women ovulated and achieved pregnancy; however, clomiphene is superior to metformin in achieving live births in infertile women with PCOS.³⁰³⁻³⁰⁵ Among published studies of metformin use in women with PCOS, subject characteristics and control measures for effects of weight change, dose of metformin, and outcome vary widely. A meta-analysis of 13 studies in which metformin was administered to 543 participants reported that patients taking metformin had an odds ratio for ovulation of 3.88 (95% confidence interval [CI], 2.25 to 6.69) compared with placebo and an odds ratio for ovulation of 4.41 (95% CI, 2.37 to 8.22) for metformin plus clomiphene compared with clomiphene alone.³⁰⁶ Although the addition of metformin to clomiphene seems to increase the ovulation rate, it does not result in a higher rate of live births.³⁰⁴ Metformin also improved fasting insulin levels, blood pressure, and levels of LDL-cholesterol. These effects were judged to be independent of any changes in weight that were associated with metformin, but controversy persists about whether the beneficial effects of metformin are

entirely independent of the weight loss that is typically seen early in the course of therapy.^{305,306}

The thiazolidinediones are pharmacologic ligands for the nuclear receptor peroxisome proliferator-activated receptor- γ (PPAR γ). They improve the action of insulin in the liver, skeletal muscle, and adipose tissue and have only a modest effect on hepatic glucose output. As with metformin, the thiazolidinediones are reported to affect ovarian steroid synthesis directly, although most evidence indicates that the reduction in insulin levels is responsible for decreased concentrations of circulating androgen.³⁰⁰

Women with PCOS who took troglitazone had consistent improvements in insulin resistance, pancreatic beta cell function, hyperandrogenemia, and glucose tolerance.^{307,308} In a double-blind, randomized, placebo-controlled study, ovulation was significantly greater for women with PCOS who received troglitazone than for those who received placebo; free testosterone levels decreased, and levels of SHBG increased in a dose-dependent fashion.³⁰⁹ Although troglitazone is no longer available because of its hepatotoxicity, subsequent studies using rosiglitazone and pioglitazone had similar results.³¹⁰⁻³¹² Because of concern about the use of thiazolidinediones in pregnancy and recent evidence linking these drugs to serious side effects such as heart failure and stroke, they have been less readily adopted for routine treatment of PCOS. The success of the strategy of reversing insulin resistance as a way to correct the critical abnormalities in PCOS argues for this defect as central to the pathogenesis of the disorder.

Management of Long-Term Deleterious Effects of Polycystic Ovary Syndrome

The long-term consequences of PCOS include irregular uterine bleeding, anovulatory infertility, androgen excess, chronically elevated levels of free estrogen associated with an increased risk of endometrial cancer, and insulin resistance associated with an increased risk of CVD and diabetes mellitus. Treatment must aid in achieving a healthy lifestyle and normal body weight, protect the endometrium from the effects of unopposed estrogen, and reduce testosterone levels.

Any woman with PCOS should be counseled to maintain a healthy lifestyle. In obese PCOS women, permanent lifestyle modification should be emphasized as the primary preventive measure to minimize short-term and long-term deleterious effects. Simple measures such as decreasing daily food intake by 500 kcal and introducing any type of moderate exercise for 30 minutes daily for 6 months can decrease hyperandrogenemia and diastolic blood pressure.²⁴⁶ Because insulin resistance contributes to the abnormal lipid profile and increased cardiovascular risk in women with PCOS, weight loss is a high priority for patients who are overweight.³¹³ Insulin resistance and androgen excess can be reduced with a weight reduction of at least 5%.^{314,315} Significant weight loss has also resulted in ovulation and pregnancy in a number of patients with PCOS.³¹⁶ Nutritional counseling and an emphasis on lifestyle changes are essential components of the long-term management of PCOS.

If the patient does not wish to become pregnant, medical therapy is directed toward the interruption of the effect of unopposed estrogen on the endometrium. Nonfluctuating levels of unopposed estradiol in the absence of progesterone cause irregular uterine bleeding, amenorrhea, and infertility and increase the risk of endometrial cancer. Anovulatory women with PCOS may have endometrial cancer even in their early 20s.³¹⁷ Endometrial biopsy should be performed periodically in untreated women with PCOS

regardless of age. Pregnancy should be ruled out before each endometrial biopsy. The uterine bleeding pattern should not influence the decision to perform an endometrial biopsy. The presence of amenorrhea does not rule out endometrial hyperplasia. The critical factor that determines the risk of endometrial neoplasia is the duration of anovulation and exposure to unopposed estradiol. Long-term treatment with a progestin or oral contraceptive significantly decreases the risk of endometrial cancer.

One of the simplest and most effective ways to administer a progestin in the long term is to use an oral contraceptive. Oral contraceptives provide two additional benefits: reduction of androgen excess and contraception. Oral contraceptive pills reduce circulating androgen levels through suppression of circulating LH and stimulation of SHBG levels, and they have been shown to reduce hirsutism in hyperandrogenic patients.¹⁴⁸ Oral contraceptive treatment for anovulation and hyperinsulinemia in women with androgen excess does not increase cardiovascular risk.³¹⁸⁻³²⁰

For the patient who does not complain of hirsutism but is anovulatory and has irregular bleeding, treatment with a single progestin may be attempted as an alternative to oral contraceptive use. Progestin therapy is directed toward interruption of the chronic exposure of endometrium to unopposed effects of estrogen. MPA may be administered intermittently (e.g., 5 mg daily for the first 10 days of every month) to ensure withdrawal bleeding and prevent endometrial hyperplasia. This treatment does not decrease androgen excess, nor does it provide contraception. Because newer oral contraceptives (with an ethinyl estradiol content of 30 μ g or less and a new progestin) suppress androgen excess of ovarian origin, provide contraception, protect the endometrium, and do not increase insulin resistance, a low-dose oral contraceptive is the treatment of choice for nonsmokers with PCOS. An oral contraceptive together with the antiandrogen spiro lactone (100 mg/day) is the recommended starting treatment for a hirsute woman with PCOS. The dose of spiro lactone can be increased in increments to suppress hair growth, as described earlier.

Treatment with an oral contraceptive, with or without spiro lactone, may not be effective in androgen suppression in severe cases of PCOS. In patients resistant to oral contraceptives, suppression of the ovary with a GnRH agonist may be required. Because glucocorticoids increase insulin resistance, they should be used with caution in patients with hyperinsulinemia. Spiro lactone does not affect insulin sensitivity in anovulatory women and can be used safely without causing adverse effects on carbohydrate or lipid metabolism.³²¹

The clinician must counsel women with PCOS regarding their increased risk of future diabetes mellitus. The age at onset of NIDDM is significantly earlier in these women than in the general population.²⁴⁷ Women with PCOS are more likely to experience gestational diabetes.³²² Long-term follow-up studies have shown a significantly increased risk for frank diabetes mellitus in anovulatory patients with PCOS.¹⁴² It is therefore important to monitor glucose tolerance with periodic measurements of glucose levels after fasting and after a 75-g glucose load. The place of insulin sensitizers, such as metformin and thiazolidinediones, in the long-term treatment of PCOS remains to be determined by data from future large clinical trials.^{305,307,308,323}

The physician should alert the patient with PCOS that up to one half of first-degree relatives and sisters may be affected by PCOS or at least by androgen excess in the presence of regular menses.²⁴⁹ These individuals may be at

higher than average risk for CVD and may benefit from preventive measures that reduce this risk.

Ovulation Induction in Polycystic Ovary Syndrome

Clomiphene Citrate. Patient with PCOS who desire pregnancy are candidates for the medical induction of ovulation. When pregnancy is achieved, patients with PCOS appear to have an increased risk of spontaneous miscarriage.³²⁴ This increased risk may be related to elevated levels of LH that may produce an adverse environment for the oocyte and the endometrium. LH levels should be suppressed with oral contraceptives before ovulation is induced. Suppression can be achieved in most patients with PCOS by the use of an oral contraceptive for 4 to 6 weeks before ovulation induction with clomiphene citrate or recombinant FSH.

To induce ovulation in women with PCOS, FSH levels are increased by administration of clomiphene citrate or by injection of recombinant FSH. Presumably, pharmacologic levels of FSH overcome the ovarian defect that is responsible for anovulation in PCOS.

Clomiphene citrate is a nonsteroidal, ovulation-inducing ER ligand with mixed agonistic-antagonistic properties.³²⁵ Acting as an antiestrogen, clomiphene citrate is thought to displace endogenous estrogen from hypothalamic ERs, thereby removing the negative feedback effect exerted by endogenous estrogens. The resultant change in pulsatile GnRH release is thought to normalize the release of pituitary FSH and LH, which is followed by follicular recruitment and selection, assertion of dominance, and ovulation.³²⁵

Clomiphene citrate treatment can be started at any time in an amenorrheic and anovulatory patient provided that a pregnancy test is performed beforehand (Fig. 17-34). Alternatively, uterine bleeding may be induced after a 10-day treatment with a combination oral contraceptive or MPA (5 mg/day). On cycle day 2 or 3 (day 1 is the first day of uterine bleeding), a baseline ultrasound study is performed to rule out any ovarian follicular cyst of more than 25-mm average diameter. If one or more large cysts are seen, ovulation induction should be delayed until after gonadotropin suppression by continuous oral contraception treatment for 4 to 6 weeks to eliminate these cysts or decrease their size. Clomiphene citrate is started at 50 mg/day orally on day 3 of the cycle and continued for 5 days. Ultrasonography is performed on cycle day 13 or 14 to ensure follicular development (i.e., at least one new follicle measuring at least 16 mm in diameter). The patient should be encouraged to have intercourse every other day during

the 10-day period following the last clomiphene citrate dose. Alternatively, measurement of urinary LH to detect an LH surge can be used to time intercourse. Intercourse is recommended on the day of a positive urinary LH peak and on the next day. Intercourse is recommended within 24 to 36 hours after an hCG injection.

If follicular development does not occur after the first course of therapy with clomiphene citrate at 50 mg/day, a second course of 100 mg daily for 5 days may be started. Lack of response at doses of 150 to 200 mg daily for 5 days should be an indication for a change of treatment. Most patients destined to conceive do so with the starting dose of clomiphene citrate (50 mg/day for 5 days). Most clomiphene citrate-initiated conceptions occur within the first 6 ovulatory cycles.³²⁵ The incidence rate for multiple gestation in clomiphene citrate-induced pregnancies is 6% (4% for twins and 2% for triplets).³⁰⁴ Failure to achieve pregnancy after 3 clomiphene cycles despite sonographic evidence of follicular development should prompt the clinician to perform a comprehensive infertility workup, including a semen analysis and evaluation of the uterine cavity and tubal patency.

Metformin. Head-to-head randomized trials showed that clomiphene alone is clearly superior to metformin only with respect to achieving ovulation and live births in women with PCOS.³⁰⁴ However, the ovulatory response to clomiphene was increased in obese women with PCOS by decreasing insulin secretion with the addition of metformin.^{307,308,323} A later randomized study showed that the higher rate of ovulation in the users of clomiphene plus metformin seemed to be offset by a higher rate of pregnancy losses, producing similar live birth rates in clomiphene-only and clomiphene plus metformin groups.³⁰⁴ The benefit of the addition of metformin to clomiphene in obese clomiphene-nonresponders with PCOS needs to be assessed further.

Aromatase Inhibitors. Aromatase inhibitors reduce hypothalamic-pituitary estrogen feedback that leads to increased GnRH secretion, concomitant elevations in LH and FSH, and increased ovarian follicular development in premenopausal women.^{114,326} The gonadotropin-stimulating aromatase inhibitors letrozole and anastrozole have been used off-label in the treatment of patients with ovulatory dysfunction, such as PCOS, and for increasing the number of ovarian follicles recruited for ovulation in women who are already ovulatory.³²⁶⁻³²⁸ Oral administration of letrozole (2.5 or 5 mg/day) or anastrozole (1 mg/day) on days 3 to

Figure 17-34 Monitoring of clomiphene citrate-initiated ovulation. On cycle day 2 or 3, a baseline ultrasound examination is performed to rule out any large ovarian follicular cyst. Clomiphene citrate is started on day 3 of the cycle and continued for 5 days. Ultrasonography is performed on cycle day 13 or 14 to ensure follicular development. The patient should be encouraged to have intercourse every other day during the 10-day period after the last clomiphene citrate dose. Urinary human chorionic gonadotropin (hCG) levels are checked to determine whether pregnancy has occurred.

7 after uterine bleeding is effective for ovulation induction in women with anovulatory infertility.³²⁸⁻³³⁰ Clomiphene resistance in women with PCOS has been particularly studied as a potential indication for aromatase inhibitors; no difference between anastrozole (1 mg/day) and letrozole (2.5 mg/day) was demonstrated.³²⁸ A head-to-head randomized study did not show any advantage to the use of letrozole (5 mg/daily) over clomiphene citrate (100 mg daily) as first-line treatment for induction of ovulation in women with PCOS.³²⁹ Another randomized study, however, demonstrated that letrozole (2.5 mg/day) and metformin (1500 mg/day) plus clomiphene (150 mg/day) were equally effective for inducing ovulation and achieving pregnancy in patients with clomiphene-resistant PCOS.³³⁰ A retrospective study did not show any difference in the overall rates of major and minor congenital malformations among newborns from mothers who conceived after letrozole or clomiphene treatment.³³² Although worldwide experience with aromatase inhibitors for ovulation induction is increasing, definitive studies in the form of randomized, controlled trials comparing live birth rates and safety associated with clomiphene citrate and an aromatase inhibitor are lacking.³³¹

Low-Dose Gonadotropin Therapy. For women who do not ovulate in response to clomiphene citrate, FSH injections are started on day 3 of spontaneous or progestin-induced uterine bleeding. Recombinant FSH is administered subcutaneously starting with a daily dose of 75 IU for up to 10 days, if necessary, and using small incremental dose increases (12.5 to 37.5 IU) from then on at 3- to 7-day intervals until serum estradiol concentrations begin to increase. The dose is then maintained until follicular rupture, which is induced by subcutaneous injection of recombinant hCG (250 µg). Follicular growth is monitored by transvaginal ultrasonography and blood estradiol levels, which serve as biochemical markers for the granulosa cell mass in the growing follicle.³³³ This regimen induces development of a single follicle in most cycles and has succeeded in reducing the rate of multiple pregnancies to as low as 6% in some series.²⁷⁹ The low-dose regimen also practically eliminated the complication of severe ovarian hyperstimulation syndrome (OHSS).²⁷⁹ Conception rates are comparable to those achieved with conventional therapy. The miscarriage rate remains somewhat higher than that after spontaneous conceptions (20% to 25%).

Conventional-dose gonadotropin therapy (starting FSH dose, 150 IU daily) should not be used as first-line treatment in patients with PCOS because it causes two important complications: an alarming number of multiple pregnancies (14% to 50% of treatment cycles) and a significantly increased risk of severe ovarian hyperstimulation syndrome (1.3% to 9.4% of treatment cycles). Three important complications of gonadotropin therapy in PCOS patients are significantly increased rates of multiple pregnancies, severe ovarian hyperstimulation syndrome, and spontaneous miscarriage.³³⁴

OHSS is a more common complication of conventional-dose gonadotropin treatment. Milder forms are relatively common and are characterized by weight gain, abdominal discomfort, and enlarged ovaries. Home bedrest and oral intake of fluids are sufficient to manage this form. Severe OHSS occurs in 0.1% to 0.2% of stimulation attempts and is accompanied by severe ascites, pleural effusion, electrolyte imbalance, and hypovolemia with oliguria. The most dreaded complication is deep venous thrombosis and embolism. Its cause is poorly understood. Large number of follicles, peak estradiol levels greater than 2000 pg/mL, and

pregnancy are associated with a higher likelihood of OHSS. Prevention includes withholding of hCG injections and intrauterine insemination. Treatment of severe OHSS includes hospitalization, maintenance of fluid and electrolyte balance, prophylaxis of thromboembolism by heparin, and drainage of severe ascites or pleural effusions. Frequently, supportive measures are sufficient to manage this self-limited condition.

Premature Ovarian Insufficiency

Premature ovarian insufficiency, which is defined as early depletion of ovarian follicles (before the age of 40 years), is a state of hypergonadotropic hypogonadism. These patients go through a normal puberty and a variable period of cyclic menses followed by oligomenorrhea or amenorrhea accompanied by hot flashes and urogenital atrophy. Premature ovarian insufficiency should always be included in the differential diagnosis of chronic anovulation. History and physical examination may reveal menstrual irregularity or secondary amenorrhea accompanied by symptoms and signs of estrogen deficiency, such as hot flashes and urogenital atrophy. Elevated FSH levels greater than the 95% CIs of the midcycle gonadotropin peak of the normal menstrual cycle (>40 IU/L) on at least two occasions confirm the diagnosis.³³⁵

On average, menopause occurs at the age of 50 years, with 1% of women continuing to menstruate beyond the age of 60 years and another 1% whose menopause occurs before 40 years. Premature menopause or ovarian insufficiency has been arbitrarily defined as the cessation of menses before 40 years of age.³³⁶

The cause or genetic basis of premature ovarian insufficiency is not well understood. Two genetic syndromes associated with premature ovarian insufficiency are gonadal dysgenesis with primarily mosaic X-chromosome defects and *FMRI* gene premutation, a variant of fragile X syndrome.³³⁷ Syndromes resulting from single-gene mutations (e.g., blepharophimosis-ptosis-epicanthus inversus syndrome [*FOXL2* mutation], galactosemia [*GALT* mutation]) may be associated with premature ovarian insufficiency.³³⁷ Despite these observations, the cause of premature ovarian insufficiency remains unknown in most cases.

The underlying ovarian defect may manifest at various ages, depending on the number of functional follicles left in the ovaries. The different symptoms may be regarded as phases in the process of perimenopausal change, regardless of the actual age of the patient. If loss of follicles occurs rapidly before puberty, primary amenorrhea and lack of secondary sexual development ensue. The degree to which the adult phenotype develops and the age at which secondary amenorrhea actually occurs depend on whether follicle loss took place during or after puberty. In cases of primary amenorrhea associated with sexual infantilism, the ovarian remnants exist as streaks, and transvaginal ultrasonography usually cannot detect any ovaries. Many gene defects (e.g., *FSHR*, *CYP17A1*, *CYP19A1*) involve ovarian failure at the expected time of puberty, and the phenotypes manifest with primary amenorrhea and lack of secondary sexual development (see Chapter 25).³³⁷

Premature ovarian insufficiency can result from an autoimmune process, and it is frequently associated with autoimmune polyendocrine syndromes.³³⁸ Other causes of premature insufficiency can be related to the sudden destruction of follicles by chemotherapy, irradiation, or infections such as mumps oophoritis. The effect of irradiation depends on the patient's age and the x-ray dose.³³⁹ Steroid levels begin to fall and gonadotropins rise within

2 weeks after irradiation of the ovaries. Young women exposed to radiation are less likely to have permanent ovarian insufficiency because of the higher number of oocytes present at younger ages. When the radiation field excludes the pelvis or the ovaries are transposed out of the pelvis by laparoscopic surgery before irradiation, there is no risk of premature ovarian insufficiency.³⁴⁰ Most chemotherapeutic agents used for eradication of malignancies are toxic to the ovaries and cause ovarian insufficiency.³⁴¹ Resumption of menses and pregnancy have been reported after radiotherapy or chemotherapy,³⁴² but premature ovarian insufficiency may occur years after these therapies.³¹⁶

Diagnosis and Management of Premature Ovarian Insufficiency

Premature ovarian insufficiency should be suspected in a woman younger than 40 years of age who presents with amenorrhea, oligomenorrhea, or another form of menstrual irregularity. Menopausal serum FSH levels (40 IU/L) on at least two occasions are sufficient for the diagnosis of premature ovarian insufficiency. These young women can be diagnosed with ovarian insufficiency and infertility if gonadotropin levels are repeatedly elevated.

Case reports of pregnancies in affected women occurring during hormone replacement therapy have been published.^{343,344} In particular, young women with premature ovarian insufficiency may experience intermittent periods of ovarian function, with antral follicles present at ovarian ultrasonography and ovulation described in cases that followed up with regular endocrine assessments. A randomized trial of hormone therapy in this setting showed that folliculogenesis occurred often but was less frequently followed by ovulation and even less frequently by pregnancy (up to 14%); conventional-dose estrogen therapy did not improve the rate of folliculogenesis, ovulation, or pregnancy.³³⁵ Later pilot studies or case reports suggested that lowering FSH levels to less than 15 IU/L by use of high-dose estrogen or a GnRH antagonist in young women with premature ovarian insufficiency may trigger ovulation or permit ovulation induction and pregnancy in a small number of patients.^{345,346}

The clinician should inform patients diagnosed with premature ovarian insufficiency that there is a small but significant likelihood of spontaneous pregnancy or pregnancy after ovulation induction in the future. Women who desire pregnancy are still best served by assisted reproductive technology employing donor oocytes, because the probability of pregnancy with an autologous egg is low. Use of donor oocytes followed by IVF with the partner's sperm and intrauterine embryo transfer after synchronization of the recipient patient's endometrium with the donor's cycle using exogenous estrogen and progesterone is offered to the patient who wishes to carry a pregnancy in her uterus (see Fig. 17-25). This approach offers an excellent chance of pregnancy (>50% per donor oocyte IVF cycle).

Patients with premature ovarian insufficiency have an increased incidence of an abnormal complement of chromosomes.³⁴⁷ The risk of having an abnormal karyotype increases with decreasing age at onset of the ovarian insufficiency. A chromosomal analysis is recommended for some of these patients because of the increased risk of a gonadal tumor associated with the presence of a Y chromosome.³⁴⁸ The arbitrarily chosen age group for chromosomal analysis includes women 30 years of age or younger because it is rare to encounter a gonadal tumor in patients with premature ovarian insufficiency after the age of 30 years.³⁴⁹

Mosaicism that includes a Y chromosome has been associated with a high incidence of gonadal tumors.³⁴⁸ These malignant tumors arise from germ cells and include gonadoblastomas, dysgerminomas, yolk sac tumors, and choriocarcinoma. Secondary virilization in patients with karyotypic abnormalities and premature ovarian insufficiency significantly increases the risk of a dysontogenetic gonadal tumor. The precise risk of a tumor in various subsets of these patients is not well known because a significant number of women carrying a Y chromosome do not have symptoms of virilization. The frequency of Y chromosomal material determined by polymerase chain reaction is high in those with Turner's syndrome (12.2%), but the occurrence of a gonadal tumor among these Y-positive patients seems to be as low as 7% to 10%.³⁵⁰

Fragile X-associated disorders are caused by a CGG trinucleotide repeat expansion in the promoter region of the *FMR1* gene. Expansion of the CGG trinucleotide repeats to more than 200 copies induces methylation of the *FMR1* gene, with an outcome of transcriptional silencing.³⁵¹ This so-called full mutation was linked to mental retardation or autism. Individuals who carried the premutation (defined as >55 but <200 CGG repeats) have increased *FMR1* mRNA levels with decreased levels of fragile X mental retardation protein (FMRP). Convincing evidence relates the *FMR1* premutation to altered ovarian function and loss of fertility.³⁵² The natural history of the altered ovarian function in women who carry the *FMR1* premutation is still not well understood. Women with premature ovarian failure are at increased risk for an *FMR1* premutation and should be informed of the availability of fragile X testing.

Premature ovarian insufficiency usually occurs as an isolated autoimmune disorder. Rarely, it may be associated with hypothyroidism, diabetes mellitus, hypoadrenalism, hypoparathyroidism, or systemic lupus erythematosus.³⁵³ It can be part of an autoimmune polyendocrine syndrome.³³⁸ Thyroid insufficiency, adrenal insufficiency, and diabetes mellitus are the endocrine disorders most frequently associated with premature ovarian insufficiency.³⁵⁴ Periodic endocrine testing for glucose intolerance, adrenal or parathyroid function, and autoimmune disease (e.g., systemic lupus erythematosus) should be considered based on the clinical presentation (Table 17-7).

Treatment of premature ovarian insufficiency should be directed toward its specific cause. In most cases, however, it is not possible to identify a specific cause if there are no karyotypic anomalies. Besides infertility, long-term ovarian steroid deficiency has far-reaching health implications. Early menopause has been associated with increased cardiovascular mortality and stroke, bone fracture, and colorectal cancer risks.³³⁷ Despite reduced risks for development of breast cancer, overall quality of life and life expectancy decline with early menopause.³³⁷ Hormone therapy, using combined estrogen and progestin or a low-dose oral

contraceptive, is the cornerstone of the management for these women. The added value of androgen replacement remains uncertain.³³⁷

DIAGNOSIS AND MANAGEMENT OF ANOVULATORY UTERINE BLEEDING

Acyclic production of estrogen during anovulatory cycles gives rise to irregular shedding of the endometrium. These bleeding manifestations of anovulatory cycles in the absence of uterine pathology or systemic illness are commonly referred to as *dysfunctional uterine bleeding*. Anovulatory uterine bleeding, which is the most common cause of chronic menstrual irregularities, is a diagnosis of exclusion. Pregnancy, uterine leiomyomas, endometrial polyps, and adenomyosis should be ruled out as anatomic causes of irregular uterine bleeding. Malignancies of the vagina, cervix, endometrium, myometrium, fallopian tubes, and ovaries should also be ruled out before a diagnosis of anovulatory uterine bleeding is made. Coagulation abnormalities should be excluded.

Anovulatory uterine bleeding can be managed without surgical intervention by either restoring ovulation or mimicking the ovulatory hormonal profile by providing exogenous steroids. The rationale for use of exogenous steroids is based on the knowledge of predictable responses of the endometrium to estrogen and progesterone. Physiologic responses of the endometrium to natural ovarian steroids have been uncovered by observation of the gross and microscopic changes occurring in the endometrium during thousands of normal ovulatory cycles in humans and other primates.^{151,153,355} The pharmacologic application of exogenous estrogens and progestins in women with anovulatory bleeding aims to correct the production of local tissue factors that mediate physiologic steroid action and reverse the excessive and prolonged flow typical of anovulatory cycles.

Clinical management of irregular uterine bleeding with exogenous hormones is a time-honored method, and it has diagnostic value. Failure to control vaginal bleeding with hormonal therapy, despite appropriate application and use, makes the diagnosis of anovulatory uterine bleeding considerably less likely. In such cases, attention is directed to an anatomic pathologic entity within the reproductive axis as the cause of abnormal bleeding.

Heavy but regular menstrual bleeding (i.e., hypermenorrhea) can be encountered in ovulatory women. It may have an anatomic cause, such as a leiomyoma impinging on the endometrial cavity or the diffuse and pathologic presence of benign endometrial glands in the myometrium (i.e., adenomyosis). In the absence of a specific pathologic cause, it is presumed that hypermenorrhea reflects subtle disturbances in the endometrial tissue mechanism. In essentially all cases, evaluation and treatment are identical to the approach detailed in this section.

Characteristics of Normal Menses

Normal menstruation takes place about 14 days after each ovulation episode as a consequence of postovulatory estrogen-progesterone withdrawal. The quantity and duration of bleeding are quite reproducible. This predictability leads many women to expect a certain characteristic flow pattern. Any slight deviations, such as plus or minus 1 day in duration or minor deviation from expected tampon use, are causes for major concern in the patient. Most women of reproductive age can predict the timing of their flows so

Figure 17-35 Variation of the duration of the menstrual cycle in women with regular cycles. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In: Cunningham FG, ed. *Williams Obstetrics*, 19th ed. Stamford, CN: Appleton & Lange, 1993:81-109.)

accurately that even minor variability may require reassurance by the clinician. Although variability of menstrual cycles is a common feature during the teenage years and perimenopausal transition, the characteristics of menstrual bleeding do not undergo appreciable change between ages 20 and 40.³⁵⁶

For ovulatory women, the changes in the length of the menstrual cycle over the period of reproductive age are predictable. Between menarche and age 20, the cycle length for most ovulatory women is relatively longer. Between 20 and 40 years, there is increased regularity as cycles shorten. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles occurs before age 20 and after age 40.³⁵⁷ In these age groups, the average length of a cycle is between 25 and 28 days. Among ovulatory women, the frequency of a cycle of less than 21 days or more than 35 days is rare (<2%).³⁵⁸ Overall, most women have cycles that last 24 to 35 days (Fig. 17-35).³⁵⁶ Between ages 40 and 50, menstrual cycle length increases and anovulation becomes more prevalent.³⁵⁹

The average postovulatory bleeding lasts from 4 to 6 days. The normal volume of menstrual blood loss is 30 mL. More than 80 mL is considered abnormal. Most of the blood loss occurs during the first 3 days of a period, so excessive flow may exist without prolongation of flow.^{360,361}

During an ovulatory cycle, the duration from ovulation to menses is relatively constant and averages 14 days (see Fig. 17-1A). Greater variability in the length of the proliferative phase, however, produces a distribution in the duration of the menstrual cycle. Menstrual bleeding more often than every 24 days or less often than every 35 days requires evaluation.^{356,359} Flow that lasts 7 or more days also requires evaluation. A flow that totals more than 80 mL per month usually leads to anemia and should be treated.³⁶² In clinical practice, however, it is difficult to quantify menstrual flow because evaluation and treatment are based solely on the patient's perceptions regarding the duration, amount, and timing of her menstrual bleeding. Despite this difficulty in quantifying menstrual blood loss, the clinician should

evaluate the cause of excessive uterine bleeding. Anemia should be ruled out by a complete blood cell count.³⁶³ A low hemoglobin value accompanied by microcytic and hypochromic red blood cells suggests excessive blood loss during menses. These patients should be provided with iron supplementation. The likely presence of coagulation defects, uterine leiomyomas, or adenomyosis underlying prolonged menses should be evaluated in anemic patients through a meticulous history and physical examination followed by relevant laboratory tests.

