The dynamic aspects of OCD were first described by Sigmund Freud, who referred to OCD as "obsessional neurosis." The disorder was thought to result from a regression from the oedipal phase to the anal phase, with its characteristic ambivalent emotional stage. The ambivalence is connected to the unraveling of the smooth fusion between sexual and aggressive drives characteristic of the oedipal phase. The coexistence of hatred and love toward the same person leaves the patient paralyzed with doubt and indecision. Freud originally suggested that obsessive symptoms result from unconscious impulses of an aggressive or sexual nature. These impulses could cause extreme anxiety, which is avoided by the defense mechanisms of repression and reaction formation. One of the striking features of OCD patients is the degree to which they are preoccupied with aggression or cleanliness (anal phase), either overtly in the content of their symptoms or in the associations that lie behind them. Thus the psychogenesis of OCD may lie in disturbances in normal growth and development related to the anal-sadistic phase.

Freud described three major psychological defense mechanisms that are important in OCD: isolation, undoing, and reaction formation. According to the psychoanalytic formulation, OCD develops when these defenses fail to contain the anxiety. *Isolation* is the separation of the idea and the affect that it arouses, when the patient is only aware of the affectless idea (i.e. a doctor that performs resuscitation and is not overwhelmed by the scene, the patient's condition, and the surroundings). *Undoing* is a secondary defense in order to combat the impulse and quieten the anxiety that its imminent eruption into consciousness arouses. Undoing is a compulsive act that is performed in an attempt to prevent or undo the results that the patient irrationally anticipates from a frightening obsessional thought or impulse. *Reaction formation* is related to the production of character traits rather than symptom formation (characteristic of the above defenses). The

trait seems highly exaggerated and inappropriate. An example can be the switch of anger and hate into exaggerated love and dedication. Ambivalence and magical thinking are additional features of the psychological texture of the OCD patient.

7 Treatment

7.1 Pharmacological Treatment

The outlook for patients with OCD was not very promising in the early 1980s. However, since then, several potent SRI have been studied extensively in OCD. Aggregate statistics for all SRI suggest that 70% of treatment-naive patients will improve at least moderately (Rasmussen et al. 1993).

CMI was the first to be used and the most extensively studied. CMI was reported to be an effective medication for OCD in the late 1960s (Fernandez-Cordoba and Lopez-Ibor 1967; Ronynghe de Voxirie 1968). Since then, numerous placebo-controlled studies have clearly shown CMI's effectiveness. This research direction culminated in the multicenter, controlled trial in the United States ($n = 520$) that conclusively confirmed CMI's effectiveness (Clomipramine Collaborative Study Group 1991). This study showed that, after 10 weeks of treatment, 58% of patients treated with CMI rated themselves much or very much improved versus only 3% of placebo-treated patients.

Beside CMI, other non-tricyclic SRI, such as fluoxetine, fluvoxamine, paroxetine, and sertraline, are gaining acceptance as effective alternatives for the treatment of OCD in controlled studies.

7.1.1 Efficacy of Serotonergic Versus Adrenergic Antidepressants

While anecdotal reports have suggested that clinical benefit can be obtained with a range of antidepressant medications, consistent effectiveness has only been demonstrated for the SRI. Several studies have directly compared CMI to other antidepressants, and a consistent pattern emerges: antidepressant drugs that are less potent SRI than CMI are generally ineffective in OCD (Thoren et al. 1980; Zohar and Insel 1987; Leonard et al. 1991; Goodman et al. 1990).

7.1.2 Other Pharmacological Approaches

The treatment of resistant OCD patients has also contributed to the understanding that serotonergic tricyclics and SSRI are important in the management of these patients. Providing further support for the importance of serotonin neurotransmission in the pathophysiology and treatment of OCD are early observations regarding the effectiveness of isocarboxazid and more recently phenelzine, MAO inhibitors with prominent effects on serotonin metabolism. However, this efficacy was not replicated in recent studies. Further studies on the therapeutic role of MAO inhibitors in OCD, especially in OCD with comorbidity of panic disorder, are warranted. Considered as one of the anxiety disorders according to DSM-IV (but not according to ICD-10), it is not surprising that anxyolitics have been suggested in the treatment of OCD patients. Thus alprazolam and clonazepam have been reported as efficient in several uncontrolled studies and case series, and even in a small double-blind randomized, multiple crossover study. However, since OCD is a chronic disorder, the use of anxyolitics for long periods raises questions of dependency brought about by long-term use of benzodiazepines.

Despite reports in open studies as regards the efficacy of trazodone, buspirone, fenfluramine, and lithium (drugs that have some serotonergic effect), the results in double-blind studies were mainly negative. However, it is important to stress that not all serotonergic drugs are efficacious in this disorder. Thus, the serotonin precursor tryptophan exhibited only mixed efficacy.

Adding drugs affecting dopamine function (pimozide, haloperidol, risperidone) to SRI therapy in treatment-resistant OCD patients may result in improvement in patients with a personal or family history of tics (McDougle 1997).

Neurosurgery has been reported to be effective in some OCD patients, with procedures that disconnect the outflow pathways originating from the orbitofrontal cortex. Cingulotomy can help some intractable patients, but although the immediate results may be striking, the long-term prognosis is more reserved (Jenike et al. 1991) and a second operation or suicide are not infrequent.

7.1.3 Treatment Algorithm

The first line of treatment in an OCD patient is an SSRI. If the patient cannot tolerate the drug or does not respond, a switch to CMI (or to another SSRI) is warranted. The third line of treatment consists of a combination of SSRI and CMI or the addition of small doses of neuroleptics (in comorbidity with Tourette's syndrome or schizophrenia), as well as the addition of one of the following: lithium, trazodone, buspirone, tryptophan. The fourth stage consists of either atypical neuroleptics, thyroid supplementation, clonidine,

MAO inhibitors, I.V. CMI, or clonazepam. In resistant cases, electroconvulsive therapy (ECT) or neurosurgery is indicated.

7.1.4 Onset of Treatment Response

It has been suggested that a relatively long period (as long as 10–12 weeks) is needed for CMI to be significantly effective. Up to 6 months or even longer is needed to achieve maximum response.

7.1.5 Long-Term Treatment

It has been demonstrated that the length of treatment should be considerable and that most patients relapse after premature discontinuation. Pato et al. (1988) reported that 16 out of 18 patients with OCD relapsed within 7 weeks after stopping CMI, although some had been treated for more than 1 year (mean, 10.7 months). All patients regained therapeutic effects when CMI was reintroduced. Leonard et al. (1991) examined the effect of CMI substitution during long-term CMI treatment in 26 children and adolescents with OCD (mean duration of treatment, 17 months; range, 4–32 months). Half of the patients were blindly assigned to 2 months of desipramine (DMI) treatment, and then CMI was reintroduced. Almost 90% relapsed during the 2-month substitution period in comparison with only 18% of those kept on CMI.

OCD patients should be maintained on CMI more than 1 year after the disappearance of symptoms before a very gradual attempt to discontinue the treatment is carried out. The maintenance dose needed in OCD is also unclear. In a recent study that examined this issue, Mundo et al. (1997) investigated the effect of dose reduction in 30 patients previously treated successfully with CMI or fluoxetine. Patients were randomized to receive the same drug dosage, a reduced dose, or a very reduced dose. There was no difference between the groups during the 102 days of the study.

7.1.6 Drug Dosage

Higher doses of antidepressants have been used in the treatment of OCD than of depression, although empirical data supporting this practice is scant. Some fixed-dose studies using fluoxetine have found some advantage with using higher doses, while others have not. The tradition of using high doses has to be supported by further research, although it seems reasonable to use higher doses in nonresponders or when only partial relief is attained.

7.1.7 Comparative Studies of Clomipramine and Selective Serotonin Reuptake Inhibitor

The introduction of SSRI has raised the question regarding the comparative efficacy of CMI versus that of the SSRI. SSRI are important alternatives to CMI, since their range of side effects is clearly different (lacking anticholinergic side effects, sedation, weight gain to name but a few). Although SSRI may provoke nausea, headaches, and sleep disturbances, these side effects are usually less troublesome to most patients.

Fluoxetine was compared with CMI by Pigott et al. (1990) in 11 OCD patients in a 10-week crossover study. Although no significant differences were noted regarding efficacy, the proportion of fluoxetine nonresponders who later responded to CMI tended to be higher in comparison to the CMI nonresponders who were switched to fluoxetine. Patients reported significantly fewer side effects while on fluoxetine.

Freeman et al. (1994) compared the efficacy of fluvoxamine and CMI in a multicenter, randomized, double-blind, parallel-group comparison ($n = 66$). Both drugs were equally effective and well-tolerated, but fluvoxamine produced fewer anticholinergic side effects and caused less sexual dysfunction, and more reports of headache and insomnia. Paroxetine was of comparable efficacy to CMI, and both were significantly more effective than placebo in a multinational, double-blind, placebo-controlled, parallel-group study with 399 OCD patients (Zohar and Judge 1996). Bisserbe et al. (1997) reported that sertraline (50–200 mg/day) was significantly more effective than CMI (50–200 mg/day) in a double-blind study ($n = 160$).

Greist et al. (1995) compared the results from the four large multicenter placebo-controlled trials of the SRI: CMI ($n = 520$), fluoxetine ($n = 355$), fluvoxamine ($n = 320$), and sertraline ($n = 325$). All four agents were significantly more effective than placebo. A significantly greater percentage of patients treated with CMI were rated as much or very much improved in comparison with patients on other treatments. However, the studies included in this meta-analysis had different subject characteristics, and this might have affected the results, as more treatment-naive patients (who are more likely to respond) participated in the CMI study.

7.1.8 Predictors of Treatment Outcome

Several predictors of negative outcome were suggested based on small studies: male gender, longer duration of illness, higher initial Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) score, cleaning rituals, axis II diagnosis, baseline depression, overvalued ideas and

high avoidance, nonsuppression on the DST at baseline, increased prolactin blunting, and behavioural exacerbation on mCPP challenge (Dolberg et al. 1996; Sasson and Zohar 1996; Ravizza et al. 1995). However, based on a large multicenter CMI study, the abovementioned predictors were not confirmed. Additional studies on possible predictors of outcome in OCD are of great importance, with sound methodology and large samples of patients warranted.

7.2 Behavior Therapy

Behavior therapy is as effective as pharmacotherapy in OCD (Marks et al. 1975), and some data indicate that the beneficial effects are longer-lasting with behavior therapy (Greist 1996). About two-thirds of patients with moderate or severe rituals can be expected to improve substantially, but not completely. A combination of behavior therapy and pharmacotherapy might constitute the optimal treatment for OCD. Two recent neuroimaging studies found that patients with OCD who are successfully treated with behavior therapy show changes in cerebral metabolism similar to those produced by successful treatment with SRI (Schwartz et al. 1996; Baxter et al. 1992). Behavior therapy is considered less effective for obsessive thoughts occurring without rituals. Behavior therapy can be conducted in inpatient and outpatients settings. The principal behavioral approaches in OCD are exposure for obsessions and response prevention for rituals. Desensitization, thought stopping, flooding, implosion therapy, and aversion conditioning have also been used in OCD patients. In behavior therapy, the patient must be truly committed to improvement. In a recent study, 18 OCD patients were randomly assigned to receive exposure and response prevention or a general anxiety management intervention (control) for 3 weeks. The first group showed significant improvement, whereas the control group showed no improvement from baseline (Lindsay et al. 1997). Direct comparisons of behavior therapy and pharmacotherapy are few and are limited by methodological issues. Cox et al. (1993) reported equal efficacy in a meta-analysis. However, behavior therapy might have a lower relapse rate, even after interruption of therapy.

7.3 Psychotherapy

Despite the fact that biological interventions are more efficacious in OCD patients, psychodynamic factors might be of considerable benefit in understanding what precipitates exacerbations of the disorder and in treating various forms of resistances to treatment, such as noncompliance to medications or to homework assignments. It is important to remember that the symptoms may have important psychological meanings that make patients reluctant to give them up. A psychodynamic exploration into the patient's resistance to treatment may result in improved compliance.

In the absence of controlled studies of insight-oriented psychotherapy for OCD, the anecdotal reports reporting lasting change do not enable us to generalize about its efficacy. In addition, the efficacy of medications in producing quick improvement has rendered slow and long-term psychotherapy out of favor.

Supportive psychotherapy has a place in the treatment of OCD patients and may help patients to improve their functioning and adjustment. Management should also include attention to family members through the provision of emotional support, reassurance, explanation, and advice on how to manage and respond to the patient. Family therapy may reduce marital discord and build a treatment alliance, also to help in the resistance to compulsions. Group therapy is useful as a support system for some patients.

8 Conclusion

The treatment of OCD was characterized by pessimism until 20 years ago, when effective treatments using behavior therapy and SRI were developed. Although introduced for OCD in 1967, it was only in the 1980s that double-blind studies confirmed the efficacy of CMI, an SRI, for this disorder. This was followed by the further introduction of the SSRI, which also proved effective for OCD patients (Greist et al. 1995). The antiobsessive activity of these drugs was found to be independent of the drugs' antidepressant effect, as established by efficacy both in depressed and nondepressed patients. Overall, serotonergic therapies have enabled a better outlook for these patients and have enlarged our understanding of the pathophysiology of this disorder (Dolberg et al. 1996; Zohar and Insel 1987).

Previously thought to be a rare and untreatable disorder, OCD is now recognized as common, and there is now good reason to expect that OCD patients will benefit substantially from behavior therapy and potent SRI. Unfortunately, some OCD patients do not seek treatment and the disease tends to be chronic. There is a 10-year lag between the onset of symptoms and the seeking of professional help due to feelings of humiliation and embarrassment. A further lag is caused until diagnosis and correct treatment are given (Hollander 1997).

The efficacy of the SRI together with the lack of efficacy on the part of adrenergic antidepressants as medications for OCD have suggested that serotonin is involved in the pathophysiology of OCD. This relationship was validated only later by research on serotonergic markers in OCD and by the challenge paradigm (Dolberg et al. 1996). Which type of serotonergic receptor is involved in the pathogenesis and/or the mechanism of action of antiobsessional drugs is still unclear. The studies by Lesch et al. (1991) with ipsapirone, a 5-HT1A ligand, have shown that ipsapirone had no notable effect on behavioral measures, nor did it produce thermoregulatory or neuroendocrine responses that were significantly different from placebo. Moreover, the lack of therapeutic effectiveness of the 5HT1A agent buspirone adds to the impression that this receptor is not involved in the pathophysiology and management of OCD. Further studies of the involvement of the serotonergic system in OCD are crucial to elucidating the role of this neurotransmitter in the pathophysiology and management of OCD.

U.S. census data suggest that over $8 billion are spent each year on the management of OCD, one fifth of that spent for heart disease (DuPont et al. 1995). Because OCD patients often attempt to conceal their symptoms, it is incumbent on clinicians to screen for OCD in every mental status examination, since appropriate treatment can result in improved quality of life, reduced OCD chronicity, and reduced costs to the individual and society.

Anxiety Disorders: Diagnosis and Epidemiology

Translator: E. Taub

1 Introduction

Anxiety is a universal human experience. Since its earliest literary mention in the Epic of Gilgamesh in about 2000 B.C., it has been dealt with in many different ways in literature, philosophy, religion, and, of course, psychology and medicine. In 1826, the Belgian psychiatrist Joseph Guslain first pointed out the important role played by anxiety in the generation of some psychopathological conditions (McReynolds 1985). In 1871, Westphal gave the original description of agoraphobia. In 1895, Sigmund Freud published a paper entitled *Über die Berechtigung, von der Neurasthenie einen bestimmten Symptomenkomplex als 'Angstneurose' abzutrennen* (English title in the Standard Edition: "On the Grounds for Detaching a Particular Syndrome from Neurasthenia Under the Description 'Anxiety Neurosis' "). In 1920, Watson and Rayner first reported the experimental induction of an anxiety reaction by conditioning.

In keeping with this clinical tradition, anxiety disorders were listed under the major category of the neuroses in the diagnostic key and glossary of psychiatric diseases of ICD-8 (Mombour and Kockott 1971), and there subdivided into anxiety neurosis, phobia, and obsessive-compulsive neurosis. Subsequently, DSM-III (APA 1980) provided a major extension and refinement of this classification, which largely remains current today. An entire chapter was devoted to the anxiety disorders, which were subdivided into agoraphobia with panic attacks, agoraphobia without panic attacks, social phobia, simple phobia, panic disorder, generalized anxiety disorder, obsessive-compulsive disorder, post-traumatic stress disorder, and atypical anxiety disorder. DSM-III originally included a hierarchical rule, according to which the diagnosis of an anxiety disorder required the exclusion of other psychiatric disorders, such as depression or schizophrenia. This rule was dropped in the revision of DSM-III, DSM-III-R (APA 1987).

Both the question of the differentiation of anxiety disorders from other mental disorders, which is dealt with in a particular way by the diagnostic hierarchical or stratification rule (Jaspers 1948), and the problem of diagnostic subdivision arise because there is a continuous spectrum of anxiety ranging from normal to pathological conditions (Rapee 1991) and because anxiety is found as a symptom or syndrome in practically every other mental disorder, most typically in depression (Helmchen and Linden 1986). Nevertheless, the anxiety disorders listed in the present systems of classification by their nature unambiguously merit designation as independent illnesses, both because of the degree of subjective suffering and impairment they cause, and because of their phenomenological features. Thus, even when depression is present, it is entirely reasonable to diagnose the simultaneous presence of phobia, obsessive-compulsive manifestations, or a condition in which depressed mood and generalized anxiety are present to an equal degree. If one prefers not to assign double diagnoses in such cases, single diagnostic categories are also available from other classification schemes, such as anxiety-depression (Gurney et al. 1972) or mixed anxiety and depression, as in ICD-10 (F41.2).

The operationalized diagnostic criteria now available make it possible for the first time to collect comparable data from different countries on the frequency of anxiety disorders in the population. Anxiety disorders are among the more common mental illnesses; they are set apart from other mental illnesses by their specific manifestations, course, and treatment. Unless proper treatment is given, the danger exists that they may become chronic and lead to disability. The remainder of this chapter contains a brief overview of the diagnostic criteria for the most important anxiety disorders, followed by a summary of the findings of epidemiologic studies.

2 Diagnosis

While the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; APA 1994) contains an independent chapter entitled "Anxiety Disorders," ICD-10 (WHO 1992) lists this group of illnesses in chapter F4 among the neurotic, stress-related, and somatoform disorders. Despite this difference, there is a large degree of agreement between these two classification systems, as seen in Fig. 1. In both systems, for example, phobic disorders are subdivided into three types: specific phobias, social phobias, and agoraphobia.

2.1 Agoraphobia

The two systems differ with respect to the differential diagnosis of panic disorder and agoraphobia. In ICD-10, agoraphobia is listed as an independent clinical syndrome in the group of phobic disorders and can be further specified according to the presence or absence of a (hierarchically subordinated) panic disorder. In DSM-IV, in contrast, panic attacks occupy a higher position in the diagnostic hierarchy than agoraphobia;

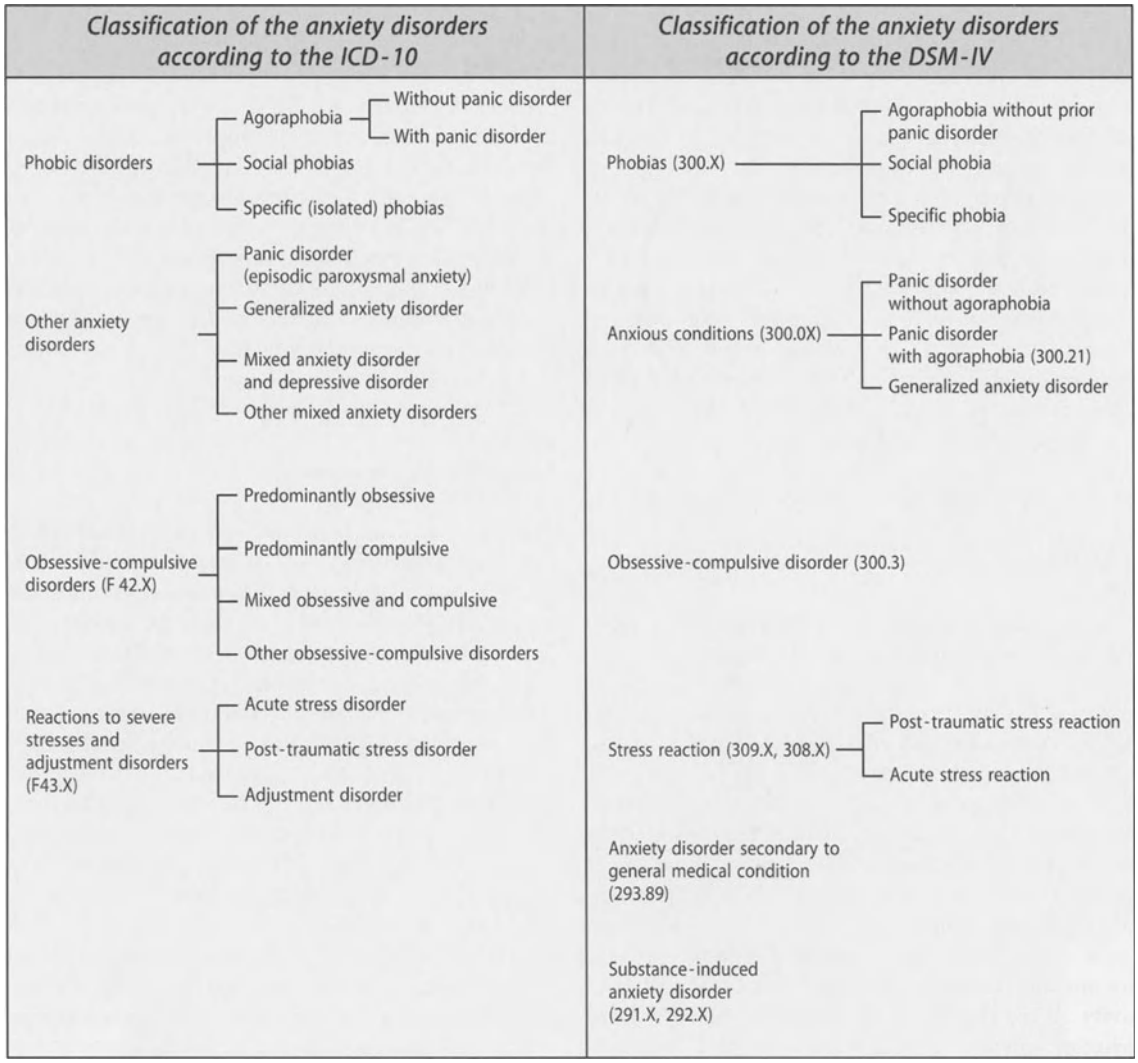

Fig. 1. Classification of the anxiety disorders according to ICD-10 and DSM-IV

this ordering may be traced back to the works of Klein (1964, 1981).

The major feature of agoraphobia is the avoidance of situations or places that are experienced as unpleasant or dangerous and that cause the patient to fear that an anxiety attack or panic-like symptoms will occur. Patients imagine that it is difficult or unpleasant to escape from these situations or places, or that they are helpless. As a rule, anxiety appears in circumscribed situations such as in crowds, in public places, far from home, etc. and these particular situations are avoided. The radius of activity of the affected individuals is thereby greatly constricted.

The term "agoraphobia" ("fear of the marketplace") refers only to the most prominent symptom of this disorder, but patients suffering from it have, as a rule, multiple other anxieties, such as acrophobia, claustrophobia, or thanatophobia. Thus we may speak of agoraphobia as a complex phobia, in contradistinction to the specific phobias. According to DSM-IV, the diagnosis of agoraphobia without panic syndrome may be assigned if the criteria for a panic disorder have never been met, and the diagnosis of a panic disorder with agoraphobia may be assigned if the criteria for both agoraphobia and panic disorder are or have been met at some time.

2.2 Social Phobia

The distinguishing feature of social phobia is an excessive fear of other people and a consequent avoidance of social situations, especially when the

affected individuals think they will be observed or evaluated. They fear that they will fail, appear ridiculous, or be humiliated by their maladroit behavior. Social anxieties may be limited to specific situations (e.g., fear of public speaking) or may be nonspecific, even to the extent of affecting the majority of interpersonal activities. Typically, almost any confrontation with, or anticipation of, a social situation immediately induces fear, which may take the form of a situational panic attack. Social phobia can be understood as a disturbance of patients' positioning of themselves in social groups and rank orderings ("pecking orders"), in which they are always relegated to the omega position - with all of the resulting problems in social adjustment.

2.3 Specific Phobias

The distinguishing feature of the specific (also called isolated or simple) phobias is an inappropriate and excessive fear and avoidance of specific objects or situations. The most common phobias involve animals (spiders, snakes, mice, birds), heights, narrow spaces, airplanes, and the sight of blood or syringes. Almost any confrontation with these situations or objects immediately induces anxiety, which may rise to the severity of a panic attack. The resulting impairment depends on the ease with which the affected person can avoid the phobic situation or object; it may range from a mild impairment to a major limitation of life activities and constriction of the patient's radius of activity. It is typical of the objects and situations provoking specific phobias that they are unconditioned stimuli to which nearly all people spontaneously respond with fear or avoidance, even in the absence of prior learning or experience.

2.4 Panic Disorder

Panic disorder consists of frequently recurring, usually very intense attacks of anxiety, which the affected person does not spontaneously attribute to any particular provoking factor. These suddenly appearing states are characterized by multiple physical and mental symptoms, including palpitations, chest pain, a sensation of asphyxiation, vertigo, and depersonalization or derealization. They generally last only a few minutes, occasionally longer. Patients subsequently develop anxiety about the anxiety or a fear of the consequences of the symptoms connected with anxiety, e.g., fear of dying, losing control, or becoming insane. These symptoms are extremely stressful for the patients and usually produce significant impairment in everyday life.

The fact that the patients cannot state spontaneouslyt why the anxiety attacks occur has given rise to the assumption that they are endogenous. If the diagnostician realizes, however, that thoughts, recollections, or internal images, i.e., cognitions, can induce anxiety reactions just as strongly as, and sometimes even more strongly than, external stimuli, then a correspondingly thorough evaluation usually reveals a provoking factor for the symptoms of anxiety in the pure form of panic disorder, just as in agoraphobia.

2.5 Generalized Anxiety Disorder

The distinguishing feature of generalized anxiety disorder is the presence of excessive, general, and multifarious worries, fears, or anxieties. On most days, over a period of at least 6 months, the patient suffers from excessive worry. These worries, fears, and anxieties, which are not restricted to specific situations or, if accentuated in specific situations, are nonetheless also present at other times, are experienced by the patient as difficult to control and lead to significant impairment in everyday life. In addition, at least three of the following six symptoms must be simultaneously present for the diagnosis of a generalized anxiety disorder to be assigned: muscle tension, restlessness, easy fatigability, difficulty concentrating, sleep disturbance, and irritability. The patients typically think of themselves not as anxious, but as under excessive stress because of the many problematical situations to which they imagine they are exposed. A patient might think that he or she is overburdened by problems with a child, for example, without realizing that the actual source of worry is "self-worry."

2.6 Obsessive–Compulsive Disorder

In obsessive–compulsive disorder, there are either recurrent obsessive thoughts or recurrent compulsive behaviors. Obsessive thoughts (obsessions) are continually recurring ideas, thoughts, or conceptions that patients recognize as their own but nonetheless experience as importunate, tormenting, and burdensome, either because they consider them nonsensical, or because they are of a violent or obscene nature. The patient tries to ignore the obsessive thoughts or to neutralize them through other thoughts or through the performance of rituals.

Compulsive behaviors (compulsions) are recurring, intentional behaviors carried out according to precise

rules or in stereotypic fashion, usually motivated by the desire to avert unpleasant consequences or disasters. The connection between the compulsive behavior and its purpose may be quite far-fetched, e.g., frequent hand-washing to prevent the outbreak of an epidemic. Compulsions, like obsessions, are generally experienced by the affected persons as senseless, ineffectual, and unpleasant. The attempt to suppress them induces severe anxiety or revulsion. Obsessions and compulsions take up a great deal of time. The diagnosis requires the demonstrable presence of obsessions or compulsions that disturb the patient's normal activities on most days for a period of at least 2 weeks. A thorough discussion of obsessive-compulsive disorders is found in Chap. 1 (Vol. 3, Part 2).

2.7 Post-traumatic Stress Disorder

Post-traumatic stress disorder arises as a protracted reaction to an extraordinarily threatening or catastrophic event, such as a natural disaster, wartime experience, serious accident, or violent crime. Typical symptoms of post-traumatic stress disorder include an intense fear and avoidance of activities and situations related to the trauma and, most prominently, the frequent, intense, and unavoidable reliving of the trauma in importunate recollections (nightmares, daydreams, "flashbacks"); emotional insensitivity, blunting, and indifference with respect to the present environment and other persons; and a simultaneous state of vegetative hyperexcitation with increased vigilance, sleeplessness, etc. The symptoms must produce clinically significant stress or impairment. Acute and chronic subtypes are distinguished. A thorough discussion of post-traumatic stress disorder is found in Chap. 4 (Vol. 3, Part 2).

3 Epidemiology

3.1 General Prevalence Rates

Anxiety disorders are among the more common mental illnesses. Table 1 contains a summary of the findings of several epidemiologic studies in different countries. Approximately 5% of the general population suffers from an anxiety disorder. This order of magnitude is roughly comparable to that of the prevalence of depressive illnesses.

The exact figures obtained for prevalence are, however, highly dependent on the detailed criteria for the diagnosis of anxiety disorder applied in such studies. Thus the studies conducted by Bebbington et al. (1981) and Henderson et al. (1979) mentioned in Table 1 were carried out using the Present State Examination (PSE; Wing et al. 1974), while that by Regier et al. (1988) employed the Diagnostic Interview Schedule (DIS; Robins et al. 1981). The latter American study counted simple phobias among the anxiety disorders and thus arrived at a value for prevalence considerably above the mean of those found in other studies (7.3% vs. 3.4%).

As for the prevalence of individual subtypes of the anxiety disorders (Table 2), the different international studies all show that simple phobia is the most common subtype, with a lifetime prevalence of 5.4%–11.3%. Panic disorders are rather uncommon: their lifetime prevalence in the population lies between 1.1% and 3.5%. Obsessive-compulsive disorders occur with a lifetime prevalence of 2%–3%, and generalized anxiety disorders with a 1-year prevalence of 2.3%. There is no reliable estimate to date of the prevalence of post-traumatic stress disorder. Helzer et al. (1987) gave the lifetime prevalence of post-traumatic stress

Table 1. One-month prevalence (%) of anxiety disorders compared to overall psychiatric morbidity and depressive disorders

disorder as 1% in one of the five study areas of a large-scale American epidemiologic study. The rate was 0.5% in men and 1.3% in women.