Terminology Describing Abnormal Uterine Bleeding

Oligomenorrhea is defined as intervals between episodes of uterine bleeding longer than 35 days, and the term *polymenorrhea* is used to describe intervals shorter than 24 days. *Hypermenorrhea* refers to regular intervals (24 to 35 days) but excessive flow or duration of bleeding, or both. *Hypomenorrhea* refers to diminution of the flow or shortening of the duration of regular menses, or both.

Uterine Bleeding in Response to Steroid Hormones

Estrogen Withdrawal Bleeding

Uterine bleeding follows acute cessation of estrogen support to the endometrium. This type of uterine bleeding can occur after bilateral oophorectomy, irradiation of mature follicles, or administration of estrogen to a castrate followed by discontinuation of therapy. Similarly, the bleeding that occurs after castration can be delayed by concomitant estrogen therapy. Flow occurs on discontinuation of exogenous estrogen. Estrogen withdrawal by itself (in the absence of progesterone) almost invariably causes uterine bleeding.

Estrogen Breakthrough Bleeding

Chronic exposure to various quantities of estrogen stimulates the growth of endometrium continuously in the absence of progesterone, as in the case of excessive extragonadal estrogen production in PCOS. After a certain point, the amount of estrogen produced in extraovarian tissue remains insufficient to maintain structural support for the endometrium. This gives rise to unpredictable episodes of shedding of the surface endometrium. Relatively low doses of estrogen yield intermittent spotting that may be prolonged, but the quantity is light. High levels of estrogen and sustained availability lead to prolonged periods of amenorrhea followed by acute, often profuse episodes of bleeding with excessive loss of blood.

Progesterone Withdrawal Bleeding

Typical progesterone withdrawal bleeding occurs after ovulation in the absence of pregnancy. Removal of the corpus luteum also leads to endometrial desquamation. Pharmacologically, a similar event can be achieved by administration and then discontinuation of progesterone or a synthetic progestin. Progesterone withdrawal bleeding occurs only if the endometrium is initially primed by endogenous or exogenous estrogen. If estrogen therapy is continued as progesterone is withdrawn, the progesterone withdrawal bleeding still occurs. Only if estrogen levels are increased markedly is progesterone withdrawal bleeding delayed.³⁶⁴ Progesterone withdrawal bleeding is quite predictable in the presence of previous or concomitant estrogen exposure.

Progestin Breakthrough Bleeding

The pharmacologic phenomenon of breakthrough bleeding occurs in the setting of an unfavorably high ratio of progestin to estrogen. In the absence of sufficient estrogen, continuous progestin therapy leads to intermittent bleeding of variable duration, similar to the low-dose estrogen breakthrough bleeding described previously. This type of bleeding is associated with combination oral contraceptives that contain low-dose estrogen and the long-acting, progestin-only contraceptive methods such as Norplant and Depo-Provera.³⁶⁵ Progestin breakthrough bleeding is highly unpredictable and is characterized by extensive variability among women.

Causes of Irregular Uterine Bleeding

Pregnancy and its complications represent one of the most common causes of irregular uterine bleeding (Table 17-8). Pregnancy should be ruled out by a urine test in any woman of reproductive age who presents with irregular bleeding (Table 17-9).

Anovulatory uterine bleeding arising from responses of the endometrium to inappropriate production of ovarian steroids has also been called *dysfunctional uterine bleeding* because treatments that restore ovulatory function potentially reverse the irregular bleeding pattern. Common examples of anovulatory bleeding include those associated with exercise-related anovulation, hyperprolactinemia, hypothyroidism, or PCOS.³⁶⁶ In these cases, restoration of ovulatory menses by correction of the underlying disorder or use of exogenous hormones can achieve predictable uterine bleeding. Various pathologic entities of the genital tract (i.e., ovaries, uterus, vagina, or vulva) or coagulation abnormalities can cause deviation from normal menses (see Table 17-8).

Anovulatory uterine bleeding is a diagnosis of exclusion for several reasons. Vulvar, vaginal, or uterine malignancies or an estrogen- or androgen-secreting ovarian tumor may cause abnormal uterine bleeding (see Table 17-8). Pregnancy and pregnancy-related problems such as ectopic pregnancy or spontaneous miscarriage are extremely common causes of abnormal uterine bleeding. The most common cause of disruption of a normal menstrual pattern is pregnancy or a complication of pregnancy. Another common cause of irregular uterine bleeding is observed in oral contraceptive users in the form of progestin breakthrough bleeding. Progestin breakthrough bleeding during postmenopausal hormone therapy is also common. Patients may be unknowingly using other hormonal medications with an impact on the endometrium. For example, the use of ginseng, an herbal root, has been associated with estrogenic activity and abnormal bleeding.³⁶⁷ Although uterine bleeding is a common benign side effect of various long-term hormone treatments, the clinician should always be convinced first that no other pathology is present. Anatomically demonstrable pathologies of the menstrual outflow tract include endometrial hyperplasia and cancer, endometrial polyps, uterine leiomyomas, adenomyosis, and endometritis. Irregular, serious bleeding may be associated with chronic illness, such as renal insufficiency, liver insufficiency, or AIDS. Careful examination may discover genital injury or a foreign object (see Table 17-8).

At puberty, the most common cause of irregular uterine bleeding is anovulation. Approximately 20% of adolescents with excessive irregular uterine bleeding have a coagulation defect.^{368,369} Among all women of reproductive age with hypermenorrhea, the prevalence of a coagulation

TABLE 17-8**Causes of Irregular Uterine Bleeding****Complications of Pregnancy**

Threatened miscarriage
Incomplete miscarriage
Ectopic pregnancy

Anovulation

Physiologic
Uncomplicated pregnancy (amenorrhea)
Pubertal (postmenarchal) anovulation
Anovulation immediately before menopause
Medications (e.g., oral contraceptives, GnRH agonists, danazol)
Hypothalamic (frequently presents as amenorrhea)
Functional (e.g., diet, exercise, stress)
Anatomic (e.g., tumor, granulomatous disease, infection)
Medications
Other
Hyperprolactinemia, other pituitary disorders
Prolactinoma
Other pituitary tumors, granulomatous disease
Hypothyroidism
Medications
Other
Androgen excess
PCOS, hyperthecosis
Ovarian tumor (e.g., Sertoli-Leydig cell tumor)
Nonclassic adrenal hyperplasia
Cushing's syndrome
Glucocorticoid resistance
Adrenal tumor (e.g., adenoma, carcinoma)
Medications (e.g., testosterone, danazol)
Other
Premature ovarian insufficiency (frequently presents as amenorrhea)
Chronic illness
Liver insufficiency
Renal insufficiency
AIDS
Other

Anatomic Defects Affecting the Uterus

Uterine leiomyomas
Endometrial polyps
Adenomyosis (usually manifests as hypermenorrhea)
Intrauterine adhesions (usually manifests as amenorrhea)
Endometritis
Endometrial hyperplasia, cancer
Chronic estrogen exposure (e.g., PCOS, medication, liver insufficiency)
Estrogen-secreting ovarian tumor (e.g., granulosa cell tumor)
Advanced cervical cancer
Other

Coagulation Defects (Usually Manifest as Hypermenorrhea)

Von Willebrand's disease
Factor XI deficiency
Other

Extrauterine Genital Bleeding (May Mimic Uterine Bleeding)

Vaginitis
Genital trauma
Foreign body
Vaginal neoplasia
Vulvar neoplasia
Other

AIDS, acquired immunodeficiency syndrome; GnRH, gonadotropin-releasing hormone; PCOS, polycystic ovary syndrome.

TABLE 17-9**Diagnostic Tests to Evaluate Irregular Uterine Bleeding****Commonly Used Tests**

Urine hCG test
Serum hCG level (incomplete miscarriage, ectopic pregnancy)
Transvaginal pelvic ultrasonography (intrauterine or ectopic pregnancy, uterine leiomyoma, endometrial polyp or neoplasia, ovarian tumor)
Serum FSH, LH (anovulation; ovarian insufficiency)
Serum prolactin, TSH (anovulation; hyperprolactinemia)
Complete blood count, PT, PTT (evaluation for anemia, coagulation defect)
Liver and renal functions, HIV (anovulation; chronic disease)
Endometrial biopsy (endometrial disease; polyp, neoplasia, endometritis)

Less Commonly Used Tests

Evaluation for PCOS, ovarian or adrenal tumor; nonclassic adrenal hyperplasia, Cushing's syndrome, and glucocorticoid resistance (androgen excess)
Head CT or MRI scan (hypothalamic anovulation, hyperprolactinemia)
Pelvic MRI scan (adenomyosis, uterine leiomyoma)
Hysterosonography with intrauterine saline installation (endometrial polyp, uterine leiomyoma)
Hysteroscopy (endometrial polyp, uterine leiomyoma)
Dilatation and curettage (endometrial disease not diagnosed by ultrasonography or biopsy)

CT, computed tomography; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; HIV, human immunodeficiency virus; LH, luteinizing hormone; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TSH, thyroid-stimulating hormone.

disorder is 17%; von Willebrand's disease is the most common defect, and factor XI deficiency is the second common diagnosis. Bleeding because of a coagulation defect usually consists of a heavy flow with regular, cyclic menses (i.e., hypermenorrhea), and the same pattern can be seen in patients being treated with anticoagulants.³⁷⁰ Bleeding disorders are usually associated with hypermenorrhea since menarche and a history of bleeding with surgery or trauma. Hypermenorrhea may be the only sign of an inherited bleeding disorder.³⁷¹

Early pregnancy or its complications should always be ruled out first by a sensitive urine hCG measurement in any reproductive-age woman presenting with irregular bleeding. Threatened or incomplete miscarriage and ectopic pregnancy are common causes of irregular uterine bleeding. Other tests should be ordered on the basis of the initial clinical evaluation, including tests to evaluate anovulatory disorders of various causes (see Table 17-9). In patients with a history of prolonged heavy menses (i.e., hypermenorrhea) of pubertal origin, coagulation studies (e.g., prothrombin time, partial thromboplastin time, bleeding time) and a complete blood cell count should be obtained.

Pelvic ultrasonography through a vaginal probe is an extremely useful test for the evaluation of normal or abnormal pregnancy, uterine leiomyomas, endometrial neoplasia, and ovarian tumors (see Table 17-9). Other imaging studies may be used judiciously to rule out pathologies of the hypothalamus, pituitary, and adrenal (discussed earlier). Pelvic MRI is used to rule out adenomyosis, a uterine disorder characterized by the abnormal presence of diffuse endometrial tissue in the myometrial layer. Advanced adenomyosis is associated with diffuse enlargement of the uterus, hypermenorrhea, and anemia.

Endometrial histology should be determined by an endometrial biopsy performed in the physician's office in patients at risk for endometrial hyperplasia or cancer (e.g., PCOS, liver insufficiency, obesity, diabetes mellitus, hormone therapy). A benign endometrial polyp or a uterine leiomyoma protruding into the uterine cavity can be diagnosed by hysterosonography using intrauterine saline installation or by hysteroscopy. Hysterosonography and hysteroscopy are not appropriate tests to evaluate endometrial hyperplasia or cancer because these procedures may cause dissemination of malignant cells. If malignancy is suspected, it should be ruled out by an office endometrial biopsy (see Table 17-9). Occasionally, an office endometrial biopsy cannot be performed or is not diagnostic of endometrial neoplasia. In these rare instances, endometrial curettage under anesthesia is performed for a reliable tissue diagnosis.

A careful history and physical examination eliminate the need for most of these diagnostic tests. Before ordering a certain diagnostic study, it is useful to consider whether a particular test result would alter the ultimate clinical management.

Management of Anovulatory Uterine Bleeding

The terms *dysfunctional uterine bleeding* and *anovulatory bleeding* are used interchangeably and denote inappropriate stimulation of the endometrium during dysfunctional states of the reproductive system. If ovulatory function can be restored, anovulatory bleeding usually gives way to predictable cyclic periods. Because restoration of ovulatory function may not be possible or practical in many of these women, exogenous estrogen and progestin are administered for several purposes. The indications for hormonal treatment of uterine bleeding include the need to stop acute uterine bleeding, to maintain predictable bleeding episodes, or to prevent endometrial hyperplasia. Hormonal treatments are used to stop anovulatory uterine bleeding and to induce predictable bleeding episodes.

Anovulatory uterine bleeding is a diagnosis of exclusion. Various anatomically demonstrable pathologies of the genital tract (see Table 17-8) should be ruled out before administration of estrogen, progestin, or GnRH analogues.

Oral Contraceptives

Use of combination oral contraceptives in an acute or chronic fashion is the most common treatment for irregular uterine bleeding. The estrogen component of the combination pill stabilizes the endometrial tissue and stops shedding within hours; it decreases ovarian secretion of sex steroids by suppression of gonadotropins within several days. The progestin component of the pill directly affects endometrial tissue to decrease shedding over days and potentiates ovarian suppression induced by estrogen. The progestin (in the presence of estrogen) induces differentiation of the endometrial tissue into a stable form called *pseudodecidua*. Typically, a monophasic oral contraceptive preparation that contains 30 or 35 μg of ethinyl estradiol is preferred. Triphasic oral contraceptives and those with less than 30 μg of ethinyl estradiol are not suitable for the treatment of excessive anovulatory uterine bleeding. A combination oral contraceptive in high doses (2 or 3 pills per day) can be used for short intervals (i.e., weeks) to treat an acute episode of excessive uterine bleeding. A usual dose of 1 pill per day may be administered for years to manage

chronic anovulatory bleeding associated with PCOS or hyperprolactinemia.

Oral Contraceptives and Acute Excessive Uterine Bleeding Associated with Anemia. Unopposed estrogen exposure in women with anovulatory uterine bleeding is commonly associated with chronic endometrial buildup and heavy bleeding episodes. Therapy is administered as 1 combination oral contraceptive pill twice daily for 1 week. In obese women, the oral contraceptive may be given three times daily. This therapy is maintained despite cessation of flow within 2 days. If flow does not abate, other diagnostic possibilities (e.g., polyps, incomplete abortion, neoplasia) should be reevaluated. In case of anovulatory bleeding, the flow does diminish rapidly within 2 days after the beginning of high-dose oral contraceptive treatment (i.e., 1 pill two or three times daily). Specific causes of anovulation and possible coagulation disorders should be evaluated during the next few days. The physician also should consider whether blood replacement or initiation of iron therapy is necessary. The high-dose estrogen-progestin combination has produced the structural rigidity intrinsic to the compact pseudodecidual reaction. Continued random breakdown of formerly fragile tissue is avoided, and blood loss stopped. However, a large quantity of tissue remains to react to estrogen-progestin withdrawal. The patient must be warned to anticipate a heavy flow with severe cramping a few days after stopping this therapy. The patient should also be warned of possible nausea that may be caused by high-dose oral contraceptive treatment.

At the end of a week of high-dose oral contraceptive treatment, the pill is stopped temporarily. A heavy flow usually starts within a few days. On the third day of this withdrawal bleeding, a regular dose of combination oral contraceptive medication (1 pill/day) is started. This is repeated for several 3-week treatments interrupted by 1-week withdrawal intervals. A decrease in volume with each successive cycle is expected. Oral contraceptives reduce menstrual flow by more than one half in most women.³⁷²

Early application of the estrogen-progestin combination limits growth and allows orderly regression of excessive endometrial height to normal levels. Because oral contraceptives do not treat the underlying cause of anovulation but provide symptomatic relief by directly affecting the endometrium, cessation of oral contraceptives results in the return of erratic uterine bleeding. Regardless of the requirement for contraception, use of oral contraceptives represents the best choice for hormonal management of heavy anovulatory bleeding and should be offered as long-term management.

Oral Contraceptives and Chronic Irregular Uterine Bleeding. PCOS is a common form of anovulation associated with chronic steady-state levels of unopposed estrogen that may give rise to endometrial hyperplasia and cancer (discussed earlier). Hypothalamic anovulation and hyperprolactinemia are associated with low estrogen levels that are insufficient to prevent bone loss. A combination oral contraceptive is a suitable long-term treatment for both forms of chronic anovulation.

Oral contraceptives represent the most suitable long-term symptomatic management option for any kind of anovulatory uterine bleeding, including oligomenorrhea. Before the administration of an oral contraceptive, pregnancy should be ruled out. One pill per day is ordinarily administered for 3-week periods interrupted by 1-week hormone-free intervals. Withdrawal bleeding is expected

during the hormone-free interval. The progestin component serves to prevent endometrial hyperplasia associated with steady-state unopposed estrogen exposure in PCOS. In cases of anovulation associated with hypoestrogenism (e.g., hypothalamic anovulation, hyperprolactinemia), the estrogen component of the pill provides sufficient replacement to prevent bone loss. The risk of thromboembolism, stroke, or myocardial infarction associated with long-term administration is extremely low in current nonsmokers and in the absence of a history of thromboembolism. Provided that the oral contraceptive controls the abnormal uterine bleeding effectively, a chronically anovulatory woman can continue this regimen until menopause.

Synthetic Progestins

Synthetic progestins enhance endometrial differentiation and antagonize the proliferative effects of estrogen on the endometrium (see Fig. 17-24).^{165,373} The effects of progestins or natural progesterone include limitation of estrogen-induced endometrial growth and prevention of endometrial hyperplasia. The absence of naturally synthesized progesterone in anovulatory states is the rationale for administering a progestin.

The most common indication for long-term cyclic progestin administration is to prevent endometrial malignancy in a patient with PCOS and unopposed chronic estrogen exposure of the endometrium. A combination oral contraceptive is the treatment of choice in these cases. If the patient cannot use an oral contraceptive for some reason (e.g., history of thromboembolism), a progestin may be administered in a cyclic fashion to prevent endometrial hyperplasia. Before the administration of a progestin (or oral contraceptive), pregnancy should be ruled out. In the treatment of oligomenorrhea associated with PCOS, orderly, limited withdrawal bleeding can be accomplished by administration of a progestin such as MPA (5 mg/day) for at least 10 days every 2 months. Alternatively, norethindrone acetate at 5 mg/day or megestrol acetate at 20 mg/day may be administered for 10 days every 2 months. Absence of withdrawal bleeding requires further workup.

In the treatment of excessive uterine bleeding (i.e., hypermenorrhea or polymenorrhea), these progestins at higher daily doses (20 mg/day of MPA, 10 mg/day of norethindrone acetate, or 40 mg/day of megestrol acetate) are prescribed for 2 weeks to induce predecidual stromal changes in the endometrium. A heavy progestin withdrawal flow usually follows within 3 days after the last dose is administered. Thereafter, repeated progestin treatment (5 mg/day of MPA, 5 mg/day of norethindrone acetate, or 20 mg/day of megestrol acetate) is offered cyclically for at least the first 10 days of every other month to ensure therapeutic effect. Failure of progestin to correct irregular bleeding requires diagnostic reevaluation such as endometrial biopsy. Predictable withdrawal bleeding within several days after each cycle of progestin administration suggests the absence of endometrial malignancy.

High-Dose Estrogen for Acute Excessive Uterine Bleeding

An oral contraceptive given two or three times daily is the treatment of choice to stop heavy anovulatory bleeding. A high-dose oral contraceptive regimen should be offered to women with heavy uterine bleeding with or without asymptomatic anemia after anatomically demonstrable pathology of the genital tract has been ruled out (see Table 17-8). A patient with acute and severe anovulatory bleeding accompanied by symptomatic anemia represents a medical emergency. These patients should be hospitalized

immediately and offered a blood transfusion. After genital tract pathology has been ruled out by history, physical examination, and pelvic ultrasonography, intravenously administered high-dose estrogen is the treatment of choice to stop life-threatening bleeding. A well-established regimen is to administer 25 mg of conjugated estrogen intravenously every 4 hours until bleeding markedly slows down or for at least 24 hours.³⁷⁴ Estrogen most likely acts on the capillaries to induce clotting.³⁷⁵ Before intravenous estrogen treatment is discontinued, an oral contraceptive pill is started three times daily. Oral contraceptive treatment is then continued as described previously.

Because high-dose estrogen is a risk factor for thromboembolism, taking two or three oral contraceptive pills per day for a week or large doses of intravenous conjugated estrogens for 24 hours should be regarded as presenting a significant risk. However, no data are available to evaluate any risk associated with this type of acute use of hormonal therapy for such short intervals. The physician and patient should make a decision regarding high-dose hormone therapy after considering its risks and benefits. Alternative treatment options may be offered to patients with significant risk factors. Exposure to high doses of estrogen should be avoided in women with a past episode of idiopathic venous thromboembolism or a strong family history. High-dose hormone treatment should also be avoided in women with severe chronic illness such as liver insufficiency or renal insufficiency. One alternative for these patients is dilatation and curettage, followed by treatment with an oral contraceptive (one pill per day) until the uterine bleeding is under control.

Gonadotropin-Releasing Hormone Analogues for Excessive Anovulatory Uterine Bleeding

A GnRH analogue may be given to women with excessive anovulatory bleeding or hypermenorrhea related to severe chronic illness such as liver insufficiency or coagulation disorders. Monthly depot injections of GnRH agonists are not effective for acute excessive uterine bleeding and may increase uterine bleeding for the first 2 weeks. GnRH antagonists downregulate FSH and LH without a delay and achieve amenorrhea more rapidly. The GnRH agonist leuprolide acetate depot (3.75 mg/month intramuscularly) may be administered for 6 months or longer to control uterine bleeding due to chronic illness. GnRH antagonists can probably be used to halt acute or chronic anovulatory bleeding; however, insufficient published data are available to provide dose recommendations. Long-term side effects of GnRH analogues, including osteoporosis, make this an undesirable choice for long-term therapy. If long-term treatment with GnRH analogues is chosen, norethindrone acetate (2.5 mg daily) should be added back. This add-back regimen is usually sufficient to prevent osteoporosis and does not ordinarily worsen the uterine bleeding.

HORMONE-DEPENDENT BENIGN GYNECOLOGIC DISORDERS

Endometriosis

Endometriosis is defined as the presence of endometrium-like tissue in ectopic sites outside the uterine cavity, primarily on pelvic peritoneum and ovaries, and it is associated with chronic pelvic pain, pain during intercourse, and infertility.³⁷⁶ It is an estrogen-dependent inflammatory disease that affects 5% to 10% of U.S. women of reproductive age.³⁷⁶ This classic presentation may represent a

common phenotype resulting from diverse anatomic or biochemical aberrations of uterine function. As cellular and molecular mechanisms in endometriosis are uncovered, this condition is coming to be viewed as a systemic and chronic complex disease such as diabetes mellitus or asthma.³⁷⁷ Endometriosis may be inherited in a polygenic manner, because its incidence is increased by up to sevenfold in relatives of women with endometriosis.³⁷⁸

Pathology

There are three clinically distinct forms of endometriosis: endometriotic implants on the surface of pelvic peritoneum and ovaries (i.e., peritoneal endometriosis), ovarian cysts lined by endometrioid mucosa (i.e., endometriomas), and a complex, solid mass composed of endometriotic tissue blended with adipose and fibromuscular tissue and residing between rectum and vagina (i.e., rectovaginal nodule). These three types of lesions may be variant phenotypes of the same pathologic process, or they may be caused by different mechanisms.^{379,380} Their common histology is the presence of endometrial stromal or epithelial cells, chronic bleeding, and inflammatory changes. These lesions may occur singly or in combination and are associated with significantly increased risk of infertility and chronic pelvic pain.^{379,380} The inflammatory process in endometriosis may stimulate nerve endings in the pelvis to cause pain, impair the function of the uterine tubes, decrease receptivity of the endometrium, and impair development of the oocyte and embryo. Endometriosis may also cause infertility by physically blocking the tubes.

Clinical evidence points to a deleterious effect of uninterrupted ovulatory cycles on the development and persistence of endometriosis.³⁷⁷ First, symptoms of endometriosis usually appear after menarche and vanish after menopause. Occasionally, a rectovaginal nodule remains symptomatic in a postmenopausal woman, suggesting that its persistence is independent of ovarian estrogen. Second, multiparity is associated with a decreased risk of endometriosis. Third, disruption of ovulation by GnRH analogues, oral contraceptives, or progestins reduces pelvic disease and associated pain. In line with these observations, basic and clinical research findings indicate major roles of the ovarian steroids estrogen and progesterone in the pathology of endometriosis. In humans and primate models, estrogen stimulates the growth of endometriotic tissue, whereas aromatase inhibitors that block estrogen formation and anti-progestins are therapeutic.³⁷⁷ Levels of nuclear receptors for estrogen and progesterone in endometriotic tissue are strikingly different from those in normal endometrium.³⁷⁷ Fourth, biologically significant quantities of progesterone and estrogen are produced locally by an abnormally active steroidogenic cascade that includes aromatase.³⁷⁷

Mechanism

A number of hypotheses have been proposed regarding the histologic origin of endometriosis. Sampson suggested that fragments of menstrual endometrium pass retrograde through the tubes and then implant and persist on peritoneal surfaces.³⁸¹ This mechanism has been demonstrated in primate models and observed naturally in human disease, and it is supported by the observation that spontaneous endometriosis occurs exclusively in species that menstruate. Alternatively, the celomic-metaplasia hypothesis describes the genesis of endometriotic lesions within the peritoneal cavity by differentiation of mesothelial cells into endometrium-like tissue. A third hypothesis argues that menstrual tissue from the endometrial cavity reaches other body sites through veins or lymphatic vessels.³⁷⁷ Finally, it

has been proposed that circulating blood cells originating from bone marrow differentiate into endometriotic tissue at various body sites.³⁸² Sampson's implantation hypothesis offers a plausible mechanism for most endometriotic lesions but does not explain why only some women develop endometriosis. Although most women of reproductive age have reflux menstruation into the peritoneal cavity, endometriosis is encountered in only 5% to 10% of this population.

Two possible mechanisms may explain the successful implantation of refluxed endometrium to the peritoneal surface. First, the eutopic endometrium of women with endometriosis exhibits multiple subtle but significant molecular abnormalities, including activation of oncogenic pathways or biosynthetic cascades favoring increased production of estrogen, cytokines, prostaglandins, and metalloproteinases.³⁷⁷ When this biologically distinct tissue attaches to mesothelial cells, the magnitude of these abnormalities is amplified drastically to enhance implant survival.³⁷⁷ A second mechanism suggests that a defective immune system fails to clear implants off the peritoneal surface.³⁷⁷ It is possible that both mechanisms may contribute to the same phenotype.

Clear molecular distinctions, such as overproduction of estrogen, prostaglandins, and cytokines, are observed between endometriotic tissue and endometrium (Fig. 17-36).³⁷⁷ More subtle forms of these abnormalities are also observed in endometrium from an patient with endometriosis compared with endometrium from a disease-free woman. Inflammation is a hallmark of endometriotic tissue that overproduces prostaglandins, metalloproteinases, cytokines, and chemokines.³⁷⁷ Increased levels of acute inflammatory cytokines such as interleukin-1 β (IL-1 β), IL-6, and tumor necrosis factor (TNF) likely enhance adhesion of shed endometrial tissue fragments on peritoneal surfaces, and proteolytic membrane metalloproteinases may further promote their implantation.³⁷⁷ Monocyte chemoattractant protein 1, IL-8, and RANTES (i.e., regulated on activation, normal T cell expressed and secreted) attract the granulocytes, natural killer cells, and macrophages typically observed in endometriosis.³⁸³ Autoregulatory positive feedback loops ensure further accumulation of these immune cells, cytokines, and chemokines in established lesions.

Basic biologic functions such as inflammation, immune response, angiogenesis, and apoptosis are altered in favor of survival and replenishment of endometriotic tissue.³⁷⁷ These functions depend in part on estrogen or progesterone action. Excessive formation of estrogen and prostaglandin and development of progesterone resistance have emerged as clinically useful concepts, because targeting of aromatase in the estrogen biosynthetic pathway, cyclooxygenase 2 (COX2) in the prostaglandin pathway, or the progesterone receptor (PR) significantly reduces laparoscopically visible endometriosis or pelvic pain (see Fig. 17-36).³⁷⁷ These three critical mechanisms have been linked by specific epigenetic (hypomethylation) defects that cause overexpression of the nuclear receptors SF1 and ER β .³⁷⁷

Diagnosis

Reliable diagnosis of peritoneal endometriosis can be made only by direct visualization of these lesions by laparoscopy or laparotomy. Ovarian endometriotic cysts filled with a thick, bloody fluid (i.e., endometriomas) can be diagnosed accurately by vaginal ultrasonography.

Treatment

Treatment of infertility caused by endometriosis consists of surgical removal with or without assisted reproductive

Figure 17-36 Molecular mechanisms in endometriosis. Two nuclear receptors, steroidogenic factor 1 (SF1) and estrogen receptor- β (ER β), play significant roles in the pathology of endometriosis. In normal endometrial stromal cells, cytosine-phosphate-guanine (CpG) islands located at the SF1 and ER β promoters are robustly methylated and silenced. A lack of promoter methylation is associated with promoter activation and the presence of extraordinarily large quantities of these nuclear receptors in endometriotic stromal cells. Prostaglandin E_2 (PGE $_2$) induces multiple steroidogenic genes, including aromatase (arom), and formation of estradiol from cholesterol. SF1 mediates this steroidogenic action of PGE $_2$. ER β suppresses ER α and progesterone receptors (PRs). This results in defective retinoic acid (RA) production and action, leading to 17 β -hydroxysteroid dehydrogenase 2 (HSD17B2) deficiency and failure to metabolize estradiol. ER β also induces cyclooxygenase 2 (COX2) and formation of PGE $_2$. Estradiol and PGE $_2$ are produced in large quantities and enhance cell survival and inflammation in endometriotic tissue.

technology, whereas pain is usually treated with a combination of medical suppression of ovulation and surgery. Peritoneal implants are resected or vaporized by electric current or laser. Ovarian endometriomas and rectovaginal endometriotic nodules may be effectively removed only by full dissection. Epidemiologic and laboratory data suggest a link between ovarian endometriosis and distinct types of ovarian cancer.³⁷⁷

Although current hormonal therapy for infertility associated with endometriosis is not of proven value, it is somewhat successful for pelvic pain associated with endometriosis.³⁸⁴ However, the duration of relief provided by medical treatment is relatively short.³⁸⁵ Various agents used are comparable in terms of efficacy. Most of the current medical treatments were designed to suppress ovulation (e.g., GnRH agonists, oral contraceptives, danazol, progestins). A possible alternative mechanism of action of the androgenic steroid danazol or a progestin is a direct antiproliferative effect on endometriotic tissue.

Many patients and physicians do not favor danazol because of its anabolic and androgenic side effects of weight gain and muscle cramps and occasional irreversible virilization (e.g., clitoromegaly, voice changes).³⁸⁶ Up to 50% of patients with endometriosis fail to complete 6 months of treatment with danazol.³⁸⁷ The rest of the hormonal agents—oral contraceptives, progestins, and GnRH agonists—show comparable efficacy for control of endometriosis-associated pain.³⁸⁸⁻³⁹⁰ A 6-month course using any one of these agents results in a significant reduction of pain in more than 50% of patients.³⁸⁸⁻³⁹⁰ Induction of pain relief with a continuously administered oral contraceptive or progestin takes longer than with a GnRH agonist.

There is a high incidence of persistence of the disease after all of these medical therapies.³⁹¹ Six months after completion of a 6-month course of treatment with a progestin, oral contraceptive, or GnRH agonist, moderate to

severe pain symptoms recurred in 50% of initial responders.³⁸⁹ The recurrence rate of pain in the rest of the patients was approximately 5% to 20% per year during a 5-year follow-up.³⁹¹ A 6-month course of GnRH agonist treatment is currently the most popular regimen. The most serious side effect of GnRH agonist treatment for endometriosis is bone loss related to estrogen deficiency, and oral estrogen-progestin preparations or bisphosphonates are usually added back to minimize bone loss.³⁶

We are still far from the cure of endometriosis, and current treatments are not satisfactory for effective control of pain. The radical treatment is removal of both ovaries, and even this was not found to be effective in a number of cases of postmenopausal endometriosis.³⁸⁹ New alternative strategies are needed to offer women with endometriosis a reasonable chance to live without suffering from chronic pelvic pain for decades.

There are two important caveats about GnRH agonist treatment. First, large quantities of estrogen can be produced locally within the endometriotic cells. This represents an intracrine mechanism of estrogen action, in contrast to ovarian secretion, which is an endocrine means of supplying this steroid to target tissues (see Fig. 17-21).^{275,389} Second, estradiol produced in peripheral tissue sites (e.g., adipose tissue, skin fibroblasts) may give rise to pathologically significant circulating levels of estradiol in a subset of women.²⁷⁵ GnRH agonists do not inhibit peripheral estrogen formation or local estrogen production within the estrogen-responsive lesion. Moreover, endometriosis is resistant to selective effects of progesterone and progestins.³⁷⁷

Aromatase inhibitors and selective progesterone response modulators are candidate therapeutic agents for endometriosis. Aromatase expression and local estrogen biosynthesis in endometriotic implants prompted pilot studies to target aromatase in endometriosis using its third-generation inhibitors. Among these inhibitors, anastrozole

and letrozole were used successfully to treat endometriosis in postmenopausal and premenopausal women.^{387,392-395} These studies suggested the following:

1. Aromatase inhibitors effectively treat pelvic pain associated with endometriosis, which is resistant to existing therapeutic modalities.
2. An aromatase inhibitor is the medical treatment of choice for persistent postmenopausal endometriosis.
3. Use of aromatase inhibitors in premenopausal women with endometriosis requires ovarian suppression by the addition of a GnRH analogue, progestin, or combination oral contraceptive.
4. Pilot data showed that side effect profiles were quite favorable and did not include bone loss in regimens that combined an aromatase inhibitor with an oral contraceptive or a progestin.^{393,395}

Aromatase inhibitors represent one of the most promising new treatments for pain associated with endometriosis.

Uterine Leiomyomas

Uterine leiomyomas (fibroids) originate from the myometrium and are the most common solid tumor of the pelvis.³⁹⁶ Leiomyomas are responsible for more than 200,000 hysterectomies per year in the United States. They are almost invariably benign and represent clonal expansion of individual myometrial cells. Leiomyomas can cause a variety of symptoms, including irregular and excessive uterine bleeding, pressure sensation in the lower abdomen, pain during intercourse, pelvic pain, recurrent pregnancy loss, infertility, and compression of adjacent pelvic organs, or they may be totally asymptomatic. Uterine fibroids are reported to occur in 20% to 40% of reproductive-age women with symptoms.³⁹⁷ Leiomyomas are more common in African American women and have a polygenic inheritance pattern. Diagnosis can be made by abdominal and transvaginal ultrasonography. Transvaginal ultrasonography is a sensitive method for determining the size, number, and location of uterine leiomyomas.

Uterine leiomyomas appear during the reproductive years and regress after menopause, indicating their ovarian steroid-dependent growth potential, although the role of steroids or other growth factors in the initiation and growth of these tumors is not well understood. The neoplastic transformation of myometrium to leiomyoma probably involves somatic mutations of normal myometrium and the complex interactions of sex steroids and growth factors.³⁹⁸ Traditionally, estrogen has been considered the major promoter of myoma growth. Later biochemical, histologic, and clinical data suggest an important role for progesterone in the growth of uterine leiomyomas. Progesterone and progestins, acting through the PR, enhance proliferative activity in leiomyomas.^{164,399,400}

The therapeutic choices depend on the goals of therapy, with hysterectomy most often used for definitive treatment and myomectomy used when preservation of child-bearing capability is desired. Intracavitary and submucous leiomyomas can be removed by hysteroscopic resection. Laparoscopic myomectomy is technically possible but involves an increased risk of uterine rupture during pregnancy. The overall recurrence rate after myomectomy varies widely, from 10% to 50%. Other FDA-approved treatment options include selective uterine artery embolization and extracorporeal ablation of uterine fibroids with MRI-guided, high-intensity, focused ultrasound.³⁹⁷

Although GnRH agonist-induced hypogonadism can reduce the overall volume of the uterus containing

leiomyomas and tumor vascularity, the severe side effects and prompt recurrences make GnRH agonists useful only for short-term goals such as reducing anemia related to uterine bleeding or decreasing tumor vascularity before hysteroscopic resection. Trials have consistently demonstrated that treatment with an antiprogestin such as mifepristone reduces fibroid size.³⁹⁷ This observation underscores the role of progesterone in the cause of uterine fibroids and opens a new area of therapeutic investigation.

MANAGEMENT OF MENOPAUSE

Consequences of Menopause

Perimenopause

Menopause is the permanent cessation of menses as a result of the irreversible loss of a number of ovarian functions, including ovulation and estrogen production. Perimenopause is a critical period of life during which striking endocrinologic, somatic, and psychological alterations occur in the transition to menopause. Perimenopause encompasses the change from ovulatory cycles to cessation of menses and is marked by irregularity of menstrual bleeding.

The most sensitive clinical indication of perimenopause is the progressively increasing occurrence of menstrual irregularities. The menstrual cycle for most ovulatory women lasts 24 to 35 days, and approximately 20% of all reproductive-age women experience irregular cycles.³⁵⁶ When women are in their 40s, anovulation becomes more prevalent and the menstrual cycle length increases beginning several years before menopause.³⁵⁹ The median age at the onset of perimenopause is 47.5 years.⁴⁰¹ Regardless of the age at onset, menopause (i.e., cessation of menses) is consistently preceded by a period of prolonged cycle intervals.⁴⁰² Elevated circulating levels of FSH mark this menstrual cycle change before menopause and are accompanied by decreased inhibin levels, normal levels of LH, and slightly elevated levels of estradiol.⁴⁰³ These changes in serum hormone levels reflect a decreasing ovarian follicular reserve and can be detected most reliably on day 2 or 3 of the menstrual cycle.

Serum estradiol levels do not begin to decline until less than a year before menopause. The average circulating estradiol levels in perimenopausal women are estimated to be somewhat higher than those in younger women because of an increased follicular response to elevated FSH levels.⁴⁰⁴ The decline in inhibin production by the follicle, which allows a rise in FSH levels, in the later reproductive years reflects diminishing follicular reserve and competence. Ovarian follicular output of inhibin begins to decrease after 30 years of age, and this decline becomes much more pronounced after age 40. These hormonal changes parallel a sharp decline in fecundity, which starts at age 35.

Perimenopause is a transitional period during which postmenopausal levels of FSH can be observed despite continued menses; LH levels remain in the normal range. Pregnancy is still possible in the perimenopausal woman, because occasional ovulation and functional corpus luteum formation can occur. Until complete cessation of menses is observed or FSH levels higher than 40 IU/L are measured on two separate occasions, some form of contraception should be recommended to prevent unwanted pregnancy.

Perimenopause represents an optimal period in which to evaluate the general health of the mature woman and introduce measures to prepare her for the striking physiologic changes that come with menopause. The patient and her clinician should attempt to achieve several important aims during perimenopause. The long-term goal is to maintain an optimal quality of physical and social life. Another immediate objective is the detection of any major chronic disorders that occur with aging. The clinician should counsel the perimenopausal woman about the symptoms and long-term consequences of menopause. The benefits and risks of hormone therapy should be discussed thoroughly at this time.

Menopause

The median age at menopause is approximately 51 years.⁴⁰⁵ The age at menopause is probably determined in part by genetic factors, because mothers and daughters tend to experience menopause at the same age.⁴⁰⁶⁻⁴⁰⁸ Environmental factors may modify the age at menopause. For example, current smoking is associated with an earlier menopause, whereas alcohol consumption delays menopause.⁴⁰⁵ Oral contraceptive use does not affect the age at which menopause begins.

The symptoms frequently seen and related to decreased estrogen production in menopause include irregular frequency of menses followed by amenorrhea, vasomotor instability manifested as hot flashes and sweats, urogenital atrophy giving rise to pain during intercourse and a variety of urinary symptoms, and consequences of osteoporosis and CVD. The combination and extent of these symptoms vary widely for each patient. Some patients experience multiple severe symptoms that may be disabling, whereas others have no symptoms or only mild discomfort associated with perimenopause.

Biosynthesis of Estrogen and Other Steroids in the Postmenopausal Woman

No follicular units can be detected histologically in the ovaries after menopause.⁴⁰⁹ In reproductive-age women, the granulosa cell of the ovulatory follicle is the major source of inhibin and estradiol. In the absence of these factors that inhibit gonadotropin secretion, FSH and LH levels increase sharply after menopause. These levels peak a few years after menopause and decrease gradually and slightly thereafter.⁴¹⁰ The postmenopausal serum level of either gonadotropin may be more than 100 IU/L. FSH levels are usually higher than LH levels because LH is cleared from the blood much more quickly and possibly because the low levels of inhibin in menopause selectively lead to increased FSH secretion. Nevertheless, increased LH is a major factor that maintains significant quantities of androstenedione and testosterone secretion from the ovary, although the total production rates of both steroids decline after menopause.

The primary steroid products of the postmenopausal ovary are androstenedione and testosterone.⁴¹¹ The average premenopausal rate of production of androstenedione of 3 mg/day is decreased by one half to approximately 1.5 mg/day.⁴¹¹ The decrease primarily results from a substantial reduction in the ovarian contribution to the circulating androstenedione pool. Adrenal secretion accounts for most of the androstenedione production in the postmenopausal woman, with only a small amount secreted from the ovary.⁴¹² DHEA and DHEAS originate almost exclusively from the adrenal and decline steadily with advancing age independent of menopause. The serum levels of DHEA and DHEAS after menopause are about one fourth of those in young adult women.⁴¹³

Testosterone production is decreased by approximately one third after menopause.⁴¹¹ Total testosterone production can be approximated by the sum of ovarian secretion and peripheral formation from androstenedione (see Fig. 17-28). In the premenopausal woman, significant amounts of testosterone are produced by conversion of androstenedione in extraovarian tissues. Because ovarian androstenedione secretion is substantially decreased after menopause, the decrease in postmenopausal testosterone production is accounted for in large measure by a decrease in the relative contribution of extraovarian sources.⁴¹¹ With the disappearance of follicles and decreased estrogen, the elevated gonadotropins drive the remaining stromal tissue in the ovary to maintain testosterone secretion at levels observed during the premenopausal years. The contribution of the postmenopausal ovary to the total testosterone production is increased in the presence of seemingly unaltered ovarian secretion.

The most dramatic endocrine alteration of perimenopause involves the decline in the circulating level and production rate of estradiol. The average menopausal level of circulating estradiol is less than 20 pg/mL. The estradiol and estrone levels in postmenopausal women are usually slightly less than those in adult men. Circulating estradiol in postmenopausal women (and men) is derived from the peripheral conversion of androstenedione to estrone, which is converted peripherally to estradiol (see Fig. 17-21).⁴¹⁴ The mean circulating level of estrone in postmenopausal women (37 pg/mL) is higher than that of estradiol. The average postmenopausal production rate of estrone is approximately 42 μ g per 24 hours. After menopause, almost all estrone and estradiol is derived from the peripheral aromatization of androstenedione. There is a drastic change in the androgen-to-estrogen ratio because of the sharp decrease in estradiol level and the only slightly reduced testosterone. The frequent onset of mild hirsutism after menopause reflects this striking shift in the hormone ratio. During the postmenopausal years, DHEAS and DHEA levels continue to decline steadily with advancing age, whereas serum androstenedione, testosterone, estrone, and estradiol levels do not change significantly.⁴¹⁰

The aromatization of androstenedione to estrone in extraovarian tissues correlates positively with weight and advancing age (see Figs. 17-21 and 17-33).¹²¹ Body weight correlates positively with the circulating levels of estrone and estradiol. Because aromatase enzyme activity is present in significant quantities in adipose tissue, increased aromatization of androstenedione in overweight individuals may reflect the increased bulk of tissue containing the enzyme.¹²⁰ There is a twofold to fourfold increase in the specific activity of aromatase per cell with advancing age.¹²² An increased overall number of adipose fibroblasts with aromatase activity and a decrease in the levels of SHBG increase the free estradiol level and contribute to the increased risk of endometrial cancer in obese women.¹²² The production rate and circulating levels of estradiol after menopause are insufficient to provide support for urogenital tissues and bone. Osteoporosis and urogenital atrophy are some of the most dramatic and unwanted consequences of estradiol deficiency during menopause.

Estrogen is produced locally in pathologic tissues such as breast cancer through the aromatase and reductive 17 β -HSD enzymes (Fig. 17-37).^{122,415} In postmenopausal women, androstenedione of adrenal origin is the most important substrate for aromatase in tumor tissue.^{122,415} Estrone is produced primarily by aromatase that resides in undifferentiated adipose fibroblasts surrounding malignant epithelial cells (see Fig. 17-37).^{122,415} Estrone then

Figure 17-37 Tissue sources of estrogen in postmenopausal breast cancer. The important pathologic roles of extraovarian (peripheral) and local estrogen biosynthesis are shown for an estrogen-dependent disease in postmenopausal women. The estrogen precursor androstenedione (A) originates primarily from the adrenal in the postmenopausal woman. Aromatase expression and enzyme activity in extraovarian tissues such as fat increase with advancing age. The aromatase activity in skin and subcutaneous adipose fibroblasts gives rise to formation of systemically available estrone (E_1) and, to a smaller extent, estradiol (E_2). The conversion of circulating A to E_1 in undifferentiated breast adipose fibroblasts compacted around malignant epithelial cells and subsequent conversion of E_1 to E_2 in malignant epithelial cells provide high tissue concentrations of E_2 for tumor growth. The clinical relevance of these findings is exemplified by the successful use of aromatase inhibitors to treat breast cancer in postmenopausal women. 17β -HSD, reductive-type 17β -hydroxysteroid dehydrogenase.

diffuses into malignant epithelial cells that contain reductive 17β -HSD activity and is converted to biologically active estradiol (see Fig. 17-37).¹⁴⁴ Paracrine interactions in breast tumor tissue produce estradiol in malignant epithelial cells that enhances proliferation. The clinical relevance of these findings was exemplified by the successful use of aromatase inhibitors as first-line and second-line endocrine treatments for postmenopausal breast cancer.^{416,417}

Management of Postmenopausal Uterine Bleeding

Perimenopausal or postmenopausal bleeding can be caused by hormone administration or excessive extraovarian estrogen formation. Irregular uterine bleeding is commonly observed during the perimenopausal transition as anovulatory cycles alternate with ovulatory cycles. Uterine bleeding after menopause is less common if the patient is not receiving hormone therapy treatment. Obese women are more likely to experience postmenopausal bleeding because of increased peripheral aromatization of adrenal androstenedione. Patients receiving a continuous combination regimen of hormone therapy may experience unpredictable uterine bleeding. The major objective in these circumstances is to rule out endometrial malignancy. This can be best achieved by tissue diagnosis through an office endometrial biopsy using a plastic cannula. Transvaginal ultrasonographic measurement of endometrial thickness may be used in postmenopausal women to avoid unnecessary biopsies.¹⁷³ A biopsy is required if an endometrial thickness of 5 mm or greater is observed.

Before employing ultrasonography and endometrial biopsy to explore the cause of bleeding that is assumed to arise from the intrauterine cavity, the clinician should rule out diseases of the vulva, vagina, and cervix. Careful inspection of these organs along with a normal cervical Pap smear within the past year is sufficient to rule out the vulva, vagina, and cervix as potential sources of bleeding. Postmenopausal uterine bleeding is the most common initial event that alerts the patient and her physician to

the possibility of endometrial cancer. The causes of postmenopausal uterine bleeding are benign most of the time. Endometrial malignancy is encountered in patients with bleeding in only about 1% to 2% of postmenopausal endometrial biopsies.⁴¹⁸ Approximately three fourths of these biopsies reveal no pathology or an atrophic endometrium. Other histologic findings include hyperplasia (15%) and endometrial polyps (3%). Persistent unexplained uterine bleeding requires repeated evaluation, biopsy, hysteroscopy, or dilatation and curettage.

Unpredictable irregular uterine bleeding is observed in approximately 20% of postmenopausal women receiving a long-term (>1 year) continuous estrogen-progestin combination. This should also be evaluated appropriately with ultrasonography or biopsy, or both.¹⁷³

Hot Flashes

The most frequent and striking symptom during perimenopause is the hot flash. It typically occurs during the transition from perimenopause to postmenopause. The flash is also a major symptom of postmenopause, and it can occur up to 5 years after menopause.⁴¹⁹ More than four fifths of postmenopausal women experience hot flashes within 3 months after the cessation of ovarian function, whether natural or surgical in origin. Of these women, more than three fourths have hot flashes for more than 1 year, and approximately one half have them for up to 5 years.⁴¹⁹ Hot flashes lessen in frequency and intensity with advancing age, unlike other sequelae of menopause, which progress with time.

A hot flash is a subjective sensation of intense warmth of the upper body, which typically lasts for approximately 4 minutes but may range in duration from 30 seconds to 5 minutes. It can follow a prodrome of palpitations or headache and is frequently accompanied by weakness, faintness, or vertigo. The episode usually ends in profuse sweating and a cold sensation. Hot flashes may occur rarely or recur every few minutes. At night, hot flashes are more frequent and can be severe enough to awaken a woman

from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment.⁴²⁰

The hot flash results from a sudden reduction of estrogen levels rather than from hypoestrogenism itself. Regardless of the cause of menopause—natural, surgical, or estrogen withdrawal caused by a GnRH agonist—hot flashes are associated with an acute and significant drop in estrogen level. The consistent association between the onset of flashes and acute estrogen withdrawal is supported by the effectiveness of estrogen therapy and the absence of flashes in prolonged hypoestrogenic states, such as gonadal infection or hypothalamic amenorrhea. Hypogonadal women experience hot flashes only after estrogen is administered and withdrawn.⁴²¹

Not all hot flashes are caused by menopause. Sudden episodes of sweating and flashes may be caused by catecholamine- or histamine-secreting tumors (e.g., pheochromocytoma, carcinoid), hyperthyroidism, or chronic infection (e.g., tuberculosis). The hot flash may also be psychosomatic in origin. In these circumstances, the clinician should obtain a serum FSH level to confirm perimenopause or menopause before initiating hormone therapy. The relation of obesity to hot flashes has been debated. Early work was suggestive that body fat protected against vasomotor symptoms due to the aromatization of androgens to estrogens in fat tissue.⁴²² Recent evidence, however, indicates that higher body mass index, and body fat in particular, is associated with greater vasomotor symptom reporting, primarily hot flashes.⁴²³ These findings are consistent with a thermoregulatory model of vasomotor symptoms in which body fat acts as an insulator, rendering vasomotor symptoms, a putative heat dissipation event, more likely.⁴²³

Urogenital Atrophy

The urogenital sinus gives rise to development of the lower vagina, vulva, and urethra during embryonic development, and these tissues are estrogen dependent. The decrease in estrogen at menopause causes the vaginal walls to become pale because of diminished vascularity and to thin down to only three or four cell layers. The vaginal epithelial cells in postmenopausal women contain less glycogen; before menopause glycogen is metabolized by lactobacilli to create an acidic pH, thereby protecting the vagina from bacterial overgrowth. Loss of this protective mechanism leaves the thin, friable tissue vulnerable to infection and ulceration. The vagina also loses its rugae and becomes shorter and inelastic. Postmenopausal women may complain of symptoms caused by vaginal dryness, such as pain during intercourse, vaginal discharge, burning, itching, or bleeding. Genitourinary atrophy leads to a variety of symptoms that affect the ease and quality of living.

Urethritis with dysuria, stress urinary incontinence, urinary frequency, and dyspareunia are further results of mucosal thinning of the urethra and bladder. Intravaginal estrogen treatment can effectively alleviate recurrent urinary tract infections and vaginal symptoms in the postmenopausal patient.⁴²⁴

Postmenopausal Osteoporosis

Osteoporosis is a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in

fracture risk. The most frequent sites of fracture are the vertebral bodies, distal radius, and femoral neck. Osteoporosis has become a global health issue. It is at epidemic proportions in the United States, affecting more than 20 million people.⁴²⁵ Most osteoporotic patients are postmenopausal women.

Osteoporosis in postmenopausal women is a function of advancing age and estrogen deficiency. Seventy-five percent or more of the bone loss in women during the first 15 years after menopause is attributed to estrogen deficiency rather than to aging.^{426,427} For the first 20 years after the cessation of ovarian estrogen secretion, postmenopausal osteoporosis accounts for a 50% reduction in trabecular bone and 30% loss of cortical bone.^{426,427} Vertebral bone is especially vulnerable because the trabecular portion of the vertebral bodies is metabolically very active and decreases dramatically in amount in response to estrogen deficiency. Vertebral bone mass is already significantly decreased in perimenopausal and early postmenopausal women who have rising FSH and decreasing estrogen levels, whereas bone loss from the radius is not detected until at least 1 year after menopause.⁴²⁷

The risk of fracture depends on two factors: the peak bone mass achieved at maturity (at approximately age 30) and the subsequent rate of bone loss. An accelerated rate of bone loss after menopause strongly predicts an increased risk of fracture. The unfavorable effects of low premenopausal bone mass and accelerated loss of bone after menopause are additive, and these individuals are at the highest risk for fracture. An increased rate of average bone loss during menopause is an indicator of lower endogenous estrogen levels, possibly because postmenopausal bone loss is considerably slower in women with increased adipose tissue mass and consequent increased peripheral estrogen formation.²⁷³

Numerous studies show that hormone therapy started at perimenopause prevents postmenopausal bone loss.⁴²⁸ Hormone therapy started at any age in a postmenopausal woman has potential beneficial effects by at least preventing additional bone loss. However, the incidence of fractures or rate of height loss was not reduced during a 4-year follow-up of women starting hormone therapy at a mean age of 66.7 (± 6.7) years. The Women's Health Initiative (WHI) trial results revealed a decreased number of vertebral and hip fractures in the group of postmenopausal women receiving estrogen plus progestin or estrogen only; this important evidence was the first from randomized trials suggesting that estrogen prevents fractures.¹²²

POSTMENOPAUSAL HORMONE THERAPY

Postmenopausal women who have undergone a hysterectomy should receive hormone therapy with estrogen only (HT-E). A progestin is added to estrogen (HT-EP) in the postmenopausal woman with a uterus to prevent endometrial hyperplasia or cancer. HT-EP is much more commonly prescribed than is HT-E, because most postmenopausal women do not undergo hysterectomy. The risks and benefits of these two regimens are distinct, and we refer to each separately in this section.

Until late 1990s, the most common practice was to treat all women disturbed by the symptoms of hormone deprivation (e.g., hot flashes) with estrogen and to use long-term hormonal prophylaxis against osteoporosis. The assumption that HT was cardioprotective played an important role

in encouraging postmenopausal women to stay on this regimen indefinitely.⁴³¹ Estrogens and progestins used for postmenopausal HT were among the most commonly prescribed medications in the United States. A national survey suggested that there was a significant upward trend for the use of any form of HT from the 1970s until the 1990s. Many women started HT at menopause or later and remained on it. At one point, 46% of women who had experienced a natural menopause and 71% of women who had undergone bilateral oophorectomy reported having used postmenopausal HT.⁴³² The average duration of use in the United States in 1992 was 6.6 years, but only 20% of users had maintained treatment for at least 5 years.