As can be seen in Table 2, the point prevalence of the overall category of anxiety disorders, as well as that of its individual subtypes, is generally approximately half of the corresponding lifetime prevalence.

3.2 Comorbidity

It is already clear from a comparison of the prevalences of individual subtypes of the anxiety disorders with that of the overall category of such disorders that many patients suffer from more than one anxiety disorder (see Table 2). In the Munich Follow-Up Study (Wittchen 1991), only 20% of panic disorders and 48% of phobias were pure disorders for life; all other cases met the criteria for at least one other anxiety disorder, and often more than one. According to the findings of the National Comorbidity Survey (NCS; Wittchen and Vossen 1995), approximately 20% of patients with agoraphobia simultaneously meet all of the criteria for a generalized anxiety disorder, and approximately 22% meet all of the criteria for a panic disorder.

A comparable degree of overlap is found with respect to other psychiatric illnesses, including, in particular, depressive illnesses. A total of 21% of patients with anxiety disorders simultaneously meet all of the criteria for a depressive disorder, and 33% of patients with depressive disorders simultaneously have anxiety disorders (Regier et al. 1990).

Clinical findings have long implied a close relationship between anxiety disorders and personality disorders. A study by Sanderson et al. (1993) of 347 patients diagnosed as having an anxiety disorder according to the DSM-III-R criteria revealed that 35% met the diagnostic criteria for at least one personality disorder. A total of 61% of patients with social phobia and 49% of patients with a generalized anxiety disorder had at least one personality disorder, while patients with specific phobias had comorbid personality disorders much less frequently (12% of patients).

These high rates of comorbidity raise the fundamental question as to whether anxiety disorders should indeed be considered independent illnesses. The problem is one of content, as well as of method. In methodological terms, it must be determined to what extent the reported results are an artifact brought about by the admittedly broad symptom profile of the anxiety disorders, many components of which are simultaneously used as criteria for the diagnosis of other disorders. As a matter of content, it must be determined whether distinguishable core symptoms or syndromes occur simultaneously, a state of affairs known in the literature as syndromal association or "co-occurrence," or whether an actual comorbidity is present in the proper sense of the term, i.e., the simultaneous occurrence of different diseases (Wittchen 1993). Finally, syndrome changes over the course of anxiety disorders must also be taken into account (Wittchen et al. 1989).

Empirical research at present offers no more than an attempt at clarifying these issues. Nonetheless, it already seems clear that the use of a highly differentiated diagnostic scheme, and the determination of spectra of comorbidity, are more helpful for an understanding of the course and treatment of these disorders than subsuming their heterogeneity under hierarchically ordered categories (Bronisch 1995).

3.3 Incidence Rates

The initial appearance of anxiety disorders has a characteristic distribution over the human life span. According to the findings of the Munich Follow-up Study (Wittchen 1991), the specific phobias largely arise in childhood and adolescence. Examples include fear of the dark, separation anxiety, and fear of animals. Social phobias are generally said to appear in adolescence (Van Ameringen et al. 1991). Panic disorders, agoraphobia, generalized anxiety disorders, and obsessive–compulsive disorders usually appear in early adulthood; the age-related incidence of generalized anxiety disorder also has a second peak between the ages of 30 and 35 (Scheibe and Albus 1992). In general, these data indicate that early adulthood is a critical time of life for the generation of these disorders.

3.4 Differential Prevalence Rates

As seen in Table 1, anxiety disorders are nearly twice as common in women as in men. This is largely due to differences in the prevalence of phobias and generalized anxiety disorders; differences in the prevalence of the obsessive–compulsive disorders, for example, are much less marked. The prevalence of anxiety disorders is higher in women than in men in all age-groups, as shown in Table 3.

A methodological limitation necessarily applies to the question of the frequency of anxiety disorders in different age-groups: differences in prevalence are not necessarily the result of differences in age and may, instead, reflect cohort effects. Thus older individuals who lived through one or both world wars may be affected by anxiety disorders to a different extent than younger people who were spared such experiences. With these reservations in mind, it may be concluded

Table 3. One-month prevalence of anxiety disorders in different age-groups (after Regier et al. 1988)

Age (years)	Both sexes (%)	Men (%)	Women (%)
18–24	7.7	4.9	10.4
25–44	8.3	4.7	11.7
45–64	6.6	5.1	8.0
6+	5.5	3.6	6.8
All age-groups	7.3	4.7	9.7

from the data shown in Table 3 that anxiety disorders are less common with advancing age and that young adults are affected by them particularly frequently. This conclusion is in accordance with the findings on age-related incidence presented above. Anxiety disorders according to the DSM-III-R criteria are found in only 1.9% of those above age 70 (Helmchen et al. 1996a,b).

A comparison of the frequency of anxiety disorders across social classes yields the interesting finding that they become much more common with lower social status and level of education (Kessler et al. 1994). If we assume that anxiety disorders are at least partly learned disorders, whose appearance and course may be determined by life experiences, by the so-called coping repertoire, or by framing conditions such as alcohol abuse, then this finding opens the way to diverse etiological speculations. Epidemiologic studies alone, however, cannot confirm or refute such hypotheses; to do so, more specific scientific study is required.

With respect to the frequency of anxiety disorders and relationship status, a consistent finding is that they are more prevalent by approximately one third among separated, divorced, and widowed individuals than among married people, people who have never been married, and people living alone (Regier et al. 1990). The question arises as to what extent traumatic experiences in the context of the separation can account for the elevated prevalence rates. Once again, it must be stated that epidemiologic data alone can be used only to generate such hypotheses, not to confirm them.

If we consider the foregoing findings from the perspective of risk estimation, it may be concluded that women between the ages of 15 and 24, of low social and educational status, who are separated, divorced, or widowed, have a significantly elevated risk of developing an anxiety disorder.

3.5 Familial Prevalence

Studies on the frequency of illness in first-degree relatives in comparison to unrelated control subjects suggest that genetic vulnerability is a risk factor for the occurrence of anxiety disorders. When interpreting such data, it must, of course, be borne in mind that family-specific child-rearing styles and life experiences, or the presence of illness in another family member as an environmental stress factor, may favor the familial appearance of certain illnesses.

An overall consideration of the findings of studies on the frequency of panic disorders in first-degree relatives of affected individuals reveals that relatives are approximately four times more likely to be affected than unrelated control subjects (Noyes et al. 1986). First-degree relatives of individuals with anxiety disorders, in comparison with relatives of patients with affective disorders, are approximately seven times as likely to suffer from a panic disorder and twice as likely to suffer from a generalized anxiety disorder (Skre et al. 1994).

Further evidence for a genetic vulnerability factor is derived from studies on mono- and dizygotic twins (Torgersen 1983; Kendler et al. 1992): the concordance rate for monozygotic twins is approximately 25%–30%, twice as high as that for dizygotic twins. These findings imply the existence of a genetically determined constitutional vulnerability for both panic disorders and generalized anxiety disorders.

3.6 Course

Anxiety disorders tend to take a chronic course. According to the findings of the Munich Follow-up Study (Wittchen 1991), a chronic course is found in just over 50% of patients, regardless of the type of the disorder. If we count episodic and less marked cases of illness, then agoraphobia and obsessive-compulsive disorders are found to have an overall chronification rate of approximately 80%. An asymptomatic state is reached, at least temporarily, at some point in the course of 30%–40% of simple phobias and panic disorders. Yonkers et al. (1996) prospectively studied the course of generalized anxiety disorder over an interval of 2 years. The frequency of remission was found to be 15% at 1 year and 25% at 2 years; the presence of a comorbid psychiatric illness reduced the frequency of remission at 1 year by nearly half.

These high rates of chronic disease imply that the anxiety disorders must be considered serious mental illnesses. The same conclusion is reached if we consider the severity of the disorder in the synchronic perspective and the disturbance of social adaptation that it produces. A follow-up study with an interval of 7 years (Wittchen 1991) revealed that a major impairment of social adaptation and a degree of disease-

related disability corresponding to a score of less than 80 on the Global Assessment Scale (GAS; Spitzer et al. 1978) were present in 71% of patients with panic disorders, 50% of those with agoraphobia, 47% of those with simple phobias and social phobia, and 58% of those with obsessive-compulsive disorders.

Data from the American Epidemiologic Catchment Area Study (ECA) reveal the impact of anxiety disorders on patients' ability to function in an occupation, a component of the social cost of these disorders. A total of 60% of affected men and 68% of affected women stated that they were unemployed at the time of the study; 25% of the men and 29% of the women with panic disorders had been unemployed for at least 5 years (Leon et al. 1995). A study by Massion et al. (1993) of the quality of life of patients with generalized anxiety disorder and/or panic disorder revealed that 9% of patients with one or both of these disorders had attempted suicide in the past, 31% had been hospitalized at least once, and 25% of patients with generalized anxiety disorders were receiving disability payments. Chronification of anxiety disorders thus implies a chronic impairment in everyday life, including occupational activity.

3.7 Institutional Prevalence Rates

It is typical of the anxiety disorders that somatic manifestations are often their most prominent feature. We are thus led to ask not just how frequently these disorders come under general medical, as opposed to specifically psychotherapeutic, treatment, but also how frequently the anxiety disorders are in fact recognized as such.

An investigation of the prevalence of mental illness in patients treated in general medical practice, which was carried out as part of an international study by the World Health Organization (Linden et al. 1996), revealed that generalized anxiety disorders are the type of mental illness most likely to be encountered. A total of 9% of general medical patients in Berlin and 7.9% in Mainz suffer from a generalized anxiety disorder. Panic disorders are comparatively uncommon: 0.9% and 1.7% in Berlin and Mainz, respectively. Approximately 60% of all psychiatric illnesses were recognized by the physicians as such; anxiety disorders were less commonly recognized as such in primary care practice than were depressive illnesses (Ormel et al. 1990).

Much more than in general medical practice, anxiety disorders are frequently encountered in psychotherapeutic practice, and particularly in the practice of behavioral therapy. A study of patients treated by behavioral therapists in the out-of-hospital office setting, in the framework of care provided by the German quasi-governmental health insurance scheme (*Krankenkassen*; Linden et al. 1993), revealed that 40% of such patients suffered from an anxiety disorder. Approximately half of these patients had phobias, and approximately 10% obsessive-compulsive disorders. Anxiety disorders are thus second in frequency only to depressive syndromes among patients treated using behavioral therapy. This finding suggests that patients with anxiety disorders are being referred appropriately, as behavioral therapy is currently considered the method of choice for the treatment of these disorders (Michelson and Marchione 1991). It is not clear, however, whether the quantity of treatment currently available and the quantity actually delivered actually satisfy the need for treatment in this patient group.

Pathogenesis and Treatment of Anxiety Disorders

Translator: E. Taub

1 Phenomenology of Anxiety

Anxiety (from the Latin *anxietas,* in turn derived from *angere,* to choke, throttle, trouble, distress) is an emotional state induced by the perception of danger or threat arising from the environment or from within the individual him- or herself. In humans, as in animals, anxiety is necessary for survival, as it protects the individual from repeated contact with threatening situations. It can also be understood as a preparatory reaction for fight or flight. The behavioral inhibition accompanying anxiety also has an important protective function: in both animal and human social conflicts, it brings about the retreat of the aggressor.

Anxiety is seen as one of the so-called primary human emotions (Pekrun 1990). The subjective experience of anxiety comprises the following components (Lòpez-Ibor 1952):

1. An affective component, i.e. an emotional experience
2. A somatosensory component, i.e. perception of physiologic changes
3. A cognitive component, i.e. worry about a threat or impending loss
4. Characteristic behavior that may express itself either as inhibition or as alertness, defense, fight, or flight

Even though certain behavior patterns are characteristic of anxiety (see item 4, above), the subjective experience of anxiety need not be congruent with observable behavior. Thus anxiety research revealed long ago that there may be a considerable discrepancy between observed behavior, physiologic measurements, and subjective reports (Lader and Marks 1971; Fahrenberg 1987; Lang 1993).

The proneness to react in an anxious way is variable among individuals and may thus be thought of as a personality trait. All human beings have a behavioral disposition to experience anxiety at varying intensities for varying lengths of time (Amelang and Bartussek 1985). Anxiousness in this sense (the proneness toward anxiety) is distinct from situation-related fear, which is immediately preceded by a fear-inducing stimulus and which, on the behavioral level, leads either to flight and avoidance or to aggression and fighting, depending on the particular stimulus that induced it (Fröhlich 1983).

For anxiety, unlike other psychopathological phenomena, such as perceptual illusions, a continuous transition exists from "normal" to "pathological" forms (Strian 1983). The criteria for pathological anxiety are as follows:

- Anxiety in the absence of a real threat
- An anxiety reaction that is subjectively or objectively judged to be disproportionate to the inducing stimulus
- Severe anticipatory anxiety
- Fear of anxiety (phobophobia)
- Socially or personally limiting avoidance behavior
- Anxiety that persists even when the threat is no longer present
- Anxiety of such intensity that the individual's ability to cope with life is affected

Anxiety may occur as an disease in itself or as a symptom, or constellation of symptoms, in the context of other mental or organic illnesses.

Some anxiety disorders are listed in ICD-10 (WHO 1992) under chapter headings specifically relating to anxiety (F40, F41, F42), while other anxiety disorders appear under headings such as somatization disorder and hypochondriacal disorders (F45), organic anxiety disorders (F06, F10), and severe personality disorders (F60). Anxiety may also occur as a symptom, or syndrome, accompanying mental disorders of practically any type. Free-floating anxiety is one of the hallmark symptoms of depressive illness; anxiety may also occur in association with delusional mood changes or with delusions of harmful influence or persecution due to schizophrenia.

Physical illness must always be considered in the differential diagnosis of anxious conditions. The following list of differential diagnoses (mental and physical illnesses accompanied by anxiety; after Deister 1995) shows that the initial diagnosis of anxiety disorders always requires a comprehensive medical evaluation:

1. Nonorganic mental disorders:
   - Schizophrenic psychosis
   - Affective psychosis
   - Personality disorders
2. Organic mental disorders:
   - Delirium
   - Organic delusional disorder
   - Organic depressive disorders
   - Organic personality disorders
3. Substance-related disorders:
   - Intoxication with amphetamines, cocaine, hallucinogens, alcohol, nicotine, caffeine
   - Withdrawal of alcohol, opiates, anxiolytics
4. Neurological diseases:
   - Epilepsy
   - Huntington's disease
   - Migraine
   - Multiple sclerosis
   - Elevated intracranial pressure

5. General medical illnesses:
   - Angina pectoris
   - Myocardial infarction
   - Cardiac dysrhythmias
   - Hyperchloremia
   - Hypoxia
   - Pulmonary embolism
   - Hyperthyroidism
   - Carcinoid
   - Pheochromocytoma
   - Anaphylaxis

2 Neurobiology of Anxiety Disorders

2.1 Genetic Aspects

Both animal experiments and human twin studies have yielded evidence that genetic factors play a role in anxiety and anxiety disorders.

A number of rat strains have been bred selectively according to their rate of defecation when at large, and these rats may be classified as either reactive or nonreactive (Weyers and Fritze 1995). It has been shown that reactive rats tolerate stress less well in conflict tests, that chlordiazepoxide has a lesser anxiolytic effect in such rats, and that young reactive rats, when separated from their mothers, vocalize more than nonreactive rats.

There are also significant differences in anxiety reactions among different breeds of dog. Thus two lines of pointers were bred (McKinney 1988). The "nervous" line is characterized by extreme fearfulness, avoidance of human beings, reduced exploratory behavior, a more extreme fright reaction, and an elevated incidence of atrioventricular heart block. The administration of chlordiazepoxide to such dogs enables them to cope with an anxiety-producing lever-pressing task, while the administration of amphetamines or cocaine leads to a markedly more severe behavioral disorder. Nervous pointers were found to have a higher concentration of norepinephrine in the reticular formation, and a lower concentration of serotonin in the septal nuclei, than normal pointers (Gurgius et al. 1990).

Studies of human families have yielded evidence that genetic load affects the risk of developing an anxiety disorder (Linden 1993). Studies have revealed that the first-degree relatives of patients with panic disorders have such disorders themselves with a prevalence of 15%–20%, significantly higher than the rates of 2%–4% found among controls (Crowe et al. 1983; Harris et al. 1983; Noyes et al. 1986). Twin studies (Kendler et al. 1992; Torgersen 1983) have shown a concordance rate of approximately 20%–30% for generalized anxiety disorder among monozygotic twins, approximately three times as high as the rate among dizygotic twins. These findings imply that there is a genetically transmitted, constitutional vulnerability to panic disorders and to generalized anxiety disorder.

2.2 Neural Structures

Anxiety, as discussed above, is a reaction that prepares the organism to respond to a threat in any of several different ways. It is thus not surprising that anxiety activates a number of different areas of the brain simultaneously. The limbic system plays an important role in this process; occupying an anatomical position between the neocortex, the hypothalamic-pituitary axis, the reticular formation, and the sensory system, the limbic system is strategically placed to influence a large number of different cerebral functions and modes of behavior. It has important connections both to lower brain centers, such as the locus ceruleus, and to higher brain centers, such as the frontal cortex. Brain stimulation experiments have revealed that stimulation of the amygdala, in particular, evokes fear (Kuhar 1986). In animal experiments, electrical stimulation of the amygdala leads to intense anxiety reactions involving increased fearfulness, a change in pulse and respiratory rate, and the interruption of behavior currently being performed. If lateral, basal, or central amygdaloid nuclei are destroyed, the symptoms of fear and anxiety disappear (Davis 1992).

It is likely that the septohippocampal system plays a role in anxiety, because destruction of these areas has been found to have a sedative and anxiolytic effect which is similar to that of the administration of benzodiazepines or barbiturates.

Studies employing positron emission tomography (PET) in patients with panic disorders before and during an infusion of lactate have revealed an abnormal asymmetry of perfusion in the parahippocampal gyrus; during panic attacks, these patients have a significant increase of cerebral blood flow, particularly in the temporal lobes bilaterally (Reiman et al. 1984). This activation of the temporal lobe was also observed in normal subjects trained to expect a painful electric shock (Reiman et al. 1989). The limbic and septohippocampal systems may be activated by lower brain areas, such as the reticular formation and especially the locus ceruleus (Gray 1982).

2.3 Transmitter Systems

The benzodiazepines are, the substance class with the greatest anxiolytic effect. Their mechanism of action involves the so-called benzodiazepine γ-aminobutyric acid (GABA) receptor (see Chap. 6, Vol. 1). It is now known that there are several different types of $GABA_A$ receptor that are differentially distributed in different brain areas; some types of $GABA_A$ receptor may be more closely related to anxiety than others (Sieghart 1995). Changes in $GABA_A$ receptor activity can both induce fear and counteract it. Any increase of GABAergic transmission, e.g. after the administration of benzodiazepines, barbiturates, anxiolytic steroids, or alcohol, has an anxiolytic effect, while any decrease of GABAergic transmission, e.g. after receptor blockade with substances such as pentylenetetrazol and picrotoxin, is anxiogenic. These effects occur immediately, without delay, after the administration of the corresponding substances. It therefore has to be concluded that $GABA_A$ receptors are directly involved in the modulation of the anxiety reaction.

It is conceivable that differences among individuals in the proneness to anxiety might be explained by differences in $GABA_A$ receptor affinity. It is also possible that anxiety disorders lead to an overproduction of endogenous reverse agonists, or to a change of receptor density, and thereby to prolonged states of anxiety and, finally, to neural structural changes (Sieghart 1995). A number of endogenous ligands for the benzodiazepine binding site of the $GABA_A$ receptor have been discovered to date, and endogenous agonists are also known.

A number of experimental findings reveal that fear and anxiety can be induced by electrical stimulation of the primate brain by way of a mechanism involving overfunction of the noradrenergic system, in particular of the locus ceruleus, whose predominantly adrenergic neurons make synaptic connections throughout the brain (Gray 1982). If the locus ceruleus is destroyed, such reactions become less pronounced. It has also been shown that benzodiazepines reduce the activity of locus ceruleus neurons. Furthermore, pharmacologic studies have shown that the administration of α_2-adrenergic antagonists such as yohimbine can induce anxiety, both in animals and in humans (Charney et al. 1984). These α_2-adrenergic receptors are typically localized presynaptically on noradrenergic cell bodies and serve to regulate the release of norepinephrine.

It is known that benzodiazepines also inhibit the electrical activity of serotonergic neurons in the dorsal raphe nuclei and reduce the functioning of the serotonin system in general. Conversely, serotonin agonists can have an anxiogenic effect in patients with panic disorders (Sieghart 1995). It seems, however, that long-term stimulation of the serotonin system has different physiologic effects than acute serotonergic activation, which causes acute excitement or anxiety. Long-term pharmacologic serotonergic stimulation, either with serotonin reuptake inhibitors or with $5\text{-}HT_{1a}$ agonists such as buspirone, has a clearly anxiolytic clinical effect (Rickels et al. 1982b). This may be explained as the result of an activation of presynaptic autoreceptors, which would then, in turn, lead to a reduction of serotonin release.

2.4 Neuroendocrinology

It is generally recognized that anxiety is associated with a large number of vegetative manifestations, such as alterations of skin conductivity, of blood pressure, and of heart rate. These effects may be explained as the result of increased release of epinephrine, norepinephrine, adrenocorticotropic hormone (ACTH), cortisol, prolactin, and growth hormone (Hemmeter and Holsboer-Trachsler 1995; see also Chap. 8, Vol. 1, Part 1).

These vegetative phenomena are mainly short-term, nonspecific adaptive changes, which may be understood as reactions preparing the organism for fight or flight. Long-term adaptive biological changes, as seen in the anxiety disorders, take place mainly along the hypothalamic-pituitary axis. It has been known since the studies carried out by Selye (1956) that anxiety and stress are associated with cortisol secretion. Many experimental studies have documented a positive relationship between anxiety reactions and cortisol release in normal individuals (Nesse et al. 1985; Schedlowski et al. 1992); furthermore, in similar studies, subjects with an elevated proneness to anxiety as a personality trait respond with a greater rise of the serum cortisol level than others (Hemmeter et al. 1991). Those who have lived in anxiety-producing circumstances for prolonged periods have elevated salivary cortisol levels, even after the acute threat is removed (Rahe et al. 1990).

Counterregulatory adaptation also appears to occur in chronic anxiety disorders. Thus some patients with post-traumatic stress disorder (PTSD), when given dexamethasone, actually have lower cortisol levels than normal control subjects (Halbreich et al. 1989; Yehuda et al. 1993). Holsboer (1993) hypothesizes that an increased endogenous secretion of corticotropin-releasing hormone (CRH) during the anxious state leads

to secondary hyposensitivity of CRH receptors in the pituitary gland.

Not only adrenal cortical function, but also the regulation of growth hormone secretion depends on the function of the hypothalamic-pituitary axis. In individuals exposed to anxiety-producing situations, an increased secretion of growth hormone can be observed, though the threshold for growth hormone secretion is apparently higher (Greenwood and Landon 1966; Greene et al. 1970). Patients with panic disorders, and those with social phobia, have been found in several studies to have a diminished sensitivity of this system, as shown, e.g. by measurements after clonidine infusion. This is also thought to be a result of hyposensitivity of postsynaptic α-adrenergic receptors (Charney and Heninger 1986; Tancer et al. 1993; Holsboer 1993).

These central and peripheral neurobiological changes associated with anxiety have not yet been shown to be specific enough to allow a distinction between different anxiety, or even between pathological and normal states of anxiety. They have been useful to date mainly as aids in the development of explanatory hypotheses for the phenomenon we call "anxiety."

3 Psychology of Anxiety Disorders

In psychoanalytic theories, it has been proposed that excessive separation anxiety in childhood predisposes to panic attacks in adulthood (Klein 1981), although the former may well be an early manifestation of the latter, or an actual etiologic factor for it. Other authors were unable to provide support for this association (Deltito et al. 1986, Margraf et al. 1986).

With respect to parental child-raising styles, it has been claimed of patients with social phobia, in particular, that they had been held back by their parents in social situations and had been led to overvalue the opinions of others and to undervalue the attitudes of family members (Bruch et al. 1989). Agoraphobia has been said to result from the reactivation of early bonding behavior in patients with excessively solicitous mothers (Solyom et al. 1976; Parker 1979; Faravelly et al. 1991; Willi 1972).

The learning-theoretic view of anxiety disorders describes a number of types of stimulus that unconditionally induce anxiety by way of an innate mechanism. Examples include physically painful stimuli, social threat, heights, and narrow spaces. It can be shown in animal experiments that the coupling of an initially nonaversive stimulus (i.e. an conditioned stimulus, such as a light signal) with a definitely aversive stimulus (i.e. and unconditioned stimulus) leads to a learned anxiety response to the first stimulus, according to classical conditioning (Brady and Hunt 1955). Such conditioning processes are potentiated in the presence of an already high level of anxiety, e.g. after previous aversive stimulation (Davis 1988).

Such conditioning is especially powerful when certain forms of aversive stimuli are used for which there is a genetic predisposition, e.g. with olfactory or gustatory stimuli (Weyers and Fritze 1995; Seligman 1971). In accordance with this learning principle, agoraphobia is thought to start from an initially unconditioned aversive stimulus, which is followed by an unconditioned anxiety reaction (Mowrer 1960). Patients, when questioned, can often state the exact time and place at which the illness began. Because of association with a conditioned stimulus, which thereby obtains signal character for the actual threat (Reinecker 1993), the affected individual learns to experience anxiety even in the absence of the primary stimulus. Just as in animal experiments, such associations are formed more or less rapidly depending on the particular stimulus involved.

In the further course of the disorder, operant conditioning leads to generalization, as the anxiety-inducing signal stimuli lead to avoidance behavior, and the anxiety reactions thus become generalized to other situations rather than simply forgotten. Avoidance, which may be understood as negative reinforcement, accounts for the generalization and further course of phobic disorders.

In addition to these conditioning processes, model learning also plays a role in the generation of anxiety (Bandura and Menlove 1968; Reinecker 1993). With respect to model learning, it should be borne in mind that observation alone does not induce an anxiety reaction; rather, the model must be perceived as self-relevant by additional evaluative processes of the observer.

Social skills are also important in the development of anxiety. It has been shown that social phobics, in particular, suffer from a lack of social skills (Dow et al. 1985). In such cases, however, the affected person's cognitive assessment of his or her own competence, and of the degree of competence demanded in particular situations, plays a larger role than factual competence (Edelmann 1985).

In summary, anxiety reactions are the final common pathway of a multidimensional array of contingencies. These include individual excitability, fearfulness, and conditionability, the nature and intensity of the anxiety-inducing stimulus, its duration, rate of repetition, and repetition interval, the conditioning processes involved, cognitive processes for evaluating the situation and the individual him- or herself, the

individual's own available resources, and the selective direction of attention toward potentially anxiety-inducing stimuli.

These mechanisms are involved in all clinically observed anxiety disorders, though to different degrees in different disorders. As mentioned above, agoraphobia can be explained as a product of classical and operant conditioning processes (Reinecker 1993; Margraf and Schneider 1989, 2000). Anticipatory cognitions are of central pathogenetic importance in the further development of the disorder. In panic disorder, unlike agoraphobia, anxiety states are induced not by external, but rather by internal stimuli, such as memories or associations; as a rule, they can be triggered at any time by the corresponding stimuli (contrary to the original definition) (Margraf and Schneider 2000).

Traumatic, unconditioned anxiety-inducing stimuli play an important etiologic role in PTSD (Foa et al. 2000; cf. also Chap. 4 of this volume). The diagnostic criteria for PTSD require an initial event that led to panic-like anxiety reactions: examples of such events include rape, wartime experiences, and traffic accidents. Later, this unconditioned panic reaction can be reactivated by signal stimuli, at progressively decreasing threshold levels. A major pathogenetic role is played by memories that bear such a strong emotional charge that they come into consciousness over and over again, calling forth a stronger emotional reaction each time.

In generalized anxiety disorder, the most important etiologic and pathogenetic factors are primary, anticipatory, catastrophizing cognitions and, above all, a direction of attention toward potential anxiety-inducing stimuli in the environment (Linden and Zubrägel 2000; Turowsky and Barlow 2000). Patients suffering from social phobia (Juster et al. 2000) have been found to have a lack of social competence as well as a cognitive perception of their own inadequacy and lack of social skills. Social phobia may possibly also result from a genetically based, unconditionally anxiety-inducing stimulus related to social hierarchy or "pecking order."

Inborn unconditioned stimuli of this type are, indeed, the central pathogenetic factor of the monophobias (Öst 2000), such as those relating to spiders, snakes, mice, or birds; what all of these phobias have in common is that rapid rustling movements are followed by an unconditioned fright reaction.

4 Treatment of Anxiety Disorders

4.1 Pharmacotherapy

Nearly all psychotropic drugs have anxiolytic effects (Linden et al. 1988). This is true not only of benzodiazepines and 5-HT_{1a} antagonists, which are classified as anxiolytics, but also of antidepressants, whether sedating (e.g. trimipramine) or nonsedating (serotonin reuptake inhibitors, such as paroxetine, and monoamine oxidase (MAO) inhibitors, such as moclobemide). Sedating neuroleptics of low potency (e.g. thioridazine), as well as highly potent neuroleptics in low doses (e.g. fluspinilene), also have anxiolytic effects. There are also a large number of herbal drugs with anxiolytic effects, both sedating (e.g. baldrian) and nonsedating (e.g. kavain) (Kapfhammer 1995; Wurthmann 1995; Laux 1995; Volz 1995; Kasper 1995). Both the existence of so many different substances that may be used to treat the anxiety disorders and the diversity of the disorders themselves are reflections of the multiplicity of biological and psychological mechanisms participating in anxiety and further indicate that their mechanisms of action are highly nonspecific.

Benzodiazepines, acting through the benzodiazepine GABA receptor, open a chloride channel in the cell membrane and thereby bring about a hyperpolarization of the membrane potential, which makes the cell less responsive to excitatory synaptic input. Benzodiazepines act immediately and are thus highly effective in the acute treatment of anxiety. They are less suitable for the long-term treatment of anxiety disorders, though some authors do regard long-term benzodiazepine administration as an option in special cases (Rickels et al. 1982a,b, 1985, 1993b; Ballenger et al. 1988; Burrows et al. 1993; Curtis et al. 1993). The high efficacy of the benzodiazepines and the immediate onset of their effect give rise to the danger that patients may become psychologically dependent. There are patients with agoraphobia, for example, who will not leave the house unless they have the medication in their pocket.