This trend changed drastically in the early 2000s, after publication of the principal results of two large randomized trials, the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998 and the WHI trial in 2002.⁴³³⁻⁴³⁵ WHI results constituted the direct cause of discontinuation of HT in approximately 30% of postmenopausal women.⁴³⁵ A discussion of HERS and WHI trials and how they changed HT practices is warranted. Debate continues regarding the applicability of the WHI and HERS results to all or various subsets of postmenopausal women.⁴³¹ Although the use of HT has dramatically decreased, these influential studies raised a number of important issues that require further studies to address.^{431,436}

The WHI trial was a tremendously important contribution to understanding menopausal therapy. Most earlier cohort, retrospective, and prospective observational studies had demonstrated significant (40% to 60%) reductions in coronary heart disease (CHD) in postmenopausal women taking HT-E or HT-EP. These studies also showed reductions in all-cause mortality and osteoporotic fractures. However, there were modest increases in the risk of breast cancer, on the order of 20% to 30% (attributable as a risk of approximately 1 case per 1000 person-years).⁴³³⁻⁴³⁵ These earlier studies also demonstrated a reduced incidence of Alzheimer's-type dementia in women who had used HT-EP compared with women who had not.⁴³⁷ Given the inherent biases that confound observational studies, randomized clinical trials were needed to establish whether HT protects against CVD or dementias.^{431,437}

The HERS and other secondary prevention studies demonstrated no benefit for women with known CVD initiating HT 8 to 23 years beyond menopause.⁴³³⁻⁴³⁵ In the WHI hormone trials, women with no prior history of clinical CVD who started HT-EP (i.e., combined conjugated equine estrogens [CEE] and MPA) an average of 12 years after menopause increased their CHD risk slightly and nonsignificantly, whereas HT-E (i.e., CEEs given without MPA) did not increase CHD risk but failed to significantly reduce it.⁴³⁷ There were modest increases in thromboembolic disease and stroke in both trials and a borderline statistically significant increase in breast cancer only in the HT-EP arm of the WHI. Cognitive evaluation of older women (>65 years) in the WHI cohort demonstrated increases in incidence of new dementia and no difference in overall rates of cognitive decline.⁴³⁷ Surprisingly, both HT preparations were associated with adverse effects on urinary incontinence.⁴³⁷

It was concluded that the overall risk/benefit ratio for HT was unfavorable. Results from the WHI study indicated that the combination of CEE (0.625 mg/day) and MPA (2.5 mg/day) should not be initiated or continued for the primary prevention of CHD in postmenopausal women. The substantial risks for CVD and breast cancer must be weighed against the beneficial effect on fracture risk

when selecting from the available agents to prevent osteoporosis.

Historical Perspective of Scientific Studies Regarding Hormone Therapy

In the 1950s, a growing number of physicians and their patients believed that replacement of the estrogen lost at menopause would prevent many of the manifestations of aging, including CHD, osteoporotic fractures, and a decline in cognitive and sexual function. This led to widespread use of HT-E after menopause. Other evidence in support of the CHD benefit were also consistent. Observational studies showed less heart disease among women taking estrogen, pathophysiologic mechanisms provided biologic plausibility, and clinical trials revealed improvements in blood lipid levels and other surrogate measures.^{431,437,438}

The most commonly used form of HT-E was CEEs. In the 1980s, it was recognized that postmenopausal HT-E treatment was causing endometrial cancer. Although uncommon and usually curable, this cancer can be prevented by antagonizing the estrogen with a progestin, and several HT-EP combinations were explored in the search for one that preserved the benefits of estrogen. In the 1990s, after it was demonstrated that lipid effects remained largely favorable when CEEs were combined with MPA, this particular estrogen plus progestin regimen became the most widely used form of HT in the United States for postmenopausal women with a uterus.⁴³⁸

In the late 1980s and 1990s, it became apparent that HT-EP increased the breast cancer incidence.⁴³⁹ This increase was significant but minimal. In view of HT's perceived cardiovascular benefits and bone-protective effects, many women and their clinicians still considered the overall benefit largely to exceed the risk.⁴³⁸

In 1998, the HERS study, the first major randomized trial of HT, unexpectedly found an increase in CHD events during the first year and no overall cardiovascular benefit with longer follow-up when HT-EP was compared with placebo in 2763 women with prior coronary disease.⁴⁴⁰ This trial also found that HT-EP caused venous thromboembolism. In 2002, the WHI HT-EP trial was interrupted prematurely because of a perceived net harm.⁴²⁹ Among 16,608 healthy postmenopausal women with a uterus, HT-EP caused an increased risk of coronary events, stroke, venous thromboembolism, breast cancer, and pulmonary embolism. A global index formulated by the investigators found these harmful outcomes to outweigh the decreased risk of hip fracture and colon cancer (Table 17-10). A subsequent report showing a significant twofold increase in dementia among WHI women older than 65 years accentuated these concerns.⁴⁴¹ Results from the HERS and WHI led the FDA to require a warning of harm and to recommend that estrogen preparations not be used to prevent CHD and not be considered first-line therapy for prevention of osteoporosis. In view of these WHI study findings, a number of professional societies changed their guidelines to recommend that HT not be used for prevention of disease and that its use for treatment of symptoms should be at the lowest dose and for the shortest time possible.⁴³¹

Women and their clinicians anxiously awaited the results of the WHI HT-E trial in 10,739 healthy women with hysterectomy who were randomly assigned to receive CEEs only or placebo.⁴³⁰ As in the HERS and WHI HT-EP trials, HT-E did not reduce the risk of CHD, although early CHD harm, which may be a consequence of progestin, appeared to be less pronounced.⁴³⁰

TABLE 17-10

Results of the Women's Health Initiative Randomized Controlled Trial of Postmenopausal Hormone Therapy with Estrogen Alone (E-alone) or Estrogen Plus Progestin (E+P)*

Factor	Hypothesized Effect	E+P			E-alone		
		HR	95% CI	AR	HR	95% CI	AR

Resolution of the Discrepancies between Observational and Randomized Studies

The WHI program included a randomized, controlled trial and a large observational study.⁴³⁷ Results from the observational component of the WHI were in agreement with the many observational studies performed earlier in the 1990s.⁴³⁷ A confusing debate followed the conflicting conclusions from the observational studies and randomized trials on the effect of HT on CHD and breast cancer. HT appeared to be protective against CHD in observational studies, but randomized trials showed an increase in CHD during the first years of use.⁴³⁷ Moreover, HT-EP use was associated with a lesser risk of breast cancer in the randomized WHI trial than in observational studies.⁴³⁷ HT-E was associated with a smaller breast cancer risk than HT-EP in observational studies, but it carried no risk in the randomized WHI trial.⁴³⁷ This led investigators to reanalyze data from randomized trials and observational studies with a different perspective.

With respect to CHD risk, the results of observational studies and randomized trials were well aligned, primarily by analyzing the data according to time since initiation of HT.⁴⁴² This analysis was naturally performed in randomized trials, because HT was started at randomization. In the WHI and HERS studies, HT-EP did increase CHD risk, which later vanished. In observational studies, in which current users were contrasted with never-users at the time of enrollment, most current users were already past the window of increased CHD risk and were in a phase of diminished risk. For example, when cohort data from the observational part of the WHI were reanalyzed according to time since start

of therapy, the same pattern emerged as in the randomized trials: an initial increase in risk followed by a decrease.⁴³⁷ The misleading conclusions drawn from the observational studies were not necessarily because of poor-quality data; the problem was that the initial analysis of these data did not take into account that HT might produce different effects over a period of time.⁴³⁷ The reanalysis of the Nurses Health Study on HT-EP and CHD confirmed this conclusion by finding the same pattern of an initial increase in risk, whereas the original analysis had suggested overall protection.⁴⁴²

The discrepancy between the conclusions from randomized trials and those from observational studies with respect to breast cancer risk was explicable by a similar "timing hypothesis." Women in the randomized trials had on average been in menopause longer, whereas in the observational study, the women had started HT closer to menopause.^{437,442} The findings of observational and randomized studies fell in line after the randomized trial data were reanalyzed and adjusted for the interval between menopause and treatment.⁴³⁷ This reanalysis showed a clear increase in risk for HT-EP and a slight increase for HT-E. In this case, the observational studies had indicated a true risk for the women closer to menopause. In the randomized trial, that risk was diluted because fewer women close to menopause were included. In clinical practice, this risk is important because HT is usually started close to menopause. The discrepancies were not caused by differences in study design but instead reflected a lack of appreciation for the timing of initiation of treatment relative to menopause.^{437,442} These reanalyses confirmed that the CHD and stroke risks are significant and slightly higher in older

women, whereas the actual breast cancer risk is higher in women closer to menopause.⁴³⁷

Risks and Contraindications of Hormone Therapy

Coronary Heart Disease

Data suggest that initiation of HT many years after menopause is associated with excess CHD risk, whereas HT given for a limited period soon after menopause is not. HT-EP or HT-E does not prevent CHD as was previously proposed. To the contrary, there may be a small but significant increase in the rate of CHD among women taking HT-EP.^{429,440} Women with preexisting CHD and healthy women are at risk. HT-E, on the other hand, does not increase the risk for CHD in healthy women.⁴³⁰

Stroke

Another outcome that was consistent across the three trials is the increased risk of stroke among women assigned to HT-E or HT-EP. Increased stroke risk may be attributable to the estrogen component of the hormone regimen, because it is the only statistically significant adverse effect of HT-E.^{429,430,440}

Pulmonary Embolism

A pattern of increased pulmonary embolism was observed in all randomized studies, although the risk was attenuated and was not statistically significant in the WHI HT-E trial.^{429,430,440}

Breast Cancer

Findings of the WHI HT-E trial were markedly different from those of the HERS and WHI HT-EP trials with respect to breast cancer risk. The WHI HT-E trial indicated a trend, albeit statistically not significant, toward a lower breast cancer risk, in contrast to an observational literature that mostly reports a moderate increase in risk with estrogen-alone preparations. However, after control for prior use of postmenopausal hormone therapy and additional control for time from menopause to first use of postmenopausal hormone therapy, the hazard ratios agreed closely between the observational and randomized trial data.⁴⁴³ Nonetheless, the higher risk for breast cancer observed in the HT-EP trials probably represents a harmful additional effect of MPA, the progestin used in these studies. The increased breast cancer risk was statistically significant in the WHI HT-EP trial, which demonstrated an attributable risk of 6 cases per 10,000 person-years.⁴³⁷ This was matched by a trend of the same magnitude in the HERS study and was supported by evidence from large observational studies suggesting that the addition of MPA or another progestin to estrogen may significantly increase the risk for breast cancer (see Table 17-10).

Ovarian Cancer

A retrospective 1979-1998 cohort study of 44,241 postmenopausal women revealed that HT-E, particularly when taken for 10 or more years, significantly increases risk of ovarian cancer. The relative risks for 10 to 19 years and for 20 or more years were 1.8 (95% CI, 1.1 to 3.0) and 3.2 (95% CI, 1.7 to 5.7), respectively (*P* value for trend, <.001). This study did not show an increased risk among women who used short-term HT-EP, but the investigators suggested that the risk associated with longer-term HT-EP use warrants further investigation.⁴⁴⁴ The WHI HT-EP study found a

trend for increased ovarian cancer risk that was not significant.⁴³⁰

Lung Cancer

One report suggested that HT-EP significantly increases the number of deaths from non-small-cell lung cancer in postmenopausal women.⁴⁴⁵ However, the observed trend toward increased lung cancer incidence was not statistically significant.⁴⁴⁵

Dementia

In postmenopausal women 65 years of age or older, HT-EP significantly increased risk and resulted in an additional 23 cases of probable dementia per 10,000 women per year.⁴⁴⁶ Alzheimer's disease was the most common classification of dementia. A similar trend was observed for HT-E but did not reach statistical significance.⁴⁴⁶ When the data were pooled, HT significantly increased probable dementia risk.⁴⁴⁶

Hyperlipidemia

Hyperlipidemia is a rare side effect observed in patients with severe familial hypertriglyceridemia. An oral estrogen regimen can hasten development of severe hypertriglyceridemia or pancreatitis in women with severely elevated triglyceride levels.⁴⁴⁷ Estrogen replacement is relatively contraindicated in women with substantially increased triglyceride levels.

Gallbladder Disease

Both WHI trials (HT-E and HT-EP) showed greater risk for any gallbladder disease or surgery with estrogen.⁴⁴⁸ Both trials indicated a higher risk for cholecystitis and for cholelithiasis. Women on either HT regimen were more likely to undergo cholecystectomy.^{429,430} These data suggest an increase in risk of biliary tract disease among postmenopausal women using estrogen therapy. The morbidity and cost associated with these outcomes may need to be considered in decisions regarding the use of estrogen therapy. Preexisting gallbladder disease is a relative contraindication for estrogen replacement.

Benefits of Hormone Therapy

Hot Flashes

HT-E or HT-EP reliably treats hot flashes in most women. Currently, hot flashes constitute the most common indication for a short course of HT (<5 years).

Fractures

HT-EP or HT-E significantly decreased the incidence of hip, vertebral, and other osteoporotic fractures. In this case, the results of observational studies of estrogen and fracture risk and of trials using a surrogate end point (i.e., bone mineral density) agree with the results of clinical trials of fracture prevention.

Colon Cancer

Colon cancer was significantly less common with HT-EP in the WHI study but not with HT-E, for reasons that are not clear.^{429,430} It is possible that progestin is the protective hormone in this case.

Negative Women's Health Initiative Results Relevant to Previously Postulated Benefits

In the WHI study, HT-EP resulted in no significant effects on general health, vitality, mental health, depressive

symptoms, or sexual satisfaction.⁴⁴⁹ Contrary to expectations, HT-EP and HT-E increased symptoms of urinary incontinence.⁴³⁷ HT-EP was associated with a statistically significant but small benefit in terms of sleep disturbance, physical functioning, and bodily pain after 1 year.⁴⁴⁹ At 3 years, however, there were no significant benefits in any quality-of-life outcomes.⁴⁴⁹ The group that received HT-E in the WHI trial also did not have a meaningful improvement in health-related quality of life after 1 or 3 years.⁴⁵⁰

HT-EP did not improve cognitive improvement, as was previously anticipated.⁴⁴¹ The group receiving HT-E showed a trend for worsened mild cognitive impairment, although this was not significant.⁴⁴¹ Among postmenopausal women 65 years old or older, HT-EP did not improve cognitive function when compared with placebo, whereas HT-E had an adverse effect on cognition, which was greater among women with lower cognitive function at initiation of treatment.^{451,452}

Interpretation of the WHI and HERS Results in a Broader Perspective

The mean age of participants in all three randomized trials was in the mid-60s, raising the concern that these results may not apply to treatment begun early in menopause.^{429,430,440} In this regard, the WHI HT-E trial found that the subgroup of women in the youngest age group (50 to 59 years) appeared to respond to estrogen more favorably than older women for many of the outcomes, including the global index. However, differences in hazard ratios among subgroups were statistically significant for only 1 of 23 tests and could well have occurred by chance.⁴³⁰

Even if hazard ratios are similar in women of all ages, the absolute risks differ substantially. The absolute risk for many diseases approximately doubles with each decade of age. Women in their 50s have about one half of the risk of women in their 60s and one fourth of the risk of women in their 70s. This means that any effect of hormone therapy on these diseases will be less marked in younger than in older women. The possibility of more favorable findings in 50- to 59-year-old women and the low absolute risk of adverse outcomes at this age suggest that use of HT-E to treat menopausal symptoms for a limited duration early in menopause is reasonable.

The WHI trials suggested that HT-E has advantages over HT-EP for treatment in postmenopausal women. It has only one or two adverse outcomes (i.e., increased strokes and probably pulmonary emboli) rather than four (i.e., increased strokes, CHD, pulmonary emboli, and breast cancer), and both regimens have an important benefit (i.e., decreased fractures). However, this risk/benefit assessment does not take into account the dementia findings, and even in their absence, HT-E produced no improvement in the overall global index. HT-E in women with a uterus increases the risk of uterine cancer and rates of uterine bleeding, biopsy, and hysterectomy. As more deliberate and exhaustive analyses of this trial become available, they will likely contribute to new practice guidelines.

There is considerable debate regarding the type of estrogen and mode of administration. Estradiol may have advantages over CEEs, and transdermal administration, by avoiding high levels in the portal circulation and delivery to the liver, may have advantages over oral delivery.⁴⁵³ Trials employing transdermal estradiol are being conducted.⁴⁵⁴

Post-WHI Recommendations for Hormone Therapy

Decision making for women interested in HT involves balancing the potential benefits of hormone therapy against the potential risks.⁴⁵⁵ HT is effective for treatment of hot flashes, and for this indication, HT-E seems to be associated with less risk than HT-EP. However, HT-E does have adverse effects, and it is prudent to keep the dose low and the duration of treatment short. A progestin should be added only to prevent endometrial cancer. Women without a uterus should receive HT-E.

Many clinicians and epidemiologists agree that short-term estrogen therapy using the lowest effective estrogen dose is a reasonable option for recently menopausal women who have moderate to severe symptoms and no previous history or elevated risk of CHD, stroke, breast cancer, or venous thromboembolism. HT usually lasts for 2 to 3 years but rarely more than 5 years, because menopausal symptoms diminish after several years, whereas the risk of breast cancer increases with longer duration of HT.

A small group of women may need long-term therapy for severe, persistent symptoms after stopping HT. These few women may be encouraged to first try nonhormonal options such as gabapentin; estrogen treatment should be resumed only if these alternatives are not helpful. For isolated symptoms of genitourinary atrophy, low-dose vaginal estrogens with minimal systemic absorption and endometrial effects are highly beneficial.⁴⁵⁵

In the absence of evidence for an overall net benefit of postmenopausal treatment with HT-E and with the evidence that HT-EP is harmful, neither therapy should be used for preventing CHD or improving mental function.

Target Groups for Hormone Therapy

In women with gonadal dysgenesis and surgical menopause, the duration of estrogen deprivation is prolonged. Estrogen replacement is recommended for these patients for reduction of hot flashes and for long-term prophylaxis against osteoporosis and target organ atrophy. A low-dose contraceptive may be offered to nonsmoking women until the age of 45 years. After that point, doses of estrogen equivalent to 0.625 mg of conjugated estrogens may be more appropriate because of a sharp age-related increase in risk for thromboembolic events. The physician should recommend a continuous estrogen-progestin combination to those women with a uterus and an estrogen-only regimen to women without a uterus.

During perimenopause, hot flashes can be suppressed with an estrogen-progestin combination. Because bone loss related to estrogen deprivation also begins during this period, a benefit for women who take HT to prevent hot flashes is that bone loss will not start for the few years of therapy.⁴⁵⁶ In perimenopausal women, unexplained uterine bleeding should be evaluated with an endometrial biopsy before the start of hormone therapy.

Estrogen Preparations and Beneficial Dose of Estrogen

Oral Estrogens: Combined Conjugated Equine Estrogens

The amount of estrogen that is effective for hot flashes varies. For this purpose, it is reasonable to start with CEEs at 0.3 mg/day (or micronized estradiol at 0.5 mg/day) and

gradually increase this dose to CEEs at 0.625 mg/day (equivalent to micronized estradiol at 1 mg/day) and 1.25 mg/day (equivalent to micronized estradiol at 2 mg/day). If hot flashes in a postmenopausal woman are not alleviated by 1.25 mg/day of CEEs or an equivalent transdermal estradiol dose, it is unlikely that higher doses will be effective. In this case, alternative diagnoses (e.g., tuberculosis, depression, thyroid disease) should be ruled out.

Low-dose estrogen (0.3 mg/day of CEEs or 0.5 mg/day of micronized estradiol) maintain blood estradiol levels between 17 to 32 pg/mL (average, 22 pg/mL) and may be sufficient for preserving bone density and for alleviating menopausal symptoms in early postmenopausal women.⁴⁵⁷ The effect of estrogen on arterial thrombosis is probably dose related.⁴⁵⁷ For example, oral contraceptives with higher doses of estrogen are more likely to be associated with increased risks of myocardial infarction and stroke, especially in smokers. When choosing a dose for HT, it is imperative to achieve and maintain the lowest beneficial levels of circulating estradiol and to avoid higher levels, to minimize the risk of thrombosis.

The addition of a progestin, either cyclically or continuously, to concomitant estrogen replacement reduces the risk of estrogen-induced endometrial hyperplasia or carcinoma but poses additional problems.⁴⁵⁸ These include regular withdrawal bleeding in up to 90% of women treated with cyclic therapy and irregular spotting in 20% of women treated with continuous estrogen plus progestin. Progestins appear to reduce the beneficial effects of estrogen on high-density lipoprotein (HDL)- and LDL-cholesterol and to increase the risks of pulmonary embolism, CHD, and breast cancer.^{429,430,440}

A time-honored sequential regimen involves oral administration of 0.625 mg of CEEs or the equivalent dose of a variety of available products on days 1 through 25 of each month (Fig. 17-38). A daily dose of 5 mg of MPA is added on days 12 through 25 or on days 16 through 25. Withdrawal bleeding is expected on or after day 26 of each month. Another common cyclic regimen involves continuous oral administration of 0.625 mg of conjugated estrogens or the equivalent daily dose (see Fig. 17-38). A daily dose of 5 mg of MPA is added for the first 10 to 14 days of every month. One-year randomized trial data indicate that the 5-mg dose protects the endometrium as well as the 10-mg dose does.⁴⁵⁹ Progestin withdrawal bleeding occurs in 90% of women with a sequential or cyclic regimen.^{460,461} These regimens can also cause adverse symptoms related to the relatively high daily doses of progestin, including breast tenderness, bloating, fluid retention, and depression. The lowest possible dose of a progestin is recommended.

The continuous combined method of treatment has the potential benefit of reduced bleeding and amenorrhea, but it is occasionally complicated by breakthrough bleeding (see Fig. 17-38).^{460,461} In this regimen, a combination of 0.625 mg of conjugated estrogens and 2.5 mg of MPA is given orally every day. The continuous combination regimen is simple and convenient, and it is associated with an incidence of amenorrhea in 80% of patients after at least 6 months of use. The other 20% of patients continue to experience some degree of unpredictable spotting. Overall compliance is much better in users of the continuous combination regimen. Moreover, the lower daily dose of MPA is associated with a lower incidence of breast tenderness with this regimen. Other estrogen-progestin combinations are also available for similar continuous use.

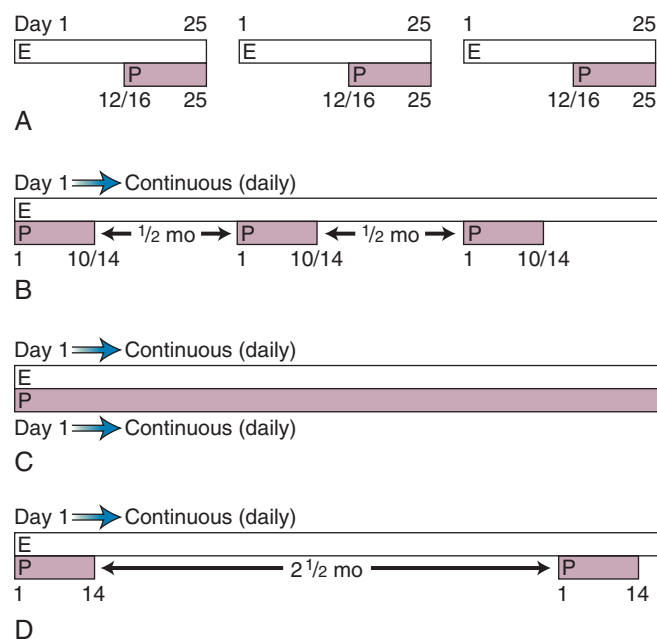

Figure 17-38 Regimens of hormone therapy. Estrogen (E) is replaced in a postmenopausal woman to prevent osteoporosis, urogenital atrophy, and hot flashes. In the postmenopausal woman with a uterus, a progestin (P) should be added to estrogen to prevent endometrial hyperplasia and cancer. E and P can be administered in several ways. **A** and **B**, Postmenopausal women receiving hormone therapy have predictable withdrawal bleeding episodes after each P course. **C**, E and P are administered together. After a year of continuous combination therapy, the rate of unpredictable breakthrough spotting is 20%. **D**, This relatively new regimen was introduced to minimize the harmful effects of a progestin. Its long-term safety for endometrial hyperplasia or cancer risk is unknown. Predictable bleeding after each P course every 3 months is presumed to be reassuring.

Cyclic progestin has also been used at less frequent intervals, such as every 3 to 6 months. When added to standard-dosage estrogen, 10 mg of MPA every 3 months for 14 days produced a 1.5% rate of hyperplasia (a rate low enough to be interpreted as endometrial protection), and long-term use of MPA at 6-month intervals was associated with a low rate of endometrial cancer. However, clinicians have not determined the optimal progestin dosage and schedule to use with low-dosage estrogen. Low-dosage estrogen use can reasonably be assumed to require less progestin for protection of the endometrium.

Most postmenopausal women can switch their HT regimen from standard-dosage HT to low-dosage estrogen opposed by MPA at 3-month intervals or start HT at this low dose.⁴⁵⁷ Although its long-term safety has not been proved with respect to endometrial hyperplasia, the following regimen appears to be a reasonable compromise for treating hot flashes and preventing osteoporosis while minimizing the harmful effects of progestins and high-dose estrogen⁴⁵⁷: 0.3 mg/day of CEEs or 0.025 mg of transdermal estradiol is administered continuously. Every 3 months, a 14-day course of 5 mg of MPA is added (see Fig. 17-38 D). Endometrial biopsy is not required in the presence of withdrawal bleeding after each periodic progestin intake and in the absence of irregular bleeding. This regimen may be continued for up to 5 years. After discontinuation of HT, the postmenopausal woman can be switched to a bisphosphonate or a selective estrogen receptor modulator (SERM) for bone protection.

Transdermal Estrogen

Transdermal estrogen preparations appear to be as effective as oral estrogens for treating hot flashes and maintaining bone mineral density, but they have different metabolic profiles. Oral estrogens are easier to administer and seem to have favorable effects on lipoprotein profiles. However, oral estrogens are associated with several disadvantages, including unfavorable changes in serum levels of triglycerides, C-reactive protein, fibrinogen, factor VII, and plasminogen activator inhibitor type 1.⁴⁵⁵ A meta-analysis of clinical trials suggested a higher risk of venous thromboembolic events among oral HT users compared with transdermal estrogen users.⁴⁵⁵ Clinical trial data that address the effect of transdermal estrogen on CHD and stroke risk are limited.⁴⁵⁵

A daily dose of 0.05 mg of transdermal estradiol is equivalent to 0.625 mg of oral CEEs or 1 mg of oral micronized estradiol. A lower-dose transdermal preparation includes 0.025 mg of estradiol (equivalent to 0.3 mg of oral CEEs). An ultra-low-dose transdermal estradiol preparation (0.014 mg) is also available. In women with symptoms not responding to smaller doses, high-dose transdermal estradiol at 0.1 mg/day (equivalent to CEEs at 1.25 mg/day) may be used. For the average menopausal woman with hot flashes, it is reasonable to start with a daily dose of 0.025 mg. This should be accompanied by a progestin in a woman with a uterus.

Management of Breakthrough Bleeding during Postmenopausal Hormone Therapy

Approximately 90% of women receiving estrogen plus cyclic administration of a progestin have monthly progestin withdrawal bleeding in a predictable fashion. Continuous combined estrogen-progestin therapy causes breakthrough bleeding in approximately 40% of women during the first 6 months, with the remaining 60% being amenorrheic. The pattern of vaginal bleeding in women taking the continuous combined regimen is unpredictable and causes anxiety in most patients, but the incidence of breakthrough bleeding decreases to 20% after 1 year of treatment.⁴⁶⁰⁻⁴⁶² Nevertheless, breakthrough bleeding remains the most important reason for discontinuance of this therapy. Most patients find it unacceptable and prefer to switch to a cyclic progestin regimen or to discontinue hormone therapy altogether. There is no effective pharmacologic method to manage the breakthrough bleeding associated with continuous combined estrogen-progestin regimens. The physician can only reassure the patient that the bleeding is likely to subside within 1 year from the start of HT. If breakthrough bleeding continues beyond 1 year, the regimen should be changed to daily estrogen plus cyclic progestin.