The antidepressants are currently regarded as the agents of choice for prophylactic long-term treatment of the anxiety disorders. Either tricyclic antidepressants, such as imipramine (Kahn et al. 1986; Rickels et al. 1993a), or serotonin reuptake inhibitors (Sternbach 1990; Schneier et al. 1990; Black et al. 1993) may be used. Data derived mainly from studies of 6 weeks' to 6 months' duration reveal that syndrome scores on anxiety scales decline significantly over the course of treatment. Tricyclic antidepressants, serotonin reuptake inhibitors, and MAO inhibitors are all effective

against panic disorders, agoraphobia, generalized anxiety disorders, and social phobia.

4.2 Psychotherapy

Anxiety disorders have played a major role in psychotherapy ever since Freud (Freud 1926). The basic psychoanalytical model of anxiety postulates that certain situational conditions induce anxiety because their unconscious processing recalls previously repressed traumatic situations to memory, usually events that took place in childhood (Brenner 1982; Rocah 1991). Thus phobic symptoms, or other expressions of anxiety, are to be understood as expressions of latent content, whose analysis can then lead to a resolution of the anxiety neurosis (Lewin 1935). Though quite elaborate theories of the treatment of anxiety have been developed, no controlled studies on the psychoanalytical and psychodynamic treatment of the anxiety disorders are available to date, and the effectiveness of such methods thus remains a matter of speculation.

The current state of the empirical literature suggests that anxiety disorders should be regarded as a primary indication for cognitive behavioral therapy (Margraf 2000). The underlying principle of the therapeutic intervention is the so-called vicious circle of anxiety. In this model, external stimuli, perceptions, cognitive judgments, physiologic and psychological reactions, and behavior are all regarded as components of a single feedback loop. The explanatory power of this approach is relevant not only in the theoretical sense, but also for the patient. The patient, bearing this model in mind, can observe how certain stimuli lead to the evocation of certain thoughts and associations, which, in turn, lead to excitatory reactions, to the experience of anxiety, and, finally, to the corresponding behavioral consequences. As the latter often consist of flight and avoidance behavior, the model further explains why anxiety becomes generalized, rather than subsiding, and grows ever more intense through a process of continued self-reinforcement.

After individual behavioral analysis with reference to the vicious circle of anxiety, the most important component of the next phase of therapy is the so-called reframing process, through which subjective experience is given a new meaning. Physical reactions that may themselves induce anxiety, such as cardiac palpitations, are discussed in detail with the patient, their a priori interpretations are analyzed, and alternative interpretations are suggested. This process results in a reattribution of the patients' personal reactions. Then, in a further step, the patient tries to control anxiety reactions by internal dialogue and other coping strategies. An important part of this form of treatment is the reorientation of the patient away from anxiety-producing stimuli toward his or her own reactions, so that so-called reaction management can take place.

Once this phase of treatment is completed, the next, decisive step is a confrontation with anxiety-inducing situations in the framework of exposure exercises, the purpose of which is to enable the application of the learned coping mechanisms in real-life situations and thus give the patient confidence in his or her own ability to deal with anxiety and to overcome the situations that induce it. It is a common mistake to assume that confrontation alone reduces anxiety; in fact, it is more likely to lead to a reinforced learning of anxiety. Many empirical studies have now shown that behavioral therapy, when performed as recommended, can yield lasting therapeutic success in approximately 80% of agoraphobic patients so treated (Clum 1989; Margraf and Schneider 1989; Chambless and Gillis 1993; Clum et al. 1993; Clark 1994; Emmelkamp et al. 1994; Hollon and Beck 1994).

The treatment of generalized anxiety disorder (Brown et al. 1993; Turowsky and Barlow 2000; Linden and Zubrägel 2000) is primarily focused on the typical "sensitizer orientation" of these patients and the catastrophizing cognitions attached to it. These patients do not realize at first that they have an anxiety disorder; rather, they believe that their perception of multiple dangers in the environment is correct. Thus the first step of treatment is to make the patient understand that he or she suffers from a perceptual stereotype that is not limited to a particular situation, i.e. that any situation is seen only in terms of the disasters it may produce. The patients learn to recognize that many other people deal with everyday situations in a far more relaxed way, and they often come to wish that they, too, could do so. Building on this wish, the therapist works with the patient to change both the perceptual stereotype and the associated expectations of disaster. This is done by means of internal dialogue and exercises to promote the alternative direction of attention or the self-observation of catastrophizing conditions. Finally, exposure exercises are carried out, both in sensu and in real life, in which the patients learn to control thoughts of disaster and the accompanying emotions (e.g. "My daughter is on vacation and hasn't phoned yet today; she might have had an accident").

A number of well-controlled studies are now available in which different forms of intervention are compared with one another with respect to clinical efficacy (Fisher and Durham 1999). Remission rates of approximately 70% were obtained with either of two types of cognitive behavioral therapy specifically focusing on coping with anxiety and on changing

catastrophizing cognitions. Interestingly, behavioral-therapy strategies directed toward external problems, rather than the central pathogenetic process of worrying behavior, as well as psychodynamic interventions aimed at the uncovering of problems from a historical perspective turned out to yield even lower rates of remission than placebo therapy. The experience to date with group therapy has also failed to show an adequate therapeutic effect.

The treatment of social phobia is multidimensional, in accordance with the theoretical models of its underlying pathogenesis (Hoppe and Heimberg 1993; Juster et al. 2000). Its initial emphasis is the analysis of automatic thoughts in social situations. The patient's fantasies of failure, self-reproach, and inadequacy are identified. In the next step, typical cognitive distortions are dealt with, such as all-or-nothing thinking, magnification (i.e. the exaggerated perception of one's own minor mistakes as major disasters), and arbitrary inferences (i.e. the unfounded perception of reference to oneself in any situation, e.g. the patient connects the boss's bad mood to him- or herself, without examining the issue any more closely). In a further step, these dysfunctional cognitions are replaced with alternative ones. Thus, in social phobia, too, confrontation exercises play an important role.

Moreover, possible deficiencies of social competence must be worked on, though the basic problem in most cases is not an actual lack of social skills, but an inhibition in the application of skills that are, in fact, present. Effective treatment, therefore, must go beyond exposure exercises to include exercises aimed at a general improvement of "experienced self-effectiveness." Self-confidence is understood, in this sense, as a self-attribution. The goal of the treatment of social phobia is a change in the patient's self-image.

5 Concluding Remarks

Anxiety disorders are among the common mental illnesses (Achberger and Linden 1998; Linden 1993). The danger is, however, that their effect on patients and on society may be underestimated. One reason is that these disorders are often not particularly conspicuous; in social phobia, for example, patients are even characterized by their high degree of unobtrusiveness. A further reason is that the patients' anxiety may merely evoke astonishment or amusement, because the observer would feel no anxiety himself in such situations (e.g. a subway train) and thus lacks any understanding of the patients' reaction. Yet anxiety disorders can destroy these patients' lives.

Patients with agoraphobia can no longer fulfill their occupational, social, and family responsibilities. They may become completely disabled and bound to their own home. Patients with generalized anxiety disorders are subject to constant stress and worry and are thus in danger of creating becoming a burden to their social partners, which, in turn, results in further negative reactions. Patients with social phobia are unable to pursue a career because they always come out behind in competitive situations.

In view of the high prevalence of these disorders, their severity, and their significance in society as a whole, the development of pharmacologic and psychotherapeutic treatments with comparatively high rates of success must be considered one of the major therapeutic advances of recent years.

Post-traumatic Stress Disorder

1 Introduction

Society is increasingly affected by all types of human violence, including rape, robberies, assault, natural disaster, and accidents. This can leave the individual with intense terror, fear, and paralyzing helplessness. About 60% of men and 50% of women have experienced psychological trauma (defined as threat to life of self or significant other) at some time in their lives. As many as 39% of these individuals exposed to a traumatic event will develop post-traumatic stress disorder (PTSD). The lifetime prevalence of PTSD in the United States is estimated at 7.8% and is twice as common in women as in men. This is more than twice the prevalence of bipolar disorder or schizophrenia. PTSD is strongly comorbid with other lifetime psychiatric disorders. More than one third of people with an index episode of PTSD fail to recover even after many years (Kessler et al. 1995). PTSD has long been recognized as being related to wartime experiences, and only more recently has been recognized as being associated with other types of trauma (Weisaeth and Eitinger 1993; Wilson 1994; Saigh and Bremner 1999). PTSD is increasingly recognized as being present in diverse cultures (Kleber et al. 1995; I.M. Allen 1996). The diagnosis of PTSD was first included in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) in 1980 (APA 1980), where it was categorized as an anxiety disorder. Its first appearance in the *International Classification of Diseases* (ICD) is of more recent date (WHO 1992).

Recently, there has been a rapid expansion of empirical studies that have led to a significant increase in our knowledge of the phenomenology and biology of PTSD (Ursano et al. 1994). Over 4000 papers have been published on PTSD in the last 35 years, as well as numerous books and dissertations (see Fig. 1). The *American Journal of Psychiatry* has shown the greatest interest in PTSD overall, publishing 221 papers on this disorder in the last 10 years alone, by far more than any other journal in the field of general psychiatry. *Biological Psychiatry* has showed a marked increase in publication in PTSD in recent years. The *Journal of Traumatic Stress* is a specialty journal that started in 1987 and deals with all PTSD-related issues. This chapter will highlight these findings in PTSD and give a comprehensive overview on the history, diagnosis, epidemiology, and treatment of the disorder.

2 History and Conceptual Development of the Disorder

2.1 From "Soldier's Heart" to Post-traumatic Stress Disorder

Although the diagnosis of PTSD was only recently established, there is a long history of observations of the effects of stress on the individual (for a review, see Saigh and Bremner 1999). Much of the history of stress and psychiatric diagnosis has been determined by ebb and flow of attention paid to this area with each new major military conflict. During the American Civil War, DaCosta (1871) first described a syndrome involving symptoms of exhaustion and increased physiological responsivity ("soldier's heart" or DaCosta's syndrome) seen in soldiers exposed to the stress of war. DaCosta felt that this syndrome was a physical disorder involving the cardiovascular system that was caused by the extreme stress of war. DaCosta's approach was similar to theories of the time advanced by Kraepelin (1919), who also believed that schizo-

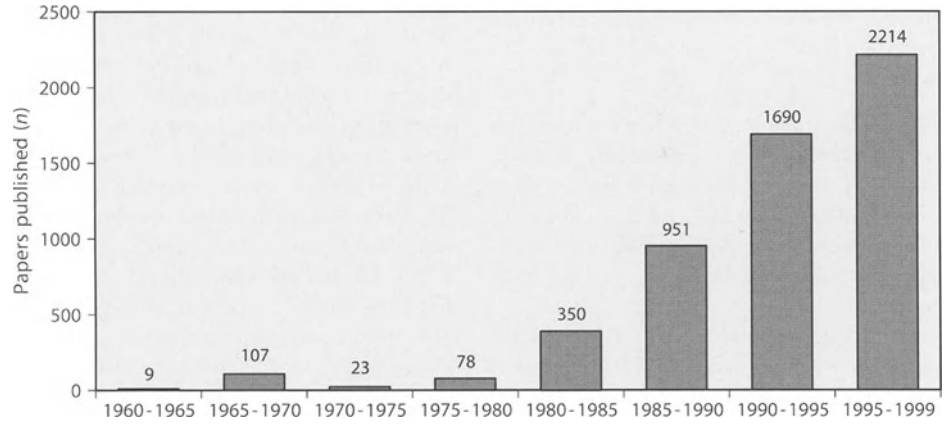

Fig. 1. Increase in the number of publications in the field of PTSD over time (1960–1999)

phrenia had its basis in the constitution, leading to abnormalities in the brain and physiology. Brain-based explanations of psychiatric disorders left the scene at the turn of the century with Sigmund Freud. Freud originally believed that his famous case of Anna O. was a victim of exposure to traumatic sexual experiences in childhood and only later changed his views into the theory that fantasies, and not the reality, of childhood sexuality led to mental illness (Nemiah 1998). His final formulation of psychodynamic theory did not incorporate environmental events such as traumatic stress in the development of mental disorders.

During the First World War, the large number of psychiatric casualties of combat forced attention on the effects of the stress of war and led to the description of "combat fatigue," or "physioneurosis." Experimental studies revealed intolerance in these patients to carbon dioxide and exaggerated psychological and physiological responses to epinephrine. Psychiatrists described phenomena such as amnesia on the battlefield, where soldiers forgot their name or who they were. After the war, however, the effects of combat stress on the mind were soon forgotten. With World War II, interest in the mental health effects of the stress of war was revived. Again, psychiatrists described amnesia and other dissociative responses to trauma (Sargent and Slater 1941; Torrie 1944). Studies in Danish police interned in German concentration camps noted symptoms in the survivors including recurrent memories of the camps, feelings of detachment and estrangement from others, sleep disturbance and hyperarousal, as well as problems with memory and concentration (Thygesen et al. 1970). Abraham Kardiner, who treated many casualties in World War II, which he described in *Traumatic Neuroses of War* in 1941, recognized a set of symptoms that underlies the current conceptualization of PTSD, a condition he referred to as "physioneurosis":

1. Preoccupation with the trauma
2. Constriction of personality
3. Atypical dream life
4. Startle response
5. Irritability

Survivors of death camps in this war were found to have symptoms of anxiety, motor restlessness, hyperarousal, sleeping difficulties, nightmares, fatigue, feeling worse with traumatic reminders, and a constant preoccupation with recollections of persecutory experiences. These symptoms became known as the "concentration camp syndrome."

The experience of the Second World War was still fresh in the minds of psychiatrists when the first edition of the *Diagnostic and Statistical Manual* (DSM-I), nicknamed the "Grey Manual," was formulated in 1952 (APA 1952). This led to the addition of gross stress reaction in DSM-I. Gross stress reaction described a series of stress-related symptoms in response to an extreme stressor that would be traumatic for almost anyone. This may have stemmed from the experience of military psychiatrists in the Second World War, who observed during the war that many normal men were having mental breakdowns in the face of combat. However, gross stress reaction specified that the individual must have a normal prestressor personality and that the symptoms should naturally resolve with time. This disorder did not take into account the fact that individuals with preexisting psychiatric disorders may develop a new disorder that is specifically related to the stressor, or that acute responses to stress can translate into long-term pathology. It is as if gross stress reaction was a response to the reality that extreme stressors such as war can lead to psychiatric outcomes that are not secondary to "bad personalities" (military psychiatrists in the Second World War had tried in vain to find premilitary personality traits that would help them predict who was most vulnerable to the stress of combat). Embodied in gross stress reaction was the ambivalence that has pervaded psychiatry until the current time about whether stress has merely transient effects or whether it can lead to permanent psychopathology.

It was perhaps the forgetting of the horrors of the Second World War that resulted in gross stress reaction being dropped from DSM-II in 1968 (APA 1968). Oddly enough, this took place just in the same year as the major outburst of the Vietnam War. The gross stress reaction was replaced in DSM-II by "transient adjustment reactions." These included acute reactions to overwhelming environmental stress, but did not name any specific catastrophes, such as war, death camps, or Hiroshima. Combat cropped up in one line, as an example of the adult type of adjustment reaction: "fear associated with military combat and manifested by trembling, running and hiding." The important work of Kardiner (1941), *Traumatic Neuroses of War*, of Grinker and Spiegel (1945), *Men Under Stress*, and the impressive follow-up studies conducted by Archibald and Tuddenham (1965) were overlooked by many. These studies suggested that the argument of preexisting disorders as an explanation for traumatic stress disorders was largely irrelevant. It was only later in the aftermath of the Vietnam War that the *lasting* effects of traumatic stress on the mind were recognized. Researchers and clinicians such as Robert Jay Lifton, Chaim Shattan, and Charles Figley argued at that time that the stress of war itself led to psychopathology as opposed to factors such as "bad character" (preexistent and preceding the war) (see Figley 1978a). This was the background leading to the inclusion of PTSD (with both acute and chronic types) as a disorder in DSM-III in 1980. In the DSM-III-based criteria for

PTSD, there was fortunately resistance by Nancy Andreasen (Andreasen et al. 1971; Andreasen 1985) and others to those who argued against the uniqueness of individual traumas. For example, at the time, some advocated a "Vietnam syndrome" which would describe a constellation of symptoms unique to Vietnam veterans, while others have argued for "post-rape syndrome" or specific childhood sexual abuse syndromes (ideas for which there is little empirical evidence). This resistance was indispensable to the scientific advancement of the study of traumatic stress.

DSM-III represented a departure from the approaches to stress represented in earlier versions of DSM. DSM-I and DSM-II followed the view that, if the patient had good adaptive capacity, his or her symptoms usually receded as the stress diminished. Both DSM-I and DSM-II added that, if the symptoms persisted "after the stress was removed, the diagnosis of another mental disorder was indicated." A neurotic or psychotic label replaced the diagnosis of stress disorder or adjustment reaction. Stress disorders were held to be transient and reversible, with no rubric for the continuance of stress-induced symptoms as such. With DSM-III-based PTSD, there was finally a diagnosis that recognized the lasting pathological effects of traumatic stress. DSM-III also found a place for code 308.33 delayed catastrophic stress disorder following an asymptomatic interval ("incubation period"). This phenomenon was seen by clinicians, resembling ongoing, chronic, low-grade, or latent subclinical disturbance that years later can be triggered into acute disorder by events which symbolize or recapture the original trauma (helicopters, smells, war in Kosovo), probably best understood by a model of stress sensitization.

Some authors still noted gaps in the classification of PTSD in DSM-III. These were related to the etiology of the disorder, its natural history, and diagnostic specificity. A demand was made for research in theoretical issues and to collect empirical data in order to be more precise in later diagnostic descriptions and understanding (Green et al. 1985). DSM-IIIR (APA 1987) included specification of generic characteristics of traumatic stressors, clearer organization of symptoms around three dimensions of stress response (reexperiencing, avoidance and numbing, and physiological arousal), inclusion of symptoms specific to children, and specification of onset and duration of the disorder (Brett et al. 1988).

2.2 Definition of Psychological Trauma: The A Criterion

One of the most vexing issues in the field of traumatic stress is the Criterion A problem, or the definition of psychological trauma. In earlier versions of DSM, this was centered on questions of how to define a traumatic event and whether experiencing a traumatic event should be a requirement for a PTSD diagnosis. The definitions in DSM-III and DSM-IIIR defined psychological trauma as an event "outside the range of human experience" and required the presence of psychological trauma for the diagnosis. This definition seems unsatisfactory, however, because traumatic events are actually fairly common. For example, a large epidemiological study found that 60% of men and 51% percent of women experienced at least one traumatic event in their lives (Kessler et al. 1995). Other epidemiological studies showed similar prevalence figures (for a review, see Acierno et al. 1999). In response to these concerns, a two-part definition for DSM-IV was developed, where the first part was "the person experienced, witnessed or was confronted with an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others," which distinguishes traumatic events from ordinary stressors. The second part required that the person's response involved intense fear, helplessness, or horror, giving recognition to the fact that an individual's subjective response is an important dimension to consider in defining a traumatic event. Although the definition of psychological trauma continues to be a matter of debate, there appears to be a growing consensus that traumatic events can be distinguished from ordinary stressors and that the use of specific criteria for psychological trauma serves a useful gatekeeping function that preserves the meaningfulness of the disorder as a distinct diagnostic entity and prevents trivialization of the suffering of survivors of overwhelming stressors.

2.3 Classification Systems: DSM Versus ICD

The *International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD) developed in parallel with DSM over the past half-century. This classification system was originally formalized as the *1892 Bertillon Classification List of Causes of Death.* ICD is meant to cover the worldwide classification of diseases and has been used more in Europe than DSM. In 1948, the World Health Organization (WHO) decided to include mental disorders in the sixth revision of the ICD (ICD-6; WHO 1948), since many psychiatric hospitals were dealing with a nomenclature that did not appropriately describe the majority of the cases handled. DSM, which was developed in the United States, has only focused on disorders of mental health.

The formulation of stress-related psychopathology in the later ICD systems and in the DSM classification is

based upon attempts to describe post-traumatic psychopathology. The perspective that traumatic reactions were short-lived responses in essentially normal individuals with no premorbid psychopathology can be originally found in both the international and American classifications. Prototypes of PTSD were called "acute situational maladjustment" in ICD-6 and "transient situational personality disturbance" in DSM-I. There were no changes in the mental disorders section in ICD-7. In ICD-8 (WHO 1968), there was a rephrasing to "transient situational disturbance." DSM-II was mostly based on the mental disorder section of this eighth edition of ICD. DSM-II focused on the diagnosis "adjustment reaction" and specified the phase in life to which this was related. In DSM-III and ICD-9, there were significant revisions of the conceptualization of post-traumatic stress reactions, with the most important change being the notion that stress disorders were no longer acute responses in healthy individuals. Traumatic stress was considered to cause chronic reactions, and responses to stress were considered to occur with previous and simultaneous conditions. Another significant change was the categorization of the diagnosis in the anxiety disorders section of DSM-III. ICD went along the same line; however, it also incorporated a variation of PTSD in its classification. In ICD, under Sect. F62.0, there is also a diagnosis named "enduring personality changes after catastrophic experience" alluding to some variation of a personality disorder. The American approach was to consider anxiety a core phenomenon of both PTSD and obsessive-compulsive disorder (OCD), whereas the Europeans regarded anxiety as a common and nonspecific feature of many disorders and located OCD and PTSD in their classification system in ICD on the basis of other features.

The most recent version of ICD is ICD-10 (1992). This version now consists of a three-volume work, with one section on mental health. ICD-10 was field-tested in over 100 institutions in 40 countries, making this book the product of a very large research effort. PTSD is coded as F43.1 and subsectioned under "neurotic stress-related and somatoform disorders" and further under "other anxiety disorders and reactions to severe stress," where it is grouped with "acute stress reaction," "adjustment disorders," "other reactions to severe stress," and "reaction to severe stress unspecified." PTSD is defined as follows:

A mental disorder characterized by a preoccupation with traumatic events beyond normal human experience; events such as rape or personal assault, combat, violence against civilians, natural disasters, accidents or torture precipitate this mental disorder; patients suffer from recurring flashbacks of the trauma and often feel emotionally numb, are overly alert, have difficulty remembering, sleeping or concentrating, and feel guilty for surviving.

ICD-10 defines the A criterion "beyond normal human experience," whereas DSM-IV is more stringent. Although an essential criterion, the A criterion does not predict PTSD or the course of PTSD. As stated earlier, the latest revision of ICD-10 has a wider variety of diagnoses for traumatic reactions, with the inclusion of enduring personality changes after catastrophic experience (F62.0) (WHO 1992). In their latest releases, both classification systems seem to be more in line in their description of PTSD (see Table 1). However, in a comparison of 12-month prevalence of PTSD using ICD-10 and DSM-IV criteria , Peters et al. (1999) found

Table 1. Comparison of ICD and DSM diagnoses in traumatic stress over time

Year	ICD	DSM
1948	Acute situational maladjustment (ICD-6; WHO 1948)	
1952		Transient situational personality disturbance; gross stress reaction; adult situational reaction; adjustment reaction of infancy, childhood, adolescence, or late-life (DSM-I; APA 1952)
1968	Transient situational disturbance (ICD-8; WHO 1968)	Adjustment reaction of infancy, childhood, adolescence, or late-life (DSM-II; APA 1968)
1977	Acute reaction to stress with predominant disturbance of emotions, consciousness, or psychomotor disturbance or mixed (ICD-9; WHO 1977)	
1980		Post-traumatic stress disorder (DSM-III; APA 1980)
1987		Post-traumatic stress disorder (DSM-III-R; APA 1987)
1992	Acute stress reaction; post-traumatic stress disorder; enduring personality changes after catastrophic experience (ICD-10; WHO 1992)	
1994		Acute stress disorder; post-traumatic stress disorder (DSM-IV; APA 1994)

that, using the ICD criteria, the prevalence was more than double (3% using DSM-IV and 7% using ICD-10 criteria). Almost half of the discrepancies between the classification systems could be explained by the F criterion in DSM-IV requiring clinically significant distress or impairment in social, occupational or other important areas of functioning. Another factor that accounted for 18% of the discrepancies was the C criterion in DSM-IV (see the Appendix for an overview of the diagnostic criteria for PTSD; see also Lundin and Lotfi 1996).

3 Diagnostic Features

3.1 Traumatic Stress: The A Criterion

PTSD is the only psychiatric condition whose definition demands that a particular stressor precede its appearance. PTSD is characterized by specific symptoms which develop following exposure to psychological trauma, defined as a situation in which a person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others, and where the person's response involved intense fear, helplessness, or horror. According to DSM-IV (APA 1994), PTSD can result from combat, violent personal assault (sexual assault, physical assault, robbery, mugging), being kidnapped, being taken hostage, terrorist attack, torture, incarceration as a prisoner of war or in a concentration camp, or natural or manmade disasters (severe automobile accidents, being diagnosed with a life-threatening disease, or other threat to life) (e.g. Tucker et al. 1997; Foa 1997; Schnurr and Spiro 1999; Walker et al. 1999; Alonzo 1999; Conlon et al. 1999). Sexually traumatic events may include developmentally inappropriate sexual experiences without threatened or actual violence (e.g. Davidson et al. 1998a). PTSD may also be induced by observing events such as the serious injury or unnatural death of another person due to violent assault, accident, war, or disaster or unexpectedly witnessing a dead body or body parts (e.g. Zisook et al. 1998; Ursano et al 1999a). Traumatization can also occur where the individual receives information about the stressful experiences of others such as personal assault, serious accident or serious injury experienced by a family member or a close friend, or learning that one's child has a life-threatening disease, if this is associated with intense fear, helplessness, or terror (e.g. Manne et al. 1998). Psychological trauma may occur as a single episode or repetitive ongoing trauma (as sexual or physical abuse); however; studies demonstrate that cumulative effects of trauma are an important determinant of risk for PTSD (Bremner et al. 1993a; Bremner et al. 1995a).

3.2 Diagnostic Categories

Symptoms of PTSD are divided into three categories:

1. Reexperiencing of the event
2. Avoidance of stimuli
3. Persistent symptoms of increased arousal

At least one symptom of reexperiencing is required for the diagnosis, including recurrent and intrusive distressing recollections of the event, recurrent distressing dreams of the event, acting or feeling as if the traumatic event were recurring, intense psychological distress at exposure to internal or external cues that resemble an aspect of the traumatic event, or physiological reactivity upon exposure to internal or external cues that symbolize an aspect of the traumatic event. Three avoidance symptoms are required, including avoidance of stimuli associated with the trauma and numbing of general responsiveness by efforts to avoid thoughts, feelings, or conversations associated with the trauma, efforts to avoid thoughts, feelings, activities, places, or people that arouse recollections of the trauma, inability to recall an important aspect of the trauma, markedly diminished interest or participation in significant activities, feeling of detachment or estrangement from others, restricted range of affect (e.g. unable to have loving feelings), a sense of a foreshortened future (e.g. does not expect to have a career, marriage, children, or a normal life span). The third cluster consists of persistent symptoms of increased arousal that were not present before the trauma. At least two of these symptoms are required, including difficulty falling or staying asleep, irritability or outbursts or anger, difficulty concentrating, hypervigilance, or an exaggerated startle response. The duration of the disturbance needs to be more than 1 month and the symptoms must be associated with significant distress or impairment in social, occupational, or other areas of functioning. DSM categorized three subtypes of the disorder: acute, chronic, and a subtype with delayed onset. PTSD is described as delayed onset if the symptoms appear more than 6 months after the event has passed (an overview of diagnostic criteria is given in the Appendix).

Two typical cases of PTSD are given below.

- *Case example I:* A 27-year-old female reported freezing responses, anxiety, and uncontrollable flashbacks. She stated she sometimes lashes out at

her children for no reason. She sleeps 4 h a night and weighs 245 lb. She is living with her boyfriend and her two children aged 13 and 8. Her eldest child was born when she was 13 years old. She states that her PTSD symptoms gradually became worse as she became older. She hesitated volunteering for the clinical research we were conducting, but did so because she felt she was in despair. She disclosed that her current feeling of despair is the result of experiencing and witnessing traumatic events during childhood (e.g. she was raped at age 6; she witnessed several shootings in the neighborhood where she was living and saw her brothers being molested by strangers; her youngest brother was once kidnapped and was found days later bruised and naked). She is the eldest of four children and has three brothers. All her brothers are currently into drugs and deal on the street. She stated that her brothers may have fathered several children, but she is uncertain of this for sure. She disclosed that her father "never cared" for her. She reported that both her father and mother are "crackheads." She begins crying as she says "my life has holes in it." She says that she has no memory for things others tell her she has done as a teenager. No matter how hard she tries, the memories do not come back. She was told she was dating men and that she often went out with them and slept with them.

She attempted suicide when she was 16 years, but was never hospitalized at the time of the attempt. She has been in counseling in the past. She is currently employed as a nurse assistant and works 80–100 h per week. She stated, "I have to keep going, for if I don't I'll fall apart." She reports she is afraid of being alone. Recently, she smelled the scent of grease and fried eggs, which overwhelmed her and placed her in a flashback. As a result, she "lost control," dissociated, and became extremely frightened. This apparently is related to one of the traumatic scenes from her childhood when she was raped near a kitchen by a neighbor. He had been baking eggs. It happened 3 days before her birthday. She now "hates" her birthday and spends it alone away from home. She reports she has always had a clear memory of this incident, stating, "that is what made it all start," referring to her current symptoms.

She reported later that after disclosing information about her childhood trauma to the phone screener, she showered for 1 h. In addition, she wanted her boyfriend to be with her all the time, did not want to be alone at night, and was thinking of binding a bell around his legs so that she would hear him if he were to leave.

- *Case example II:* A 50-year-old Vietnam veteran seeks help on the encouragement of his wife. He had always tried to avoid clinical treatment, stating he felt fine periodically attending a Veterans Administration (VA) support group. His wife urged him to participate in our clinical research as his irritability has been gravely impacting his family. She felt that the news about the Kosovo war had triggered his irritability and his own memories of war. Upon our meeting, he presented as a friendly man, cooperative and quiet. He complained of irritability and of often lashing out. He reported concentration problems at work, memory problems, crying spells, and often wanting to be left alone. He felt easily startled, jumpy, and on edge. His stated his sleep has always been severely disruptive as he sleeps only 3–4 h a night, frequently wakes up sweating, derealized and extremely afraid. This had been going on for the last 30 years, unchanged. He disclosed that after his return from Vietnam, the relationship with his fiancée had ended. Soon after the breakup, he married his current wife, who, at the time, was actively protesting against the war. With her he had two children. They never discussed the war in any way until years later. After returning from Vietnam, he began working for a telephone company and continues to this day, stating he feels he cannot perform on another level. He complains about his increasing forgetfulness. He also reports suicidal thoughts, but has never acted upon them. He cannot picture himself years from now, feeling his future has been taken away by Vietnam. He disclosed that he was on the frontline during the war, seeing several of his fellow soldiers die or get wounded. He reported that, during that time, he often imagined himself dead during active combat. He then pictured himself saying goodbye to his family, which resulted in him feeling detached from his body. He still wears some representation of Vietnam to show he is a veteran, but does not want people to comment on it. He avoids going to any annual ceremony. He reported that he avoids talking about Vietnam because it is "too intense," that he "cannot cope" as it has left him feeling irritable for the remainder of the day when speaking about it in the past. He is convinced he will die a premature death.

The longitudinal course of PTSD was retrospectively assessed in a sample of Vietnam combat veterans with PTSD (Bremner et al. 1996a). The onset of symptoms in this group typically occurred at the time of exposure to combat trauma in Vietnam and increased rapidly during the first few years after the war. Symptoms plateaued within a few years after the war, following which the disorder became chronic and unremitting. Hyperarousal symptoms such as feeling on guard and feeling easily startled developed first, followed by avoidant symptoms and finally by symptoms from the

intrusive cluster. Onset of alcohol and substance abuse typically was associated with the onset of symptoms of PTSD, and the increase in use paralleled the increase in symptoms. Patients reported a tendency for alcohol, marijuana, heroin, and benzodiazepines to make PTSD symptoms better, while cocaine made symptoms in the hyperarousal category worse. No relationship was found between treatment interventions and the natural course of PTSD. Figure 2 shows the longitudinal course of PTSD in this patient sample.

Symptoms of PTSD generally become evident within the first 3 months following the trauma; sometimes acute stress disorder (ASD) develops into PTSD. ASD is a rather similar disorder compared with PTSD that may occur immediately after traumatic stress exposure and may last from 2 days to 4 weeks. ASD also includes symptoms of dissociation, such as derealization and depersonalization, as well as one symptom from each of the PTSD symptom clusters. Both the occurrence of dissociative symptoms at the time of trauma and their duration afterward predict later PTSD, as well as dissociative reactions to subsequent trauma (Bremner and Brett 1997; Classen et al. 1998). Brewin et al. (1999) found that ASD diagnosis predicts 83% of cases of PTSD at 1 year. This study also found that reexperiencing and hyperarousal (but not avoidance) were equally adept at predicting development of chronic PTSD. Most individuals who, shortly after trauma, express symptoms of PTSD recover within 1 year of their traumatic experiences (Kulka et al. 1990). In contrast, those who remain ill for 1 year rarely recover completely (Freedman et al. 1999). In many individuals, PTSD can be a chronic disorder that they take with them to their graves, putting a burden on physical and mental health and also on health providers (Blank 1993; Friedman and Schnurr 1995; Solomon and Davidson 1997).

3.3 Conditions Associated with Post-traumatic Stress Disorder

Psychological trauma can have can have far more pervasive consequences than the current PTSD criteria would suggest. A close relationship exists between PTSD, dissociation, somatization, and a variety of other problems. Some authors have argued that chronic interpersonal trauma, especially with a childhood onset such as incest, physical abuse, torture, or neglect, leads to a much broader range of symptoms, described as complex PTSD (Herman 1992; Van der Kolk et al. 1996). Individuals with PTSD may also experience profound feelings of guilt and may blame themselves for surviving when others did not, keeping the guilt inside. This conflict, in its most acute presentation, typically resembles an agitated depression and is described as being associated with frequent dreams of friends dying (e.g. in battle) and by avoidance of interpersonal intimacy because they fear the other party may abandon them or die (e.g. Glover 1984; Henning and Frueh 1997). This can also cause phobic avoidance that interferes with daily activities and social interactions. Interpersonal stressors, such as childhood sexual abuse, domestic violence, or being held a hostage or a prisoner of war, may be associated with a constellation of impaired affect modulation, self-destructive and impulsive behavior, dissociative symptoms, feelings of ineffectiveness, difficulties in sexual involvement, shame, despair, or hopelessness. It may also lead to feeling permanently damaged, a loss of previously sustained beliefs, hostility, social withdrawal, feeling constantly threatened, and impaired relationships with others or may induce a change away from the individuals' previous personality characteristics (DSM-IV; APA 1994).

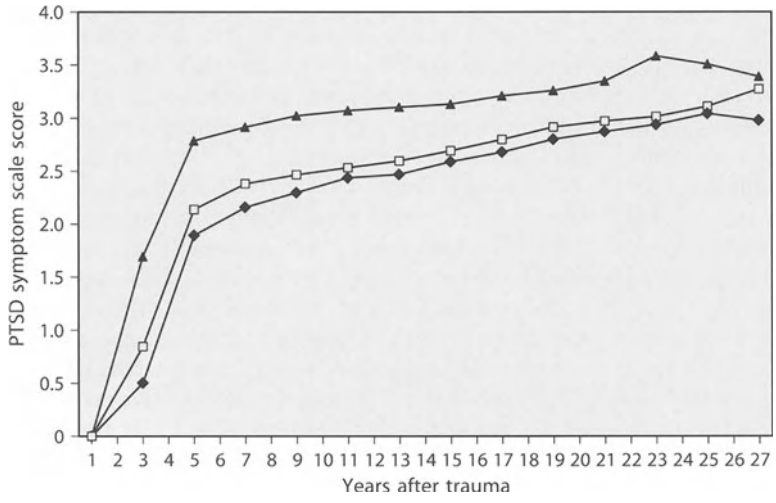

Fig. 2. Longitudinal course in PTSD in a population of Vietnam war veterans. *Triangles*, hyperarousal; *squares*, avoidance; *diamonds*, intrusions

PTSD is also frequently comorbid with other psychiatric disorders, such as depression, substance abuse, and anxiety disorders. These comorbid disorders may predate PTSD, may be related to traumatic stress, or may also be a reflection of inadequacies of our diagnostic schema. For example, data from the National Vietnam Veterans Readjustment Study (Kulka et al. 1990) show that 98% of patients with Vietnam combat-related PTSD have a comorbid lifetime psychiatric disorder. Studies to date show an increased risk for comorbid anxiety disorders (agoraphobia, panic disorder, OCD, social phobia) as well as major depressive disorder, somatization disorder, and substance-related disorder in PTSD (for a review, see Keane and Kaloupek 1997; Weathers and Keane 1999). Clinicians assessing victims of chronic interpersonal trauma need to be particularly aware that the presentation may very well include many other problems than the core symptoms of PTSD. Comorbidity may also reflect a more general vulnerability to psychopathology that renders some individuals more susceptible to developing a variety of disorders, including PTSD (Weathers and Keane 1999).

Depression is one disorder that often occurs in conjunction with PTSD. Workers in the PTSD field have long been forced to explain the "comorbidity" of depression in patients with PTSD. However, Koren and colleagues have used a prospective design to show that depression and non-PTSD anxiety disorders develop in conjunction with PTSD in stress survivors (Koren et al. 1999). This is consistent with other data, e.g. from the National Vietnam Veterans Readjustment Study, which showed that rates of depression and anxiety disorders (as well as alcohol and substance abuse) are increased in combat veterans with PTSD (Kulka et al. 1990). Zimmerman and Mattia (1999) investigated whether an association exists between psychotic subtyping of major depressive disorder and PTSD. They interviewed 500 psychiatric outpatients using the Structured Clinical Interview for DSM-IV. Almost half of these patients had a major depressive disorder ($n = 235$). Nineteen percent of this sample met criteria for PTSD. These results indicate that the presence of psychosis in psychiatric outpatients with major depressive disorder is associated with concurrent PTSD. Clearly, trauma results in a range of outcomes, and although PTSD patients may meet symptom criteria for other psychiatric disorders (e.g. major depression), they may not be equivalent to nontraumatized patients with these disorders.

From a practical assessment perspective, comorbid disorders complicate differential diagnosis and treatment planning. For example, PTSD and depression share anhedonia, sleep disturbance, and impaired concentration as core diagnostic criteria, and there is an arguable overlap in terms of restricted range of affect, impairment in personal functioning, and guilt. Interestingly enough, there are no explicit exclusion criteria for PTSD as there are for other axis I disorders. For an overview of the range of symptomatology among psychiatric disorders linked with trauma, see Fig. 3.

Bereavement or traumatic grief (involving a pathological reaction to loss of a loved one) could be argued to be subsumable under PTSD using current criteria, since loss of a loved one can be included under "threat to life of self or a loved one," although it would not be under previous criteria of an event "beyond the range of human experience" (Prigerson et al. 1999). Murphy et al. (1999) studied the prevalence of PTSD among parents bereaved by the violent deaths of their 12- to 28-year-old children. A community-based sample of 171 bereaved mothers and 90 fathers was followed for 2 years. Both parents' gender and children's causes of death significantly affected the prevalence of PTSD symptoms; twice as many mothers and fathers whose children were murdered met PTSD caseness (full diagnostic criteria) compared with accident and suicide bereavement; symptoms in the reexperiencing domain were the most commonly reported. PTSD symptoms persisted over time, with 21% of the mothers and 14% of the fathers who provided longitudinal data still meeting caseness criteria 2 years after the deaths.

3.4 Dissociative Disorders and Post-traumatic Stress Disorder

The requirement of exposure to a traumatic stressor for PTSD has led to an odd dichotomy over the years between PTSD and other psychiatric disorders. However, now that a strong and well-documented relationship between trauma (especially in early childhood) and development of the dissociative disorders has been established (e.g. Putnam et al 1986; Spiegel and Cardena 1991), the dissociative disorders still need to be theoretically linked with traumatic exposure and somehow integrated with PTSD and ASD. There is ample evidence to support a close integration between these disorders. For instance, we found that 86% of a PTSD sample met criteria for a "comorbid" dissociative disorder (Bremner et al. 1998), while essentially 100% of patients with dissociative identity disorder (DID) meet criteria for PTSD (R. Loewenstein, personal communication). We found that Vietnam combat veterans with PTSD had increased dissociative symptom levels compared to combat veterans without PTSD, and that individuals with dissociative responses to trauma are at increased risk for PTSD (Bremner et al. 1992) and continue to have dissociative responses to subsequent stressors (Bremner et al. 1998).

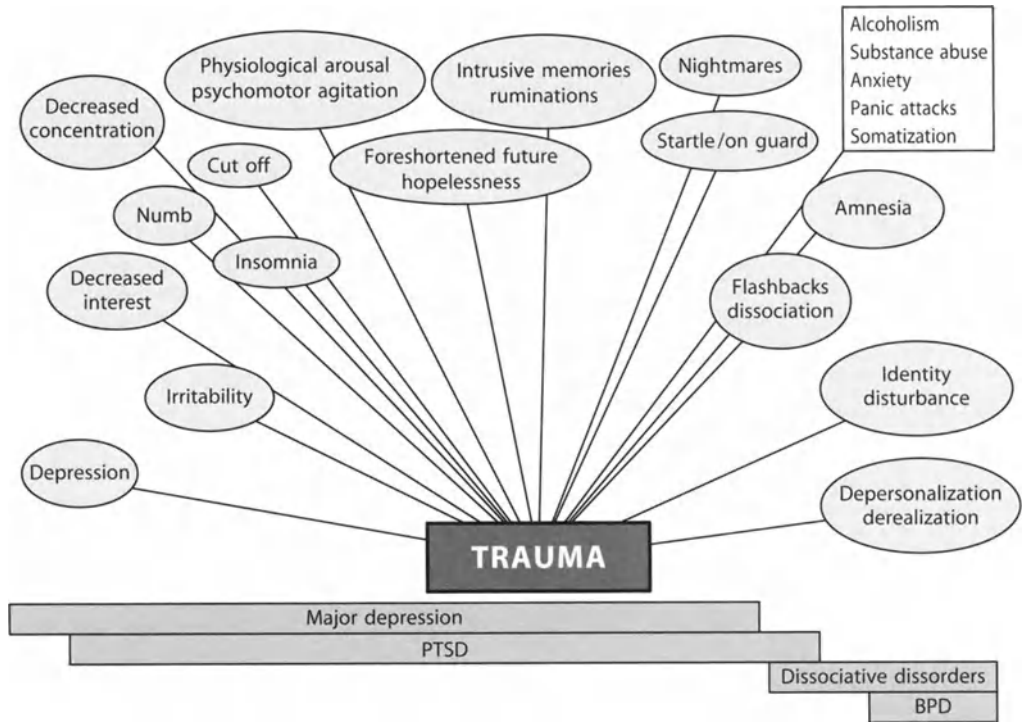

Fig. 3. Range of symptomatology among psychiatric disorders linked with trauma; BPD = borderline personality disorders with the underlying disorder that represents them

Similarly, Marmar et al. (1996) found that dissociative responses to trauma predict long-term PTSD in emergency personnel, while more recent prospective studies have documented the association between dissociative states at the time of trauma and the development of chronic PTSD (Koopman et al. 1994; Shalev et al. 1996a).

The fact that the dissociative disorders are rarely used in routine diagnosis highlights the limitations of our current diagnostic schema for clinical practice. For example, we recently searched the medical records of Psychiatric Hospital Maastricht in The Netherlands for medical chart diagnoses of dissociative amnesia and were only able to find five reported cases in well over 17,000 discharge diagnoses in the period 1980–1999. However, when structured interviews were performed on a ward at the West Haven VA, Connecticut, United States, of patients with a history of exposure to the stress of Vietnam combat and the diagnosis of PTSD, we found that 29% met DSM-IV criteria for dissociative amnesia (Bremner et al. 1998), excluding the possibility that this is an extremely rare disorder. Currently, PTSD is a rule-out for dissociative amnesia. We found that symptom levels from different dissociative symptom areas (e.g. amnesia, depersonalization) are highly correlated with one another (Bremner et al. 1998), challenging the uniqueness of individual dissociative disorders. The artificial separation of dissociative disorders such as dissociative amnesia, dissociative fugue, and depersonalization disorder, however, contributes to the fact that they are not used in clinical practice (Vermetten and Bremner 2000).

3.5 Proposal for Trauma Spectrum Disorders

The validity of diagnostic criteria of PTSD has recently been criticized (Maes et al. 1998a,b). There may be two subtypes of acute trauma response, one primarily dissociative and the other intrusive/hyperarousal, that both can lead to chronic PTSD. The weak predictive value of avoidance raises questions about this symptom cluster. Inspection of the symptoms of avoidance shows that several are in fact dissociative (e.g. amnesia and emotional numbing), others represent the behavioral response to trauma (being cut off from others or avoiding reminders), and some simply do not make sense (i.e. avoiding thinking about the trauma). Sense of foreshortened future is related to the central existential dilemma of the trauma survivor, and it might be questioned whether it should be included as a symptom of a disorder. The current intrusion and avoidance clusters were originally based on the influential theory of alternating waves of intrusions and avoidance proposed in 1976 by Mardi Horowitz in

Stress Response Syndromes. This theory has survived as dogma in the PTSD field for many years, although there has not been supportive empirical data. In a retrospective longitudinal study of the course of symptoms in PTSD patients (Bremner et al. 1996a), we found no evidence for the theory of alternating intrusions and avoidance or for another popular but unsupported theory, that of delayed onset. Rather, symptoms increased soon after the trauma, following which they plateaued and remained largely unchanged over time. In the earlier cited prospective study, Koren et al. (1999) found a similar pattern of increase in symptoms soon after the trauma, followed by a plateau, with no evidence of delayed onset. These findings may finally allow us to lay to rest the theories of alternating intrusion/avoidance and of delayed onset.

An accurate description of psychiatric responses to trauma might be served by the development of a new category of trauma spectrum disorders. This would include both acute PTSD (the current ASD) and chronic PTSD (using revised criteria to be in line with ASD), dissociative identity disorder, conversion disorder, adjustment disorders, and acute and chronic dissociative disorder not otherwise specified (NOS). A diagnosis to capture pathological responses to bereavement (traumatic grief) has been proposed as a separate diagnosis (Prigerson et al. 1999). If traumatic grief is introduced as a diagnosis in subsequent editions of DSM, it should be included in the trauma spectrum disorders. PTSD and ASD would be dropped from the anxiety disorders, since they share little relationship with several anxiety disorders (i.e. OCD).

4 Epidemiology

4.1 Prevalence

When PTSD was first defined in DSM-III (APA 1980), the original stressor criterion characterized traumatic experiences as being outside the range of human experience. However, when the prevalence of such events was systematically examined, it became apparent that trauma is surprisingly commonplace. Several studies have investigated the overall prevalence of traumatic events in the general population, looking both at community-based populations and populations of individuals at high risk for trauma or exposed to events such as natural disasters (Acierno et al. 1999). In a study by Resnick et al. (1993), 4008 adult women randomly selected from a U.S. nationwide sampling were interviewed over the phone. Prevalence of crime and non-crime civilian traumatic events, lifetime PTSD, and PTSD in the past 6 months were assessed by telephone interview. The authors found a lifetime exposure to any type of traumatic event of 69%, whereas exposure to crimes that included sexual or aggravated assault or homicide of a close relative or friend occurred among 36%. Overall sample prevalence of PTSD was 12.3% lifetime and 4.6% within the past 6 months. The rate of PTSD was significantly higher among crime versus non-crime victims (25.8% vs. 9.4%). Norris (1992) assessed the frequency and impact of ten potentially traumatic events in a sample of 1000 men and women drawn from four southeastern U.S. cities. Over their lifetimes, 69% of the sample experienced at least one traumatic event, while 21% experienced a traumatic event in the past year alone. The ten events varied in importance, with tragic death occurring most often, sexual assault yielding the highest rate of PTSD, and motor vehicle accident presenting the most adverse combination of frequency and impact. Numerous differences were observed in the prevalence of these events across demographic groups. Lifetime exposure was higher among whites and men than among blacks and women; past-year exposure was highest among younger adults. When impact was analyzed as a continuous variable (perceived stress), black men appeared to be most vulnerable to the effects of events, and young people showed the highest rates of PTSD.

Another study by Breslau et al. (1999a) involved 2181 individuals in the United States, aged 18–45 years, who were interviewed by telephone to assess the lifetime history of traumatic events and PTSD. PTSD was assessed using a modified version of the DSM-IV and ICD-10 criteria. The risk of PTSD following exposure to trauma was 9.2%. The highest risk of PTSD was associated with assaultive violence (20.9%). The trauma most often reported as the precipitating event among individuals with PTSD (31% of all PTSD cases) was sudden unexpected death of a loved one, an event experienced by 60% of the sample, and with a moderate risk of PTSD (14.3%), indicating the importance of traumatic grief. Women were at higher risk for PTSD than men, controlling for type of trauma. Although recent research had focused on combat, rape, and other assaultive violence as causes of PTSD, sudden unexpected death of a loved one was considered a far more important cause of PTSD in the community, accounting for nearly one third of PTSD cases.

Kessler et al. (1995) reported a study in a large national sample of 5877 individuals aged 15–54 years. This study obtained information on estimated life-time prevalence of trauma and PTSD, the kinds of traumas that were most often associated with PTSD, sociodemographic correlates, the comorbidity of PTSD with

other lifetime psychiatric disorders, and the duration of an index episode. The estimated lifetime prevalence of PTSD was found to be 7.8%. Prevalence was elevated among women and the previously married. The traumas most commonly associated with PTSD were combat exposure and witnessing of violence among men and rape and sexual molestation among women. PTSD was strongly comorbid with other lifetime DSM-III-R disorders. Survival analysis showed that more than one third of people with an index episode of PTSD failed to recover even after many years. These studies led to the conclusion that PTSD is more prevalent than previously believed and that PTSD often persists throughout the lifespan.

4.2 Childhood Abuse

Childhood abuse is a phenomenon that occurs on a wide scale and has quite dramatic proportions. Childhood physical or sexual abuse is a strong predictor of PTSD later in life. One million children are documented to have been exposed to abuse each year, and the prevalence of self-reported abuse is much higher. To investigate the prevalence of type of trauma and relate it with adult health problems, including physical symptoms, psychological problems, and substance abuse, McCauley et al. (1997) examined 1931 women of varied age and looked at prevalence of each symptoms cluster. Of this sample, 424 (22.0%) reported childhood or adolescent physical or sexual abuse. Compared with women who reported never having experienced abuse ($n = 1257$), women who reported abuse as children ($n = 204$) had more physical symptoms and had higher scores for depression, anxiety, somatization, and interpersonal sensitivity; they were more likely to be abusing drugs or to have a history of alcohol abuse; were more likely to have attempted suicide; and were more likely to have had a psychiatric admission.

Violence is a major public health problem that increasingly involves children and adolescents as both victims and witnesses (e.g. for reviews, see Lyons 1987; Terr 1991; Young 1993; Pfefferbaum 1997). In one study, victims of substantiated child abuse and neglect were assessed and compared with a group of matched nonabused and non-neglected children and followed into adulthood. Victims of child abuse (sexual and physical) and neglect were found to be at increased risk for developing PTSD. Slightly more than a third of the childhood victims of sexual abuse (37.5%), 32.7% of those physically abused, and 30.6% of victims of childhood neglect met DSM-III-R criteria for lifetime PTSD. Family, individual, and lifestyle variables also placed individuals at risk and contributed to the symptoms of PTSD (Widom 1999).

Interventions related to childhood abuse tend to include efforts within families, schools, and/or communities. A variety of factors influence response to trauma and affect recovery. They include characteristics of the stressor and exposure to it; individual factors such as gender, age and developmental level; and psychiatric history; family characteristics; and cultural factors (Pfefferbaum 1997). Since there is growing recognition that violence deeply affects the lives of children, there is great concern over the effect these terrible experiences will have on present and future generations. It has not only awakened the consciousness of mental health workers, but also awakened the collective consciousness of our society that the impact of violence extends well beyond the child who is physically victimized to other larger groups of children such as those who witness these events (Knapp 1998).

4.3 Disaster Situations

The Buffalo Creek disaster of 1972 involving the collapse of a slag dam and subsequent flood in West Virginia was one of the most extensively studied natural disasters of recent history. The rate of disaster-related PTSD was 7%, down from a post-flood rate at follow-up of 32%. There were no differences by age-group in their current psychological status; however, women evidenced more PTSD-related symptoms than did men (Green et al. 1990, 1994). Initially, the intrusive symptoms and nightmares and sleep disturbances were the most frequent difficulties. An exaggerated startle response was somewhat more frequent than the avoidance and numbing symptoms, such as loss of interest and caring (Green 1993). Survivor guilt was a relatively uncommon phenomenon in disaster-affected populations and was possibly one of the reasons why it was left out of the DSM-IV criteria for PTSD.

In other disaster, North et al. (1999) report about a follow-up on the terrorist Oklahoma City bombing in 1995, where a bomb blast killed 168 people. In their sample of 182 participating adults, 45% had a postdisaster psychiatric disorder and 34% had PTSD. The onset of PTSD was swift, with 76% reporting same-day onset. The relatively uncommon avoidance and numbing symptoms virtually dictated the diagnosis of PTSD (94% meeting avoidance and numbing criteria had full PTSD diagnosis) and were further associated with psychiatric comorbidity, functional impairment, and treatment received. Intrusive reexperiencing and hyperarousal symptoms were nearly universal, but by themselves were generally not associated with other psychopathology or impairment in functioning (North et al. 1999).

Disasters have a dramatic impact pending on the region of occurrence. Focusing solely on disasters as a traumatic stress experience, McFarlane reports about a Red Cross report issued in 1993 that highlighted the differential impact of disasters in Third World countries. In the period from 1967 to 1991, an average of 17 million people living in developing countries were affected by disasters each year, as compared to about 700,000 in developed countries, which is a difference of 166:1 (McFarlane and Potts 1999, p. 94).

Table 2 presents an overview of recent epidemiological data (1996–1999) on PTSD. This list is not exhaustive, but gives an impression of the wide range of target populations as well as differences in prevalence (for a comprehensive review of epidemiological data on child/adolescent PTSD, see Saigh et al. 1999a; on adults in criminal victimization, see Acierno et al. 1999; on combat-related PTSD, see Schlenger et al 1999; for epidemiological data on PTSD in disasters, see McFarlane and Potts 1999). In this table, the

Table 2. Prevalence of PTSD in epidemiologic studies 1996–1999

Author(s)	Trauma	Population	Sample	Method of measurement	Prevalence (%)

PTSD, post-traumatic stress disorder; SCID, Structured Clinical Interview for DSM; DIS, Diagnostic Interview Schedule; CAPS, Clinician Administered PTSD Scale; PSS, PTSD Symptom Scale-Interview.

prevalence of PTSD varies (from 1.7%–86%) according to the population studied, the nature of the traumatic stress, length of follow-up (not included in the table), and the instrument used. Most of these recent studies do report variables that are necessary to make an estimate of prevalence and to interpret the relevance in relation to the course of PTSD: nature or type of the trauma, sample size, recruitment of study population (help seeking, mailing, or advertisement), method of assessment, interval between stress exposure and assessment, lifetime and current PTSD. However, better standardization is needed to make comparisons between studies.

5 Etiology

There are multiple variables that play a role in the development of trauma-related psychopathology. Models of PTSD take into account genetic constitution, prestressor factors (defined as vulnerability), peritraumatic factors (characteristics of stress, of length of dissociative response), and poststressor factors in the development of PTSD (for a review, see Bremner et al. 1995a).

5.1 Genetic Contribution

Genetic contributions to PTSD have been studied using monozygotic twins. Goldberg et al. (1990) studied the impact of military service during the Vietnam era (1965–1975) on PTSD using a sample of 2092 male–male, monozygotic, veteran twin pairs. In 715 monozygotic twin pairs who were discordant for military service in Southeast Asia (SEA), PTSD was found to be strongly associated with military service in SEA. The prevalence of PTSD was 16.8% in twins who served in SEA compared with 5.0% in co-twins who did not serve in SEA. There was a ninefold increase in the prevalence of PTSD comparing twins who experienced high levels of combat with their co-twin who did not serve in SEA (Goldberg et al. 1990). True et al. (1993) followed up on this and looked at effects of heredity, shared environment, and unique environment on the liability for 15 self-reported PTSD symptoms. He studied 4042 Vietnam era veteran monozygotic and dizygotic male twin pairs. Quantitative genetic analysis revealed that inheritance had a substantial influence on liability for all symptoms. This study showed (a) that there are significant genetic influences on symptom liability, even after adjusting for differences in combat exposure, and (b) that genetic factors account for 13%–30% of the variance in liability for symptoms in the reexperiencing cluster, 30%–34% for symptoms in the avoidance cluster, and 28%–32% for symptoms in the arousal cluster (True et al. 1993). These findings were supported by a study conducted by Skre et al. (1993), who found a genetic contribution in the etiology of panic disorder, generalized anxiety disorder, and PTSD. Simple and social phobia were found to be mainly caused by environmental experiences.

5.2 Early Trauma

As stated earlier, early trauma in the form of childhood physical or sexual abuse has been associated with adult psychopathology in the stress-sensitization model: prior stressors increase risk for PTSD with reexposure to stress (for reviews, see Bremner et al. 1999a; Bremner 1999b). Consistent with this, Vietnam veterans with PTSD had higher rates of childhood physical abuse than Vietnam veterans without PTSD (26% vs. 7%). The association between childhood abuse and PTSD persisted after controlling for the difference in level of combat exposure between the two groups. Patients with PTSD also had a significantly higher rate of total traumatic events before joining the military than patients without PTSD. This supported the notion that childhood physical abuse may be an antecedent to the development of combat-related PTSD in Vietnam combat veterans (Bremner et al. 1993a).

In a large epidemiological study, Breslau et al. (1999a) found that subjects who experienced multiple events involving assaultive violence in childhood were more likely to experience PTSD from trauma in adulthood. Furthermore, previous events involving assaultive violence – single or multiple, in childhood or later on – were also associated with a higher risk of PTSD in adulthood (Breslau et al 1999a).

5.3 Predictive Factors

Predicting who would develop PTSD in response to a stressor can have many implications for the development of screening instruments, treatment strategies, and policy. The influence of Freud's original and somewhat misleading "war neurosis" led the military to attempt to predict vulnerability to combat stress based on premilitary developmental variables assuming they could be found in conflicts in early development. In different epidemiological studies, prestressor factors in the development of combat-related PTSD are found to be age of traumatization, years of education, minority status, pretrauma and psychiatric disorder, substance abuse, history of childhood abuse, antisocial

behavior, academic difficulty, family history of psychiatric disorders, family environment, and lack of social support. In civilian PTSD, a previous history of stress and previous psychiatric disorders may increase both the risk of exposure to a traumatic stressor as well as the development of PTSD. Factors in PTSD associated with combat veterans are severity and length of exposure, seeing others killed or wounded, participating in atrocities, and dissociation at time of trauma. Research has not found a direct association between drug and alcohol abuse in Vietnam combat veterans (Fontana and Rosenheck 1994). A postmilitary risk factor is lack of social support. Since most victims of civilian trauma, such as rape or childhood sexual abuse, feel shame and guilt, which discourages them from talking openly about their feelings and seeking social support, this may contribute to a decrease in social support analogous to that of combat veterans with PTSD (for a review, see Bremner et al. 1995a).