HT can be started in the amenorrheic postmenopausal patient at any time. Perimenopausal women with oligomenorrhea, hot flashes, or other associated symptoms can also be treated with HT. In the oligomenorrheic patient, a hormone therapy regimen may be initiated on day 3 of one of the infrequent menses. If the candidate for hormone therapy does not have irregular uterine bleeding, it is not essential to perform endometrial biopsies routinely before beginning treatment. Studies indicate that asymptomatic postmenopausal women rarely have endometrial abnormalities.⁴⁶²⁻⁴⁶⁴ Pretreatment biopsies using a thin plastic biopsy cannula in the office may be limited to

patients who are at higher risk for endometrial hyperplasia (e.g., unpredictable uterine bleeding, history of PCOS or chronic anovulation, obesity, liver disease, diabetes mellitus).

Giving a woman a combined estrogen-progestin regimen does not preclude the development of endometrial cancer.⁴⁶⁵ Therefore it is necessary to rule out endometrial malignancy in women receiving HT who are experiencing irregular uterine bleeding. The important task is to differentiate breakthrough bleeding from bleeding induced by hyperplasia or cancer. Because breakthrough bleeding is extremely common, many biopsies must be performed to detect a rare case of endometrial abnormality during HT. To decrease the number of endometrial biopsies, a screening method using transvaginal ultrasonography has been introduced.¹⁷³ The thickness of the postmenopausal endometrium as measured by transvaginal ultrasonography in postmenopausal women correlates with the presence or absence of pathology.¹⁷³ Patients receiving a cyclic or daily combination hormone therapy regimen who have an endometrial thickness of less than 5 mm can be managed conservatively.⁴⁶⁶⁻⁴⁶⁸ An endometrial thickness equal to or greater than 5 mm requires biopsy. Based on this algorithm, it is estimated that 50% to 75% of bleeding patients receiving HT and evaluated by ultrasonography require biopsy.¹⁷³

Management of Menopausal Symptoms in Breast Cancer Survivors

Vasomotor symptoms constitute a major problem for survivors of breast cancer. Approximately 65% of women become symptomatic with hot flashes (mostly severe) after treatment for breast cancer.⁴⁶⁹ Hot flashes are encountered more frequently among tamoxifen users and women treated with chemotherapy. Up to 90% of premenopausal women who receive chemotherapy and tamoxifen have vasomotor symptoms.⁴⁶⁹

Breast cancer survivors often seek relief from hot flashes. HT is typically withheld from women with breast cancer because of concerns that estrogen may stimulate recurrence. One randomized study showed that after extended follow-up, there was a statistically significant increased risk of a new breast cancer event in survivors who took HT.⁴⁷⁰ In this randomized, non-placebo-controlled study, 442 women assigned to receive HT-EP/HT-E or best symptomatic management without hormones were followed for a median of 4 years. Thirty-nine of the 221 women in the HT arm and 17 of the 221 women in the control arm had a new breast cancer diagnosed (hazard risk, 2.4; 95% CI, 1.3 to 4.2). Cumulative breast cancer incidences at 5 years were 22.2% in the HT arm and 8.0% in the control arm. No difference in mortality from breast cancer was found.⁴⁷⁰

Because of higher breast cancer recurrence associated with HT, many breast cancer survivors have sought non-hormonal alternatives,⁴⁶⁹ including other pharmaceutical agents, herbal or dietary remedies, and mind-body or behavioral therapies. Mind-body or behavioral treatments for hot flashes are particularly attractive to survivors of breast cancer because they do not have the side effects caused by pharmaceutical agents, but it is not yet known whether they are effective.⁴⁶⁹

Several nonhormonal pharmaceutical agents have been used off-label for women who cannot take or elect not to take HT. Among the non-HT treatments, selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), clonidine, and gabapentin

were found to be more effective than placebo.⁴⁵⁵ Although all of these nonsteroidal medications could reduce the number of hot flashes per day, their beneficial effects were far less than what has been observed with estrogen, and these drugs are all associated with significant side effects that can limit their use in some women. Extracts of black cohosh or red clover were found to be ineffective, and the results for soy isoflavone extracts were mixed.⁴⁵⁵ The beneficial doses for hot flashes include paroxetine (an SSRI) at 10 to 20 mg/day, paroxetine controlled release at 12.5 to 25 mg/day, venlafaxine (an SNRI) at 75 mg/day, desvenlafaxine (an SNRI) at 100 mg/day, and gabapentin at 900 mg/day. Gabapentin should be started with a smaller dose given at bedtime, and the dose should be gradually increased. Paroxetine reduces the metabolism of tamoxifen to its most active metabolite, endoxifen, and should be avoided in women with breast cancer who are receiving tamoxifen.⁴⁵⁵

Tibolone, a synthetic steroid with estrogenic, androgenic, and progestagenic properties, is approved in 90 countries for treatment of menopausal symptoms and in 45 countries for prevention of osteoporosis. Tibolone preserves bone mineral density, reduces hot flashes, and may increase libido and vaginal lubrication in postmenopausal women.⁴⁷¹ A randomized study showed that tibolone reduced the risks of fracture and breast cancer and possibly colon cancer but increased the risk of stroke in older women with osteoporosis.⁴⁷¹ Tibolone is not available in the United States.

For long-term prophylaxis against osteoporosis in breast cancer survivors, tamoxifen, raloxifene, or a bisphosphonate are viable options. However, tamoxifen and raloxifene intensify hot flashes.

Selective Estrogen Receptor Modulators and Bisphosphonates as Alternatives to Hormone Therapy

SERMs are compounds that act like estrogen in some target tissues but antagonize estrogenic effects in others (see Chapter 30).⁴⁷² One of the first SERMs was tamoxifen, for which estrogen-like agonist activity on bone was observed to occur simultaneously with estrogen antagonist activity on the breast.⁴⁷² Tamoxifen had been approved initially for treatment and prevention of breast cancer. An unwanted effect of tamoxifen is its estrogen-like action on the endometrium. Second-generation compounds have since been developed, most notably raloxifene, which has estrogen-like actions on bone, lipids, and the coagulation system; estrogen antagonist effects on the breast; and no detectable action in the endometrium.⁴⁷³ In 2007, the FDA approved raloxifene for reducing the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women who are at high risk for invasive breast cancer. Raloxifene is most often used to prevent and treat osteoporosis in postmenopausal women.

In placebo-controlled trials, raloxifene reduced vertebral fractures, whereas tamoxifen reduced nonvertebral fractures.⁴⁷³ Tamoxifen and raloxifene had similar effects on fractures at multiple sites in a randomized, head-to-head trial.⁴⁷³ Tamoxifen or raloxifene reduced risk for invasive breast cancer compared with placebo by approximately 7 to 10 cases per 1000 women per year.⁴⁷³ Tamoxifen and raloxifene reduced ER-positive breast cancer but not ER-negative breast cancer, noninvasive breast cancer, or mortality.⁴⁷³ Tamoxifen and raloxifene increase thromboembolic events by 4 to 7 cases per 1000 women per year;

raloxifene causes fewer events than tamoxifen. Tamoxifen increases risk for endometrial cancer compared with placebo by 4 cases per 1000 women per year and causes cataracts.⁴⁷³ Raloxifene use is not associated with endometrial cancer or cataract risk.⁴⁷³ The most common side effects for tamoxifen are hot flashes and other vasomotor symptoms and vaginal discharge, itching, or dryness. For raloxifene, vasomotor symptoms and leg cramps are most common. In a head-to-head trial, raloxifene users reported more musculoskeletal problems, dyspareunia, and weight gain, whereas tamoxifen users had more gynecologic problems, vasomotor symptoms, and bladder control symptoms.⁴⁷³ Tamoxifen and raloxifene may be used to reduce the incidence of vertebral fractures and invasive breast cancer in postmenopausal women. The major drawbacks include hot flashes and increased thromboembolic events for both drugs and endometrial cancer for tamoxifen. Data are lacking on optimal doses, duration, timing, long-term effects, and effects in nonwhite women.

The major treatment goal in postmenopausal osteoporosis is to prevent fractures by maintaining or increasing bone mineral density and reducing excessive bone turnover.⁴⁷⁴ Bisphosphonates suppress resorption by inhibiting the attachment of osteoclasts to bone matrix and enhancing programmed cell death in osteoclasts. They have increased bone mineral density and reduced the risk for osteoporotic fractures in numerous clinical trials.⁴⁷⁴ The FDA has approved four bisphosphonates for treatment or prevention of osteoporosis. Oral alendronate and oral risedronate were approved in 1995 and 2000, respectively. In 2003, oral ibandronate was approved, followed by intravenous ibandronate in 2006. Intravenous zoledronic acid was approved in 2007. A 5-mg dose of zoledronic acid is infused over 15 minutes once each year. Alendronate is given as a once-weekly 35- or 70-mg tablet or a once-daily 5- or 10-mg tablet; risedronate is given as a once-daily 5-mg tablet, a once-weekly 35-mg tablet, or a once-monthly 150-mg tablet, and ibandronate is given as a once-monthly 150-mg tablet or as 3 mg intravenously every 3 months.⁴⁷⁵

Compared with placebo controls, all four approved bisphosphonates reduce the relative risk of new vertebral fractures by on average 50% in women with postmenopausal osteoporosis.^{475,476} Alendronate, risedronate, and zoledronic acid reduce the relative risk of new nonvertebral and hip fractures.⁴⁷⁴ Clinical trial extensions of up to 10 years with alendronate and 7 years with risedronate have shown that efficacy is maintained during long-term treatment.⁴⁷⁴ Moreover, discontinuation of long-term (≥ 5 years) alendronate therapy results in minimal bone loss over the ensuing 3 to 5 years.⁴⁷⁷ As in the case of SERMs, definitive data are lacking on optimal doses, duration, timing, long-term effects, and effects in nonwhite women. Once-yearly zoledronic acid infusions appear to be an attractive choice because of better compliance and lack of esophagitis, a side effect associated with oral bisphosphonates.

Osteonecrosis of the jaw is a rare but serious side effect of bisphosphonate therapies. Bisphosphonate users who plan to undergo tooth extraction should discuss this side effect to their dental surgeons, because tooth extraction may predispose them to osteonecrosis of the jaw.⁴⁷⁸ The addition of zoledronic acid to adjuvant endocrine therapy reduced disease recurrence in all body sites and improved disease-free survival in premenopausal patients with estrogen-responsive early breast cancer.⁴⁷⁹ Further studies are required to explore the potential of bisphosphonates in preventing breast cancer in postmenopausal women with no previous history of breast cancer.

A number of case reports and a recent retrospective study suggested that the risk of esophageal cancer increased with oral bisphosphonate use over about a 5-year period. In western countries, the incidence of esophageal cancer in patients over the age of 60 is estimated to increase from 1 to 2 per 1000 population with 5 years' use of an oral bisphosphonate.^{480,481} Another retrospective study, however, did not find such a link.⁴⁸² Until more accurate data are available, health-care providers should avoid prescribing oral bisphosphonates to patients with Barrett esophagus, a known risk factor for esophageal cancer.⁴⁸⁰

CHAPTER 18

Hormonal Contraception

MARTHA HICKEY • ANDREW M. KAUNITZ

Prevention of unplanned pregnancy continues to challenge clinicians and consumers in developed and developing countries. In the United States and other developed countries, the birth rate continues to fall according to the U.S. National Center for Health Statistics. On average, women devote more than 3 decades of their lives to avoiding unintended pregnancy. In developing countries, child-birth and unsafe abortion are important causes of maternal mortality and morbidity.

Contraceptive advice and provision should start before the commencement of sexual activity and continue through the reproductive years. The United States has one of the highest teenage pregnancy rates in the developed world.¹ Teenaged parenting commonly has adverse consequences for the adolescent, her children, and her family.² Programs to prevent unplanned pregnancy by promoting abstinence have largely been ineffective. Nonhormonal contraceptives, such as male condoms, may offer benefits in terms of protection against sexually transmitted infection (STI), but they are highly user dependent and do not reliably prevent unplanned pregnancy in many populations. Female hormonal contraception is the most effective and acceptable reversible contraceptive option; male hormonal contraception has not achieved this goal. Despite the wide variety of female hormonal contraceptive methods

and other methods available, about one half of all pregnancies in developed countries are unplanned. In the United States, almost 3.2 million unintended pregnancies occur annually.³ Figures are not available for most developing countries, but it is likely that the proportion of pregnancies that are unintended is much higher.

The ideal contraceptive would be safe, highly effective, discreet, cheap, long acting, easily reversible, and under the patient's control. It would not need to be activated at or around the time of intercourse and would not disrupt vaginal bleeding patterns. The ideal contraceptive would also protect against STI. Because an ideal contraceptive does not exist, the challenge for clinicians is to tailor the available methods to the medical, personal, and social needs of the consumer and her partner as they evolve throughout her reproductive life span. The clinician must also learn to recognize and address barriers to the safe and effective implementation of the selected methods. Hormonal contraceptives are most effectively used by consumers who are well informed about the advantages and likely side effects of the method and who have actively participated in selecting the method. Expert contraceptive advice and provision can significantly reduce maternal mortality and can improve the social and educational status of women worldwide.

COMBINED ESTROGEN AND PROGESTIN CONTRACEPTIVES

Methods that combine estrogen and progestin offer the advantage of relatively regular bleeding patterns and high efficacy if used consistently. Increasing flexibility in delivery systems means that combined methods are available in oral, transdermal, and transvaginal preparations.

The Combined Oral Contraceptive Pill

Combined oral contraceptive pills (COCs) offer safe, reversible, and convenient birth control that is highly effective for those who consistently take pills correctly. In many settings, oral contraception provides important non-contraceptive benefits. By individualizing counseling and follow-up strategies based on relevant behavioral and medical considerations, physicians can maximize their patients' success with COCs. The effectiveness of COCs correlates with correct and consistent use. Women who consistently take pills correctly have one or two pregnancies per 100 women-years. Teenagers may have more than 15 pregnancies per 100 women-years. COCP use reduces the risk of malignant and borderline epithelial ovarian tumors by about 40% among short-term users and by as much as 80% among women who have used COCs for a decade or more. Unscheduled spotting and bleeding occur in about one fourth of women during the first 3 months of use but become much less common with ongoing use. Counseling patients to anticipate early breakthrough bleeding and reassuring those who experience this side effect may improve continuation rates.

Women who are bothered by hormone withdrawal symptoms or who may benefit from less frequent withdrawal bleeding may benefit from the newer formulations of oral contraceptives that shorten or eliminate the hormone-free interval. Perimenopausal women benefit from the regularity of menses, relief from vasomotor symptoms, and positive impact on bone mineral density (BMD) offered by combination oral contraception. Women with diabetes, controlled hypertension, lupus, or obesity may be candidates for a trial of low-dose oral contraception provided they are younger than 35 years, nonsmokers, and otherwise show no evidence of vascular damage.

COCs have been available for more than 50 years and have gradually been refined to improve safety, efficacy, and acceptability. COCs are used by more than 10 million U.S. women, making them the most widely used hormonal contraceptive method. Current methods contain estrogen, usually as ethinyl estradiol at doses of 20 to 50 µg/day and with a range of progestins. COCs offer women safe, convenient, effective, and reversible fertility regulation. Use of COCs also confers important noncontraceptive health benefits that should be discussed during counseling. This section describes COCs available in the United States, focusing on education, counseling, and management measures to maximize contraceptive efficacy.

Composition and Formulations

Over time, the dose of estrogen and progestin in COCs has gradually decreased, and the type of progestin has changed. Currently, the highest-dose formulations marketed in the United States contain 50 µg of estrogen, and most COCs prescribed contain 35 µg or less. All modern COCs formulated with 35 µg of estrogen or less use the potent estrogen ethinyl estradiol. Older COCP preparations contain one of five progestins: norethindrone,

norethindrone acetate, ethynodiol diacetate, norgestrel, or levonorgestrel. Newer formulations contain the less-androgenic progestins, norgestimate, desogestrel, and drospirenone.

Many COCP formulations are marketed in the United States (Table 18-1). These products are not different in terms of safety or efficacy if used correctly.⁴ COCs were originally formulated to mimic the normal menstrual cycle by providing 21 days of combined estrogen and progestin, followed by a 7-day pill-free week when withdrawal bleeding occurred. Modern COCs mainly continue to follow this regimen and contain active pills for 21 to 24 days, although there is no evidence that a hormone-free interval provides any health benefits. Hormone-withdrawal symptoms, including pelvic pain and mood symptoms, may occur during the pill-free week.⁵ COCP regimens differ in whether the dose of ethinyl estradiol and progestin is the same throughout the 21 days of use or the doses vary. Monophasic preparations have a constant dose of estrogen and progestin in each of the 21 or 24 active hormone tablets in each cycle pack. Phasic preparations alter the dose of the progestin and, in some formulations, the estrogen component among the active tablets in each pack. COCs typically come in 28-day packages designed to be simple to use. Pills are still taken during the hormone-free interval, but they do not contain sex steroids.

The hormone-free interval can be modified or eliminated. This may improve contraceptive success; reduce hormone-withdrawal symptoms; improve treatment of problems such as dysmenorrhea, pelvic pain, and anemia; and be more convenient for some women.⁶ Newer oral contraception pills offer extended-cycle regimens of 91 pills, with inert tablets or tablets containing 10 µg of ethinyl estradiol in place of the conventional hormone-free interval.

Mechanism of Action, Efficacy, Administration, and Effect on Pregnancy

Administration of COCs prevents ovulation by inhibiting gonadotropin secretion through the effect of estrogen and progestin on the pituitary and hypothalamus. The progestin component of the pill primarily suppresses luteinizing hormone secretion, whereas the estrogenic component suppresses follicle-stimulating hormone. Both steroids in COCs contribute to the suppression of ovulation. Because the contraceptive efficacy of COCs relies on daily use, failure rates are largely attributable to poor adherence. Pregnancies range from less than 1 per 100 women-years (Pearl index) with excellent adherence to more than 15 pregnancies per 100 women-years with low adherence. Typical first-year combination oral contraception failure rates are estimated at 8 per 100 women.⁷

Traditionally, COCs have been started on the first day of menses, but the pills can be safely started at any time if pregnancy has been excluded (quick start method).⁸ This approach may reduce unplanned pregnancies occurring while women are waiting to start the pills. If the COCs are inadvertently taken during pregnancy, they do not appear to increase the rate of miscarriage or adversely affect the developing fetus.⁹

Because daily use is critical to ensure contraceptive efficacy, some women prefer to link pill taking with a daily ritual (e.g., tooth brushing). Clear instructions for managing missed pills are an essential component of COCP counseling. If a woman misses 1 or 2 tablets, she should take 1 pill as soon as possible. She should then continue to take 1 tablet twice daily until each of the missed tablets have

[†]Chewable tablets.[‡]Indicated for the treatment of acne in women desiring to use oral contraception.[§]Indicated for the treatment of premenstrual dysphoric disorder in women desiring to use oral contraception.

been taken. If she has missed more than two consecutive tablets, she should use an additional form of contraception (e.g., condoms) until the current pack of pills is finished and she experiences expected withdrawal bleeding. COCPs are not suitable for women who consistently miss pills, because this undermines contraceptive efficacy. In these cases, a method that does not require daily adherence (e.g., contraceptive rings; patches; an injectable, intrauterine, or implantable method) should be considered.

After discontinuation of COCPs, most women rapidly recommence ovulation. Some women may ovulate if the hormone-free interval is extended beyond 7 days. In some women, ovulation may be delayed for several months after discontinuing oral contraception.¹⁰

Noncontraceptive Health Benefits

For some users, COCPs offer substantial noncontraceptive health benefits. These advantages include reducing in dysmenorrhea and symptoms of premenstrual syndrome, creating predictable withdrawal bleeding in women with dysfunctional uterine bleeding, reducing the daily intensity and duration of menstrual flow, improving anemia, and markedly reducing the risk of ovarian and endometrial cancer. Educating COCP candidates and users regarding these noncontraceptive benefits can assist the patient in making a choice and can increase oral contraception adherence and continuation.

Benign breast diseases, including fibroadenoma and cystic changes, occur less commonly in COCP users.

Functional cysts are not reliably suppressed by modern COCP formulations containing 35 µg of estradiol or less. COCP use reduces the incidence of pelvic inflammatory disease (PID)¹¹ and ectopic pregnancy,¹² two common and potentially life-threatening conditions. In perimenopausal women, COCPs can maintain BMD, improve reduced BMD, and possibly reduce the risk of postmenopausal fracture. Skeletal health benefits associated with COCP use may also apply to women who have been hypoestrogenic and those with hypothalamic amenorrhea.¹³

Reducing the risk of epithelial ovarian and endometrial cancer is perhaps the most important noncontraceptive benefit of COCP use. Although the incidence is low, epithelial ovarian cancer is the most common cause of death from gynecologic malignancy in the United States. The reduction in borderline and invasive ovarian cancer risk with COCP use is consistently about 40% among short-term users and as much as 80% among women who have taken COCPs for more than 10 years; risk reduction persists for more than 15 years after discontinuation of oral contraception.¹⁴ A woman in her late 30s or 40s taking COCPs reduces her risk of ovarian cancer during the peak presentation of this disease (i.e., 50 to 60 years). Worldwide, an estimated 100,000 deaths from epithelial ovarian cancer have been prevented since COCPs first became available in the 1960s; current COCP use is estimated to prevent an additional 30,000 such deaths each year.¹⁵ Epidemiologic data suggest that COCP use reduces the risk of ovarian cancer for those at increased risk for this disease.¹⁶

Endometrial adenocarcinoma is the most common gynecologic cancer in U.S. women. The risk of endometrial adenocarcinoma is reduced by 50% with COCP use, and the protection persists for at least 20 years after oral contraception discontinuation.¹⁷ COCP use may also decrease the risk of colorectal cancer.¹⁸

All COCP formulations appear to treat acne. Selected COCP formulations are approved by the U.S. Food and Drug Administration (FDA) for the treatment of acne (i.e., ethinyl estradiol/triphasic norgestimate, estrophasic norethindrone acetate, and ethinyl estradiol/drospirenone)¹⁹ and for premenstrual dysphoric disorder (24/4 20-µg ethinyl estradiol/3-mg drospirenone).²⁰

Side Effects

Although COCPs are well tolerated by most users, some experience side effects that may affect quality of life, contraceptive continuation, and patient satisfaction. Counseling about side effects is an important aspect of contraceptive care and may improve patient tolerance when they occur.

Nausea and breast tenderness affect about 10% to 15% of COCP users, particularly during the initial months of use, and they tend to resolve with long-term use.²¹ Contrary to popular perception, randomized, placebo-controlled trials have not shown that the pills cause weight gain.

Unscheduled vaginal bleeding is common, affecting about 25% of COCP users during the initial 3 months of use, but the incidence declines with ongoing COCP use. Unscheduled bleeding is more common with lower-dose (20 µg) than standard-dose (30 or 35 µg) ethinyl estradiol preparations.²¹ Because irregular bleeding may be a manifestation of pathology such as cervical or endometrial infection, polyps, or neoplasia, persistent or new-onset bleeding should be investigated. There are no FDA-approved treatments for unscheduled bleeding associated with hormonal contraception. Amenorrhea may occur with long-term COCP use, and it is variably tolerated by patients. It may be more acceptable with counseling that provides appropriate reassurance. Urine pregnancy tests

should be made readily available to women who experience absence of withdrawal bleeding or who for other reasons suspect they could be pregnant during use of any method of hormonal contraception.

Headaches affect up to 10% of COCP users and do not require neurologic evaluation unless migraines with focal neurologic symptoms are reported. A history of migraine plus aura is a contraindication for use of COCPs.²² For women 35 years old or older, combination estrogen-progestin contraceptives should be avoided by all with migraines.²³ Similarly, any COCP users who experience increased frequency or intensity of any type of migraine headache should discontinue estrogen-containing contraceptives. If migraine headaches occur only during withdrawal bleeding, elimination of the hormone-free interval may be therapeutic.

Health Risks

Extensive studies in large populations have established the risks and benefits of COCPs for most women. Results indicate that for most women, use of COCPs represents a safe contraceptive choice. However, clinicians should be aware of circumstances in which the COCP may pose health risks. The World Health Organization (WHO) has developed guidelines to help clinicians determine the safety of COCP and other contraceptive methods.²⁴ The safety of COCP is considered in four categories:

1. Conditions with no restriction on the use of the contraceptive method
2. Conditions in which the advantages of the method usually outweigh the theoretical or proven risks
3. Conditions in which the theoretical or proven risks usually outweigh the advantages; examples include gallbladder disease, less than 21 days after delivery, lactation up to 6 months after delivery, and taking medications that may interfere with COCP efficacy
4. Conditions that present an unacceptable health risk if the contraceptive method is used; examples include a personal history of deep venous thrombosis or pulmonary embolism, cardiovascular accident, known thrombophilia tendency, and migraine headaches with aura or other neurologic signs.

Thromboembolic Disease. The established increased risk of venous thromboembolism (VTE) is related to the estrogenic component. Low-dose preparations carry a lower risk, but the incidence of VTE is still increased.²⁵ COCPs containing less than 50 mg of ethinyl estradiol are associated with a fourfold increased risk of VTE. No differences in VTE risk between 35- and 20-µg preparations have been established. Cigarette smoking further increases the risk of for arterial and venous thrombotic events.^{26,27} In otherwise healthy women taking COCPs, the absolute risk of VTE remains small at 1 to 1.5 cases per 10,000 women-years compared with nonpregnant nonusers (0.4 per 10,000 women-years). The VTE risk for COCP use is significantly lower than that for pregnancy (6 per 10,000 women-years).²⁵ The pill is contraindicated for those at increased risk for VTE: these high-risk women include those with a personal history of VTE, women immediately after delivery, those with known inherited thrombophilic conditions, and obese women 35 years old or older. Routine screening of women for familial thrombophilic markers is not recommended before initiating COCP use.²⁸ However, women with known thrombophilic conditions should be encouraged to use progestin-only and intrauterine contraceptives.

Myocardial Infarction and Thrombotic and Hemorrhagic Stroke. The relationship between COCP use and cardiovascular disease is complex. Retrospective studies in humans and animal data suggest that COCP use does not increase the risk of atherosclerosis.²⁹ Myocardial infarction occurs rarely in COCP users, and these users are almost exclusively smokers; in these women, the infarctions usually are linked to thrombotic rather than atherosclerotic causes.²⁹ Because cigarette smoking and COCP may act synergistically to increase the risk of myocardial infarction, COCPs are contraindicated in smokers older than 35 years. Among other women with risk factors for myocardial infarction or stroke, including hypertension, diabetes, and migraine headache, COCPs should be avoided by those older than 35 years.

Breast Cancer. The association between use of menopausal estrogen-progestin therapy and breast cancer has led many to assume that COCP use is associated with an increased risk of breast cancer. However, findings from a large, long-term cohort study in Britain and large case-control studies in the United States found that regardless of duration of use, neither current nor prior use of COCP is associated with an increased risk of invasive or in situ breast cancer or death from breast cancer.²³ Although many women at elevated risk for breast cancer due to affected family members are concerned that use of COCP is unsafe, a large, Canadian, prospective study of women with a family history of breast cancer found that neither current nor prior use of COCP was associated with an elevated risk of breast cancer.³⁰ Studies of women with known *BRCA* gene mutations have yielded mixed results with respect to the impact of COCP use on breast cancer risk.³¹

Cervical Cancer. Pooled data from 24 studies including more than 16,000 women with cervical cancer and 35,000 without cervical cancer found that for current COCP users, the risk of invasive cervical cancer increased with increasing duration of use (relative risk for ≥ 5 years' use versus never use = 1.90; 95% confidence interval [CI], 1.69 to 2.13). The risk declined after use ceased, and after 10 or more years, it returned to the risk level of never users. A similar pattern of risk was seen for invasive and in situ cancer and for women who tested positive for high-risk human papillomavirus (HPV) strains. Ten years' use of oral contraceptives from about age 20 to 30 years is estimated to increase the cumulative incidence of invasive cervical cancer by age 50 from 7.3 to 8.3 cases per 1000 women in less developed countries and from 3.8 to 4.5 cases per 1000 women in more developed countries.³² Regular cytologic screening according to national protocols is advised for all sexually active women, regardless of contraceptive use. A history of cervical intraepithelial neoplasia or genital HPV infection is not a contraindication for COCP use.