6 Diagnosis and Assessment

Trauma measures vary widely in scope and format, ranging from self-report checklists assessing the presence or absence of a limited range of potentially traumatic events to comprehensive protocols assessing a wide range of stressors through both self-report and interview (for an overview of psychological assessment in PTSD, the reader is referred to Wilson and Keane 1997; for an overview of assessment of PTSD in children, see March 1999; on assessment in traumatized adults, see Weathers and Keane 1999; on forensic assessment, see Sparr and Pitman 1999). Recommended clinician-administered instruments with good reliability and validity include the following:

1. *Structured Clinician Interview for DSM-IIIR and DSM-IV* (SCID; Spitzer et al. 1990). The SCID is a comprehensive structured interview that assesses all of the major axis I disorders. A revised module of the original DSM-III-R PTSD module is now introduced in the DSM-IV section of the SCID. This module appears to have adequate reliability and validity (Kulka et al. 1991).
2. *Diagnostic Interview Schedule* (DIS; Robins et al. 1981). The DIS is a highly structured, comprehensive interview designed for use by lay interviewers in the context of epidemiological research. Like the SCID, the DIS provides a standard prompt question for each of the 17 PTSD symptoms. Each symptom is scored dichotomously on its presence or its absence. The DIS was found to be one of the best predictors of a clinical diagnosis of PTSD (Kulka et al. 1991).
3. *Clinician-Administered PTSD Scale* (CAPS; Blake et al. 1995). The CAPS is a comprehensive scale developed by the U.S. National Center for PTSD (Blake et al. 1990 1995). It is intended to be used by clinicians and addresses some of the limitations of the other instruments. It assesses the 17 core symptoms for PTSD, as well as associated symptoms, response validity, overall symptom severity, and the impact of symptoms on social and occupational functioning. The CAPS assesses the frequency and intensity of each symptom on a 5-point scale, yielding continuous and dichotomous scores for each symptom and across the 17 symptoms. The CAPS also contains behaviorally anchored prompt questions and rating scales to help increase the reliability of symptom inquiry and severity ratings. These are specific guidelines for assessing lifetime diagnostic status. With its recent revision for DSM-IV, the CAPS is divided into CAPS-DX, for diagnostic assessment of current and lifetime PTSD, and CAPS-SX, assessing a 1-week symptom status. The CAPS takes significantly more time to administer than the other interviews.
4. *PTSD Symptom Scale-Interview* (PSS-I; Foa et al. 1993). The PSS-I is a structured interview specifically designed to assess DSM-III-R PTSD symptoms (Foa et al. 1993). It contains 17 items; interviewers rate the severity of each symptom over the past 2 weeks. The severity of each symptom is rated on a scale from 0 to 3, where 0 is "not at all," and 3 "very much." A PTSD diagnosis is obtained by considering symptom ratings of 1 or higher as present and then following the DSM-III algorithm. The PSS-I has excellent psychometric properties. The advantages of this scale are that it yields continuous and dichotomous scores, is easy to administer, and has good reliability and validity. The disadvantages are that it only uses one single prompt for each item, its rating anchors are not explicitly defined, and it assesses symptoms over a 2-week rather than a 1-month period. The instrument lacks lifetime diagnostic status.
5. *Structured Interview for PTSD* (SI-PTSD; Davidson et al. 1989). The SI-PTSD was originally designed to assess both DSM-III and DSM-III-R criteria for PTSD (Davidson et al. 1989). Items consist of initial prompt questions and follow-up questions that clarify the initial question with concrete behavioral samples. The severity is rated on a 5-point scale, both for the past month and for the worst period since the trauma. Descriptors are given for scale anchors. A total severity score is obtained by summing ratings of all 17 symptoms, and symptoms are counted if they are scored as 2 or higher.
6. *PTSD Interview* (PTSD-I; Watson et al. 1991). The PTSD-I is another structured interview for assessing

the DSM-III-R criteria for PTSD (Watson et al. 1991). The scale follows the same course as the other scales except its recommended format for administration. Interviewers are instructed to give respondents a copy of the rating scale, read the questions aloud, and ask respondents to rate themselves.

In order to assess traumatic events that may account for later-life PTSD, we developed a semistructured interview (Early Trauma Inventory, ETI). This assesses traumatic life events in the first 18 years of life. The questionnaire gives a composite score of four domains of early trauma: natural disasters, emotional trauma, physical trauma, and sexual trauma. The interview combines narrative and structured approaches to inquiring about childhood emotional, physical, and sexual abuse as well as nonabusive traumas. Each subsection begins with an open-ended format in which subjects are asked in a general way about their experiences related to that domain and are allowed to tell their story in their own words. Following this initial introduction, subjects are assessed using a series of structured questions within that particular domain. The ETI assesses a wide range of abuse experiences, including physical abuse items, such as a more common "were you ever spanked with a hand?" as well as less common events, such as "were you ever locked in a closet?" The ETI has a range of sexual abuse items, including "were you ever exposed to someone flashing" and "were you ever forced to have anal sex against your will?" Emotional abuse items range from "were you often shouted at?" to "did your parents or caretakers fail to understand your needs?" The general trauma component assesses events ranging from parental loss and natural disaster to criminal victimization. Data show excellent interrater reliability. Test–retest studies performed in a patient and nonpatient population show excellent reliability (Bremner et al. in press).

There is now considerable controversy about the validity of recall of childhood abuse. There have been studies which reported long-term correlates of abuse events which were documented at the time which they occurred (Chu et al. 1999). The relationship between reported abuse and the historical accuracy of abuse events is not known. Our findings of a strong level of agreement between test and retest administration of ETI, however, supports the stability of recalled memories of abuse and other traumas over time. Regardless of the controversy surrounding the accuracy of reported abuse, the development of standardized instruments for the assessment of reported abuse and other traumas, with demonstrated reliability and validity, will be beneficial in furthering careful research in this area (Bremner et al. 1999a).

Breslau et al. (1999b) report a short screening scale consisting of seven screening symptoms for use in computer-assisted telephone interviews. They chose five of the symptoms from the avoidance and numbing group, and two from the hyperarousal group. A score of 4 or greater on this scale defined positive cases of PTSD with a sensitivity of 80%, a specificity of 97%, a positive predictive value of 71%, and a negative predictive value of 98%, showing that this short screening scale can be an efficient method to screen for PTSD in epidemiologic and clinical studies with limited burden on respondents (Breslau et al. 1999b).

Other instruments are summarized in Stamm's *Measurement of Stress, Trauma,* and Adaptation (Stamm 1996). This book covers a rich variety of structured interviews, paper and pencil tests, and psychobiological tests. Instruments are classified according to many characteristics, including their psychometric maturity, applicability across race, sex, ethnicity, language, suitability for age-groups, types of data yielded, diagnosis, and theoretical perspectives.

7 Brain, Neurohormonal, and Transmitter Regulations

Long-standing alterations in biological stress response systems may underlie symptoms of PTSD (for an overview, see Friedman et al. 1995; Charney and Bremner 2000). Research in animals, in a paradigm of maternal deprivation of exposure to inescapable stress, has been highly relevant to our understanding of PTSD, e.g. in the model of inescapable stress, animals are exposed to repeated stressors, such as electric foot shock or being forced to swim in cold water. These stressors result in an acute release of stress-related neuropeptides, hormones, and transmitters, including corticotropin-releasing factor (CRF) – which activates the hypothalamic–pituitary–adrenal (HPA) axis to cause release of adrenocorticotropic hormone (ACTH) and cortisol – norepinephrine, benzodiazepines, serotonin (5-HT), dopamine, and opiates. Animals exposed to chronic stressors have shown to develop long-term dysregulation of these systems and typically potentiated release of transmitters with exposure to subsequent stressors. These neurochemical changes are also accompanied by behavioral changes (sometimes referred to as "learned helplessness") that are similar to human anxiety, including increased defecation and avoidance of novel stimuli such as an open field. Thus chronic stress results in long-term abnormalities in the neurochem-

ical systems that are necessary for appropriately coping with stressful situations. Specific brain areas that play an important role in a variety of types of memory are preferentially affected by stress (and mediate the stress response), including amygdala, hippocampus, hypothalamus, thalamus, medial prefrontal and parietal cortex, visual association cortex, and cingulate (Bremner et al. 1999b).

7.1 The Hypothalamic–Pituitary–Adrenal Axis in the Stress Response

The HPA axis is an important component of the stress response system. CRF is released from the paraventricular nucleus (PVN) of the hypothalamus, causing release of ACTH from the pituitary, which stimulates release of cortisol (the major stress hormone) from the adrenals. This axis is involved in a negative feedback loop that regulates cortisol release (as well as regulatory feedback with the noradrenergic system, which is discussed in more detail below).

7.1.1 Adrenocorticotropic Hormone

Acute stress of many types results in release of CRF as well as ACTH and cortisol. The mechanism responsible for transient stress-induced hyperadrenocorticism and feedback resistance may involve a downregulation of glucocorticoid receptors (J.P. Herman et al. 1989; Sapolsky and Plotsky 1990). High glucocorticoid levels (such as those elicited by acute stress) decrease the number of hippocampal glucocorticoid receptors, resulting in increased corticosterone secretion and feedback resistance. Following stress termination, when glucocorticoid levels decrease, receptor numbers are increased and feedback sensitivity normalizes (Sapolsky et al. 1984a/b). The effects of chronic stress on ACTH and corticosterone secretion vary depending on the experimental paradigm. It has been reported that an adaptation to chronic stress may occur, resulting in decreased plasma ACTH and corticosterone levels compared with levels following a single stressor (Kant et al. 1987). However, other investigations have revealed enhanced corticosterone secretion after chronic stressor regimens (Irwin et al. 1986). There is also evidence that the experience of prior stress may result in augmented corticosterone responses to a subsequent stress exposure (Dallman and Jones 1973; Caggiula et al. 1989). It is not known which factors determine whether adaptation or sensitization of glucocorticoid activity will occur following chronic stress (Yehuda et al. 1991a). The HPA axis has important functional interactions with the norepinephrine system that facilitate a sophisticated range of responses to stress. Glucocorticoids inhibit stress-induced activation of catecholamine synthesis in the PVN (Pacak et al. 1993; 1995; Vetrugno et al. 1993). CRF increases activity of the locus ceruleus (Valentino and Foote 1988), and CRF injected into the locus ceruleus intensifies anxiety-related responses (Butler et al. 1990). These findings support the notion that CRF serves as an excitatory neurotransmitter in the locus ceruleus, which may represent the pathway for the behavioral effects of CRF.

7.1.2 Norepinephrine

Norepinephrine release in the brain represents an important part of the stress response (for reviews, see Bremner et al. 1996b,c). The majority of noradrenergic cell bodies are located in the brainstem, in the locus ceruleus region of the pons, with axons that extend throughout the cerebral cortex and to multiple subcortical areas. Neurons in the locus ceruleus are activated in association with fear and anxiety states (Redmond 1987; Abercrombie and Jacobs 1987), and the limbic and cortical regions innervated by the locus ceruleus are those thought to be involved in the elaboration of adaptive responses to stress. Stressors such as a cat seeing a dog result in and increase in firing of neurons in the locus ceruleus (Levine et al. 1990) and enhanced norepinephrine release in the hippocampus (Nisenbaum et al. 1991; Petty et al. 1993) and medial prefrontal cortex (Finlay et al. 1995).

Stress sensitization refers to a stressor-induced increase in behavioral, physiologic, and biochemical responding to subsequent stressors of the same or lesser magnitude. For example, chronically stressed animals had increased norepinephrine release in hippocampus with subsequent stressors (Abercrombie et al. 1989). Significantly greater behavioral, cardiovascular, and biochemical responses to equivalent doses of yohimbine in combat veterans with PTSD compared with healthy controls are an example of evidence supporting this model (Southwick et al. 1993, 1999). It has been proposed that multiple neurobiological systems, including catecholamine systems and the HPA axis, can become sensitized over time by traumatic stress and as a result contribute to PTSD symptoms such as hypervigilance, poor concentration, insomnia, exaggerated startle response, and intrusive memories. It has been proposed that this facilitation of memory is caused by endogenous neuromodulators, such as epinephrine and norepinephrine, which are released during arousing and stressful circumstances. Overstimulation of these stress-related neuromodulators during traumatic events can cause overconsolidation and deeply engraved memories for the event.

7.1.3 Dopamine, Serotonin, Benzodiazepines, and Neuropeptides

The role of dopamine, serotonin (5-HT), benzodiazepines and neuropeptides will not be reviewed here in detail. Readers are referred to recent findings in the dopaminergic innervation of the medial prefrontal cortex, which appears to be particularly vulnerable to stress (for a review, see Thierry et al. 1998). The effects of stress on serotonin systems have been studied less thoroughly than noradrenergic systems. Although there are only a limited number of studies of serotonergic function in PTSD (L.L. Davis et al. 1997; Southwick et al. 1997; Maes et al. 1999a), there is a large body of indirect evidence suggesting that this neurotransmitter may be important in the pathophysiology of trauma-related symptomatology. In humans, low 5-HT functioning has been associated with aggression, impulsivity, and suicidal behavior. Patients with PTSD are frequently described as aggressive or impulsive and often suffer from depression, suicidal tendencies, and intrusive thoughts that have been likened to obsessions. Endogenous benzodiazepines also play an important role in the stress response and anxiety (for a review, see Guidotti et al. 1990). Benzodiazepine receptors are present throughout the brain with the highest concentration in cortical gray matter. Several neuropeptides also mediate the response to stress. Cholecystokinin (CCK) is an anxiogenic neuropeptide present in the gastrointestinal tract as well as the brain and has recently been suggested as a neural substrate for human anxiety. Stress is associated with an increase in endogenous opiate release (Maier et al. 1981; Madden et al. 1977) with decreased density of μ-opiate receptors (Stuckey et al. 1989), which may mediate the analgesia associated with stress. Other neuropeptides under investigation that appear to play role in the stress response are neuropeptide Y, somatostatin, and thyrotropin. Stress also has important effects on the immune system that are not reviewed here in detail.

7.2 Linkage with Other Neurobiological Systems

Coordinated functional interactions between the HPA axis and noradrenergic neuronal systems may be critical in promoting adaptive responses to stress, anxiety, or fear. CRF increases locus ceruleus firing, resulting in enhanced norepinephrine release in cortical and subcortical areas throughout the brain. The PVN of the hypothalamus, the site of the majority of CRF-containing neurons in the hypothalamus, is an important site in effecting cardiovascular and neuroendocrine responses to stress. Norepinephrine increases CRF in the PVN of the hypothalamus. In chronically stressed animals, the locus ceruleus (as opposed to other norepinephrine neurons in the medulla) may be preferentially responsible for norepinephrine release in the PVN. Increased CRF release from the PVN results in stimulation of ACTH secretion from the pituitary and consequently cortisol release from the adrenal gland. High levels of circulating cortisol act through a negative feedback pathway to decrease both CRF and norepinephrine synthesis at the level of the PVN. Glucocorticoid inhibition of norepinephrine-induced CRF stimulation may be evident primarily during stressor-induced cortisol release and not under resting conditions. High levels of cortisol likely inhibit the effects of norepinephrine on CRF release from the PVN, serving to restrain the stress-induced neuroendocrine and cardiovascular effects mediated by the PVN. Norepinephrine, cortisol, and CRF thus appear to be tightly linked in a functional system that offers a broad homeostatic mechanism for coping with stress.

7.3 Brain Circuitry

Based on animal research and emerging work in clinical neuroscience of PTSD, a model for a neural circuitry of anxiety and fear that is also applicable to PTSD has been described (Charney and Bremner, 2000). The model explains how information related to a threatening stimulus (e.g. someone approaches you with a gun in a dark alley) enters the primary senses (smell, sight, touch, hearing), is integrated into a coherent image that is grounded in space and time, activates memory traces of prior similar experiences with the appropriate emotional valence (necessary in order to evaluate the true threat potential of the stimulus), and subsequently triggers an appropriate motor response. Specific brain circuits that mediate these responses make up the neural circuitry of anxiety and fear and can be adapted to the field of traumatic stress (see Fig. 4). Critical processes in these circuits include failure of inhibition, stress sensitization, and fear condition. Critical brain structures are hippocampus, amygdala, and orbitifrontal cortex.

In the development of human fear or anxiety, afferent sensory input enters through the eyes, ears, nose, sense of touch, the body's own visceral information, or any combination of these. These sensory inputs are relayed through the dorsal thalamus to cortical brain areas, such as primary visual (occipital), auditory (temporal), or tactile (postcentral gyrus) cortical areas. Olfactory sensory input, however, has

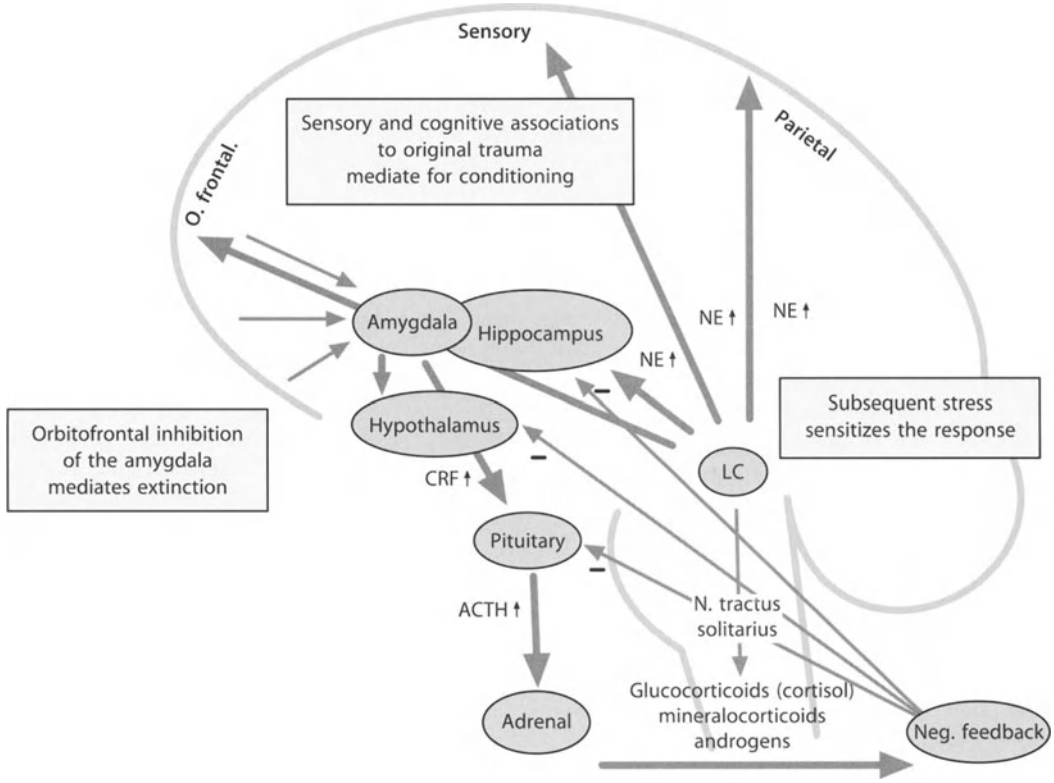

Fig. 4. Psychobiological mechanisms and their site of action, including the hypothalamic–pituitary–adrenal (HPA) axis, in PTSD. CRF, corticotropin-releasing factor; *ACTH*, adenocorticotropic hormone; *NE*, norepinephrine; *LC*, locus ceruleus. (Based on Charney et al. 1993)

direct inputs to the amygdala and entorhinal cortex (Turner et al. 1978). Input from peripheral visceral organs is relayed in the brainstem to the locus ceruleus, the site of the majority of the brain's noradrenergic neurons, and from here to central brain areas.

These brain areas have projections to multiple areas, including amygdala, hippocampus, entorhinal cortex, orbitofrontal cortex, and cingulate, that are involved in mediating memory and emotion (Vogt and Miller 1983). Cognitive appraisal of potential threat is also an important aspect of the stress response. The cognitive response to threat involves placing the threatening object in space and time. Specific brain areas are involved in these functions (such as localizing an object in space, visuospatial processing, memory, cognition, action, or planning). The anterior cingulate gyrus (Brodmann area 32) is involved in selection of responses for action as well as emotion (Devinsky et al. 1995). This area and other medial portions of the prefrontal cortex, including area 25 and orbitofrontal cortex, modulate emotional and physiological responses to stress and are discussed in more detail below.

Another important aspect of the stress response is incorporation of a person's prior experience (memory) into the cognitive appraisal of stimuli. For example, if you are approached in a potentially threatening situation, it will be important to determine whether the face of the person is someone known to you or is a stranger who may be more threatening. In addition, it is important to place the situation in time and place. Entering a dark alleyway may trigger prior memories of being robbed, with associated negative emotions and physiological arousal. These memories may have survival value, in that the individual will avoid the situation where the previous negative event took place. Finally, it is critical to effectively lay down memory traces related to a potential threat in order to avoid this type of threat in the future.

7.3.1 Hippocampus

The hippocampus, which is particularly vulnerable to stress, plays an important role in memory. The

hippocampus and adjacent cortex mediate declarative memory function (e.g. recall of facts and lists) and has been hypothesized to play an important role in integration of memory elements at the time of retrieval and in assigning significance for events within space and time (Squire and Zola-Morgan 1991). The hippocampus also plays an important role in mediating emotional responses to the context of a stressor, e.g. in animal studies, lesions of the hippocampus disrupted the formation of emotional memories of the context (i.e. the box) where the stressor (i.e. electric footshock) took place (Ross and Randich 1984; Phillips and LeDoux 1992; Kim and Fanselow 1992). High levels of glucocorticoids released during stress were also associated with damage to the CA3 region of the hippocampus (Uno et al. 1989; Sapolsky et al. 1990) as well as related deficits in memory (Arbel et al. 1994; Luine et al. 1994; McEwen et al. 1992; reviewed in more detail below).

With long-term storage, memories are felt to be shifted from hippocampus to the neocortical areas, where the initial sensory impressions take place (Squire and Zola-Morgan 1991). The shift in memory storage to the cortex may represent a shift from conscious representational memory to unconscious memory processes that indirectly affect behavior. "Traumatic cues" such as a particular sight or sound reminiscent of the original traumatic event will trigger a cascade of anxiety and fear-related symptoms will ensue, often without conscious recall of the original traumatic event. In patients with PTSD, however, the traumatic stimulus is always potentially identifiable. Symptoms of anxiety in panic or phobic disorder patients, however, may be related to fear responses to a traumatic cue (in individuals who are vulnerable to increased fear responsiveness, either through constitution or previous experience), where there is no possibility that the original fear-inducing stimulus will ever be identified.

7.3.2 Amygdala

The amygdala is involved in memory for the emotional valence of events. The paradigm of conditioned fear has been utilized as an animal model for stress-induced abnormalities of emotional memory (M. Davis 1992). Conditioned fear, in which pairing of a neutral ("conditioned") stimulus to a fear-inducing ("unconditioned") stimulus results in fear responses to the neutral (conditioned) stimulus alone, has been used as a probe of amygdala function (LeDoux 1993). Lesions of the central nucleus of the amygdala have been shown to completely block fear conditioning (Hitchcock and Davis 1986; Hitchcock et al. 1989), while electrical stimulation of the central nucleus increases acoustic startle (Rosen and Davis 1988). The central nucleus of the amygdala projects to a variety of brain structures via the stria terminalis and the ventral amygdalofugal pathway. One pathway is from the central nucleus to the brainstem startle reflex circuit (nucleus reticularis pontis caudalis). Pathways from the amygdala to the lateral hypothalamus effect peripheral sympathetic responses to stress (Iwata et al. 1986). Electrical stimulation of the amygdala in cats resulted in peripheral signs of autonomic hyperactivity and fear-related behaviors seen in the wild when the animal is being attacked or is attacking, including alerting, chewing, salivation, piloerection, turning, facial twitching, arching of the back, hissing, and snarling, associated with an increase in catecholamine turnover (Hilton and Zbrozna 1963). Electrical stimulation of the amygdala in human subjects resulted in signs and symptoms of fear and anxiety, including an increase in heart rate and blood pressure, increased muscle tension, subjective sensations of fear or anxiety, and increases in peripheral catecholamines (Chapman et al. 1954; Gunne and Reis 1963). These findings demonstrated that the amygdala plays an important role in conditioned fear and emotional responding, as well as modulating peripheral stress responses. There are also important connections between cortical association areas, thalamus, and amygdala that are important in shaping the emotional valence of the cognitive response to stressful stimuli (LeDoux et al. 1988). In addition to thalamo-cortico-amygdala connections, there are direct pathways from thalamus to amygdala, which could account for fear responding below the level of conscious awareness (Romanski and LeDoux 1992).

7.3.3 Frontal Cortex

Frontal cortical areas modulate emotional responsiveness through inhibition of amygdala function, and we have hypothesized that dysfunction in these regions may underlie pathological emotional responses in patients with PTSD and possibly other anxiety disorders. Medial prefrontal cortex (area 25) (subcallosal gyrus) has projections to the amygdala which are involved in the suppression of amygdala responsiveness to fearful cues. Dysfunction of this area may be responsible for the failure of extinction to fearful cues, which is an important part of the anxiety response (Morgan and LeDoux 1995). This area is involved in regulation of peripheral responses to stress, including heart rate, blood pressure, and cortisol response (Roth et al. 1988). Finally, case studies of humans with brain lesions have implicated medial prefrontal cortex (including orbitofrontal cortex, area 25, and anterior cingulate area 32) in "emotion" and socially appro-

priate interactions (Damasio et al. 1994). Auditory association areas (temporal lobe) have also been implicated in animal studies as mediating extinction to fear responding (Jarrell et al. 1987; Romanski and LeDoux 1993). As reviewed later, we found dysfunction of medial prefrontal cortex and auditory cortex with traumatic reminders in PTSD (Bremner et al. 1997b, 1999c,d).

7.3.4 Other Brain Structures

A final component of the stress response involves preparation for a response to potential threat. Preparation for responding to threat requires integration between brain areas involved in assessing and interpreting the potentially threatening stimulus, and brain areas involved in response. For instance, prefrontal cortex and anterior cingulate play an important role in the planning of action and in holding multiple pieces of information in "working memory" during the execution of a response (Goldman-Rakic 1988). Parietal cortex and posterior cingulate are involved in visuospatial processing, which is an important component of the stress response. Motor cortex may represent the neural substrate of planning for action. The cerebellum has a well-known role in motor movement, which would suggest that this region is involved in planning for action; however, recent imaging studies are consistent with a role in cognition as well (Ashkoomoff and Courchesne 1992). Connections between parietal and prefrontal cortex are required in order to permit the organism to rapidly and efficiently execute motor responses to threat. It is therefore not surprising that these areas have important innervations to precentral (motor) cortex, which is responsible for skeletal motor responses to threat, which facilitate survival. The striatum (caudate and putamen) modulates motor responses to stress. The dense innervation of the striatum and prefrontal cortex by the amygdala indicates that the amygdala can regulate both of these systems. These interactions between the amygdala and the extrapyramidal motor system may be very important for generating motor responses to threatening stimuli, especially those related to prior adverse experiences (McDonald 1991a,b).

7.4
Developmental and Hereditary Factors

As reported earlier, it has been estimated that between 13% and 34% of the variance for specific PTSD symptom clusters is genetically transmitted. It is possible that inherited variations in the capacity for fear conditioning, sensitization, and memory consolidation help to determine who is likely to develop PTSD. From a developmental standpoint, it has been proposed that psychological trauma in childhood may differentially affect maturation of various brain regions, particularly those regions involved in fear and alarm (De Bellis et al. 1999a,b).

8
Long-Term Alterations in Neurobiological Systems

8.1
Hypothalamic–Pituitary–Adrenal Axis

Alterations in HPA axis function have been demonstrated in PTSD (for a review, see Yehuda et al. 1991b). A decrease in urinary cortisol levels has been found in Vietnam veterans with chronic PTSD in comparison to controls and patients with other psychiatric disorders in some studies (Mason et al. 1986; Yehuda et al. 1991a; Yehuda et al. 1993) but not others (Pitman and Orr 1990; Mason et al. 1988), while decreased plasma cortisol was found in 24-h sampling in patients with combat-related PTSD relative to healthy controls and patients with depression (Yehuda et al. 1994). On the other hand, women with a history of childhood sexual abuse-related PTSD (Lemieux and Coe 1995) and patients with PTSD related to a natural disaster (Baum et al. 1993) had elevated levels of urinary cortisol relative to controls. Male patients with combat-related PTSD (Kosten et al. 1990; Kudler et al. 1987; Olivera and Fero 1990) and female patients with sexual assault-related PTSD (Dinan et al. 1990) have been shown to suppress cortisol normally with the standard 1 mg dexamethasone suppression test (DST). Studies utilizing lower doses of dexamethasone (0.5 mg) suggest that PTSD may be associated with a super-suppression of the cortisol response in comparison to normal controls (Yehuda et al. 1993; Stein et al. 1997), which appears to be the opposite of patients with major depression who are nonsuppressers with the standard 1 mg DST test. PTSD patients have also been found to have a significantly lower ("blunted") ACTH response to CRF than controls, suggesting an increased release of neuronal CRF. Consistent with this are findings of elevated levels of CRF in the cerebrospinal fluid of Vietnam combat veterans with PTSD relative to healthy subjects (Bremner et al. 1997a; Baker et al. 1999). Other studies showed that patients with combat-related PTSD had an increase in lymphocyte glucocorticoid receptors in comparison to healthy subjects, non-PTSD combat veterans, and patients with other psychiatric disorders (Yehuda et al. 1991a, 1993). These studies demonstrate that alterations in cortisol

and HPA axis function are associated with PTSD. One possible explanation of clinical findings to date is an increase in neuronal CRF release, with resultant blunting of ACTH response to CRF, increased central glucocorticoid receptor responsiveness, and resultant low levels of peripheral cortisol due to enhanced negative feedback. Interestingly, nonhuman primates with variable foraging mothers (a model for early-life stress) had elevated cerebrospinal fluid CRF and decreased CSF cortisol levels in adulthood, a picture that is closer to PTSD than depression (Coplan et al. 1996).

Studies showing decreased cortisol in chronic PTSD raise the question of how elevated cortisol can represent the etiology of hippocampal atrophy in PTSD. We have hypothesized that high levels of cortisol *at the time of the stressor* result in damage to hippocampal neurons which can persist for many years after the original trauma, leading to reductions in hippocampal volume as measured by magnetic resonance imaging (MRI) (Bremner et al. 1995c, 1997c). In this scenario, decreased cortisol characterizes the chronic stages of the disorder due to adaptation and long-term changes in cortisol regulation. Longitudinal studies of cortisol in sexually abused girls supports an elevation in cortisol around the time of the stressor, with decreased cortisol developing later in development in patients who develop chronic symptoms of PTSD (F. Putnam, personal communication). However, an alternative hypothesis for hippocampal atrophy is that small hippocampal volume, which is present from birth, is a risk factor for the development of PTSD – in this scenario, high levels of cortisol associated with stress would have nothing to do with hippocampal atrophy.

Findings of no increase in cortisol levels in the aftermath of rape in women who subsequently develop PTSD (Yehuda et al. 1998) have also been used to argue against the glucocorticoid hypothesis of stress-induced hippocampal damage. In an initial report, cortisol samples obtained days to weeks after exposure to the trauma of rape found a relationship between low cortisol in the aftermath of rape and prior history of trauma (Resnick et al. 1995). In a subsequent analysis of samples obtained 8–48 h after the rape, the authors found a relationship between low cortisol levels in the aftermath of rape and prior history of trauma. However, there was no relationship between cortisol and risk for subsequent development of PTSD (Yehuda et al. 1998). Given the finding that history of prior trauma increases the risk for PTSD with subsequent victimization, this raises the question of whether these patients had prior PTSD or were physiologically distinct from the non-stress-exposed subjects.

In animal studies, it has been demonstrated that a variety of early stressors resulted in chronic increased levels of CRF and increased responsiveness of the HPA axis to subsequent stressors in adult life. As stated earlier, several observations suggest that early-life adverse experience permanently affects the HPA axis (Plotsky and Meaney 1993; van Oers et al. 1998). In human studies, women with a history of childhood sexual abuse-related PTSD were found to have elevated levels of the stress hormone cortisol in 24-h urine (Lemieux and Coe 1995). Sexually abused girls had a blunted ACTH response to CRF, consistent with hypersecretion of CRF (De Bellis et al 1994). Consistent with this, we found increased levels of CRF in the cerebrospinal fluid in PTSD (Bremner et al. 1997a). Children with PTSD had increased levels of cortisol (De Bellis et al. 1999a/b). Our own preliminary data in women with PTSD related to early childhood sexual abuse show decreased baseline cortisol based on 24-h diurnal assessments of plasma; cortisol levels were lower at all time points of CRF and ACTH challenge. There was a blunted ACTH response to CRF and a normal cortisol response to ACTH challenge. Studies using low doses (0.5 mg) of the DST suggest that adult women with a history of childhood abuse may show a super-suppression of the cortisol response in comparison to normal controls (Stein et al. 1997), which appears to be the opposite of patients with major depression. Children with abuse-related PTSD also had smaller intracranial and cerebral volume as well as smaller hippocampal volume (De Bellis et al. 1999a,b). These studies demonstrate that early-life trauma has lasting effects on neurochemical systems that mediate the stress response (Bremner et al. 1995b; Bremner 1999a,b) and that alterations in cortisol and HPA axis function are associated with abuse-related PTSD.

8.2 Norepinephrine

Several studies have shown long-term alterations in norepinephrine systems in PTSD. PTSD is characterized by tonic autonomic hyperarousal and increases in autonomic system activity in response to trauma-relevant stimuli. The most frequently used measures are electrodermal activity as presented by skin conductance levels; skin temperature; responses such as heart rate and systolic and diastolic blood pressure; and electromyography (EMG) activity of various facial muscles. These variables reflect in part activity of the peripheral sympathetic system. Exposure to traumatic reminders and neutral scenes utilized in the psychophysiology paradigm includes slides, sounds, or scenes similar to the original trauma or reading scripts that describe what actually happened during the original trauma. Comparisons are either made between expo-

sure to trauma-related material and both the baseline and/or the neutral exposures.

Over the past 20 years, a large number of psychophysiology studies have reported heightened sympathetic nervous system activity in veterans with PTSD. Although most studies have found no difference in resting baseline heart rate and blood pressure, the majority of studies have reported exaggerated increases in cardiovascular reactivity among subjects with PTSD compared with normal control subjects when exposed to trauma-specific stimuli such as laboratory-stimulated sights and sounds of combat or tape recordings of personally experienced traumas. Such exaggerated increases have not been found in combat veterans without PTSD, in combat veterans with anxiety disorders other than PTSD, or in response to generic stressors (such as the film of an automobile accident) that have never been experienced by the trauma survivor.

Studies on autonomic arousal show some variability in their reports. Most of the studies assessing physiological characteristics in PTSD have been conducted with veteran subjects and women with histories of childhood sexual abuse (Prins et al. 1995; Carlson et al. 1997; Metzger et al. 1999; Liberzon et al. 1999). A general finding in these studies was that PTSD patients showed heightened responsivity to trauma-related cues, consistent with increased norephinephrine responsivity. Patients with combat-related PTSD were found to have elevated norepinephrine and epinephrine in 24-h urine in comparison with normal controls and patients with other psychiatric disorders (Mason et al. 1988; Spivak et al. 1999). Relative elevations of the norepinephrine metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) were found in nighttime samples in PTSD (Mellman et al. 1995). No differences were found, however, in urinary norepinephrine between patients with combat-related PTSD and combat-exposed non-PTSD subjects (Pitman and Orr 1990) or in baseline levels of plasma norepinephrine in combat-related PTSD versus healthy subjects (for a review, see Murberg 1994). Women with PTSD secondary to childhood sexual abuse had significantly elevated levels of catecholamines (norepinephrine, epinephrine, dopamine) and cortisol in 24-h urine samples (Lemieux and Coe 1995). Sexually abused girls excreted significantly greater amounts of catecholamine metabolites, metanephrine, vanillymandelic acid, and homovanillic acid (HVA) than non-sexually abused girls (DeBellis et al. 1994) and increased in abuse-related PTSD (De Bellis et al. 1999a,b). Exposure to traumatic reminders in the form of combat films resulted in increased epinephrine and norepinephrine release, and increased MHPG with physical exercise (Hamner and Hitri 1992) has been found in Vietnam veterans with PTSD in comparison to healthy subjects. Children with PTSD were found to have increased orthostatic heart rate response, suggesting noradrenergic dysregulation (Perry 1994).

Studies of peripheral norepinephrine receptor function have also shown alterations in α_2-receptor and cyclic adenosine 3′,5′-monophosphate (cAMP) function in patients with PTSD, which are similar to those in panic disorder. A decrease in platelet adrenergic α_2-receptor number as measured by total binding sites for the α_2-antagonist [3H]rauwolscine (Perry and U'Prichard 1981), and a significantly greater reduction in number of platelet a_2-receptors after exposure to agonist (epinephrine), has been observed in PTSD patients in comparison to healthy controls (Perry et al. 1987). A decrease in platelet basal adenosine, isoproterenol, and forskolin-stimulated cAMP signal transduction and basal platelet monoamine oxidase (MAO) activity (Davidson et al. 1985) was found in PTSD patients in comparison to controls. These findings may reflect chronic high levels of norepinephrine release, which lead to compensatory receptor downregulation and decreased responsiveness.

Patients with combat-related PTSD compared to healthy controls had enhanced behavioral, biochemical (norepinephrine metabolite MHPG), and cardiovascular (heart rate and blood pressure) responses to the α_2-antagonist yohimbine, which stimulates central norepinephrine release (Southwick et al. 1993). Moreover, as noted previously, a recent positron emission tomography (PET) study demonstrated that PTSD patients have a cerebral metabolic response to yohimbine consistent with increased norepinephrine release, showing failure of activation in medial prefrontal cortex and decreased metabolism in hippocampus (Bremner et al. 1997b). In summary, although there is inconsistent evidence for elevations in norepinephrine at baseline in PTSD, there is evidence for increased noradrenergic responsivity in this disorder.

8.3 Memory Function

There are a number of reasons why the investigation of memory function is clinically relevant to PTSD. As reported earlier, patients with combat-related PTSD (as well as PTSD related to other causes) demonstrate alterations in memory, including nightmares, flashbacks, intrusive memories, and amnesia for the trauma (Figley 1978b; Egendorf et al. 1981). In addition, descriptions from all wars of this century document alterations in memory occurring in combat veterans during or after the stress of battle. These include the forgetting of one's name or identity and the forgetting of events which had just taken place during the previous battle. Vietnam veterans with PTSD have been found to have an increase in current amnestic

symptomatology in comparison to Vietnam combat veterans without PTSD as measured with the SCID for dissociative disorders (Bremner et al. 1993b). Amnestic memory disturbances should not be confused with deficits in short-term memory; we have reviewed the distinction between these two phenomena in greater detail elsewhere (Bremner et al. 1995a). Explicit memory is expressed on tests that require conscious recollection of previous experiences (e.g. free recall). Implicit memory is revealed when these experiences affect performance on a test that does not require conscious recollection (e.g. perceptual identification). PTSD patients have been found to have alterations in both explicit and implicit memory (McNally 1997).

Studies have found deficits in explicit declarative memory in PTSD. Danish survivors of the concentration camps in the Second World War were described to have persistent self-reported difficulties in memory after release from internment (Thygesen et al. 1970). Korean prisoners of war have been found to have an impairment of short-term verbal memory measured by the logical memory component of the Wechsler Memory Scale in comparison to Korean veterans without a history of containment (Sutker et al. 1991). The same was found in Persian Gulf War veterans (Vasterling et al. 1998). We have found deficits in short-term memory in Vietnam combat veterans with combat-related PTSD as measured by the logical memory component of the Wechsler Memory Scale and the visual and verbal components of the Selective Reminding Test. PTSD patients in that study did not have lower scores on the Wechsler Adult Intelligence Scale-Revised (WAIS-R) than controls (Bremner et al. 1995c,d). Similar results were found in patients with abuse-related PTSD (Bremner et al. 1997c). Studies have also found deficits in explicit short-term memory as assessed with the Auditory Verbal Learning Test (AVLT) in Vietnam combat veterans with PTSD in comparison to National Guard veterans without PTSD (Uddo et al. 1993) and the California Verbal New Learning Test in Vietnam combat veterans with PTSD in comparison to controls (Yehuda et al. 1995). A decrease in IQ in combat veterans with PTSD relative to controls may be due to an increased risk for the development of PTSD with lower IQ or may be a secondary effect of exposure to trauma (McNally et al. 1995). Other studies in patients with PTSD have shown enhanced recall on explicit memory tasks for trauma-related words relative to neutral words in comparison to controls (Zeitlin and McNally 1991; McNally et al. 1998). These findings are consistent with both deficits in encoding on explicit memory tasks, deficits in retrieval, and enhanced encoding or retrieval for specific trauma-related material. These findings could be related to stress-induced hippocampal damage.

8.4 Glucocorticoids and the Hippocampus

Current research strongly advocates that stress is associated with damage to hippocampal neurons. The work of Sapolsky and McEwen is seminal in this respect. The hippocampus, a major target organ for glucocorticoids in the brain (McEwen et al. 1986), modulates the pituitary–adrenocortical response to stress (Sapolsky and McEwen 1988). Monkeys who died spontaneously following exposure to severe stress were found on autopsy to have multiple gastric ulcers, consistent with exposure to chronic stress, and hyperplastic adrenal cortices, consistent with sustained glucocorticoid release. These monkeys also had damage to the CA3 subfield of the hippocampus (Uno et al. 1989).

Follow-up studies suggested that hippocampal damage was associated with direct exposure of glucocorticoids to the hippocampus (Sapolsky et al. 1990). Early studies in a variety of animal species (Aus der Muhlen and Ockenfels 1969) suggest that direct glucocorticoid exposure results in decreased dendritic branching (Wooley et al. 1990) and a loss of neurons (Uno et al. 1990) that are steroid and tissue specific (Packan and Sapolsky 1990). Prenatal exposure to elevated levels of glucocorticoids also results in hippocampal damage (Uno et al. 1990). Glucocorticoids appear to exert their effect through disruption of cellular metabolism (Lawrence and Sapolsky 1994) and by increasing the vulnerability of hippocampal neurons to a variety of insults, including endogenously released excitatory amino acids (Sapolsky 1986; Armanini et al. 1990). Glucocorticoids have also been shown to augment extracellular glutamate accumulation (Stein-Behrens et al. 1994). Furthermore, reduction of glucocorticoid exposure prevents the hippocampal cell loss associated with chronic stress (Landfield et al 1981; Meaney et al. 1988). Differing strains of rats may have varying glucocorticoid responses to stress, suggesting the possibility that constitutional factors may influence the glucocorticoid-mediated effects of stress on hippocampal neurons (Dhabhar et al. 1993). There are also substantial gender differences in the concentrations of glucocorticoid receptors at baseline and in response to stress, suggesting that studies related to this area which are performed exclusively in males will not be applicable to females (McCormick et al. 1994). In summary, findings to date are consistent with the idea that stress results in damage to neurons of the hippocampus, possibly through the effects of increased levels of glucocorticoids. More recently, emerging studies have found evidence for the idea that other factors besides glucocorticoids, such as brain-de-

rived neurotrophic factor (BDNF), trkB mRNA, and nerve growth factor (NGF), which have a regulatory effect on neuronal morphology and proliferation, may mediate stress-induced alterations in hippocampal morphology (Nibuya et al. 1995 1996; Smith et al. 1995).

Glucocorticoids also have other actions besides a damaging effect on hippocampal neurons. For instance, low levels of glucocorticoids following adrenalectomy result in damage to neurons of the dentate gyrus of the hippocampus (Vaher et al. 1994). Glucocorticoids also have effects on brain function through modulation of gene expression and have a variety of effects on immunity, reproduction, bone formation, and other physiological functions. These effects may have a protective effect on the organism during certain situations of stress, but in other situations the effects of glucocorticoids may be damaging (McEwen et al. 1992). Hippocampal damage may also play a role in other aspects of the long-term dysregulation of brain function associated with stress. The hippocampus is in general felt to have an inhibitory effect on the HPA axis. Stress-induced damage has been shown to be associated with an increase in levels of CRF mRNA in the PVN of the hypothalamus (J.L. Herman et al. 1989) as well as a decrease in the sensitivity of rats to dexamethasone suppression of HPA function (Feldman and Conforti 1980; Magarinos et al. 1987). Consistent with this, we have found increased levels of CRF in the cerebrospinal fluid of patients with combat-related PTSD in comparison to controls (Bremner et al. 1997a).

One of the mysteries of the neurobiology of traumatic stress is why physiological systems, which are designed to protect the organism during stress, may also have detrimental effects in some situations.

8.5
Hyperarousal and Sleep Dysfunction

Alterations in sleep function may be secondary to altered pontine function and noradrenergic dysregulation in PTSD. Sleep dysfunction has been documented following acute stress and appears to be related to development of chronic PTSD (Mellman et al. 1995). PTSD patients have been found to have an increase in phasic rapid eye movement (REM) activity (Ross et al. 1994a,b), decreased total sleep time, and increased "micro-awakenings" relative to controls. These abnormalities may play a role in nightmares and sleep disturbance in PTSD patients, which according to some authors can be considered to be the hallmark symptoms of PTSD (for a review, see Ross et al. 1989).

8.6
Thyroid Function

Thyroid function tests are frequently abnormal, hyperthyroid, in PTSD and these abnormalities tend to be in an opposite direction from the abnormalities found in depressive disorder. Thyroid-stimulating hormone (TSH) has a range of actions which include energy utilization within the cell (important in stress), and stress results in long-lived elevations in thyroid hormone (Mason et al. 1986). Although few studies have looked at thyroid function in anxiety disorders, Mason et al. (1994) found elevated levels of thyroxine (T3) in patients with combat-related PTSD. While patients with major depression exhibit a blunted TSH response to thyreotropin-releasing hormone (TRH), some patients with PTSD have exhibited an augmented response to TRH (Kosten et al. 1990). Recent research includes the involvement of prolyl endopeptidase, a cytosolic endopeptidase which degrades neuropeptides, such as TRH, and which can play a role in stress responsivity PTSD (Maes et al. 1999b). More research in this area is needed.

9
Neuroimaging Studies

Preclinical and clinical investigations provide strong evidence for linking several brain structures to the signs and symptoms of anxiety and fear associated with trauma. Chief among these are the amygdala, hippocampus, thalamus, periaquaductal gray, and orbitofrontal cortex. Although there were no published studies on PTSD as recently as 5 years ago, since that time there has been a rapid growth of studies in this area. This is in part due to a growing appreciation of the neurobiologic contributions to PTSD. Another factor that explains this is that initial studies well represented direct extensions of basic science research that amplified and broadly extended the knowledge about the effects of stress on neurobiological systems.

9.1
Structural Neuroimaging with Magnetic Resonance Imaging

Studies using MRI in PTSD have measured the volume of the hippocampus. This line of research was prompted by studies in animals showing that high levels of cortisol seen during times of stress are associated with damage to the hippocampus (reviewed above). We used MRI to measure hippocampal volume in 26 Vietnam combat veterans with PTSD and 22

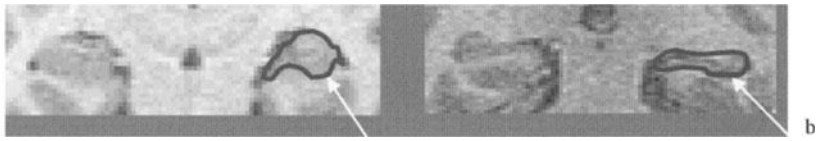

Fig. 5a,b. Magnetic resonance imaging (MRI) scan of the hippocampus in **a** a normal control and **b** a patient with PTSD secondary to childhood abuse. The hippocampus (*outlined*) is visibly smaller in PTSD. Overall, there was a 12% reduction in volume in the PTSD patient population in comparison to trauma controls without PTSD

controls matched for age, sex, race, handedness, years of education, body size, and years of alcohol abuse. We found an 8% reduction in right hippocampal volume in PTSD patients in comparison to controls, without differences in volume of comparison regions. The magnitude of reduction in hippocampal volume was associated with magnitude of deficits in short-term verbal memory (Bremner et al. 1995d). We have replicated these findings in 17 patients with PTSD related to severe childhood physical and/or sexual abuse in comparison to 17 controls matched on a case-by-case basis for several factors and found a 12% reduction in left hippocampal volume in the patients in comparison to controls in this study (Bremner et al. 1997c). Our findings of reduction in hippocampal volume have been replicated in patients with PTSD related to combat and civilian stressors (Gurvits et al. 1996; Stein et al. 1997). Figure 5 illustrates the reduction in volume in the hippocampus.

9.2 Functional Neuroimaging with Positron Emission Tomography

Sophisticated techniques have been developed for the measurement of cerebral blood flow using PET. $H_2[^{15}O]$ provides a good measure of cerebral blood flow. Cerebral blood flow has been shown to be highly correlated with local cerebral glucose metabolism. Since neurons almost exclusively utilize glucose for cell processes, glucose utilization provides a measure of local neuronal activity. Studies in PTSD have begun to use PET during pharmacologic and cognitive provocation of symptom states in order to identify neural correlates of PTSD symptomatology and of traumatic remembrance.

We also used PET and fluorodeoxyglucose (FDG) in the measurement of cerebral glucose metabolic rate following administration of yohimbine and placebo in Vietnam combat veterans with PTSD and healthy controls. Increased noradrenergic function has been hypothesized to underlie many of the symptoms of PTSD. Administration of the α_2-antagonist yohimbine, which stimulates brain norepinephrine release, resulted in increased PTSD symptoms and anxiety in the PTSD group. Norepinephrine has a U-shaped curve type of effect on brain function, with lower levels of release causing an increase in metabolism, while very high levels of release actually cause a decrease in metabolism. We hypothesized that yohimbine would cause a relative decrease in metabolism in patients with PTSD in cortical brain areas which receive noradrenergic innervation. Indeed, yohimbine resulted in differences in metabolism in orbitofrontal, temporal, parietal, and prefrontal cortex in PTSD patients relative to controls, with PTSD patients showing a pattern of decreased and normal subjects a pattern of increased metabolism in these areas. PTSD patients (but not normal subjects) had decreased hippocampal metabolism with yohimbine (Bremner et al. 1997b).

Several studies have now used PET $H_2[^{15}O]$ in a challenge paradigm. In a study of combat-related PTSD using PET and $H_2[^{15}O]$ measurement of cerebral blood flow, ten Vietnam veterans with PTSD and ten Vietnam veterans without PTSD were studied during exposure to combat-related and neutral slides and sounds. Vietnam veterans with combat-related PTSD (but not non-PTSD veterans) demonstrated a decrease in blood flow in the medial prefrontal cortex (Brodman's area 25, or subcallosal gyrus) and middle temporal cortex (auditory cortex) during exposure to combat-related slides and sounds. A failure of activation was found in anterior cingulate (area 32 and 24), and increased activation in posterior cingulate, motor cortex, and lingual gyrus in PTSD veterans (Bremner et al. 1999c). In another study, cerebral blood flow correlates of exposure to personalized scripts of childhood sexual abuse were looked at in women with histories of childhood abuse with ($n = 10$) and without ($n = 12$) PTSD. PTSD women showed decreased blood flow in medial prefrontal cortex (area 25) and failure of activation in anterior cingulate, with increased blood flow in posterior cingulate and motor cortex (replicating findings in combat-related PTSD) and anterolateral prefrontal cortex. PTSD women also had decreased blood flow in right hippocampus and parietal and visual association cortex (Bremner et al. 1999d). Other studies of traumatic imagery in combat-related PTSD found alterations in orbitofrontal and temporal cortex in PTSD (Rauch et al. 1996; Shin et al. 1997, 1999).

Another field is receptor imaging in PTSD. Based on findings of decreased benzodiazepine binding in fron-

tal cortex in animal models of stress, we measured benzodiazepine binding with single photon emission computed tomography (SPECT) [^{123}I]iomazenil in 13 combat-related PTSD patients and 13 healthy controls. We found a decrease in benzodiazepine receptor binding in prefrontal cortex (Brodmann's area 9) in patients with combat-related PTSD compared to matched healthy controls (Bremner et al. 1999e).

Human subjects with lesions of medial prefrontal cortical areas have deficits in interpretation of emotional situations that are accompanied by impairments in social relatedness. Anterior cingulate (area 32) activation might well represent a "normal" brain response to traumatic stimuli that serves to inhibit feelings of fearfulness when there is no true threat. From our studies, we learn that dysfunction in this area and/or decreased blood flow in adjacent medial prefrontal cortex (subcallosal gyrus) in PTSD may lead to increased fearfulness that is not appropriate for the context, a behavioral response that is highly characteristic of patients with PTSD (Hamner et al. 1999).

10 Pharmacological Treatment

10.1 General Considerations

Compared with other psychiatric disorders, few studies of psychopharmacology have been performed in PTSD (see Friedman 1996; Sutherland and Davidson 1999). However, with the introduction of new potential targets such as beta blockers and CFR antagonists, this field is rapidly expanding.

10.2 Pharmacotherapy

Antidepressant medications are the mainstay of treatment and are the best studied in controlled clinical trials, but there are also reports in the literature of alleviation of specific symptoms of PTSD with the use of other medications such as sympatholytic agents, mood stabilizers such as lithium and anticonvulsants, benzodiazepines, and drugs which affect the dopamine, opioid, and serotonergic system. Given the different clusters of PTSD symptoms, the clinician may find only partial response in individual patients with a single medication and will find it necessary to consider addressing the multiple symptoms with a combination of medications. Such medications will be found in the following groups: antidepressants, anxiolytics, adrenergic inhibitors, mood stabilizers, and anticonvulsants (see Table 3). The individual therapeutic dose range is listed for each drug.

No medication is approved yet for the indication of PTSD. Following expert guidelines, it is recommended that the selective serotonin reuptake inhibitors (SSRI) and nefazodone should be used as first-line drugs for PTSD (Foa et al. 1999a). In adults, it is recommended

Table 3. Classes of medication in PTSD (adapted from Sutherland and Davidson 1999)

Class	Group	Generic name	Dose range (mg)
Adrenergic inhibitors		Propanolol	20–160
		Clonidine	0.1–0.4
Anxiolytics	Benzodiazepines	Clonazepam	0.5–6
		Lorazepam	0.5–4
		Clordiazepoxide	5–40
		Diazepam	2–40
	Azapirones	Buspirone	5–60
Antidepressants	MAOI	Phenelzine	15–90
		Tranylcypromine	20–60
	SSRI	Fluvoxamine	50–300
		Fluoxetine	10–60
		Sertraline	50–200
		Paroxetine	10–60
	Phenylpiperazine	Nefazodone	200–600
	Triazolopyradine	Trazodone	150–300
	TCA	Amitryptyline	50–300
		Imipramine	50–300
Mood stabilizers	Lithium	Lithium carbonate	300–1200
Anticonvulsants		Carbamazepine	200–1500
		Valproic acid	125–2000
		Dilantin	300–600

MAOI, monoamine oxidase inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.

that buspar or benzodiazepines should be added in situations of persistent fear reactivity. There are eight double-blind placebo-controlled medication trials to date in the last 10 years showing no or on average only modest positive outcomes. Shestatzky et al. (1988) found no difference in response between placebo and 45–75 mg phenelzine in a population of ten PTSD patients with varied trauma after treating them for 4 weeks. Frank et al. (1988) gave 46 male veterans 50–300 mg imipramine or 15–75 mg phenelzine for an average duration of 6 weeks. They found that intrusive scores on the Impact of Events Scale (IES; Horowitz et al. 1979) decreased both with phenelzine and imipramine. There was some decrease in the avoidance subscale with phenelzine. However, there was no difference in measures with the placebo group. Another study in imipramine was performed by Robert et al. (1999) looking at the effects of imipramine in pediatric burn patients with symptoms of acute stress disorder in 25 children. They received either imipramine or chloral hydrate for 7 days, suggesting a place for cautious initial use of imipramine to reduce ASD symptoms in burned children. Reist et al. (1989) studied 100–200 mg desipramine in 18 male veterans with concurrent diagnoses in a 4-week cross-over design. They found significant improvement on the IES intrusion subscale and depressive symptoms only in one subgroup with concurrent major depression. There was no change overall in anxiety and PTSD symptoms. Davidson et al. (1990, 1993) studied the effects of amitriptylline in 62 male veterans, treating them for 8 weeks. The results were that amitriptylline was superior to placebo on anxiety and depression, with marginally effects on IES avoidance and intrusive scales. Braun et al. (1990) found aprazolam superior to placebo on anxiety in 16 patients with PTSD due to varied causes. They treated the patients for 5 weeks with 2.5–6 mg alprazolam. There was no difference on IES or depression. Van der Kolk et al. (1994) looked at the effects of 20–40 mg fluoxetine in a trial consisting of 5 weeks double-blind and 5 weeks of open medication in 31 veterans and 33 civilian trauma victims. They reported significant reduction in symptoms including intrusive numbing. One half of the population no longer met criteria for PTSD. Baker et al. (1995) assessed the efficacy of brofaromine in 118 PTSD outpatients, giving 56 brofaromine and 58 placebo. Their results showed that both groups showed significant reductions in the symptoms, without significant differences in the between-groups analysis.

The effect of these medications may well begin as early as 2 weeks after treatment in drug-responsive patients. Whereas earlier findings suggested that SSRI may be less effective against reexperiencing and arousal than they are against avoidant/numbing symptoms, it is still not yet clear to what extent the medication shows its efficacy in the different clusters (Davidson et al. 1997). Reports of the efficacy of different treatments are being published (sertraline: Brady et al. 1995; mirtazapine: Connor et al. 1999; Falkai 1999; fluvoxamine: Davidson et al. 1998b; nefazadone: Davidson et al. 1998c; Hidalgo et al. 1999). More double-blind, placebo-controlled clinical trials on PTSD are in progress to assess the utility of different SSRI and selective norephinephrine reuptake inhibitors (SNRI) as a treatment in this disorder.

Interestingly, antiadrenergic drugs (such as α_2-agonists or beta blockers) have so far received little systematic attention in clinical trials, despite evidence for adrenergic dysregulation in PTSD. Some authors recommended starting pharmacotherapy in new PTSD patients with an antiadrenergic agent such as clonidine or propanolol (Friedman 1998). Clonidine can be very effective in this respect, where the reduced adrenergic activity is often accompanied by a reduction in dissociative symptoms. The advantage of clonidine or a beta-adrenergic agonist is that this medication can be titrated over the course of 1–2 weeks. We suggest switching to a drug with longer half-life if a clonidine responder appears to develop tolerance to the drug. If the symptoms persist, as they often do, after optimal titration, the next drug to add is an SSRI. Using another medication from the same class is not recommended if the first drug is not effective. If patients develop insomnia or agitation, the best choice is nefazadone or trazodone at bedtime. If patients are still nonresponders after 8–10 weeks, a different class of medication (e.g. adrenergic inhibitors, anxiolytics, mood stabilizers, anticonvulsants) should be considered. The importance of pharmacoeducation has never been well studied, but every clinician knows or should know the importance of this part of the treatment.

10.3 New Developments in the Treatment of Stress-Related Brain Changes

Studies in animals have demonstrated several agents with potentially beneficial effects on the reversibility of the glucocorticoid-mediated hippocampal toxicity. It has been found that phenytoin (Dilantin) reverses stress-induced hippocampal atrophy, probably through excitatory amino acid-induced neurotoxicity. Agents such as tianeptine and dihydroepiandosterone (DHEA) have been described to produce similar effects (Watanabe et al. 1993). Neurons within the hippocampus were found to be unique within the brain in showing the capacity to regenerate themselves (Gould et al. 1999). Since these are in vitro studies that report

on neurogenesis in the hippocampus through a regulation of BDNF and cAMP by SSRI, we hypothesize that the effects of SSRI may play a role in the reversibility of the accelerated aging process in humans (Duman et al. 1997; Nibuya et al. 1999). There are findings indicating that a common action of antidepressant treatments is through upregulation of cAMP response element binding protein (CREB) and that this may lead to regulation of specific target genes. Such treatment effects on BDNF and trkB mRNA can have long-term effects on brain function. In these studies, however, it is evident that chronic, but not acute, administration of several different classes of antidepressants, including SSRI and SNRI, increase the expression of CREB mRNA. Interestingly, in contrast, chronic administration of several non-antidepressant psychotropic drugs did not influence expression of CREB mRNA, demonstrating the pharmacological specificity of this effect (Nibuya et al. 1996). If through hippocampal neurogenesis the medication has an effect on the glucocorticoid-induced impairment in declarative memory, this may have promising results if found in humans (Newcomer et al. 1994).

11 Psychological Treatment

According to expert guidelines (Foa et al. 1999a) concerning the treatment of PTSD, current psychological treatments of PTSD include the following: (a) behavioral therapy (flooding; systematic desensitization [SD] eye movement desensitization reprocessing [EMDR]), (b) cognitive-behavioral therapy, and (c) anxiety management training (stress inoculation training [SIT] biofeedback). These treatments are described in detail in Meadows and Foa (1999). Each intervention has its own merits, and all three can be very useful regardless of the stage of PTSD. It is recommended that patients should be seen in the acute situation for 3 months, with boost sessions every 2–4 weeks; in a chronic situation, the therapy can last up to 6 months, with booster sessions every 2–4 weeks. Studies have been performed to assess efficacy of psychological interventions in PTSD (see Foa et al. 1999b; Spiegel 1999).

11.1 Behavioral Treatments

Exposure techniques involve confronting one's fears. Exposure-based therapeutic regimens have had a long history in the treatment of anxiety-related disorders.

11.1.1 Flooding

Flooding involves two essential steps: (1) the administration of multiple component assessment packages and (2) the provision of imaginal flooding regimens. In the assessment phase, the goal is to identify the pathological behaviors, determine the etiological variables that maintain distress, and establish baseline data to determine treatment efficacy over time. Different sources of information should be used. The intervention phase is presented in five basic steps, which should be presented in sequential order: (1) education, (2) imagery training, (3) relaxation training, (4) presentation of traumatic scenes, and (5) debriefing. Flooding is an aversive process in that PTSD symptoms may increase during the initial phases of therapeutic exposure. (For an overview of the method, see Saigh et al. 1999b.)