Use of Combined Oral Contraceptive Pills after Abortion, after Delivery, or during Lactation

COCPs may be initiated immediately after induced or spontaneous termination of a first- or second-trimester pregnancy but not immediately after term delivery because the risk of VTE is elevated during the puerperium. Because COCPs may reduce milk production, some experts do not think they represent an optimal contraceptive choice in lactating women.³³ However, ovulation may occur as early as 3 weeks after delivery, and this consideration may be foremost for some COCP users. The use of COCP at 4 weeks after delivery is within the range approved by the FDA and

other medical authorities. The use of progestin-only contraceptives in postpartum and lactating women is addressed later in this chapter.

Use of Concomitant Medications with Combined Oral Contraceptive Pills

Anticonvulsants and antibiotics that induce hepatic enzymes may reduce the contraceptive efficacy of COCPs. In these cases, high-dose progestin-only methods such as depot medroxyprogesterone acetate (DMPA) or intrauterine contraceptives may be preferable.³⁴

Contraceptive Vaginal Ring and Contraceptive Patch

The transdermal and transvaginal routes are safe and acceptable alternatives to COCPs to deliver combined estrogen-progestin contraception. The contraceptive patch (Ortho Evra) and the contraceptive vaginal ring (Nuva-Ring) offer women combination estrogen-progestin contraception without taking pills daily. The ring is inserted in the vagina for 3 weeks and then withdrawn for 1 week, during which withdrawal bleeding is anticipated.

In consistent users, the contraceptive failure rates with the patch and ring are similar to or somewhat lower than with oral contraceptives. In the absence of adequate evidence to determine how the risks and noncontraceptive benefits of the patch and the ring compare with the COCP, they are usually considered to be equivalent. The incidence of unscheduled (breakthrough) bleeding and spotting may be somewhat lower with the ring than with COCPs.³⁵

Transdermal Contraceptive Patch

The only contraceptive patch available in the United States is Ortho Evra. It is a 4.5-cm, tan square that releases 20 μg of ethinyl estradiol daily along with norelgestromin, the biologically active metabolite of the progestin norgestimate (Fig. 18-1). A new patch is applied each week on the same day for 3 weeks, followed by a patch-free week, during which withdrawal bleeding is anticipated. Sweating associated with vigorous exercise, swimming, and use of a hot

Figure 18-1 The contraceptive patch, Ortho Evra.

Figure 18-2 The contraceptive vaginal ring.

tub or sauna do not result in patch detachment or clinically relevant changes in serum hormonal contraceptive levels.³⁶

Unscheduled bleeding in patch users is similar to that seen with COCPs.³⁷ Compared with COCP users, patch users may be more likely to report breast discomfort, dysmenorrhea, nausea, and vomiting. Mild local skin reactions are common.³⁷ The patch is easy to use for many women, but for those at high risk for unintended pregnancy, the patch may be associated with a higher failure rate than COCPs.³⁸

Contraceptive Vaginal Ring

The vaginal mucosa offers excellent absorption of sex steroids. The only contraceptive vaginal ring available in the United States is the NuvaRing, a flexible plastic ring that is 4 mm thick and has an outside diameter of 54 mm. The ring releases 15 µg daily of ethinyl estradiol along with etonogestrel, the biologically active metabolite of the progestin desogestrel (Fig. 18-2). The ring does not require individual fitting; as long as it remains in the vagina, appropriate absorption of steroids occurs. Expulsion is uncommon. Women's interest in using a contraceptive vaginal ring varies; some women are highly motivated and comfortable with this method. Some users keep the ring in place during sexual relations; in this setting, male discomfort is not common. Other users prefer to remove the ring before intercourse, and removal for 3 hours or less does not impair efficacy.³⁹ Back-up contraception is required for 7 days if the ring is removed for longer than 3 hours.

Like the traditional COCP regimen, the contraceptive vaginal ring is inserted in the vagina for 3 weeks and then withdrawn for 1 week, during which withdrawal bleeding is anticipated. A new ring is required every 4 weeks. Rates of unscheduled (breakthrough) bleeding and spotting are lower with the ring than with COCPs.³⁵

Contraceptive Mechanism of Action, Initiation, and Efficacy of the Patch and Ring

The contraceptive patch and vaginal ring act by suppression of ovulation.⁴⁰ The patch and ring are immediately effective if commenced on day 1 of menstruation, but starting at any other time requires 7 days of backup contraception, such as condoms.

The contraceptive efficacy of the patch and the vaginal ring is high when used correctly.^{40,41} Typical annual user failure rates are thought to be similar to those for the COCP at about 8%.⁷ Contraceptive efficacy may be reduced in patch users weighing more than 90 kg.⁴² Contraindications to the patch and the vaginal ring are the same as for COCPs.

Estrogen Levels with the Patch, Oral Contraceptives, and the Ring: Risk of Venous Thromboembolism

The contraceptive patch generates higher circulating levels of ethinyl estradiol than the COCP and vaginal ring generate.⁴³ It is uncertain whether use of the patch is associated with a higher risk of VTE than use of the COCP.⁴⁴

PROGESTIN-ONLY CONTRACEPTIVE METHODS

Progestin-only contraception is an option for women for whom an estrogen-containing contraceptive is contraindicated or causes additional health concerns. Progestin-only contraceptives offer many advantages over estrogen-containing methods. They can be used immediately after delivery and in women considered at risk for VTE. They are formulated in long-acting preparations that provide a high level of contraceptive efficacy and acceptability. The main disadvantage of the progestin-only contraceptives is changes in vaginal bleeding patterns. This is common in progestin-only oral contraceptive users and represents the most frequent cause for contraceptive discontinuation. Types of progestin-only contraceptives include the following:

- Oral progestin-only contraception (minipills)
- Progestin implants (Implanon)
- Intrauterine contraception (Mirena)
- Injectable contraception (DMPA Depo-provera)

Oral Progestin-Only Contraception

Only one progestin-only oral contraceptive formulation is marketed in the United States: norethindrone in 0.35-mg tablets (e.g., Micronor, Nor-QD, generics). The progestin dose is substantially lower than the dose in any combination oral contraceptive. It is dispensed in packs of 28 active pills, which are taken continuously (i.e., no pill-free or nonhormonal pill week) (see Table 18-2).

Mechanism of Action

The mechanism of action of progestin-only oral contraceptives varies among patients and may include suppression of ovulation, thickening cervical mucus, and inducing

TABLE 18-2

Summary and Recommendations for Progestin-Only Oral Contraceptive Use

1. Progestin-only contraception is an option for women in whom an estrogen-containing contraceptive is either contraindicated or causes additional health concerns.
2. Ovulation is not consistently suppressed; the main contraceptive actions of progestin-only oral contraception are effects on cervical mucus and the endometrium.
3. The typical user failure rate with progestin-only oral contraception is estimated to be >8%. Women choosing progestin-only oral contraception are often subfertile as a result of breast-feeding or older reproductive age, so the failure rate in these populations may be lower than in more fertile populations.
4. It is essential that the pill be taken at the same time each day to maximize contraceptive efficacy.
5. Menstrual irregularities are common in users of progestin-only oral contraception and represent the most frequent cause for contraceptive discontinuation.

endometrial atrophy. Unlike the mechanism of COCPs, ovulation is not consistently suppressed with progestin-only contraceptives, and the progestin effects on cervical mucus and the endometrium are critical factors in preventing conception. Within hours of administration, progestin-only oral contraceptives reduce the volume of cervical mucus and increase its viscosity, which prevents sperm from passing through the cervical canal and endometrial cavity. However, these changes persist for only 20 hours.⁴⁵

Efficacy

The efficacy of progestin-only oral contraceptives is not well established. National survey data used to estimate contraceptive failure rates with typical use have failed to distinguish between COCPs (the larger group) and progestin-only oral contraceptives. It is thought that the typical first-year failure rates with progestin-only oral contraceptives are higher than those seen with COCPs (8%).⁴⁶ Another confounding factor is that the women using progestin-only oral contraceptives may have reduced fertility as a result of breast-feeding or older reproductive age. The failure rate of progestin-only oral contraceptives in these populations is lower than it would be in more fertile populations. For women of normal fertility (e.g., women who are not breast-feeding), some experts recommend off-label use of 2 progestin-only tablets daily, with the assumption that this strategy enhances contraceptive efficacy. However, published reports have not assessed this approach, and there are no data regarding contraceptive efficacy of progestin-only oral contraceptives in obese, fertile women (discussed later).

Starting the Progestin-Only Pill

Progestin-only oral contraceptives can be initiated on the first day of menses, but a backup contraceptive should be used during the first week. Some clinicians initiate progestin-only oral contraceptives at any time in the cycle, as long as the clinician is reasonably certain that the patient is not pregnant. With this strategy, backup contraception should be used for the first 7 days of use. Because of the short duration of action and the short half-life of progestin-only oral contraceptives, the pill must be taken at the same time each day to maximize contraceptive efficacy. A backup contraceptive (e.g., condoms) should be used for at least 2 days if the progestin-only oral contraceptive is taken more than 3 hours late or forgotten on any day. The patient should also resume taking daily progestin-only oral contraceptives as soon as possible.

Side Effects of the Progestin-Only Oral Contraceptives

Follicular Cysts. Sonographic studies have shown that follicular cysts are more common among progestin-only oral contraceptive users than among other women, but they may come and go over time.⁴⁷ No intervention is required in asymptomatic women, other than reassurance and sonographic follow-up. If a follow-up sonogram in 6 to 8 weeks demonstrates resolution or decrease in size of follicular cysts, no further evaluation is required. Progestin-only oral contraceptive users who have persistent concerns about ovarian follicular changes should be offered another method of contraception.

Side effects with the progestin-only pill other than changes in bleeding patterns are relatively uncommon. Androgenic progestins may exacerbate acne. Weight gain has not been objectively documented, and headaches are uncommon.

TABLE 18-3

Conditions in Which Progestin-Only Contraception May Be Preferable to Estrogen-Containing Methods*

Migraine headaches, especially those with aura
Cigarette smoking or obesity in women >35 years
History of thromboembolic disease
Hypertension with vascular disease or age >35 years
Systemic lupus erythematosus with vascular disease, nephritis, or antiphospholipid antibodies
Less than 3 weeks postpartum
Hypertriglyceridemia
Coronary artery disease
Congestive heart failure
Cerebrovascular disease

*In women with the conditions listed, use of progestin-only contraceptives may be safer than combination oral, transdermal, or vaginal ring contraceptives. From ACOG Committee on Practice Bulletins—Gynecology. ACOG practice bulletin no. 73: Use of hormonal contraception in women with coexisting medical conditions. *Obstet Gynecol.* 2006;107:1453-1472.

Contraindications to Progestin-Only Contraceptives.

Progestin-only contraceptives may be appropriate for many women with contraindications to contraceptive doses of estrogen, including women age 35 or older who are obese, who smoke, who have hypertension, or who have diabetes. Progestin-only contraceptives are also appropriate for women with a prior medical history of VTE (Table 18-3). Unfortunately, package labeling for some progestin-only contraceptives does not reflect this distinction. For example, package labeling for DMPA inappropriately lists a history of VTE as a contraindication.²⁸

Use of Progestin-Only Contraceptives When Estrogen Is Contraindicated. Use of progestin-only oral contraceptives, injectables, and implants may be appropriate when contraceptive doses of estrogen are contraindicated. COCP use (like pregnancy) confers an increased risk of morbidity and mortality in women older than 35 years who smoke, are obese, or have hypertension; women with coronary artery disease; women at increased risk for thromboembolism; and women with active systemic lupus erythematosus. Progestin-only methods should be considered safe and effective contraceptive choices for these women (see Table 18-3).

Effect of Carbohydrate Metabolism. Most studies have reported that progestin-only oral contraceptives have little impact on carbohydrate metabolism.⁴⁸ However, one study conducted in Latina women observed that lactating women with a history of gestational diabetes who used progestin-only oral contraceptives after delivery had an almost tripled risk of diabetes compared with those who used low-dose COCPs.⁴⁹ Clinicians should monitor glucose tolerance in high-risk lactating women using progestin-only oral contraceptives.

Ectopic Pregnancy Risk. Progestin-only oral contraceptives lower the overall risk of ectopic pregnancy and intrauterine pregnancy. A history of ectopic pregnancy does not contraindicate progestin-only oral contraceptive use. However, if pregnancy occurs, the likelihood that the pregnancy is ectopic is higher in progestin-only oral contraceptive users than in nonusers of contraceptives (5% versus 2%).⁵⁰

Effect on Bone Mineral Density. The only study assessing skeletal health in progestin-only oral contraceptive users was conducted in breast-feeding women. Progestin-only oral contraceptives protected against small, reversible losses in BMD occurring during lactation.⁵¹

Effect on Cancer Risk. Progestins usually suppress endometrial growth.⁴⁷ However, few epidemiologic data address the effect of progestin-only oral contraceptives on endometrial cancer risk or on any cancer risk.

Effect on Sexually Transmitted Infections. Use of progestin-only oral contraceptives has not been shown to protect users from acquiring STIs.

Use After Abortion or Delivery. Progestin-only oral contraceptives may be initiated immediately after abortion or delivery. They should be initiated within 2 weeks to ensure effectiveness.

Progestin-Only Oral Contraceptives during Lactation. The progestin-only oral contraceptive does not interfere with the quality or quantity of breast milk.⁵² Very little progestin is passed from nursing mothers into their breast milk, and no adverse impact on infant growth has been observed. Package labeling advises delaying administration in lactating women until 6 weeks after delivery. Based on the absence of data suggesting harm to the infant or mother and the contraceptive benefits of early initiation, some experts recommend initiation of progestin-only pills or DMPA before hospital discharge and no later than the third postpartum week, regardless of lactation status.⁵³

Abnormal Bleeding. Unscheduled bleeding, spotting, and amenorrhea are common menstrual patterns during progestin-only oral contraceptive use, and users should be counseled accordingly. Interpreting signs and symptoms of pregnancy, whether intrauterine or extrauterine, can be challenging. Pregnancy testing is appropriate for progestin-only oral contraceptive users experiencing nausea, breast tenderness, a change in menstrual pattern, or lower abdominal pain (see Table 18-2).

Depot Medroxyprogesterone Acetate for Contraception

DMPA is an injectable, progestin-only contraceptive that provides highly effective, private, and reversible contraception. It avoids the need for user action daily or near the time of sexual intercourse and the need for partner cooperation (Table 18-4).

Formulations and Pharmacology

DMPA is available in two formulations: 150 mg/1 mL for intramuscular injection and 104 mg/0.65 mL for subcutaneous injection. The newer subcutaneous injection may be less painful and is available in a prefilled syringe, offering the potential for self-administration. The injections can be given every 3 months because low solubility of the microcrystals at the injection site allows pharmacologically active drug levels to persist for several months. Intramuscular DMPA is available as a generic formulation, which is less costly than subcutaneous DMPA. Otherwise, the benefits and risks are similar for intramuscular and subcutaneous administration.⁵⁴

DMPA primarily acts by inhibiting follicular maturation and ovulation through inhibition of gonadotropin secretion. Unlike other progestin-only contraceptives, mean

TABLE 18-4

Timing of Depot Medroxyprogesterone Acetate (DMPA) Injections

Method	Depot Medroxyprogesterone Acetate
First Injection	
Spontaneous menstrual cycle	Within 5 days of menses onset
Spontaneous or elective first-trimester abortion	Within 7 days
Term delivery	Within 3 wk after delivery if not lactating; within 6 wk if lactating
Switching from combined oral contraceptive pills	While on active pills or within 7 days after taking the pill pack's last active tablet
Switching from combination contraceptive patch (Ortho Evra)	While on weekly patch or within 7 days after patch removal
Switching from combination contraceptive vaginal ring (NuvaRing)	While ring is in place or within 7 days after ring removal
Switching from levonorgestrel IUD (Mirena)	First injection should occur before IUD removal and within 5 yr after IUD insertion; if patient is menstruating, a condom should be used as backup if the first injection is not given within 5 days of menses onset
Switching from Copper T 380A IUD	First injection should occur before IUD removal and within 10 yr after IUD insertion; backup contraception such as condoms should be used if the first injection is not given within 5 days of menses onset
Subsequent Injections	
Injection interval	Every 12 wk (3 mo); earlier reinjections are acceptable
Grace period	Two weeks; after 1 wk manufacturer recommends pregnancy testing before repeat injection

IUD, intrauterine device.

From Kaunitz AM. Current concepts regarding use of DMPA. *J Reprod Med.* 2002;47:785-789.

estradiol levels may be lower than normal for cycling premenopausal women. Although the endometrium becomes atrophic, vasomotor symptoms are uncommon. Because of its progestin effect, it also causes changes in cervical mucus and tubal motility that are hostile to sperm migration.⁵⁵

For the 150-mg intramuscular injection, failure rates in clinical trials have ranged from 0.0 to 0.7 per 100 woman-years. The typical-user failure rate is 7 failures per 100 woman-years, reflecting the fact that some users do not return for their injections as scheduled.⁴⁶ Because progestin levels are high, efficacy has not been reduced by high body weight or use of concurrent medications. For the 104-mg subcutaneous injection, no contraceptive failures were reported in phase III clinical trials.⁵⁶ As this formulation is relatively new, and typical-user failure rates are not available, but they are expected to be similar to those for the intramuscular preparation.

Administration of Depot Medroxyprogesterone Acetate

Starting Injections. The ideal time to initiate DMPA is within 5 days of the onset of menses. This approach ensures that the patient is not pregnant at the time of injection

and prevents ovulation during the first month of use, so that backup contraception is unnecessary. Most women have pharmacologically active drug levels and a poor cervical mucus score within 24 hours after injection.⁵⁵ The “same-day,” “quick-start,” or “Depo-now” approach when a pregnancy test result is negative facilitates DMPA initiation for many users, and it may prevent some pregnancies.⁵⁷ However, there is a small possibility of undiagnosed pregnancy despite a negative pregnancy test result. Back-up contraception should be used for 3 days because ovulation may occur within 24 hours of the initial injection. DMPA given during pregnancy does not appear to be teratogenic.⁵⁸

Repeat Injections. Repeat injections of DMPA should be given every 3 months. After a 150-mg injection, ovulation does not occur for at least 14 weeks. A 2-week grace period is appropriate for women receiving injections every 3 months. In women more than 1 to 2 weeks late for an injection, a urine pregnancy test should be performed before administering further DMPA. Timing of DMPA injections is summarized in Table 18-4.⁵⁵

Side Effects of Depot Medroxyprogesterone Acetate

Candid counseling regarding the side effects of DMPA and the need for timed injections should be provided. Women who are well informed when they choose this method of contraception are more likely to become satisfied users with high continuation rates.⁵⁵ Common side effects of DMPA (>5% of long-term users) include menstrual irregularities (i.e., bleeding or amenorrhea), weight changes, headache, abdominal pain or discomfort, nervousness, dizziness, and asthenia.⁵⁵

Menstrual Changes. Menstrual changes occur in almost all women using DMPA and are the most frequent cause for discontinuation of these and all other progestin-only contraceptives.⁵⁹ Proactive patient education before initiation of DMPA and supportive follow-up can improve tolerance of menstrual changes. During the first months of use, episodes of unpredictable bleeding and spotting lasting 7 days or longer are common. Bleeding decreases with use, and at 1 year, 50% of women experience amenorrhea; this rate increases to 75% with long-term use.⁶⁰ Similar bleeding patterns are reported with the subcutaneous preparation.⁶¹ Some women may view amenorrhea (along with a reduction or elimination of menstrual cramps) as one of the advantages of using this method.

There are no established methods for predicting, preventing, or treating unscheduled bleeding in DMPA users. In new DMPA users, 50 mg of mifepristone (not marketed in the United States for this indication) taken every 2 weeks decreases the incidence of unscheduled bleeding.⁶² Some studies have shown that estrogen supplements (e.g., 1.25 mg of oral conjugated estrogen, 1 to 2 mg of oral micronized estradiol or 0.1-mg estradiol patches) may terminate a bleeding episode.⁵⁹ However, a systematic review concluded that there is a lack of high-quality data to support routine clinical use of any interventions to treat persistent unscheduled bleeding with progestin-only contraceptives.⁶³

Weight Changes. The impact of DMPA on weight has been controversial. Level 1 data has failed to show that DMPA causes weight gain.^{55,64} Weight gain with the use of DMPA may be associated with user subgroups at

particular risk for obesity, including adolescents and ethnic minorities.⁶⁵

Other Side Effects. Observational studies have not reported any consistent effects of DMPA on mood. Some evidence indicates that progestins may cause or exacerbate depressive symptoms in certain subpopulations of women, including those with a history of premenstrual syndrome or mood disorders.⁵⁵

Risks and Benefits of Depot Medroxyprogesterone Acetate

DMPA has been used to manage a variety of gynecologic and nongynecologic disorders. The tendency of DMPA to cause amenorrhea makes it a particularly appropriate contraceptive choice for women with menorrhagia, dysmenorrhea, or iron-deficiency anemia. DMPA is a useful means of suppressing menstrual bleeding and managing menstrual hygiene in individuals with special needs (e.g., cognitive impairment, military personnel). Use of DMPA has been associated with hematologic improvement (i.e., fewer painful crises) in women with sickle cell disease.⁶⁶

DMPA users have a decreased risk of PID, although rates of *Chlamydia* infection are increased.⁶⁷ The increased risk of *Chlamydia* infection may indicate that women who choose DMPA contraception engage in higher-risk sexual behavior than women choosing other methods. The decreased risk of PID may reflect progestational changes in the cervical mucus and endometrium, along with reduced menstrual flow. Progestins inhibit endometriotic tissue growth by directly causing initial decidualization and eventual atrophy and by inhibiting pituitary gonadotropin secretion and ovarian estrogen production. Randomized trials have shown that DMPA is more effective than oral contraceptives and danazol and as effective as leuprolide injections for treatment of pain associated with endometriosis.⁶⁸ In the United States, subcutaneous DMPA is approved for the treatment of pain associated with endometriosis.

The efficacy of DMPA does not appear to be attenuated by the use of enzyme-inducing anticonvulsants,³⁴ and DMPA may have intrinsic anticonvulsant properties. For these reasons, DMPA may be a good contraceptive for many women with seizure disorders.

Effect on Cancer Risk. Large case-control studies conducted by the WHO have shown that use of DMPA is associated with an 80% reduced risk of endometrial cancer and does not affect the incidence of ovarian, cervical, or liver cancer. Multicountry data from the WHO and data from the United States, South Africa, and New Zealand provide reassurance that use of DMPA is not associated with an increased risk of breast cancer.^{69,70}

Effect on Cardiovascular Risk. DMPA has an adverse effect on circulating lipids but does not increase production of coagulation factors and has no adverse effect on blood pressure. No adverse clinical effects on cardiovascular disease have been observed.⁵⁵ Based on these findings, the American College of Obstetricians and Gynecologists (ACOG) stated that DMPA and other progestin-only contraceptives might be appropriate contraceptive options for women with a history of VTE and those in whom use of combination estrogen-progestin contraceptive is contraindicated.²⁸ This recommendation is different from package labeling for DMPA (written in the 1960s), which indicates that a prior history of VTE is a contraindication to DMPA

use. In women with multiple risk factors for cardiovascular disease (e.g., smoking, older age, hypertension, diabetes), the WHO classifies DMPA as category 3, indicating that the risks of use may exceed the benefits. The basis for this caution is uncertain.

Effect on Skeletal Health. DMPA's impact on BMD has generated much controversy. In suppressing gonadotropin production and ovulation,⁷¹ DMPA also suppresses ovarian production of estradiol.⁷² The resulting hypoestrogenemia causes a decline in BMD.⁷³ Compared with nonusers, BMD at the hip and spine of DMPA users decreases by 0.5% to 3.5% after 1 year and by 5.7% to 7.5% after 2 years of use.⁷⁴ The rate of loss is greatest during the first 1 to 2 years of use.^{75,76} The intramuscular and subcutaneous formulations of DMPA have similar effects on BMD.⁵⁴ Although it is well established that DMPA leads to BMD declines in current users, the long-term impact of injectable contraception on skeletal health, if any, is uncertain. Particular concern surrounds the long-term skeletal health impact in two groups of women⁷⁷: young women, who have not yet reached their peak bone mass, and older reproductive-age women, who are experiencing accelerated declines in BMD as they approach menopause.

Published data do not suggest that DMPA use reduces peak bone mass or increases the risk of postmenopausal osteoporotic fractures.⁷⁸ One prospective and one retrospective study in high-risk groups, however, suggested an increased risk of fracture in DMPA users.^{79,80} A Danish case-control study also suggested that DMPA is associated with an increased fracture risk.⁸¹ However, use of DMPA is rare in Danish women, and this study did not assess baseline risk factors such as smoking or body mass index (BMI). It is difficult to draw clinical inferences from this study's findings. To our knowledge, no prospective study has assessed the impact of DMPA contraceptive use on subsequent fracture risk in postmenopausal women.

Notwithstanding the lack of a known increase in fracture risk, the FDA added a black box warning to DMPA package labeling in 2004: "Women who use DMPA may lose significant bone mineral density. Bone loss is greater with increasing duration of use and may not be completely reversible. It is unknown if use of DMPA during adolescence or early adulthood, a critical period of bone accretion, will reduce peak bone mass and increase the risk for osteoporotic fracture in later life. DMPA should be used as a long-term birth control method (e.g., longer than 2 years) only if other birth control methods are inadequate." The addition of this warning to DMPA's package labeling appears to have led some physicians to limit the duration of DMPA use and to order BMD assessment in women using DMPA.⁸²

The clinical impact of decreased BMD in current DMPA users is uncertain. Studies involving premenopausal women and adolescents treated with DMPA for up to 5 years indicate that the decline in BMD associated with injectable contraception is largely reversed after discontinuation.^{64,83-87} Overall, DMPA-associated declines in bone density at the spine appear to reverse more rapidly than BMD declines occurring at the hip. Recovery of BMD deficits associated with DMPA use appears to occur more rapidly after use by adolescents than after use in adult women.⁸⁵

To summarize, current use of DMPA is associated with BMD declines, but a significant increase in risk of fractures in DMPA users has not been demonstrated.⁸⁸ Professional organizations, including the ACOG,^{28,74} the Society for Adolescent Medicine,^{74,89} the WHO,⁹⁰ and the Society of Obstetricians and Gynaecologists of Canada,⁹¹ state that

the advantages of DMPA use as a contraceptive outweigh the theoretical concerns regarding skeletal harm. Skeletal health concerns should not restrict initiation or continuation of DMPA in reproductive age women, including teens and women older than 35 years. Published evidence does not support limiting the duration of DMPA therapy. The effect of DMPA on BMD is similar to that with pregnancy (decrease in BMD of 2% to 8%) or lactation (decrease in BMD of 3% to 5%).⁷⁴ Use of DMPA is not an indication for BMD testing before, during, or as follow-up of administration.^{28,78} Likewise, antiresorptive agents, including bisphosphonates, are not appropriate to prevent bone loss in women using injectable contraception.⁷⁸

As with all reproductive-age patients, clinicians should encourage DMPA users to consume adequate amounts of calcium and vitamin D. Clinical judgment is called for when helping women with risk factors for osteoporosis make sound choices regarding DMPA and alternative contraceptives.

Effect on Sexually Transmitted Infections. Use of DMPA does not protect users from acquiring STIs. Whether it increases the risk of acquiring these infections is less clear. Results of primate studies suggest that DMPA may lead to thinning of vaginal mucosa, facilitating penetration of the HIV virus. However, human studies have failed to show any impact of DMPA or other hormonal contraceptives on HIV transmission.⁹² In HIV-infected women, DMPA does not appear to increase the rates of STI acquisition.⁹³

DMPA use may be associated with an increased incidence of endocervical chlamydial and gonococcal infection.⁹⁴ However, women who chose to use DMPA may be more likely to have STIs at baseline, which may bias study results.

Effect on Return of Fertility. Although DMPA does not permanently impact endocrine function, return of fertility may be delayed. Within 10 months of the last injection, 50% of women who discontinue DMPA to become pregnant will conceive. However, in some women, fertility is not reestablished until up to 18 months after the last injection.⁵⁵ The persistence of ovulation suppression after DMPA discontinuation is not related to the duration of use, but it is related to weight. Before initiating DMPA contraception, clinicians should counsel candidates about the possible prolonged duration of action. Women who may want to become pregnant within the next 1 or 2 years should choose an alternative contraceptive.

DMPA may be initiated immediately after abortion or delivery. It should be initiated by 2 weeks after delivery to ensure effectiveness.⁵⁵

Progestin-only contraceptives appear to be safe to use during lactation. However, high-quality studies are lacking.³³

Use When Estrogen Is Contraindicated. DMPA appears to be safe for many women with contraindications to estrogen-containing contraceptives (e.g., migraine with aura; women older than 35 years who smoke, are obese, or have hypertension; cardiovascular disease; or lupus) (Table 18-5).

Potential Drug Interactions. The contraceptive efficacy of DMPA in women taking hepatic enzyme inducers has not been explicitly studied; however, physicians with substantial experience prescribing DMPA (150 mg every 3 months) for women taking anticonvulsants have not reported contraceptive failure among such patients.³⁴

TABLE 18-5

Summary and Recommendations for Depot Medroxyprogesterone Acetate (DMPA) Use

1. DMPA is an excellent method of contraception for women who desire a long-term, reversible contraceptive method.
2. DMPA primarily acts by inhibiting follicular maturation and ovulation through inhibition of gonadotropin secretion; it also affects cervical mucus.
3. DMPA is available in two formulations: 150 mg/1 mL for IM injection and 104 mg/0.65 mL for SC injection.
4. The ideal time to initiate DMPA is within 5 days of the onset of menses, so as to ensure absence of pregnancy. The dose is repeated every 3 months, with a 2-week grace period.
5. Although DMPA does not permanently affect endocrine function, return of fertility may be delayed.
6. Thorough, candid counseling about side effects is important. Women who are well-informed when they choose this method of contraception are much more likely to become highly satisfied users with high continuation rates.
7. Menstrual changes occur in all women using DMPA and are the most frequent cause for discontinuation.
8. Because DMPA induces amenorrhea, it can be used for managing a variety of gynecologic and nongynecologic disorders, such as menorrhagia, dysmenorrhea, and iron deficiency anemia.
9. There is no high-quality evidence that use of DMPA increases the risk of developing cancer, cardiovascular disease, or sexually transmitted infection. DMPA use significantly reduces the risk of developing endometrial cancer.
10. There is an association between current DMPA use and decreased bone mineral density; losses in bone mineral density are temporary, reverse after discontinuation of DMPA, and have not been linked to postmenopausal osteoporosis or fractures.

Cost Issues. In addition to enhancing quality of life by allowing couples to choose whether and when they wish to bear children, effective contraception saves health care costs. Male and female sterilization and long-acting reversible methods (e.g., intrauterine devices, subdermal implant) constitute the most cost-effective contraceptive options, followed by other hormonal methods (e.g., oral contraceptives). DMPA is more cost-effective than oral contraception. Barrier and behavioral methods (i.e., male condom and withdrawal, respectively) are least cost-effective compared with other contraceptive options. Nevertheless, when compared with no method, they still prevent a large number of unintended pregnancies, leading to important cost savings.⁹⁵

Intrauterine Progestins for Contraception

The levonorgestrel-containing intrauterine system (LNG-IUS) is an effective, safe, and convenient form of long-term, reversible contraception. Intrauterine contraception use in the United States fell dramatically after early studies reported an association between intrauterine contraception use and later tubal infertility. Modern intrauterine contraception is highly effective and safe to use in selected populations. The addition of progestin to the intrauterine device (IUD) increases contraceptive efficacy and offers the added benefit of markedly reducing uterine blood loss. The LNG-IUS provides other therapeutic benefits, including treatment of heavy menstrual bleeding (i.e., menorrhagia) and endometriosis and suppression of endometrial growth.

IUDs are highly effective, require little patient effort, and are cost-effective. Hormone-containing devices have many potential noncontraceptive benefits and can address the medical and contraceptive needs of an individual patient.

Contraceptive Uses

Mirena (Bayer, Wayne, NJ) is the only progestin-containing IUD approved in the United States. It is a T-shaped device with a reservoir containing 52 mg of levonorgestrel. It delivers 20 mg of levonorgestrel per day and maintains its contraceptive efficacy for at least 5 years. The maximum plasma levels are reached within a few hours, and they plateau between 100 and 200 pg/mL, levels that are lower than those with implants or oral contraceptives. Data from large international studies confirm extremely low pregnancy rates, ranging between 0.1 per 100 and 0.3 per 100 women-years.⁹⁶ Despite endometrial suppression, fertility resumes rapidly after contraceptive removal.⁹⁷

The mechanism of action of the contraceptive effects of LNG-IUS is not well defined. Most LNG-IUS users continue to ovulate, even when there is amenorrhea.⁹⁸ The principal mechanism of contraceptive action cervical mucus changes and appears to be profound endometrial suppression. The latter may contribute to the reduction in uterine bleeding seen with this device.⁹⁸

Abnormal Bleeding, Expulsion, and Uterine Perforation

As with DMPA and other progestin-only contraceptives, unpredictable uterine bleeding is the most common reason for discontinuation of the LNG-IUS.⁵⁹ Unscheduled bleeding is most common during the early months of LNG-IUS use and tends to resolve with time. By 12 months, up to 50% of women have amenorrhea or infrequent bleeding.⁹⁹ Addressing patient preferences and assessing acceptance of menstrual disturbances are integral to efforts aimed at reducing early discontinuation rates. Adequate and specific counseling about likely changes in bleeding patterns before placement is essential to increase patient acceptability.

Expulsion, the most common cause of IUD failure, occurs in about 5% of users. Those at increased risk for expulsion include nulliparous women, women with severe dysmenorrhea, those with uterine cavity abnormalities, and women with insertions immediately after delivery or abortion.¹⁰⁰ The WHO recommends immediate insertion after first (category 1) and second (category 2) trimester abortions. Postpartum insertion is recommended after a 4-week interval, with more immediate insertion recommended only if the clinician decides that the risks outweigh the benefits. Because expulsion usually occurs within the first few months, women are encouraged to follow up with their care provider within 12 weeks of insertion.

Uterine perforation is an uncommon but potentially serious complication of LNG-IUS placement. Perforation rates are up to 2.6 cases per 1000 women and may be increased for lactating women.¹⁰¹

Upper Genital Tract Infection

Widespread concerns regarding a strong causative association between intrauterine contraception and pelvic infection appear to have been largely unsubstantiated. After early reports, subsequent studies have not confirmed this association.

A clinical history (including sexual history) should be taken as part of the routine assessment for intrauterine contraception to identify women at high risk for STIs; testing before insertion should be performed selectively, not routinely. Prophylactic antibiotics are not recommended. PID among users of intrauterine contraception is most strongly related to the insertion process and to the background risk of STIs. Conditions that represent an

unacceptable health risk if an IUD is inserted are current PID, current purulent cervicitis, and chlamydial or gonorrheal infection.¹⁰² If a woman develops PID with an LNG-IUS in place, Centers for Disease Control and Prevention (CDC) guidelines for treatment (available at <http://www.cdc.gov/std/treatment/2006/updated-regimens.htm> [accessed August 2010]) should be followed, and if the patient responds to therapy, the IUD can remain in place.

Infertility

The issues regarding intrauterine contraception and subsequent infertility have been the source of controversy for years. Current best evidence does not support a causative relationship. In light of the available data, the ACOG and the WHO include nulliparous women as IUC candidates (category 2).¹⁰³

Metabolic and Systemic Effects

Low but detectable circulating levels of androgenic progestins in LNG-IUS users has raised concerns that glucose control, lipid profile, and blood pressure may be negatively affected. However, these concerns have not been substantiated in high-quality clinical trials.⁹⁸ The data suggest that the LNG-IUS is safe to use in patients with diabetes, hypertension, or hyperlipidemia.¹⁰⁴ Progestins are not thought to increase the risk of thromboembolic disease, but no studies have specifically examined the comparative risk of thromboembolism among LNG-IUS users.

Noncontraceptive Uses of the Levonorgestrel-Containing Intrauterine System

Heavy Menstrual Bleeding. The LNG-IUS is a well-established and highly effective treatment intervention for heavy menstrual bleeding. In comparative studies, it offers efficacy equal to or greater than other uterine-conserving treatments (e.g., balloon ablation, transcervical endometrial resection, medical management), is an acceptable alternative to hysterectomy for many women,¹⁰⁵ and offers comparable improvement in health-related quality of life for menstrual disorders. However, more patients in the LNG-IUS group reported systemic side effects, irregular bleeding, and breast tenderness than those in the oral progestin or endometrial ablation group.

Although up to 43% of women using the LNG-IUS to treat abnormal uterine bleeding will eventually undergo hysterectomy, the system still offers lower direct and indirect health costs at 5 years (\$2817 per participant) than the hysterectomy group (\$4660 per participant).¹⁰⁵

Symptomatic Fibroids and Uterine Adenomyosis. Preliminary data suggest that the LNG-IUS is also an effective treatment for heavy menstrual bleeding associated with uterine fibroids. Submucous fibroids may be more likely to cause heavy bleeding and are more likely to lead to LNG-IUS expulsion because they distort the uterine cavity.¹⁰⁶ Additional trials are needed to define the role of the LNG-IUS in the treatment of symptomatic fibroids.

Uterine adenomyosis also is a common, benign cause of heavy menstrual bleeding; dysmenorrhea is commonly associated with this condition. Published reports suggest that the LNG-IUS reduces bleeding and pain in women with this condition.¹⁰⁷

Endometriosis. Results of small, prospective studies using the LNG-IUS as a treatment for pelvic pain and dysmenorrhea associated with endometriosis are encouraging. The system may offer effective symptom relief, at least in the

short term. However, these studies are limited by small sample sizes and vary significantly with regard to enrollment criteria and by stage and location of disease. A short-term, randomized trial found that the LNG-IUS was as effective as a gonadotropin-releasing hormone agonist in reducing pain in women with endometriosis. One advantage of the LNG-IUS in this setting is the absence of hypoestrogenic effects associated with the use of gonadotropin-releasing hormone agonists.¹⁰⁸ Follow-up of these women for 3 years showed no further improvement in pelvic pain after 12 months of use.¹⁰⁹ Additional studies are needed to confirm the original findings and to determine how to best integrate its use into current clinical protocols. As expected, all studies also reported increased menstrual disturbances in the LNG-IUS groups.

Uterine Protection with Estrogen Replacement Therapy. Good-quality evidence supports the long-term use of LNG-IUS for endometrial suppression during estrogen replacement therapy.¹¹⁰ However, the intrauterine levonorgestrel is relatively large and may be difficult to insert into a postmenopausal woman in an outpatient setting and is likely to cause irregular bleeding. Availability of a smaller progestin-releasing IUD would facilitate use in menopausal women. Acceptability studies are needed, and more studies are necessary to determine the lowest effective dose of LNG required to attain effective endometrial suppression.

Uterine Protection with Tamoxifen Use. Tamoxifen is commonly used as adjuvant endocrine therapy in the treatment of estrogen receptor-positive breast cancer in premenopausal women and in selected postmenopausal women. In postmenopausal women, tamoxifen appears to increase the risk of endometrial polyps, hyperplasia, and cancer. A systematic review of the LNG-IUS in the prevention of endometrial pathology in tamoxifen users concluded that Mirena reduced the risk of endometrial polyps in tamoxifen users, but no data demonstrate that it reduces the risk of endometrial hyperplasia or cancer. Mirena users had a higher incidence of unscheduled bleeding, which may increase the need for diagnostic intervention in this high-risk group.¹¹¹

Treatment for Endometrial Hyperplasia or Carcinoma. Small, prospective studies have shown that the LNG-IUS is an effective and safe alternative in the treatment of perimenopausal and postmenopausal women with (simple) endometrial hyperplasia without atypia.¹¹² When there is atypia, the device may be less effective. The best treatment for early endometrial cancer is hysterectomy. Progestins are sometimes used as palliative or adjuvant therapy. No randomized, controlled trials have examined the role of LNG-IUS in the treatment of atypical endometrial hyperplasia or carcinoma. Small studies of selected patients suggest that intrauterine progestin in surgical high-risk candidates with endometrial cancer may be an alternative management option.¹¹³ Larger studies are needed to better determine the value of LNG-IUS in this context.

Expanding the Use of Intrauterine Devices

There is growing consensus that it is time to broaden our use of IUDs, including the LNG-IUS. One of the greatest challenges will be to effectively counsel patients seeking contraceptives to best meet their needs and to prepare them for possible side effects. Among the demonstrated and potential noncontraceptive uses of LNG-IUS, research supports the use of this device to reduce heavy menstrual

bleeding and protect the endometrium in women during use of menopausal estrogen therapy. Other uses, such as for endometriosis, adenomyosis, or endometrial hyperplasia or carcinoma, are less clear. As with all progestin-only contraceptives, bleeding changes represent the most common reason for user dissatisfaction and premature discontinuation.

Contraceptive Implants

Contraceptive implants provide long-acting, highly effective, convenient, and reversible contraception. All subdermal implants for clinical use in humans use progestins. These methods offer an excellent contraceptive option for women who have contraindications to combined hormonal methods and an option for any woman who desires long-term protection against pregnancy that is rapidly reversible. The only subdermal implant available to women in the United States is Implanon (Schering-Plough, Kenilworth, NJ) (Fig. 18-3).

Implanon contains etonogestrel as a single-rod subdermal implant. It has been available in the United States since 2006 but has been extensively used internationally for many years. Implanon is approved for 3 years of use, provides excellent efficacy throughout its use, and is easy to insert and remove. Implanon can be used during lactation, may improve dysmenorrhea, and does not significantly affect BMD, lipids, or liver enzymes.^{114,115} Like other progestin-only contraceptives, Implanon commonly causes irregular vaginal bleeding.

Description and Pharmacology

The Implanon rod releases the gonane progestin etonogestrel, formerly known as 3-ketodeosogestrel, the biologically active metabolite of desogestrel. Etonogestrel is the same progestin used in the contraceptive vaginal ring. The implant is 4 cm long and 2 mm in diameter, and it has a core made from a nonbiodegradable solid composed of ethylene vinyl acetate impregnated with 68 mg of etonogestrel (see Fig. 18-3). The ethylene vinyl acetate copolymer of Implanon allows controlled release of hormone over 3 years of use.¹¹⁵ Each implant is provided in a disposable

sterile inserter for subdermal application. Maximum serum concentrations of etonogestrel are usually seen by day 4 after implant insertion. Etonogestrel levels decrease slightly by 1 year and further by 3 years but remain above the threshold needed to suppress ovulation.¹¹⁶ After removal, serum levels are undetectable by 1 week in most users, who resume ovulation within 6 weeks of implant removal.

Despite effective suppression of ovulation, estradiol levels only fall into the early follicular level range, and Implanon does not cause hypoestrogenism. An initial decrease in the estradiol level is followed by a gradual rise to normal levels.¹¹⁵

Mechanism of Action and Efficacy

The contraceptive action of Implanon is primarily effective inhibition of ovulation, although some thickening of cervical mucus may also occur.¹¹⁷

Implanon provides highly effective contraception. In an integrated analysis of 11 international clinical trials that included more than 900 healthy women between 18 and 40 years old, no pregnancies were reported while the etonogestrel implants were in place. Six pregnancies occurred during the first 14 days after etonogestrel implant removal. Including these six pregnancies, the cumulative Pearl index (number of pregnancies per 100 women-years) was 0.38 (year 1 and 2 Pearl indices were 0.27 and 0.30, respectively).¹¹⁷ After the Implanon has been removed, normal ovulation and fertility rapidly return.

Reported pregnancies among Implanon users primarily been due unrecognized pregnancies at the time of insertion and those caused by clinician failure when inserting the device. Postmarketing data from Australia show a failure rate of 1.07 per 1000 insertions.¹¹⁸ For the total number of confirmed pregnancies, 21% of cases had insufficient data to detect the reason for failure, and the remaining 19% of pregnancies were caused by method failure. However, even when these method failures are accounted for, Implanon continues to have one of the highest efficacies of any method available.

There are reports of Implanon failure in women using anticonvulsants, particularly carbamazepine,³⁴ and contraceptive implants are not recommended in women taking anticonvulsants or other medications that induce hepatic enzymes. Although no reports suggest higher etonogestrel implant failure rates in overweight and obese women, insufficient data address implant efficacy in these subgroups of women.

Safety and Side Effect Profile

Bleeding Patterns. Implanon users commonly experience irregular and unpredictable bleeding patterns, similar to the experience of users of other continuous progestin-only contraceptives. Combined data from 11 clinical trials showed that the most common bleeding patterns with Implanon were amenorrhea (22.2%), infrequent bleeding (33.6%), frequent bleeding (6.7%), and frequent or prolonged bleeding, or both (17.7%). The number of bleeding days usually was not increased, but the pattern was unpredictable. Of clinical relevance is that bleeding patterns experienced during the initial 3 months predicted future patterns for most women. The group of women with favorable bleeding patterns during the first 3 months tended to continue with this pattern throughout the first 2 years of use, whereas the group with unfavorable initial patterns had at least a 50% chance that the pattern would improve. Only 11.3% of patients discontinued use because of bleeding irregularities, mainly because of prolonged flow and frequent irregular bleeding. Most women (77%) who had

Figure 18-3 Implanon.

baseline dysmenorrhea experienced complete resolution of symptoms. Effective preinsertion counseling on the possible changes in bleeding patterns may improve continuation rates.¹¹⁹

Despite extensive clinical trials of agents to improve bleeding patterns with long-acting progestin-only contraceptives, there are no reliable ways of predicting or improving bleeding patterns. COCPs containing high-dose estrogen (50 µg of ethinyl estradiol/250 µg LNG for 20 days) can effectively stop a bleeding episode, but they may cause nausea.¹²⁰ Lower-dose COCPs may shorten bleeding episodes but do not decrease their frequency.⁶³ Data from a large, randomized, controlled trial enrolling Implanon users with frequent or prolonged bleeding have shown that mifepristone in combination with ethinyl estradiol or doxycycline was significantly more effective in stopping an episode of bleeding compared with doxycycline, alone or in combination with ethinyl estradiol, or with placebo. However, there was no improvement in subsequent bleeding patterns.¹²¹ Mifepristone is not readily available in the United States for the treatment of abnormal bleeding. Treatment options for problematic bleeding in progestin contraceptive users are limited, and there are no studies supporting a long-term beneficial effect of any therapeutic regimen.

Acne. Some studies have shown an improvement in acne in Implanon users, but others have found deterioration. The opposing nature of these data and the lack of control groups make it difficult to provide patients with a clear expectation regarding the incidence or severity of acne while using the etonogestrel implant. Patients should be counseled that there is no apparent trend with regard to acne incidence or improvement while using the etonogestrel implant.¹¹⁷

Bone Mineral Density. Implanon does not reduce mean circulating estradiol levels. Consistent with that observation, limited data from clinical trials does not show an adverse effect of Implanon on BMD.¹¹⁵

Dysmenorrhea. Studies of Implanon and dysmenorrhea show a consistent pattern of symptom improvement.¹¹⁵ Effective suppression of ovulation means that Implanon may also be an effective treatment for patients with cyclic exacerbation of symptoms who wish to avoid estrogen.

Weight Changes. Several studies have observed a small (<1 kg) weight increase in Implanon users.¹¹⁷ However, only 3% to 7% of women chose to remove Implanon because of weight changes.

Ovarian Cysts. Similar to the effect seen in women using progestin-only pills, ovarian cysts occur in up to 15% of Implanon users. They may take up to 2 months to resolve but usually are not symptomatic. Most cysts regress spontaneously and do not need additional treatment.¹¹⁷

Breast-Feeding. Implanon does not appear to change the content of breast milk and does not influence infant growth up to 3 years. Limited data show that Implanon is safe for use during lactation.¹¹⁵

Effect on Lipid Profile. Lipid measurements reveal an overall decrease in serum total cholesterol, high-density lipoprotein (HDL) cholesterol, and low-density lipoprotein (LDL) cholesterol. Some studies have also shown a decrease in triglyceride levels. Minor reductions in the HDL/LDL

ratio have been observed, although not into ranges thought to be clinically significant. Implanon use should not significantly increase the risk of cardiovascular disease.¹²² In those with known abnormal cholesterol or lipid profiles, these levels should be followed during Implanon use.

Effect on Liver Function. Mixed results on liver function tests have been observed for implant users. Some studies have shown mild changes, including an increase in mean total and unconjugated bilirubin and aspartate transaminase levels.¹²³ Others have shown no effect.¹¹⁶ Although results are mixed, clinicians should be aware that there may be mild changes in liver function test results during etonogestrel implant use. These changes may not be clinically significant in healthy women, but they may have clinical relevance in women with preexisting liver disease.

Before recommending Implanon, providers should review the indications and contraindications for its use. Contraindications to etonogestrel implant use listed on the package insert include known or suspected pregnancy, active venous thromboembolic disease, active liver disease, undiagnosed genital tract bleeding, known or suspected breast cancer, progesterone-dependent tumors, and allergy to any of the implant's components.¹¹⁷ Although the package insert lists VTE disease as a contraindication to etonogestrel implant use, there is no evidence to support this restriction. Because of concerns regarding an increased risk of contraceptive failure, women chronically using hepatic enzyme-inducing medications are not proper candidates for this type of contraception.

When explaining the etonogestrel implant, the physician needs to address any concerns and fears a woman may have about this method of contraception. In particular, women may have concerns about implant removal, although removal problems with single-rod devices such as Implanon are uncommon. Side effects (particularly irregular bleeding) should be discussed in advance, because an unexpected side effect may cause women to request early removal of the implant. All women should be reminded about safe sexual practices, because the implant does not provide protection against STIs. Patients who are good candidates for this form of contraception are those who desire long-term reversible birth control, have no contraindications to etonogestrel implant use, accept implant insertion and removal, and are ready to accept a change in menstrual bleeding patterns.

Insertion and Removal

Proper insertion and removal techniques are essential for clinical efficacy and for the prevention of complications. Timing of insertion depends on the patient's prior use of contraception and the clinician's evaluation of the appropriateness for the individual. In the United States, Implanon has been made available only to clinicians who have completed insertion and removal training provided by the manufacturer. Proper training of clinicians appears to reduce the incidence of complications at insertion and removal. Complications of Implanon insertion are rare (<2%) but may include local pain, infection, and bleeding.¹²⁴ There is no indication for routine follow-up.

Implanon is licensed for 3 years of use and should then be removed. Prolonged use beyond 3 years has not been associated with any specific nonpregnancy complications. Before removal, the clinician needs to palpate the implant. Under sterile conditions, a 2- to 3-mm incision is made vertically over the implant. The rod is then removed using the pop-out technique described elsewhere for Norplant

System removal.¹²⁵ If inserted correctly, removal is usually simple and should take less than 5 minutes.¹¹⁶ The most common reason for difficulty is implants that were placed too deeply. If the clinician cannot palpate the implant, imaging techniques may be necessary before proceeding.

Future Use of Implanon

Implanon provides women with an additional highly effective, non-user-dependent, reversible contraceptive option. The primary advantages of the etonogestrel implant over other types of contraception are the convenience and high level of contraception associated with implant use and, for women with contraindications to contraceptive use of estrogen, the absence of estrogen. The trade-off for women is the erratic bleeding that occurs throughout implant use.

Emergency Contraception

Emergency contraception is defined as a drug or device used to prevent pregnancy after unprotected sexual intercourse (including sexual assault) or after a recognized contraceptive failure. In the United States, 1.5 mg of levonorgestrel, packaged as Plan B, and the Copper T 380A IUD are the most common emergency contraceptives available to women and are effective up to 5 days after unprotected sexual intercourse. In August 2006, Plan B was approved for over-the-counter sale to women 18 years old or older in the United States. It is not known whether the increased availability of emergency contraception will decrease unintended pregnancy and induced abortion rates. Such reductions unfortunately have not been observed in countries where over-the-counter emergency contraception has been available for longer periods.

Unintended pregnancies, those that are mistimed or undesired at the time of conception, are common in the United States. Of the 6.4 million pregnancies recorded in 2001, approximately one half were unintended. Of these 3.1 million unintended pregnancies, 42% resulted in induced abortions. Among women with unintended pregnancies, 48% were using contraceptives during the month of conception, although not always correctly.¹²⁶ Emergency contraception is intended as a backup method for occasional use, rather than a regular method of contraception. Although emergency contraception is sometimes called postcoital contraception or the morning-after pill, these labels are confusing, because they imply that emergency contraception can be taken only the morning after unprotected sexual intercourse. Emergency contraception can reduce the risk of unintended pregnancy up to 5 days after unprotected sex. Emergency contraception should be available to all women at risk for unplanned pregnancy, including adolescents and victims of sexual assault.

Emergency contraception has the potential to reduce unintended pregnancy rates, thereby reducing the number of induced abortions. Providing education about how to use and access emergency contraception is an integral part of women's health care.

Emergency Contraception Regimens

The oral emergency contraception regimen most commonly used in the United States consists of 1.5 mg of the progestin levonorgestrel. Makers of this product, packaged and marketed as Plan B (Barr Pharmaceuticals Inc., Pomona, NY) instruct women to take the first 0.75-mg levonorgestrel tablet as soon as possible after unprotected intercourse and to take the second 0.75-mg tablet 12 hours after the first dose. The FDA approved Plan B for use as an emergency

contraceptive in 1999. Previous regimens combined progestin and estrogen, often called the Yuzpe regimen.¹²⁷ This combined regimen has been superseded by the levonorgestrel-only preparation because it is more effective and causes fewer side effects.¹²⁸

Oral emergency contraception is maximally effective within 72 hours of unprotected intercourse but may have some effect up to 120 hours later.¹²⁹ However, given the reduced efficacy of oral hormonal emergency contraception with delayed use, women should also be informed about the copper-bearing IUD as an alternative if appropriate.¹²⁶

Emergency contraception with the antiprogestin mifepristone (25 to 50 mg) is superior to other hormonal regimens. Low doses of mifepristone (<25 mg) may be more effective than 0.75 mg of levonorgestrel (two doses).¹²⁸ In the United States, mifepristone is not used for emergency contraception because of its high cost and because it is not manufactured or marketed in an appropriate dose. Other progesterone receptor modulators for emergency contraception are undergoing clinical trials.

Mechanism of Action

The mode of action of hormonal emergency contraception is multifactorial and not completely understood. Because sperm are viable in the female reproductive tract for up to 5 days but eggs can be fertilized only within 1 day of ovulation, the mechanism of action most likely depends on when levonorgestrel-only emergency contraception is given in relation to the time of intercourse and time of ovulation. No evidence supports the theory that hormonal emergency contraception interferes with postfertilization events, and most evidence suggests that it prevents pregnancy by preventing conception. Because levonorgestrel-only emergency contraception does not interrupt an established pregnancy, defined as beginning with implantation, hormonal emergency contraception is not considered an abortifacient.¹³⁰

Efficacy

The probability of pregnancy after a single act of unprotected intercourse varies (3% to 8%) according to the day of the menstrual cycle and the couple's fertility status.¹³¹ Calculating the efficacy of emergency contraception is complex because it is impossible to know how many pregnancies would otherwise have occurred. It is known, however, that the use of levonorgestrel-only emergency contraception is more effective than no treatment at all after a single episode of unprotected intercourse.¹³² Plan B labeling cites an average preventive action of 89%. If 100 women had unprotected intercourse once during the second or third week of the cycle and were not treated with emergency contraception, about 8 would become pregnant, but after treatment with emergency contraception, typically only 1 woman would become pregnant. A meta-analysis concluded that 1.5 mg of levonorgestrel (Plan B) was superior to the Yuzpe regimen, with a combined relative risk of pregnancy of 0.51 (95% CI, 0.31 to 0.83) compared with Yuzpe.² Taking a total of 1.5 mg of levonorgestrel in a single dose is as effective as the 0.75-mg split dose and more user-friendly.¹²⁸

The timing of oral emergency contraception influences its effectiveness significantly. Waiting 12 hours to initiate treatment after unprotected intercourse increases the odds of pregnancy by almost 50%, and its efficacy decreases linearly with time. Oral emergency contraception should be taken as soon as possible after unprotected intercourse or contraceptive failure.