11.1.2 Systematic Desensitization

Systematic desensitization falls at the other end of the dimensions of exposure methods, using brief, imaginal, and minimally arousing exercises. Pioneered by Wolpe (1958), SD was among the earliest behavioral treatments studies for PTSD. It involves pairing imaginal exposure with relaxation, so that the anxiety elicited by the confrontation with the feared stimuli is inhibited by relaxation. First, the patient is instructed in muscle relaxation exercises. When a state of relaxation is achieved, the feared stimuli are introduced, via imagined scenarios, in a graded hierarchical manner, with the least anxiety-provoking scenarios presented first. When the patient begins to feel anxious, the instruction is given to erase the screen, focus on relaxation, and begin again. The scenario is repeated until it no longer elicits anxiety, at which point the next scenario is introduced. This process continues until the stimuli on the hierarchy no longer elicit anxiety. For example, a therapist may teach a patient to head off panic attacks by taking slow deep breaths. The therapists may gradually expose the patient to images or sensations that remind him or her of the trauma (battle photos, loud noises, smells) and then help him or her deal with the fears that come up.

11.1.3 Eye-Movement Desensitization Reprocessing

EMDR is a form of imaginal exposure accompanied by saccadic eye movements. It is conducted by having the patient focus on a disturbing image or memory while the therapist moves a finger across the patient's visual field (Shapiro 1989). The saccadic eye movements

result from the patient's tracking the therapist's finger. (For a variety of reviews, see Lohr et al. 1995; Devilly and Spence 1999; Cusack and Spates 1999; Lazrove et al. 1998.) The most recent review by Shapiro describes four recent, independent, rigorously controlled studies of EMDR that reported that 84%–100% of single-trauma victims no longer maintain the PTSD diagnosis after the equivalent of three 90-min sessions (Shapiro 1999). Since its inception, EMDR has been the focus of much controversy.

11.2 Cognitive Therapy

Cognitive therapy was pioneered by Beck (1972) and further developed by others to help patients modify dysfunctional cognitions. The basic assumption is that dysfunctional thoughts drive negative emotional states such as fear or anger. In a given situation, this may lead to different emotions depending upon the interpretation of the situation. Pathological emotions are generated by distorted, dysfunctional thoughts. Typically, cognitive restructuring (CR) aims to teach patients to identify dysfunctional thoughts, to evaluate their validity, to challenge their erroneous or unhelpful thoughts, and to replace them with more beneficial ones. CR would focus on identifying the thoughts that precede strong emotions, such as "I am going to be assaulted." Then the validity of this belief would be evaluated. Erroneous beliefs are replaced by rational ones, suggested by the evidence reviewed in one of the previous steps.

11.3 Anxiety Management Therapies

The assumption that seems to underlie the rationale for anxiety management programs centers on the notion that pathological anxiety stems from skill deficits. This implies that providing patients with appropriate skills would enable them to manage their anxiety. Skills such as relaxation training, positive self-statements, breathing retraining, biofeedback, social skill training, and distraction methods aim at managing the anxiety when it occurs, rather than preventing pathological anxiety from occurring by correcting the supposedly underlying mechanisms.

11.3.1 Stress Inoculation Training

SIT was developed by Meichenbaum (1974) as a treatment for anxious patients. The method was adopted by Veronen et al. (1979) for treatment of rape-related disturbances. This modified SIT includes psychoeducation, muscle relaxation training, breathing training, role playing, covert modeling, guided self-dialogue, and thought-stopping. The three-component model of SIT includes patients beginning to see their responses in the physiological, behavioral, and cognitive domains. SIT is one of the most commonly used anxiety management treatments for PTSD.

11.3.2 Biofeedback

Biofeedback is a procedure in which patients learn to gain control over their physiological processes. This control is achieved by having patients observe displays or listen to tones of their physiologic activity (EMG activity) and then try to change the display or change the tone.

11.4 Other Therapeutic Interventions and Modalities

Several other therapeutic strategies are reported in PTSD. Shay and Munroe report on a treatment setting in which the encounter is the focus of attention in therapy (Shay and Munroe 1999); other reports describe psychodrama therapy (Carbonell and Parteleno-Barehmi 1999), psychodynamic approaches (Huller and Barash-Kishon 1998), or use of hypnosis (Spiegel 1992; Kluft 1992; M. Phillips 1993).

Most clinicians who treat PTSD have an eclectic approach to treatment, and systematic treatment outcome studies have yet to be performed (Brom et al. 1989; Spiegel 1999). Combining biological, psychological, and psychosocial treatment may well yield best results. Rehabilitative goals should replace curative techniques in those patients with chronic PTSD (Shalev et al. 1996b). Similar to the importance of pharmacoeducation, the importance of psychoeducation should not be underestimated (J.G. Allen et al. 1997; Lubin et al. 1998).

12 Concluding Remarks

The field of psychiatry appears to be finally coming to terms with the fact that traumatic stress can result in chronic psychiatric disorders, including PTSD. We may be ready to go beyond the thinking inherent in the gross stress reaction of DSM-I, which described a reversible mental response to stress that can affect anyone and does not constitute a true psychiatric disorder. These changes have been partially driven by

the finding, surprising to many, that events which enter the eye and the ear (trauma) can have lasting effects on the brain and physiology (Andreasen 1995; Bremner 1999b). In PTSD, we are at the crossroads between mind and brain, and our field is moving toward a breakdown between the artificial distinctions between psychology and biology. This will bring us back to the viewpoint originally encompassed by DaCosta and Kraepelin that mental disorders have their basis in the brain (DaCosta 1871; Kraepelin 1919).

The more traumatic stress is examined, the more it becomes apparent that stress may have also far-reaching influences on all of the major psychiatric disorders. This has led to a tendency for PTSD and the stress response to become like a fast-moving train that threatens to take along everything in its path. In fact, workers in the field of PTSD are now in danger of being victimized by their own success. Once again, psychiatrists may be asked to bear the responsibility for the unfairness and discrepancies of our society. The challenge in the future will be to determine the most appropriate way to use our psychiatric nomenclature to describe the relationship between environmental events such as extreme stress and psychopathology.

Future studies will need to focus on estimating age-at-onset distributions, cohort effects, and the conditional probabilities of PTSD from different types of trauma. These future epidemiologic studies will also need to assess PTSD for all lifetime traumas rather than for only a small number of retrospectively reported "most serious" traumas. As for the neurobiology and treatment of the disorder, the wealth of laboratory research and animal models has helped us understand the pathophysiology of the disorder. It is for future studies to translate these findings into optimal pharmacotherapeutic interventions that can be combined with psychological treatments for alleviation of symptoms, reduction of medical consumption, and better quality of life for patients currently suffering from PTSD – since it is not likely that traumatic stress will be eliminated from our society.

Appendix. Diagnostic Criteria for Post-traumatic Stress Disorder (from DSM-IV; APA 1994)

A. The person has been exposed to a traumatic event in which both of the following were present:
(1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
(2) the person's response involved intense fear, helplessness, or horror

Note: In children, this may be expressed instead by disorganized or agitated behavior

B. The traumatic event is persistently reexperienced in at least one of the following ways:
(1) recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions

Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.

(2) recurrent distressing dreams of the event

Note: In children there may be frightening dreams without recognizable content

(3) acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated)

Note: In young children, trauma-specific reenactment may occur

(4) intense psychological distress at exposure to internal or external cues that symbolize or resemble and aspect of the traumatic event
(5) physiological reactivity on exposure to internal or external cues that resemble an aspect of the traumatic event.

C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
(1) efforts to avoid thoughts, feelings, or conversations associated with the trauma
(2) efforts to avoid activities, places, or people that arouse recollections of the trauma
(3) inability to recall an important aspect of the trauma
(4) markedly diminished interest or participation in significant activities
(5) feeling of detachment or estrangement from others
(6) restricted range of affect (e.g. unable to have loving feelings)
(7) sense of a foreshortened future (e.g. does not expect to have a career, marriage, children, or a normal life span).

D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
(1) difficulty falling or staying asleep
(2) irritability or outbursts or anger
(3) difficulty concentrating
(4) hypervigilance
(5) exaggerated startle response.

E. Duration of the disturbance (symptoms in Criteria B, C and D) is more than 1 month.
F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

Specify if: Acute: if duration of symptoms is less than 3 months
Chronic: if duration of symptoms is 3 months or more
Specify if: With delayed onset: if onset of symptoms is at least 6 months after the stressor

Adjustment Disorders

Translator: E. Taub

1 Introduction

The diagnostic category of the adjustment disorders consists of temporally limited, event-related disorders that do not undergo a transition to one of the major psychiatric disorders, such as post-traumatic stress disorder (PTSD), severe depressive episode, or schizophrenia, but instead take a "benign," transient course. The concept of the adjustment disorders as event-related psychogenic disorders is in the tradition of the "abnormal reaction to experience" (*abnorme Erlebnisreaktion*; Schneider 1980). Adjustment disorder is a diagnostic category often applied in psychiatric practice. The development of mental symptoms as a consequence of life events or changes in life is a practically universal phenomenon (see Rahe 1995). The diagnosis of an adjustment disorder has the advantage of being plausible to laymen while not being laden with the "stigma" of a severe mental illness. It thus meets the need of the clinician for a widely accepted label for the common, transient mental disorders that are presumed to have a benign prognosis.

These same characteristics, however, make the adjustment disorders one of the more problematic categories of DSM-IV and ICD-10. DSM-IV is intended to be atheoretical; however, unlike the disorders in most other categories, the adjustment disorders have to be linked to an "etiological" event. The diagnosis of an adjustment disorder is thus exceptional in requiring more than just a clinical description. There is an implicit requirement for an assessment of the relative contributions of "exogenous" and "endogenous" factors, with a qualitative judgment of an event as a decisive change in life, as opposed to a stress of the more "usual" kind, which might coincidentally be present at the same time as the abnormal mental manifestations. Furthermore, an assessment of prognosis regarding the severity of the disorder in its future course, and its projected duration, is also required. Unfortunately, these implicitly required assessments rest on an insecure empirical foundation and are of only limited reliability. A further, potentially serious problem is that the wide acceptance of the diagnosis of adjustment disorders among both clinicians and patients leads to an excessive use of this category.

The concept of the adjustment disorders presupposes several seemingly plausible assumptions regarding the nature of life events and the manner in which individuals cope with them. One of these is the assumption that life events strike people essentially at random. This assumption, however, is not supported by the available literature. Rather, prospective studies indicate that many individuals consistently experience life events at a high frequency, while others consistently experience them at a low frequency. The frequency of life events has a moderately high, statistically significant correlation within twin pairs, and the correlation coefficient is higher for monozygotic than for dizygotic twins. Possible explanations for this that have been proposed include similar social status, level of social competence, extent of general psychopathology, lifestyle, and consumption of psychotropic substances (Kendler et al. 1993). There are as yet no research findings available concerning the relative contributions of high-risk behavior, lack of self-protective behavior, and social standing to the variation among individuals in their predisposition to life events.

A further assumption underlying the concept of the adjustment disorders is that normative coping processes exist and that the ability to cope with stressors is normally distributed around this norm. This assumption, however, conflicts with the known extreme heterogeneity of human reactions.

2 Diagnosis and Clinical Features

The diagnosis of an adjustment disorder can be made on an operationalized basis in accordance with either DSM-IV (Appendix A) or ICD-10 (Appendix B). An adjustment disorder must be linked to a specific external stressor, but its manifestations need not appear immediately. DSM-IV allows an interval of up to 3 months before the appearance of manifestations, while ICD-10 allows no more than 1 month. Furthermore, the manifestations need not remit immediately upon removal of the stressor, but they must do so within 6 months. If the stressor remains present, a chronic adjustment disorder may result; DSM-IV gives no upper limit for the duration of such a disorder, while ICD-10 allows a maximum of 2 years.

The manifestations that may be associated with the diagnosis of an adjustment disorder are extremely diverse. Characteristic manifestations include transient emotional symptoms, such as feelings of dejection, worry, grief, hopelessness, discouragement, anxiety, fear, discontentment, irritation, guilt, shame, jealousy, suspicion, weariness, humiliation, anger, rage, and aggressiveness, but also helplessness, a feeling of having no feelings, emotional depletion, or a transient affective instability, with sudden mood fluctuations lasting minutes or hours. There may be disturbances of sleep, appetite, and sexual function.

Behavioral changes are common, including neglect of occupational, scholastic, academic, social, and interpersonal responsibilities and avoidance behavior, with

transient anxious avoidance of social situations or of situations that might aggravate manifestations of anxiety or make them visible in public (e.g. use of public transport, elevators, cable cars, tunnels). Transient increased consumption of substances (alcohol, nicotine) is also common. Transient compulsive behaviors or obsessive thoughts are occasionally observed.

Somatoform symptoms, i.e. pain and other physical complaints for which there is no medical explanation, are also common, as are transient, relatively mild dissociative symptoms. Particularly in children and young adults, there are transient abnormalities of conduct with oppositional or rebellious behavior, destruction of one's own or others' property, theft, or violence.

There may be autoaggressive behavior such as physical injury to oneself or suicidal actions. Adjustment disorders are among the more common diagnoses in groups of patients studied after a first attempt at suicide (Johnsson et al. 1996). Currently available studies, however, allow no precise estimate of the risk of suicide associated with the diagnosis of adjustment disorder.

The intensity and duration of all manifestations may vary considerably. The diagnosis of an adjustment disorder, as opposed to patterns of coping lying within the behavioral "norm," requires that they be intense enough to cause marked distress and/or impair social or occupational performance ability. Furthermore, the manifestations should not merely represent a simple grief reaction. Nonetheless, the differentiation of the adjustment disorders from other, major mental disorders requires that the intensity, duration, and multiplicity of manifestations lie below the threshold values set by whichever diagnostic manual is used (DSM-IV or ICD-10) and, in particular, that they not merely represent an exacerbation of the manifestations of a chronic, or chronically recurring, anxiety disorder, depressive disorder, somatoform disorder, or personality disorder. This is especially true with respect to personality disorders with a high degree of reactivity. In such cases, the additional diagnosis of an adjustment disorder should be assigned only if the manifestations arising in response to the stressor are atypical for the personality disorder in question.

The adjustment disorders thus constitute a "transitional category" between severe mental disorders and states considered to lie within the range of normal coping patterns (Fabrega et al. 1987). The presence of perceptual disturbances such as hallucinations, formal thought disorders beyond mere brooding, disorders of thought content with delusions, or impairment of cognitive abilities is incompatible with the diagnosis of an adjustment disorder. Both DSM-IV and ICD-10 allow the coding of various subtypes of adjustment disorder according to their predominant manifestations.

3 Differential Diagnosis

The differentiation of the adjustment disorders from depressive episodes and recurrent depressive disorders (DSM-IV 296.xx and ICD-10 F32, F33), anxiety disorders, post-traumatic stress disorders, somatoform disorders, dissociative disorders (DSM-IV 300.xx and ICD-10 F40–45), disorders of conduct (DSM-IV 312.xx and ICD-10 F91, F92), and personality disorders (DSM-IV 301.xx and ICD-10 F60, F61) is of major clinical importance.

Several factors may complicate the differential diagnosis: preceding episodes of depression or anxiety, or behavioral abnormalities, may be forgotten or trivialized by the patient during history-taking ("recall bias"). A feeling that it is necessary to establish a cause for the patient's ailment, or an inappropriate attachment to an external model of disease, may lead the diagnostician to exaggerate the importance of a current external event. On the other hand, the intensity and significance of preceding mental manifestations, and of persistent dysfunctional patterns of inner experience and behavior, may occasionally be underestimated because of lack of insight into the illness and the egosyntonic character of the symptoms. Patients with cluster B personality disorders (borderline, histrionic, and narcissistic personality disorders), in particular, have a marked reactivity to external events and attribute their mood fluctuations to them. When the clinician is inadequately informed about the patient's previous history, this may lead to the erroneous diagnosis of an adjustment disorder.

The symptoms of post-traumatic disorders, such as flashbacks and nightmares, are sometimes suppressed by patients in talking with psychiatrists and psychotherapists because of associated feelings of anxiety, shame, or guilt; post-traumatic disorders are therefore underdiagnosed. The time at which the diagnosis is assigned also influences the result. If the patient is seen by the clinician early in the course of the illness, the manifestations may be less than fully developed, and the criteria for a specific disorder not yet fulfilled.

4 Etiology and Pathogenesis

By definition, adjustment disorders are induced by one or more stressors. The severity of the stressor is typically not linearly related to the nature and extent of the resulting psychopathology in the affected individuals. The level of stress experienced by the patient is a complex function not only of the intensity, duration,

controllability, and reversibility of the stressor, but also of individual factors such as the resources and coping strategies at the patient's disposal, social support, personal context, and personal value systems.

DSM-IV has no upper or lower limit for the severity of the stressor, but ICD-10 excludes catastrophic or unusual stressors while also requiring a minimal level of severity (decisive change in life). Thus, in DSM-IV, but not in ICD-10, the etiological factors of the adjustment disorders overlap with those of post-traumatic stress disorder. DSM-IV distinguishes these entities from each other solely on the basis on the severity of their manifestations. On the other hand, life events also play a major role in severe depressive episodes, particularly in the induction of the initial depressive phase, and there is therefore some overlap here as well.

Stressors may appear in the form of single events such as the loss of a partner, family member, or significant other through moving away, separation, divorce, or death; rejection or severe interpersonal conflict with significant others or with the social environment; severe physical illnesses in the affected individual, family members, or significant others; loss of employment; scholastic or academic events, such as failing an examination or having to repeat a school year; judicial events such as arrest, conviction, or losing a lawsuit; political events such as the loss of office or public disputes; mobbing; political, religious, or ethnic discrimination or persecution; crime, accidents, and natural disasters. Even "positive" life events such as marriage, pregnancy, birth of children, promotions, and financial gains can become stressors, particularly when these place demands on the affected individual that he or she cannot meet.

Stressors can also be chronic or recurrent. Examples include poverty, lack of access to health care, chronic illness in the affected individual or significant others, chronic intrafamilial conflicts, and seasonal financial or health problems (e.g. seasonal employment, extreme climatic conditions). Stressors may affect individuals, families, or entire social groups or communities. Thus, in summary, the assessment of stressors requires attention to their degree of severity and to the differentiation of adjustment disorder from post-traumatic stress disorder. DSM-IV and ICD-10 draw the distinction between these two entities in somewhat different ways.

Although the events listed above can lead, quite understandably, to the appearance of emotional symptoms and behavioral abnormalities, major negative life events do not, as a rule, produce mental functional disturbances in the clinical sense. It is assumed that the mental consequences of such events arise through an interaction of stressors, coping mechanisms, and a predisposition to mental disturbances. This interaction has indeed been the subject of scientific investigation, yet little attention has been paid to the category of the adjustment disorders: the available studies on the consequences of highly negative or catastrophic life events deal with general mental manifestations and/or the presence or absence of post-traumatic stress disorder, but hardly any data exist regarding the frequency of adjustment disorders as defined by DSM-III-R or DSM-IV.

Thus, in a study of 38 children from stable families, the death of a parent was associated with significant grief, but with no further limitation of function. The affected children were similar in most dimensions to age-matched normal control subjects, and they were in significantly better condition than a depressive control group (Fristad et al. 1993). According to another study, in the 2 years following an isolated, catastrophic accident, the prevalence of post-traumatic stress disorder in individuals providing assistance to the victims is 7%–12% (Epstein et al. 1998). Among professional firefighters, who are constantly exposed to potentially traumatizing events, the prevalence of post-traumatic stress disorder is approximately 18%, while 49% have individual manifestations of post-traumatic stress disorder (Wagner et al. 1998). In general, significant negative life events raise the risk of psychiatric disorders in the following year by a factor of 3–6 (Goodyer et al. 1987).

There may be predisposing psychological risk factors, including unstable interpersonal relationships, lack of social support, impaired social competence, poor ability to communicate, and a tendency toward overdramatic or dichotomous assessment of external events, or toward inward attribution of external problems. One of the few prospective studies to be performed did indeed reveal that a preexisting tendency to anxiety, behavioral problems, and poor school performance influenced the extent of mental symptoms in children who experienced a natural disaster (La Greca et al. 1998).

Psychobiological studies on adjustment disorder are largely absent. There is evidence, however, that the functioning of the serotonergic system may be deficient in individuals suffering from adjustment disorders associated with suicidality (Mann et al. 1999).

5 Epidemiology

Data on the lifetime prevalence of the adjustment disorders in the general population are lacking. The prevalence of adjustment disorder has been studied only in various patient populations and has been found to depend both on the care structure and on the therapeutic setting. Even though the diagnosis of the

adjustment disorders has been operationalized, traditional diagnostic habits still exert a major influence; thus biologically oriented psychiatrists assign this diagnosis less frequently than psychodynamically oriented psychiatrists. All of these factors together account for the marked variation in the reported values for the prevalence of the adjustment disorders.

An adjustment disorder was diagnosed in 5% of all patients seen in the University of Iowa psychiatry department over 4 years. At the level of manifestations, behavioral abnormalities were more common in adolescent patients than in adults (running away, rule infractions, poor school performance, substance use). Adults more commonly had depressive manifestations and disturbances of appetite and sleep (Andreasen and Wasek 1980). A multicenter study carried out by the psychiatric liaison services of seven American, Canadian, and Australian teaching hospitals revealed the presence of an adjustment disorder in 12% of patients as a single diagnosis, and in a further 4% as a second diagnosis in addition to another disorder on axis I or II (Strain et al. 1998).

In the Monroe County Psychiatric Case Register, the adjustment disorders accounted for 28% of all diagnoses in individuals aged 12–18. The frequency of the adjustment disorders was higher in outpatient care and lower in academic psychiatry departments. There was no difference between the sexes. The number of psychiatric contacts following diagnosis was similar to that of patients with neurotic disorders or personality disorders, but much lower than that of patients with schizophrenia. A study carried out in several outpatient care facilities in the United States revealed that adjustment disorder accounted for 24%–65% of all psychiatric diagnoses in patients under the age of 18 (Jacobson et al. 1980). At least one further mental disorder was diagnosed in more than half of the patients in long-term follow-up (Weiner and Del Gaudio 1976; Cantwell and Baker 1989).

6 Course and Prognosis

Adjustment disorders have a relatively benign short-term prognosis. Most patients return to their original functional level. Thus a study at the University of Pittsburgh showed that 29 of 30 study participants with an adjustment disorder went into remission, although the average duration of an episode in adolescents was longer than expected (8.9 months; Kovacs et al. 1994). Despite this favorable short-term prognosis, however, the same study revealed a relatively unfavorable long-term prognosis. Only 59% of these subjects were predominantly in good health over a follow-up period of 5 years. The frequency of new mental disturbances was considerable: 45% received the diagnosis of an adjustment disorder for a second time, while the diagnosis of an anxiety disorder was made in 10%, substance abuse in 10%, and a severe depressive episode in 17%. Thus, after correction for the extent of mental manifestations, the long-term prognosis of adjustment disorder was no more favorable than that of the other psychiatric diagnostic groups.

Adolescents often have a less favorable course than adults. In the University of Iowa study, 71% of adults with an adjustment disorder were in good mental condition 5 years after the index treatment, as compared to only 44% of adolescent study participants. A total of 19% of the adolescents and 13% of the adults had gone on to develop a severe depressive episode. Schizophrenia had been diagnosed in 6% of the adolescents. Alcohol dependency or alcohol abuse was found in 17% of the adolescents and 13% of the adults, while 2% of the adolescents and 4% of the adults had committed suicide (Andreasen and Hoenk 1982).

A follow-up study of patients treated by a German crisis intervention unit revealed a somewhat more favorable prognosis. A total of 70% of the patients were functioning at a good or very good psychosocial level, and had received no further psychiatric diagnoses after an interval of 5 years, while 30% had been treated, mostly in an inpatient setting, for personality disorders, depressive disorders, or (new) adjustment disorders (Bronisch 1991). The time to remission in patients with adjustment disorders was not significantly shorter than that in patients with severe depressive disorders. The cumulative number of patients in remission after 18 months of follow-up was no different in these two patient groups, although there was a significant difference in this respect between the adjustment disorders and the dysthymic disorders (Kovacs et al. 1984).

These studies of disease course indicate that a favorable prognosis, though implicit in the concept of the adjustment disorders, cannot be assumed for all patients. A large subgroup went on to receive the diagnoses of severe depressive disorders, anxiety disorders, post-traumatic stress disorder, somatoform disorders, psychotic disorders, and personality disorders.

7 Treatment

Psychotherapy, in the form of psychotherapeutic counseling or short-term cognitive-behavioral or depth-psychological therapy, is generally regarded as the treatment of choice. The goals of therapy include

relief from acute distress and help and support in the process of restructuring and reassessing the patient's living situation. A further goal is the prevention of further mental disturbances. Treatment may be individual or in a group; it may be offered in the outpatient setting or in an inpatient crisis intervention center. In general, treatment is given according to principles similar to those governing the treatment of post-traumatic stress disorder, albeit in modified form (Horowitz 1997). To date, there has been no systematic, indication-based evaluation of these treatment processes.

Among the pharmacotherapeutic treatment methods available, the short-term administration of benzodiazepines, or of antipsychotic substances in low doses, may be beneficial. Patients with predominantly anxious or depressive manifestations, severe mood fluctuations, or suicidality may benefit from treatment with antidepressants (Verkes et al. 1998). However, psychopharmacological treatment is only rarely recommended for the adjustment disorders. In the multicenter American–Canadian–Mexican study of liaison psychiatric services mentioned above, the administration of an anxiolytic or sedative substance was recommended in 3% of the patients treated, an antipsychotic substance in 1%, and an antidepressant in 7% (Strain et al. 1998). The possible effect of psychoactive medications on the prognosis of the adjustment disorders has not been studied to date.

8 Overview

In summary, much more research is needed in the field of the adjustment disorders. As for the definition of operationalized diagnostic criteria, the literature on the course of these disorders indicates that the temporal criteria, at least, require further empirical testing. Furthermore, longitudinal studies have shown that the long-term prognosis of these disorders is by no means as favorable as originally assumed, particularly in adolescents; rather, the diagnosis of an adjustment disorder is associated with an elevated risk of developing another mental disorder at a future time.

Studies of disease course must also be performed to examine the question of whether the phenomena currently conceptualized under the heading of the adjustment disorders might better be considered minor or subthreshold versions of other psychiatric disorders, and whether the present concept of an event-associated disorder ought to be retained. Finally, there is a lack of controlled studies on the pharmacological and psychotherapeutic treatment of adjustment disorders.

Appendix A. Diagnostic Criteria for Adjustment Disorders According to DSM-IV

A. The development of emotional or behavioral symptoms in response to an identifiable stressor(s) occurring within three months of onset of the stressor(s).
B. These symptoms or behaviors are clinically significant as evidenced by either of the following:
   1. marked distress that is in excess of what would be expected from exposure to the stressor
   2. significant impairment in social or occupational (academic) functioning
C. The stress related disturbance does not meet the criteria for another specific Axis I disorder and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.
D. The symptoms do not represent bereavement.
E. Once the stressor (or its consequences) has terminated, the symptoms do not persist for more than an additional six months.

Adjustment disorder is specified as acute or chronic, where

- acute applies if the disturbance lasts less than six months; or
- chronic applies if the disturbance lasts for six months or longer.

Adjustment disorders are coded according to the subtype corresponding to the predominant symptoms. The specific stressors can be coded on Axis IV:

309.0 with depressed mood
309.24 with anxiety
309.28 with mixed anxiety and depressed mood
309.3 with disturbance of conduct
309.4 with mixed disturbance of emotions and conduct
309.5 not otherwise specified

Appendix B. Diagnostic Criteria for Adjustment Disorders According to ICD-10

A. Onset of symptoms must occur within one month of exposure to an identifiable psychosocial stressor, not of an unusual or catastrophic type.
B. The individual manifests symptoms or behaviour disturbance of the types found in any of the affective disorders (F30–39) (except for delusions and hallucinations), any disorders in F40–F48 (neurotic, stress-related and somatoform disorders) and conduct disorders (F91.–), but the criteria for an individual disorder are not fulfilled. Symptoms may be variable in both form and severity.

The predominant feature of the symptoms may be further specified by the use of a fifth character:

F43.20 Brief depressive reaction

A transient mild depressive state of a duration not exceeding 1 month.

F43.21 Prolonged depressive reaction

A mild depressive state occurring in response to a prolonged exposure to a stressful situation but of a duration not exceeding 2 years.

F43.22 Mixed anxiety and depressive reaction

Both anxiety and depressive symptoms are prominent, but at levels no greater than those specified for mixed anxiety and depressive disorder (F41.2) or other mixed anxiety disorders (F41.3).

F43.23 With predominant disturbance of other emotions

The symptoms are usually of several types of emotion, such as anxiety, depression, worry, tensions, and anger. Symptoms of anxiety and depression may meet the criteria for mixed anxiety and depressive disorder (F41.2) or for other mixed anxiety disorders (F41.3), but they are not so predominant that other more specific depressive or anxiety disorders can be diagnosed. This category should also be used for reactions in children in whom regressive behaviour such as bedwetting or thumb-sucking is also present.

F43.24 With predominant disturbance of conduct

The main disturbance is one involving conduct, e.g. an adolescent grief reaction resulting in aggressive or dissocial behaviour.

F43.25 With mixed disturbance of emotions and conduct

Both emotional symptoms and disturbances of conduct are prominent features.

F43.28 With other specified predominant symptoms

C. Except in prolonged depressive reaction (F43.21), the symptoms do not persist for more than 6 months after the cessation of the stress or its consequences. However, this should not prevent a provisional diagnosis being made if this criterion is not yet fulfilled.

H.P. Kapfhammer

Dissociative Disorders and Conversion Disorders

Translator: E. Taub
This chapter is an abbreviated and revised version of Kapfhammer (1999a,b).

1 Introduction

The terms "dissociation" and "désaggrégation" (disaggregation) were coined by Pierre Janet (1889). Janet viewed the mental life of the individual as an aggregate of mental elements, which he designated as "psychological automatisms." Each automatism, according to his view, is a complex behavioral tendency, comprising both a performance and an emotion, which is released by a specific provoking situation. Under normal circumstances, psychological automatisms are unified in phenomenal consciousness and are accessible to voluntary control. Under traumatic, stressful conditions, however, single automatisms may become split off – dissociated – from the rest of consciousness and exert their effects in an autonomous fashion. Genetically transmitted temperamental traits as well as earlier experiences and the individual's present physical condition together define the capacity of each individual for the mental integration of new information in general, and of traumatic experiences in particular.