Indications

Emergency contraception is indicated for any woman at risk for unintended pregnancy from an identified episode of contraceptive failure or unprotected intercourse. However, surveys have found that the level of knowledge and use of emergency contraception in the United States by women and their health care providers is low. Relatively few women presenting for termination of pregnancy or antenatal care were aware of emergency contraception.¹²⁶

No clinical examination or pregnancy testing is required before using oral hormonal emergency contraception. There are no medical contraindications to the use of oral emergency contraception regimens because of their short duration of use. Plan B's labeling lists three contraindications: pregnancy, hypersensitivity to any component of the product, and undiagnosed abnormal genital bleeding. Pregnancy is a relative contraindication because emergency contraception is ineffective if a pregnancy is already established. On the basis of studies of the teratogenic risk of combined oral contraceptives, however, there is no increased risk to the fetus if oral emergency contraception is taken while pregnant. Despite information in the package labeling, there is no medical rationale to justify denying women with undiagnosed genital bleeding access to emergency contraception.¹²⁶

WHO recommendations¹³³ state that women with previous ectopic pregnancy, cardiovascular disease, migraines, or liver disease and women who are breast-feeding can use emergency contraception. There may be reduced efficacy of oral emergency contraception in women with severe malabsorption syndromes and those taking liver enzyme-inducing drugs. There is no evidence that hormonal emergency contraception increases the risk of VTE disease. There have been case reports of levonorgestrel-only emergency contraception interfering with warfarin anticoagulant action. Women taking liver enzyme-inducing medications (including but not limited to rifampin, carbamazepine, phenytoin, phenobarbital, and St. John's wort) or warfarin should seek clinical advice regarding emergency contraception use. However, there is no need to delay emergency contraception use in these women, for whom an unintended pregnancy may carry additional health risks.

Side Effects

The FDA has determined that Plan B is safe enough to be available as an over-the-counter preparation only for women at least 18 years old. Women 17 years old or younger must obtain Plan B with a prescription or without a prescription in states with direct pharmacy access. Not all pharmacies stock Plan B or participate in this program, but lists of participating pharmacies are available (<http://www.ec-help.org/PharmacyLocations.asp> or <http://www.not-2-late.com> [accessed August 2010]).

There have been no deaths or serious complications directly linked to emergency contraception. The most common short-term side effects include nausea, vomiting, and irregular bleeding, which affect up to 20% of users. Other minor adverse effects reported by women in clinical trials included dizziness, fatigue, breast tenderness, headache, and abdominal pain.¹²⁸ The levonorgestrel-only regimen results in less nausea and vomiting than the Yuzpe regimen. If vomiting occurs within 1 to 2 hours of taking Plan B, most experts recommend that the dose be repeated.

Irregular bleeding caused by hormonal emergency contraception typically resolves by the next menstrual cycle.

There is a low incidence of intermenstrual spotting after using hormonal emergency contraception, ranging from 3% to 37% in trials. After hormonal emergency contraception is taken, menses usually occurs within 1 week before or after the expected time. If the delay in the onset of menses is greater than 1 week or if the expected menses is lighter than usual, a pregnancy test should be performed. Because hormonal emergency contraception can postpone ovulation, making a woman vulnerable to pregnancy later in the cycle, women should be counseled to begin a regular method of contraception *immediately* after using emergency contraception. A woman should also be advised to seek medical attention for continued irregular bleeding or abdominal pain, because these symptoms may be a sign of a spontaneous abortion or ectopic pregnancy.

Research has shown that although increased access to emergency contraception improves use, it does not seem to reduce the rates of unintended pregnancy or abortion.¹³⁴ Although access is an important factor, how women use emergency contraception may be a stronger determinant of its ultimate effect. Studies show that even when women have emergency contraception at home, they often fail to use it after unprotected sexual intercourse. The most common reason for this is a lack of recognition of the risk of pregnancy or neglect of the perceived risk.

Future of Emergency Contraception

Emergency contraception reduces the chance of pregnancy when used correctly up to 5 days after an identified episode of contraceptive failure or unprotected sexual intercourse. The most common regimens used in the United States are levonorgestrel-only emergency contraception (Plan B) and the Copper T 380A IUD (ParaGard). In the United States, given limitations in access, advance prescriptions for Plan B are still recommended for women 18 years old or older despite its over-the-counter status. Although increasing knowledge of and access to emergency contraception is a public health priority, the use of regular, ongoing contraception must be emphasized. The worldwide experience has not shown that improved access to emergency contraception has a population-level effect of reduced unintended pregnancies. This is consistent with the hypothesis that only a small proportion of women with access to emergency contraception actually take the pills to prevent pregnancy. Along with increased access, better educating women about how to use emergency contraception and encouraging its use are required to produce a demonstrable population-level effect.

ANTIPROGESTINS AND SELECTIVE PROGESTERONE RECEPTOR MODULATORS

Use for Contraception

Although not available for contraception in the United States, mifepristone and other progestin antagonists have contraceptive potential, acting by several mechanisms. At low doses, they inhibit ovulation by blocking the luteinizing hormone surge. Low doses also retard endometrial development by virtue of their antiproliferative action. As a consequence, the endometrium cannot support implantation. Higher doses can block follicular maturation and induce follicular atresia. When administered in the late luteal phase, progestin antagonists induce endometrial bleeding, preventing implantation.¹³⁵

Long-Term Contraceptive Potential

Daily doses of 2 to 10 mg of mifepristone suppress follicular development, block the luteinizing hormone surge, and delay ovulation. A multicenter, double-blind, randomized, controlled trial comparing mifepristone with the progestin-only pill showed that mifepristone (5 mg) was as effective as the progestin-only pill for contraception and had higher rates of amenorrhea. Almost one half of the mifepristone users had cystic glandular dilatation of the endometrium, but none showed hyperplasia or atypia.¹³⁶

The lowest daily dose of mifepristone capable of inhibiting ovulation is 2 mg daily. Lower doses interfere with endometrial maturation but do not suppress ovulation.¹³⁵ Mifepristone (200 mg) in the early luteal phase can prevent embryo implantation.¹³⁷ Combined with prostaglandin, mifepristone in the late luteal phase is an effective menses regulator.¹³⁷

Management of Irregular Bleeding Induced by Progestin-Only Contraception

Unscheduled bleeding is one of the main drawbacks of progestin-only contraception. Mifepristone and other progestin antagonists may be effective treatments for abnormal bleeding with these methods. Mifepristone (150 mg monthly) reduced unscheduled bleeding in users of the progestin-only pill containing desogestrel.¹³⁸ Mifepristone (50 mg monthly) reduced the duration of bleeding in Norplant users.¹³⁹ In new users of DMPA, 50 mg of mifepristone over 2 weeks reduced unscheduled bleeding,⁶² and low-dose mifepristone in combination with ethinyl estradiol or doxycycline was effective in stopping bleeding in Implanon users.¹²¹ The action of mifepristone in improving bleeding patterns is not fully understood but is likely to be endometrial rather than permitting ovulation in these contraceptive users.¹³⁹

Emergency Contraception

In addition to providing more effective emergency contraception than other hormonal regimens, mifepristone has the distinct advantage of being effective up to 120 hours after unprotected intercourse, whereas other methods are maximally effective up to 72 hours.¹²⁸ However, a disadvantage is that more women using mifepristone have a delay in the expected onset of their next menstrual period compared with other methods. This is a drawback because the onset of menses reassures the woman that emergency contraception has been successful. Despite the proven effectiveness of mifepristone as an emergency contraceptive agent, China is the only country to have licensed and approved mifepristone for this indication.¹³⁵

CLINICAL CHALLENGES IN CONTRACEPTIVE CARE

Hormonal Contraception for Adolescents

The United States has the highest rate of teenage pregnancy and birth in the Western industrialized world.¹⁴⁰ Approximately 80% of these pregnancies are unplanned, of which about 30% end in termination, 57% in live births, and 14% in miscarriage. Teenage pregnancy and parenting are precursors of poor medical, educational, and psychosocial outcomes for mother and child. Children of teenage mothers are at greater risk for preterm birth, low birth weight, neonatal death, and later behavioral problems and

poor academic performance. Teenage parenting contributes to the intergenerational transmission of poverty.²

Considerations for clinicians advising adolescents about contraception should include the potentially high fertility rates in these young women, their high rates of unprotected intercourse, increased risk of STIs, and low compliance with contraceptive methods that require daily use.¹⁴⁰ Because rates of COCPs discontinuation and unintended pregnancy are so high among adolescents, long-acting methods, including DMPA injection, contraceptive implants, and IUDs, should be made available to teens.^{141,142} The clinician should also be aware of the legal conditions surrounding prescribing contraception to minors (<http://www.guttmacher.org>; click on *adolescents and state policies in brief* [accessed August 2010]).

All adolescents should receive health guidance annually regarding responsible health behaviors, including abstinence, latex condoms to prevent STIs, and appropriate methods of birth control, along with instructions on ways to use them effectively.¹⁴⁰ Adolescents should also be counseled in a nonjudgmental manner about the need to use condoms during anal and oral intercourse. Barriers to effective contraception use by adolescents include lack of forward planning, lack of confidential care, fear of disapproval by parents and doctors, absence of adolescent-friendly services, language and cultural barriers, fear of pelvic examination, and cost. Misconceptions about contraception, including effects on weight gain, future fertility, acne, and risk of cancer, may also prevent adolescents from using effective contraception and should be addressed in counseling. No matter how effective the method and how easy it is to use, detailed counseling is required for adolescents. Practitioners should recommend the new quadrivalent human papillomavirus (HPV) vaccine to sexually active adolescent girls.

Oral Contraceptive Pills in Adolescents

Although COCPs are potentially safe and effective methods for adolescents, many young women are not effectively educated about correct use and potential unwanted effects. They may use oral contraception inconsistently, which will lead to very high pregnancy rates.¹⁴⁰ During counseling it is important to provide clear verbal and written instructions about starting COCP use, ways to ensure daily compliance, and what to do if one or more pills is missed.

Initiating or continuing hormonal contraception does not require pelvic examination, cervical cytology, or sexually transmitted disease screening in adolescents or older reproductive-age women. A history excluding contraindications, blood pressure measurement, and a negative urinary pregnancy test result are sufficient before initiating hormonal contraception. Before beginning COCPs, education about appropriate use, missed pills, and adverse effects is appropriate. Screening for STIs or Pap smears (should be started 3 years after the onset of sexual activity or when 21 years old) should be considered regardless of contraceptive use.¹⁴⁰ The use of condoms should be encouraged in conjunction with the COCPs to prevent STIs.

Initial follow-up should be at 6 to 8 weeks after commencing the COCPs to monitor correct use and adverse events and should be done thereafter at 6 to 12 months. Education and ongoing counseling are essential to ensure correct usage. Many adolescents are concerned that the COCPs will cause weight gain or acne, and these issues should be directly addressed. A newly available chewable pill (Femcon Fe) has a mint flavor and may be more acceptable to young women who find it difficult to swallow pills. Unscheduled bleeding may be less acceptable to

adolescents compared with adult women. Clinicians must consider the possibility that unscheduled bleeding represents cervicovaginal infection in this high-risk population and investigate and treat it accordingly. Few data specifically address the use of transdermal or vaginal ring contraception in adolescents.

Injectable Contraceptives in Adolescents

Discontinuation rates for DMPA in adolescents are extremely high, with 33% not receiving a second injection at 3 months. Three fourths of adolescents initiating DMPA have discontinued it by 12 months.¹⁴⁰ However, because DMPA suppresses ovulation for an extended period of time, prior use of DMPA protects many adolescents from unintended pregnancy despite inconsistent use. Weight gain is the most commonly cited reason for adolescents to discontinue DMPA, and it may be more common in African American adolescents.¹⁴³ Although loss of bone density has been a concern in adolescents using DMPA, the position statement of the Society for Adolescent Medicine is that DMPA is an extremely effective contraceptive and that clinical concerns about loss of BMD must be placed within the context of likely bone recovery on discontinuation, low risk of fractures, and benefits of preventing unintended pregnancy among adolescents.⁸⁹

Contraception in Women with Underlying Medical Conditions

Because pregnancy in women with underlying medical conditions is associated with higher risks of maternal and perinatal morbidity and mortality, achieving effective contraception is particularly important in this setting. Although numerous studies have addressed the safety and effectiveness of hormonal contraceptive use in healthy women, data unfortunately are far less complete for women with underlying medical problems or other special circumstances. Using the best available scientific evidence, this chapter provides information to help clinicians and women with coexisting medical conditions make sound decisions regarding the selection and appropriateness of various hormonal contraceptives, including the levonorgestrel IUD.

Decisions regarding contraception for women with coexisting medical problems may be complicated. In some cases, medications taken for certain chronic conditions may alter the effectiveness of hormonal contraception, and pregnancy in these cases may pose substantial risks to the mother and her fetus. Differences in content and delivery methods of hormonal contraceptives may affect patients with certain conditions differently. Because transdermal and vaginal ring contraception is relatively new, few data address its use in women with medical concerns. In the absence of more extensive data, contraindications to the use of estrogen-progestin COCPs should also be considered as contraindications to the use of transdermal and vaginal ring contraception. Practitioners should recognize that the use of other nonhormonal forms of contraception, such as the copper IUD, remains a safe, effective choice for many women with medical conditions.

Package labeling approved by the FDA for progestin-only contraceptives is occasionally the same as that for combined estrogen-progestin methods without supporting evidence, further complicating decisions for women with coexisting medical conditions. For instance, labeling for norethindrone progestin-only oral contraceptives no longer lists a history of thromboembolism as a contraindication. Such a history, however, remains listed as a

contraindication in package labeling for DMPA injections and the contraceptive implant.

Hormonal Contraception in Women Older Than 35 Years

Use of estrogen-progestin oral contraceptives, patches, and vaginal rings should be considered safe in healthy, lean, nonsmoking women older than 35 years (Table 18-6).²³ Large U.S. population-based case-control studies have found no increased risk of myocardial infarction or stroke among healthy, nonsmoking women older than 35 years who use oral contraceptives formulated with less than 50 µg of estrogen.²⁸ Perimenopausal women may benefit from the positive effect on BMD offered by COCPs.¹³

Use of COCPs may reduce vasomotor symptoms in perimenopausal women.¹⁴⁴ The reduced risk of endometrial and ovarian cancers associated with COCP use is of particular importance to older women of reproductive age. Age, COCP use, and obesity each represent independent risk factors for thrombosis. Because VTE risk has been observed

TABLE 18-6

World Health Organization (WHO) and American College of Obstetrics and Gynecology (ACOG) Guidelines Regarding Use of Combination Estrogen-Progestin Contraceptives (Oral Contraception, Ring, Patch) in Women 35 Years of Age and Older

Variable	ACOG Guidelines	WHO Guidelines
Obesity	Progestin-only or intrauterine contraception* may be safer	Benefit usually outweighs risks [†]
Smoker	Progestin-only or intrauterine contraception* should be used	Risk unacceptable
Hypertension	Progestin-only or intrauterine contraception* should be used	Risk unacceptable
Diabetes	Progestin-only or intrauterine contraception* should be used	Risk unacceptable
Migraine	Progestin-only or intrauterine contraception* should be used	Risk unacceptable
None of the above risk factors	Healthy nonsmoking women doing well on a combination contraceptive can continue their method until age 50-55 yr, after weighing the risks and benefits	For women ≥40 yr, the risk of cardiovascular disease increases with age and may also increase with use of combined hormonal contraceptives. In the absence of other adverse clinical conditions, combined hormonal contraceptives may be used until menopause.

*Includes progestin-only oral contraception, depot medroxyprogesterone acetate (DMPA), contraceptive implants, copper intrauterine devices (IUDs), and progestin-releasing IUDs.

[†]Obesity in women age 35 and older not specifically addressed.

to rise sharply after age 39 for COCP users, these pills should be used with caution by women older than 35 years who are obese.

Discontinuation of Combined Oral Contraceptive Pills at Menopause

As increasing numbers of women in their late 40s and early 50s use combination contraceptives, the question of when women no longer need contraception will arise more frequently. Assessment of follicle-stimulating hormone levels to determine when hormonal contraceptive users have become menopausal and no longer need contraception is expensive, and results may be misleading. Until a well-validated tool to confirm menopause is available, an alternative approach is for healthy, nonsmoking women doing well on a combination contraceptive to discontinue her method between the ages of 50 and 55 years.²³

Hormonal Contraception in Cigarette Smokers

In women who use COCPs, smoking and hypertension represent synergistic risk factors for myocardial infarction and stroke. Some studies conducted outside the United States have found an increased risk of myocardial infarction and stroke with COCPs use. The prevalence of smoking and untreated hypertension was high among participants in these studies.^{28,145} Current guidelines indicate that, as with all medication, contraceptive hormones should be selected and initiated by weighing risks and benefits for the individual patient. For women 35 years old or older who have cardiovascular risk factors, including obesity, hypertension, smoking, diabetes, or migraines, progestin-only and intrauterine contraceptives are preferable to combination estrogen-progestin contraceptives (i.e., COCPs, transdermal patch, and vaginal ring).^{23,28}

Existing data are mixed with regard to possible protection from COCPs for atherosclerosis and cardiovascular events; longer-term cardiovascular follow-up of menopausal women with regard to prior COCP use, including subgroup information regarding adequacy of ovulatory cycling, the presence of hyperandrogenic conditions, and the presence of prothrombotic genetic disorders, is needed to address this important issue.¹⁴⁶

Hormonal Contraception and Chronic Hypertension

Even low-dose COCPs may increase blood pressure. The ACOG guidelines advise that women younger than 35 years with well-controlled hypertension are candidates for a trial of low-dose COCPs provided they are otherwise healthy with no evidence of end-organ vascular disease and do not smoke.²⁸ Blood pressure should be closely monitored in these women. If blood pressure remains well controlled with careful monitoring several months after contraceptive initiation, use can be continued. Progestin-only methods may be a safer option for hypertensive women. Prospective studies of progestin-only pills and DMPA have not shown any increase in baseline blood pressure.²⁹

In healthy women of reproductive age, the incidence of myocardial infarction or stroke with the use of low-dose COCPs is extremely low. Although the relative risk of these events is increased in women with hypertension, the absolute risk remains low. Because of the increased risk of myocardial infarction and stroke associated with hypertension

alone and the likelihood of additional risks associated with use of estrogen-progestin contraceptives, the decision to use combination hormonal contraceptives in these patients should be weighed against the adverse pregnancy outcomes associated with hypertension. The noncontraceptive benefits of COCPs also should be taken into account. The ACOG recommends that use of progestin-only contraceptives such as DMPA, progestin-only oral contraceptives, or the levonorgestrel-containing IUD are preferable to estrogen-progestin contraceptives in women 35 years old or older who have hypertension.^{23,28}

Hormonal Contraception in Women with Lipid Disorders

The term *dyslipidemia* includes disorders of lipoprotein metabolism that lead to atherosclerosis. These abnormalities arise from genetic and secondary factors and are caused by excessive entry of lipoproteins into the bloodstream or an impairment in their removal, or both.

The estrogen component of COCPs enhances removal of LDL cholesterol and increases levels of HDL cholesterol. Oral estrogen also increases triglyceride levels; however, in the setting of concomitantly increased HDL and decreased LDL levels, the moderate triglyceride elevations caused by oral estrogen use do not appear to increase the risk of atherogenesis.¹⁴⁶ The progestin component of COCPs antagonizes these estrogen-induced lipid changes, which increases LDL levels and decreases HDL and triglyceride levels. Among women taking COCPs with an identical dose of estrogen, the choice and dose of the progestin component may affect net lipid changes. COCPs formulated with more androgenic progestins raise HDL and triglyceride levels less than formulations with less androgenic progestins.¹⁴⁷ Use of the transdermal contraceptive patch increases HDL and triglyceride levels and lowers LDL levels, similar to the lipid changes observed in women using COCPs formulated with more androgenic progestins. As with COCPs, use of the contraceptive vaginal ring increases triglyceride levels. In contrast to COCPs, use of DMPA lowers HDL levels, raises LDL levels, and does not raise triglyceride levels.²⁹ The LNG-IUS has not been shown to affect circulating lipid or triglyceride levels.¹⁴⁸

Lipids are surrogate measures, however, and the effect of contraceptives on lipids may not necessarily correlate with effects on cardiovascular disease or mortality. It is not known whether the differential lipid effects of distinct hormonal contraceptive formulations or means of administration have any clinical significance in women with normal baseline lipid levels or those with lipid disorders. Because the absolute risk of cardiovascular events is low, most women with controlled dyslipidemia can use COCPs formulated with 35 µg estrogen or less. Fasting serum lipid levels should be monitored as frequently as each month after initiating COCPs in dyslipidemic women. Less frequent monitoring is appropriate after stabilization of lipid parameters has been observed. In women with uncontrolled LDL cholesterol levels greater than 160 mg/dL or with multiple additional risk factors for cardiovascular disease (including smoking, diabetes, obesity, hypertension, family history of premature coronary artery disease, HDL level <35 mg/dL, or triglyceride level >250 mg/dL), use of alternative contraceptives should be considered.¹³³ Use of progestin-only contraceptives does not increase triglyceride levels. The use of DMPA and other progestin-only contraceptives is appropriate in women with hypertriglyceridemia, who may be at increased risk for pancreatitis if they used COCPs.²⁸

Hormonal Contraception in Women with Diabetes

COCs do not appear to impair carbohydrate metabolism or affect vascular disease in diabetic women. A systematic review concluded that hormonal contraceptives have limited effect on carbohydrate metabolism in women without diabetes. However, studies are limited and do not inform the management of diabetic women who are overweight.¹⁴⁹

Although the existing data support the use of combination hormonal contraceptives by women with diabetes, use should be limited to nonsmoking, otherwise healthy women with diabetes who are younger than 35 years and show no evidence of hypertension, nephropathy, retinopathy, or other vascular disease.²⁸ A clinical trial found that metabolic control was similar in women with uncomplicated diabetes randomized to a copper IUD or the LNG-IUS.¹⁵⁰ The levonorgestrel-containing IUD is an appropriate option for women with diabetes.

In the general population, hormonal contraceptives do not appear to increase the risk of developing diabetes.²⁹ However, limited data from populations at increased risk for diabetes (i.e., Hispanic and Navajo women) suggest that progestin-only contraceptives may increase the risk of diabetes.²⁸

Hormonal Contraception for Women with Migraine Headaches

Headaches are common in women of reproductive age. Most of these headaches are tension headaches, not migraines. Some women with migraines experience improvement in their symptoms with the use of hormonal contraceptives, and some women's symptoms worsen. Because the presence of true migraine headaches affects the decision to use estrogen-containing contraception, careful consideration of the diagnosis is important.²⁸

Most migraines occur without aura. Nausea, vomiting, photophobia, phonophobia, visual blurring, generalized visual spots, or flashing occurring before or during a migraine headache do not constitute aura. Typical auras last 5 to 60 minutes before headache and are visual. Several reversible visual symptoms indicate the presence of aura: flickering, uncolored zigzag line progressing laterally to the periphery of one visual field; laterally spreading, scintillating scotoma (i.e., area of lost or depressed vision within a visual field, surrounded by an area of normal or less depressed vision or loss of vision) (http://64.227.208.149/NS_BASH/BASH_guideline31Aug05.pdf).

The risk of stroke is increased in women who have migraine with aura. Although cerebrovascular events occur rarely among women with migraines who use COCs, the impact of a stroke is so devastating that clinicians should consider the use of progestin-only, intrauterine, or barrier contraceptives in this setting. Estrogen-containing contraceptives are contraindicated in women migraine sufferers with aura and should be discontinued in patients suffering from migraine without aura if aura symptoms appear.²² Current COC formulations usually are well tolerated by patients with migraine without aura. The latest International Classification of Headache Disorders identifies at least two entities related to the use of COCs: exogenous hormone-induced headache and estrogen-withdrawal headache (<http://ihs-classification.org/en/> [accessed August 2010]). Other risk factors (e.g., tobacco use, hypertension, hyperlipidemia, obesity, diabetes) must be carefully considered when prescribing estrogen-containing contraceptives

for patients with migraine without aura. For women older than 35 years with migraines, combination estrogen-progestin contraceptives should be avoided in favor of progestin-only and intrauterine methods.^{23,28}

Hormonal Contraception in Women with Fibrocystic Breast Changes, Fibroadenoma, or a Family History of Breast Cancer

Women with benign breast disease with epithelial hyperplasia with or without atypia or with a family history of breast cancer are at increased risk for breast cancer.¹⁵¹ Large cohort studies have consistently shown that COCs appear to decrease the risk of benign breast disease.¹⁵² A history of benign breast disease should not be regarded as a contraindication to COC use.

Neither current nor prior use of COCs appears to elevate the risk of breast cancer in women with a family history of this common malignancy.³⁰ Studies among women with known *BRCA* gene mutations have yielded mixed results with respect to impact on breast cancer risk.¹⁵³ *BRCA1* and *BRCA2* mutations are associated with a 45% and 25% lifetime risk, respectively, for epithelial ovarian cancer.¹⁵⁴ Use of COCs reduces the subsequent risk of ovarian cancer in high-risk and low-risk women and offers important potential benefits for women with *BRCA1* or *BRCA2* mutations, particularly those who have not completed their families or have not yet undergone risk-reducing bilateral salpingo-oophorectomy.²⁸

Hormonal Contraception in Women with Uterine Leiomyomata

Uterine fibroids are common, affecting up to 50% of women of reproductive age.¹⁵⁵ Fibroids tend to be larger and clinically manifest at an earlier age in black women compared with white women in the United States.¹⁵⁶ Uterine fibroids may be asymptomatic, but they are also associated with heavy menstrual bleeding. Use of COCs may be effective in reducing menstrual blood loss in women with heavy menstrual bleeding who do not have uterine fibroids, but the evidence to support this is not strong.¹⁵⁷ There is insufficient information to conclude how hormonal contraceptives affect symptoms, including heavy menstrual bleeding, in women with uterine fibroids. COCs do not appear to induce the growth of uterine fibroids.¹⁵⁸

There is limited information about the role of other hormonal contraceptives in the development, growth, and management of uterine fibroids. Small studies suggest that DMPA may reduce abnormal bleeding in symptomatic women with uterine fibroids, and the levonorgestrel-releasing IUD may also reduce heavy menstrual bleeding associated with uterine fibroids. However, the presence of fibroids may increase the risk of expulsion of the levonorgestrel-containing IUD.¹⁰⁶

Hormonal Contraception in Postpartum and Lactating Women

Postpartum women remain in a hypercoagulable state for weeks after childbirth. Product labeling for COCs advises deferring use until 4 weeks after delivery in non-breast-feeding women. Because progestin-only oral contraceptives and DMPA do not contain estrogen, these methods may be safely initiated immediately by postpartum women.²⁸ There is no established effect of COCs on the quality or quantity of breast milk.

Traditionally, COCPs have not been recommended as the first choice for breast-feeding mothers because of concerns that the estrogenic component can reduce the volume of milk production and the caloric and mineral content of breast milk in lactating women.³³ However, use of COCPs by well-nourished breast-feeding women does not appear to result in problems with infant development. A systematic review of randomized, controlled trials concluded that existing data is of poor quality and insufficient to establish an effect of hormonal contraception on lactation.¹⁵⁹ Use of combination hormonal contraceptives can be considered after milk flow is well established. Evidence from limited studies suggests that progestin-only contraception does not interfere with lactation or infant development and does not increase the risk of thromboembolic disease.¹⁵⁹ It appears reasonable to initiate progestin-only contraception, including DMPA, progestin-only pills, and implants, immediately after delivery, regardless of whether mothers are nursing their infants.⁵³

Hormonal Contraception in Women Taking Anticonvulsants

Effective contraception is a critical component of the management of the female patient with epilepsy because of the increased risk of seizures in pregnancy and the multitude of interactions between antiepileptic drugs (AEDs) and hormonal contraception. Steroid hormones and many of the AEDs are substrates for the cytochrome P450 enzyme system, in particular, the CYP3A4 isoenzyme. Concomitant use of hormonal contraceptives and AEDs may pose a risk of unexpected pregnancy, seizures, and drug-related adverse effects.³⁴ The risk of COCP failure is slightly increased in the presence of CYP3A4 enzyme-inducing AEDs. Several AEDs induce the production of sex hormone-binding globulin (SHBG) to which the progestins are tightly bound, resulting in lower concentrations of free progestin that may also lead to COCP failure. There is no increase in the risk of COCP failure in women taking non-enzyme-inducing AEDs. Oral contraceptives significantly increase the metabolism of lamotrigine, posing a risk of seizures when hormonal agents are initiated and of toxicity during pill-free weeks. There is no evidence that COCPs increase seizures in women with epilepsy.³⁴ Although higher-dose COCPs are one contraceptive option for women on enzyme-inducing AEDs, a variety of other options are available. Injectable contraception (DMPA) appears effective with concomitant AED use, and a potential advantage of using DMPA in women with seizure disorders is DMPA's intrinsic anticonvulsant effect.⁵⁵