Janet's model of dissociation, though oriented toward trauma psychology, is nonetheless essentially based on the idea of a constitutional predisposition to dissociation ("dégénérescence"). The individual's premorbid vulnerability to dissociative disorders thus plays a decisive role. A dissociation (which is to be understood as passive) by no means requires an intense external trauma for it to be released. Rather, a reactivity to exaggerated emotions, inherent in the individual's personality, often exerts a traumatogenic effect and leads to the generation of a psychopathological disorder.

The original position of Freud and Breuer (1895) was still very close to that of Janet. They, too, viewed a traumatic exposure during a sensitive developmental phase and a predisposition to dissociative psychopathology as decisive. Like Janet, they also recognized the importance of autosuggestion, used as a defense against traumatic experiences, in the pathogenesis of dissociative syndromes, as well as the special role of hypnotic techniques in the treatment of this unique class of disorders.

As psychoanalytic theory came to be further developed, however, a major shift of emphasis took place in the conception of the dissociative disorders. The dominant idea at first was that of external events leading to traumatic excitation beyond the individual's subjective ability to cope and thus to a feeling of psychophysical helplessness. Later, Freud increasingly identified a strong influence of unconscious fantasies in the attribution of meaning to "traumatic situations." What was originally thought of as an external, traumatic situation came to be viewed as an intrapsychic situation of danger, for which the ego can prepare itself in advance with controlled amounts of signal anxiety and to which it can react with specific defense mechanisms, such as repression (Freud 1926). While developing these ideas, Freud in no way denied the existence and clinical relevance of real trauma. Yet his concept of repression and of the defense neuroses became the leading paradigm of dynamic psychiatry in the years that followed and consigned Janet's concept of dissociation to obscurity for many decades thereafter (Nemiah 1998).

Hilgard (1986), making use of the newly developed concepts of cognitive psychology, proposed a neodissociative theory that had many points of contact with the psychology of Janet. In his model of the "divided consciousness," the psyche is viewed as an organized system of mental structures controlling perceptual, cognitive, and behavioral processes in different areas. These mental subsystems bear a certain resemblance to Janet's psychological automatisms, but may also be thought of as comparable to the modules and cognitive units postulated in cognitive theories of parallel information processing. Each of these subsystems can, in principle, regulate its own input and output independently of the others, though the subsystems do communicate with one another under normal circumstances. The central element of the overall system is a structure exercising the executive functions of monitoring and control. This structure also provides the mental basis for the experience of phenomenal consciousness and for voluntary control.

According to Hilgard, this central executive system may become dysfunctional and cease to integrate and organize the individual control structures, resulting in a state of divided consciousness. Hilgard's conception is based primarily on the findings of psychological experiments involving hypnosis in mentally healthy subjects, but it is also relevant to the modern understanding of dissociative processes in psychopathological states. While Hilgard was developing these theoretical ideas, central elements of Janet's trauma psychology experienced a revival in the clinical field as well (van der Hart and Horst 1989).

2 The Concept of Dissociation

The concept of dissociation is multilayered. On one level, broadly understood, it includes a number of normal psychological phenomena, such as automatic modes of behavior, subconscious perception, implicit versus explicit memory, meditation, focused concen-

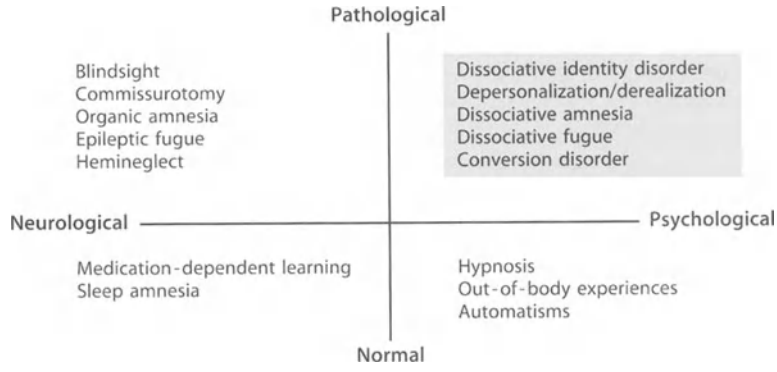

Fig. 1. Dissociative phenomena. (After Cardeña 1994)

tration, and hypnosis. On another level, it is restricted to pathological phenomena, such as disturbances of memory, identity, consciousness, and perception of the self and of the environment. It may also include certain pseudo-neurological and special neurological syndromes (Fig. 1). The term is used in both a descriptive and an explanatory sense.

Cardeña (1994) emphasized the relevant aspects of dissociation for clinical psychopathology. He opposed the extension of the term to cover stimulus-processing phenomena that do not reach consciousness because of neurophysiological or structural limitations or because of the finite capacity of attention – phenomena that can only be made perceptible to the individual, if at all, by special techniques such as biofeedback. Rather, dissociation, in his view, reflects a failure of the normally expected integration of central personality functions, leading to typical disturbances of memory, consciousness, and personal identity. Use of the term in this sense implies the inclusion of pseudoneurological conversion syndromes as well. Furthermore, dissociation is related to certain alterations of consciousness in which the central feature of phenomenal perception is an alienation from oneself or from the environment.

In the foregoing discussion, "dissociation" has been used as a descriptive term for certain clinically relevant phenomena. The term may also be used in the etiological sense to describe the defense mechanisms that are presumed to underlie these psychopathological states. Yet a conceptual differentiation between dissociative and other defense mechanisms, such as repression, may prove difficult. They may be distinguished in a psychodynamic sense as follows: Repression involves the disguise and concealment of information and, consequently, the need to transform the implicit meaning of dreams by reinterpretation, for example; it usually also involves a lack of temporal organization of repressed mental content, and it is decisively provoked by intrapsychic conflicts. In dissociation, on the other hand, information is not transformed. The information in question can often be brought to consciousness through direct psychotherapeutic techniques, such as hypnosis. Dissociation usually occurs in relation to a circumscribed period of time in the individual's biography and represents a basic mechanism of withdrawal from a mentally intolerable reality. Dissociation as a defense mechanism is thus explicitly related to an external trauma (Singer 1990).

3 Establishment of Terminology

In the modern psychiatric classification systems (DSM-IV and ICD-10), the hallmark of the diagnostic category of the dissociative disorders is a partial or total loss of the integrative functions of consciousness, memory, personal identity, and perception of the self and of the environment. These disorders were referred to in earlier diagnostic manuals as "hysterical neurosis of dissociative type." ICD-10 subsumes the complementary type of hysterical neurosis, i.e. the conversion disorders, under the same category, classifying them as dissociative motor disorders, anesthesia and sensory loss, or convulsions. In DSM-IV, in contrast, the conversion disorders appear under the separate diagnostic category of somatoform disorders. The difference between the two classification systems is based on a difference in underlying assumptions. In ICD-10, dissociation, i.e. a failure of integration of mental functioning, is viewed broadly as a classifying principle. In DSM-IV, the presence of physical symptoms with no organic medical cause in a certain group of mental disorders is taken as the defining feature of a separate diagnostic category.

It is conceivable that future editions of DSM will bring the conversion disorders and the dissociative disorders together under a single category. The two classes of disorders share a number of important features. Both are characterized by pseudo-neurological manifestations, with dysfunction in the area of conscious experience. Particular present and past

experiences become temporarily inaccessible to conscious attention, but nonetheless continue to influence the experiences, thoughts, and actions of the individual in the form of implicit perceptions and recollections. Thus certain consciously planned, goal-oriented acts cannot be performed, while other unconsciously planned acts are experienced as involuntary (Kihlstrom 1994).

ICD-10, unlike DSM-IV, has removed the depersonalization and derealization disorders from the category of the dissociative disorders and assigned them to that of "other neurotic disorders," even though they may be counted among the core syndromes in the spectrum of dissociative psychopathology.

The discussion in this chapter is organized essentially along the lines of DSM-IV. We will treat the spectrum of the dissociative disorders as composed of five clusters of manifestations that may appear in varying degrees of severity and in varying combinations (Steinberg 1994a):

- *Amnesia*: the forgetting of personal data, more severe than could be attributed to ordinary forgetfulness
- *Depersonalization*: an altered or distorted experience and perception of oneself and one's own body, with feelings of alienation and emotional removal from oneself
- *Derealization*: a feeling of alienation and emotional removal from the environment, with a possible connotation of unreality
- *Identity confusion*: the subjective feeling of uncertainty, confusion, or conflict regarding personal identity
- *Identity change*: a change of identity, possibly with the use of different names and biographies and the demonstration of otherwise unavailable knowledge and personal capabilities

This chapter also includes a discussion of conversion disorders, which involve pseudo-neurological abnormalities of voluntary motor activity, sensation, or the regulation of consciousness.

4 Dissociative Disorders

4.1 Definition and Clinical Features

4.1.1 *Dissociative Amnesia*

Dissociative or psychogenic amnesia is the forgetting of important personal data that cannot be attributed to "ordinary" forgetfulness, a neurological or general medical illness, or the effects of psychotropic substances. The amnesia is typically retrograde, i.e. it is related to a particular episode or to a stretch of time before a defined event that is usually of an unpleasant, stress-inducing, or traumatic nature. It is usually reversible. Janet (1894) provided a classification of dissociative amnesia into several distinct types, and this system remains valid in the modern clinical view:

- *Circumscribed amnesia*: the inability to remember events that took place within a defined period of time.
- *Selective amnesia*: the ability to remember some, but not all relevant events in a defined period of time.
- *Generalized amnesia*: failure to remember anything about one's own life, including one's own name.
- *Continuous amnesia*: failure to remember successively occurring events.
- *Systematic amnesia*: amnesia for highly specific categories of memory, such as recollections of one's own family or of a specific person.

In the subjective experience of the sufferer, dissociative amnesia manifests itself as a vague loss of time over the course of the preceding days or weeks. Patients find that other people behave in ways that are not familiar from the past and thus appear strange. Unknown objects suddenly appear among their possessions. Confusing changes occur in their interpersonal relationships for which they have no explanation. They may demonstrate unusual fluctuations in their capabilities, habits, preferences, or knowledge. They sometimes experience brief, trance-like amnestic episodes (microamnesia). Not uncommonly, a period of confusion occurs before the patients cognitively realize their loss of memory and then try to reorganize their life situations around this concept (Loewenstein 1996).

Dissociative amnesia has a wide-ranging differential diagnosis. It may be a manifestation of another dissociative disorder, such as dissociative fugue or dissociative identity disorder; it may appear in the context of an acute or post-traumatic stress disorder (PTSD); it may be associated with a somatoform disorder (which may be a conversion disorder); or it may be present in combination with a borderline personality disorder (Davidson and Foa 1993; Spitzer et al. 1994). In terms of clinical psychopathology, it may prove to be a simulation or an artificial disorder (Kapfhammer et al. 1998a,b; Schacter 1986). Amnestic episodes may occur early in the course of a dementing illness or during an episode of delirium, as a component of epilepsy or migraine, or in the context of transient global amnesia. Aside from these neurological disorders, other causes include toxic influences such as massive alcohol consumption or the use of

barbiturates, benzodiazepines, phencyclidine, LSD, and steroids, as well as numerous metabolic disorders, including uremia, hypoglycemia, and porphyria (Akhtar and Brenner 1979; Cummings 1985). A difficult problem in differential diagnosis may arise in the aftermath of mild head trauma in cases of post-contusional amnesia (Kopelman 1987; Lishman 1998).

4.1.2 Dissociative Fugue

A dissociative fugue (from the Latin *fuga,* flight or escape) is characterized by a sudden departure from home or the workplace. The individual does not know where he or she is going or why, and, when discovered in a strange or far-off place, can give no information about his or her own history. The dissociative amnestic component of a fugue state is broader than an isolated dissociative amnesia. There is confusion regarding personal identity, and, occasionally, a new identity is partially or completely assumed. The diagnosis of a dissociative fugue cannot be assigned when similar phenomena appear in the framework of a more comprehensive dissociative disorder, such as multiple personality disorder or dissociative identity disorder, or when they can be explained as the consequence of physical illness or other medical conditions. The behavior of patients in fugue states seems thoroughly well-organized and goal-oriented. The loss of memory and the uncertainty or disturbance of the consciousness of identity contrast markedly with the otherwise intact higher cortical functions. A new identity is assumed in only a minority of cases.

Fisher (1945) classified dissociative fugues into three clinical types:

1. Amnesia as to personal biography, change of identity, and settlement in a strange living environment (classical type)
2. Only amnesia as to personal identity, without change of identity status
3. Return to an earlier period of one's own life, with amnesia for the intervening time up to the present, and without change of identity status

When a new identity is assumed, its basic personality traits are often more expansive and less inhibited than those of the previous identity. After the change of identity status, the individual generally becomes fully integrated in and adapted to the new surroundings, in accordance with sociocultural expectations (Hilgard 1986). Considerable emotional distress accompanies the gradual return of such an individual to his or her original identity and the coming to terms with the amnestic interval (Kihlstrom 1990).

The most important item in the differential diagnosis of dissociative fugue is a post-ictal state of aimless wandering, accompanied by retrograde amnesia and disorientation, in patients with complex partial epilepsy. Further diagnoses to be excluded include poriomania, other non-epileptic organic brain disorders such as migraine and brain tumors, schizophrenia, and alcohol- and drug-induced fugue states (Akhtar and Brenner 1979; Good 1993).

4.1.3 Depersonalization and Derealization

Depersonalization is a feeling of alienation from one's own body and from oneself. Derealization is an analogous feeling with respect to the environment. In both cases, reality judgment remains intact. The subjectively experienced perceptual changes are unpleasant and often difficult to express verbally; descriptions are often of the nature of an "as if." Depersonalization and derealization constitute a continuum and may occur together or separately in the individual's experience. In the literature, these two states are often subsumed together under the term "depersonalization." Depersonalization and derealization may occur as manifestations of a large number of psychiatric and neurological disorders, but they may also constitute independent clinical syndromes. Depersonalization and derealization frequently occur as accompanying manifestations of other dissociative disorders.

In depersonalization, the individual feels entirely changed in comparison to his or her previous state. This change is felt both in the self and in the outside world. The individual perceives his or her own actions and behavior as automatic and observes them from the vantage point of an external observer. The outside world seems strange and new, and not as real as before (Schilder 1935). This altered perception of the self and the environment bears an intensively unpleasant and, at times, tormenting affect quality. It is often associated with a feeling of reduced self-esteem, humiliation, and social isolation and with the fear of losing bodily control or mental health, particularly after a traumatic experience. Diffuse symptoms of somatization, a distressing dazedness, an elementary sensation of vertigo, and a loss of clear perception of time may accompany depersonalization. Autoscopic phenomena, metamorphopsia, and disorders of the body scheme may also appear. Contact with the environment seems to be lost, without the usual affective connotation, but rather with a lack of emotional participation, a dreamlike trance state, a flatness of affect, etc. (Sims 1995).

In the differential diagnosis of depersonalization, it must be remembered that depersonalization is the third most common symptom of an anxiety disorder or of a depressive disorder (Cattell and Cattell 1974). It

appears to a particularly marked degree in cases of the phobic anxiety-depersonalization syndrome (Roth 1959) and of nonparticipatory depression (*teilnahmsarme Depression*) (Leonhard 1995).

4.1.4 Dissociative Identity Disorder

A dissociative identity disorder or multiple personality disorder is a complex, chronic, dissociative psychopathological state characterized by disturbances of memory and identity. It manifests itself in the long-term coexistence of relatively consistent, subjectively separate identities that appear in alternation, and in recurring episodes of distorted memory or overt amnesia.

Patients suffering from a dissociative identity disorder typically do not seek psychiatric or psychotherapeutic help for their primary symptoms. As a rule, they receive wide-ranging diagnoses over the course of several years of illness, usually with reference to secondary, complicating psychiatric disturbances. Psychiatric comorbidity at the time of diagnosis does, in fact, occur very prominently and may include extremely varied psychopathological syndromes.

Kluft (1996) lists the comorbid disturbances accompanying dissociative identity disorders on the basis of the available empirical studies:

- Anxious manifestations (psychophysiological, 100%; phobic, 60%; panic attacks, 55%; obsessive-compulsive manifestations, 35%)
- Affective manifestations (depressive, 90%; hypomanic, 15%–73%)
- Associated dissociative manifestations (amnesia, 57%–100%; fugue, 48%–60%; depersonalization, 38%)
- Somatoform manifestations (general, 90%; conversion, 60%; sexual dysfunction, 60%–84%)
- Suicide attempts (60%–68%)
- Self-injury (34%)
- Substance abuse (40%–45%)
- Eating disorders (16%–40%)
- Sleep disorders (65%)
- Manifestations of schizophrenia (depending on particular manifestations: 35%–73%)
- Manifestations of PTSD (70%–85%)
- Characteristics of borderline personality disorder (70%)

A great many patients display manifestations of dissociative identity disorder only temporarily, often after a prolonged course of treatment. The features of the disorder usually appear in a very mild form (Franklin 1990). The gamut of alternately appearing dissociative and post-traumatic manifestations includes amnesia, depersonalization and derealization, experiences of passive influence, sudden changes in behavior, intrusive visual images (flashbacks), and a hearing of voices in the head. This fluctuating psychopathology may prepare the way for the appearance of the disorder proper. Bizarre temporal gaps, fugue episodes, contradictory behaviors without any subjective explanation, and a confusing forgetfulness have all been reported.

The emergence of pathognomonic multiple personalities – "alter egos" – in the therapeutic conversation may take place spontaneously or only after therapeutic focusing on the amnestic symptoms, in which the patient is prompted to explore their context more closely. The use of hypnotic techniques and pharmacological interventions (e.g. amobarbital), a prolonged interview lasting 2–3 h, or the meticulous keeping of a daily diary may promote the emergence of these alter egos. The coexisting, subjectively separate identities in a single person may be conceptualized as highly distinct states of consciousness organized around a special affect or self-perception (including body image), each with its own limited repertory of behavioral modes and its own set of state-dependent memories (Putnam 1989).

Braun (1993) summarized the phenomenology of a typical dissociative identity disorder, which is as fascinating as it is confusing, as follows:

- The patient possesses two or more personalities at a given point in time (occasionally one personality with executive control and another personality in the position of an observer or in the role of an advisor).
- Each of the personalities has a complete, or nearly complete, set of personality traits; the traits of the different personalities are different and often opposite to one another.
- Transitions between the personalities may occur suddenly or gradually. Some patients may undergo this transition in the presence of the therapist.
- Amnestic barriers between the personalities may exist. One personality may know of the existence of the other(s) (but not vice versa), and two or more personalities may sometimes share a limited amount of information.
- Each personality typically manifests "temporal gaps" in the periods in which other personalities exercise executive control. The sum of the recollections of the various alter egos generally spans a longer interval than the actual elapsed time.

The differential diagnosis of dissociative identity disorder must include a consideration of its extensive psychiatric comorbidity, in particular the possible coexistence of a borderline personality disorder. Considerable difficulties in differential diagnosis may arise when patients claim to be under the influence of

multiple beings coexisting within themselves or when they report other first-rank symptoms, such as hearing commenting voices, generally localized inside the head. Even if other, determinative diagnostic criteria for schizophrenic psychosis are absent, this diagnosis is often considered probable for want of a better alternative explanation; yet modes of psychopharmacological therapy that are otherwise effective for schizophrenia, such as the administration of neuroleptics, are generally ineffective in such situations. Furthermore, an artificial disorder or simulation must also be ruled out.

4.2 Epidemiology

A number of older studies yielded unreliable estimates of the frequency of dissociative disorders, as they were exclusively symptom-oriented and could not make use of the currently accepted diagnostic criteria of DSM-III/R, DSM-IV, and ICD-10. To date, there have been only a few studies using standardized screening (e.g. the Dissociative Experiences Scale, DES; Bernstein and Putnam 1986) followed by diagnostic validation with a structured clinical interview (e.g. the Dissociative Disorders Interview Schedule, DDIS; Steinberg 1994b). The study of Ross (1991) and Ross et al. (1990) is a notable exception: in this study, the DES was administered to 1055 randomly stratified, selected inhabitants of Winnipeg, Manitoba (Canada), of whom 502 were further tested with the DDIS (Table 1).

A total of 6% of the subjects interviewed met the diagnostic criteria for dissociative amnesia. The frequency of psychogenic amnesia is probably even higher in the context of massive trauma, e.g. among survivors of the Nazi Holocaust (Kuch and Cox 1992) or war refugees (Carlson and Rosser-Hogan 1991). Among 53 Swedish survivors of the Estonia ferry disaster, 29% displayed manifestations of dissociative amnesia (Eriksson and Landin 1996). It is hardly surprising that the prevalence figures are much higher among patients presenting to special outpatient clinics for the treatment of dissociative disorders (Coons and Milstein 1992). On the other hand, considerable skepticism has been expressed regarding a linear relationship between dissociative amnesia and trauma when there has been no detailed exploration of the remembered portions of the underlying traumatic events (Pope et al. 1998).

Table 1. Prevalence of dissociative disorders in the general population ($n = 502$) according to DSM-III-R criteria (after Ross 1991)

Diagnosis	Prevalence (%)
Psychogenic amnesia	6.0
Psychogenic fugue	0.2
Depersonalization disorder	2.8
Multiple personality disorder	3.0
Dissociative disorder (other)	0.2
Total	12.2

There is a consensus that dissociative fugue is much rarer than dissociative amnesia or dissociative identity disorder (prevalence, 0.2%; Ross 1991), but it appears to be more common in wartime and in the aftermath of natural disasters or other violent events.

Estimates of the prevalence of depersonalization disorder making use of modern diagnostic standards are on the order of 3% (Ross 1991). Approximately 30%–40% of individuals exposed to life-threatening danger report having experienced a transient depersonalization syndrome (Noyes and Kletti 1977). Depersonalization in adolescents can be characterized as an independent syndrome reflecting the problems of maturation and development that are typical of this period of life (Meyer 1961).

Cases of multiple personality disorder that were published in earlier years were often viewed as exotic rarities or even literary fictions, but the prevailing attitude toward this entity has changed over the last two decades, as is reflected in its inclusion in the official psychiatric diagnostic manuals as an independent diagnostic category. It is nonetheless true that immediate sociocultural influences are reflected in the "production" of the phenomenon of dissociative identity disorder (see below).

According to American epidemiologic studies, 1%–3% of the general population suffers from a dissociative identity disorder (Ross 1991). This prevalence is comparable to that of other major psychiatric disorders. However, even though a number of American authors have reported on clinical samples of several hundred patients bearing this diagnosis, the great majority of psychiatrists and psychotherapists working in inpatient psychiatric services or outpatient practice see such patients extremely rarely, or never, in the course of their professional lives. A similar situation prevails in Switzerland and in the Netherlands, as shown in the studies by Modestin (1992) and Boon and Draijer (1993), respectively.

A possible reason for the glaring numerical discrepancy between the empirical studies and the reported experiences of a large number of psychiatrists and psychotherapists is that, despite the appearance of isolated, spectacular reports in the news media, patients with dissociative identity disorders usually display much less marked manifestations in everyday clinical practice and very rarely talk about their basic,

underlying symptoms without prompting. Instead, these patients present with a multitude of other, secondary psychiatric disturbances. In typical cases, an average of 7 years elapses before the diagnosis of a dissociative identity disorder can be made by an experienced clinician (Loewenstein and Ross 1992). The available studies of hospitalized patients reveal a strong female predominance, with a ratio of approximately 9:1 (Kluft 1996).

4.3 Etiology and Pathogenesis

4.3.1 General Conceptual Approaches

There are, in essence, two conceptual approaches to an understanding of the causation of dissociative conditions:

- A complex mode of reaction to an external trauma
- Certain primary personality attributes that can predispose an individual to the occurrence of dissociation

The first approach places dissociation and the dissociative disorders in a close pathogenetic relationship with acute and PTSD, while the second approach associates them with dissociative tendencies in the normal personality and with the distribution of such tendencies in the general population and relates dissociation to other personality constructs, including hypnotizability, mental absorption, and tendency to fantasize, among others. Both approaches thus tie factors of normal psychology and trauma psychology together in a predisposition–stress model.

Dissociation as a Reaction to Trauma

Very many patients with dissociative disorders report having experienced severe psychological trauma, mostly during the years of their early development. The most serious traumas described include sexual and physical abuse, emotional neglect, and deprivation (Spiegel and Cardeña 1991). It must be kept in mind, however, that most of the data published on this topic were gathered retrospectively and may thus give a distorted picture of reality. Researchers and therapists are currently divided into two camps with respect to their attitudes toward the dilemma of "historical" versus "narrative truth" in spontaneous reports of early childhood trauma as a major cause of dissociative disorders. Those who favor the explanation of a true post-traumatic reaction (Braun 1993) are opposed by others who prefer that of a genetically predisposed personality (Paris 1998).

A problem in many studies is the frequent lack of distinction between different types of trauma, e.g. unexpected, single-event trauma versus continued or repeated exposure to trauma (Terr 1991), or the presence or absence of protective compensation in a traumatized child (Putnam 1995). A critical stance is further indicated when the rates of traumatization derived from epidemiologic studies in the general population are considered as absolute facts even though they have not been validated by detailed clinical interview, and also, conversely, when general conclusions are extrapolated from data gathered in clinically narrowly defined and generally quite small patient cohorts. The so-called false memory syndrome, which is receiving an increasing amount of attention both from the general public and from the courts, is a telling illustration of this difficulty. The relationship between trauma and dissociation does seem to be a close one, but it should not be thought of as linear and monocausal. The interrelatedness of trauma, memory, and dissociation must always be analyzed on multiple levels (Bremner et al. 1998).

Trauma and the Neurobiology of Dissociation

Dissociative processes cannot be regarded as exclusively "mental" events without any connection to cerebral information processing and the associated neurochemical changes. In the context of adjustment to a traumatic event, there are two basic modes of reaction to be distinguished. Particularly in children, these two modes can be connected to specific aspects of the individual's previous development.

An individual typically reacts to an external threat with an alarm reaction consisting of an elevation of sympathetic tone in preparation for a basic fight-or-flight response pattern. This *hyperarousal continuum* is brought about mainly by the centrally driven peripheral secretion of epinephrine and norepinephrine, by the secretion of adrenal corticotrophic hormone (ACTH) and cortisol by the hypothalamic–pituitary–adrenal (HPA) axis, and by activation of the immune system. The decisive mediating role is played by the locus ceruleus; the ventral tegmental nucleus is also an important regulator of the activity of the pontine and medullary sympathetic nuclei. Prolonged or repeated threats may lead to a sensitization of these two control centers, possibly resulting in catecholamine over-reactivity, even to less threatening stimuli.

On the other hand, a *dissociative continuum* is associated with a basic response pattern of surrender. It seems to be activated preferentially when an organized fight-or-flight response appears unlikely to succeed, or when this type of response is not yet fully developed, as in children. Just as in the hyperarousal continuum, there is initially a stress response with secretion of catecholamines and corticoids. However, in dissociation, and not in hyperarousal, there is also a

strong vagal activation. Moreover, the mesolimbic and mesocortical dopaminergic systems play an important role and, by way of the central reward systems, exert a primary influence on affect modulation. Collateral connections to the endogenous opioid system lead to a change in the perception of noxious stimuli and also to a distortion of the sense of time, place, and reality. In fact, most opiate agonists can induce dissociative reactions. Dissociation, like hyperarousal, may become sensitized, i.e. there may be a use-dependent cerebral organization of dissociation as a primary adaptive response pattern.

Both response patterns can be combined, to varying relative extents, in basic adaptive styles (Perry et al. 1995). A neurobiological interrelationship of dissociative disorder and PTSD is suggested by the fact that peritraumatic dissociative symptoms have a high predictive value for the later development of PTSD (Marmar et al. 1998).

Findings from the field of experimental neuropharmacology yield interesting insights into the neurobiology of dissociative processes. Certain substances, such as yohimbine (noradrenergic) or metachlorophenylpiperazine (m-CPP; serotonergic), indirectly induce a dissociative state in vulnerable individuals after first stimulating intense anxiety or traumatic memories. Glutamatergic neurons clearly play a decisive role in the mediation of dissociative states by the serotonergically and noradrenergically activated systems of the amygdala, hippocampus, thalamus, and cortex. It is thus not surprising that ketamine, for example, which influences glutamatergic neurotransmission, can directly induce an experience of dissociation even in normal subjects, i.e. without the need for a preceding intense anxiety reaction or traumatic memory. A possible approach to pharmacotherapy involves the use of anti-dissociative *N*-methyl-D-aspartate (NMDA) agonists (Krystal et al. 1998).

Dissociation and Dissociative Tendencies in the "Normal Personality": Distribution in the General Population

The assumption that there is a continuum extending from mild forms of dissociation in everyday life all the way to severe psychopathological dissociative states, such as a multiple personality disorder or dissociative identity disorder in extreme cases, is derived from epidemiological findings on the dissociative disorders (Kihlstrom et al. 1994). Studies have shown that normal subjects and patients with dissociative disorders differ less in terms of distinct symptom clusters than in terms of the quantitative extent, frequency, and intensity of dissociative symptoms.

The self-rating scale for dissociative experiences developed by Bernstein and Putnam (1986) (DES) is based on this conceptual approach. It assesses the frequency of dissociative phenomena in the areas of memory, cognition, consciousness, and identity. It has been shown that a high score on the DES is a highly sensitive and specific indicator of the presence of diagnostically validated dissociative disorders. The average DES score declines significantly with advancing age (Ross et al. 1991).

The adaptive function of "normal dissociation" seems to lie in the automatization of certain modes of behavior, which allows a division of attention for the performance of complex tasks. The dissociability of an individual may be defined as a function of the frequency and duration of spontaneous occurrences of a dissociated state of consciousness under natural conditions. From this perspective, a "pathological dissociation" is present when the quantitative extent of dissociability negatively interferes with necessary psychosocial adaptive behavior. On the other hand, dissociability, as measured by DES scores, also seems to be strongly influenced by psychological stressors (Putnam 1995).

Dissociation and Hypnotizability

Janet (1889) viewed hysteria and hypnosis as closely related states. He thought that both reflected the same process of dissociation. He was also convinced that only "hysterical patients" were hypnotizable. In the modern conception, hypnosis is described as a controlled and structured dissociative process characterized by total absorption, compartmentalization of experience, and elevated suggestibility (Spiegel and Cardeña 1991). In fact, the ability to be hypnotized is much more common than Janet assumed and represents a nonpathological personality trait that can be measured reliably by means of standardized psychometric instruments (e.g. the Stanford Hypnotic Susceptibility Scale, SHSS).

This trait is at its most pronounced in the early school years and normally becomes less so with increasing age and over the course of cognitive-affective maturation (Morgan and Hilgard 1973). Nonetheless, it may persist relatively unchanged into adulthood as a consequence of constitutional factors or experiences during early development. Traumatic life circumstances exert a negative influence in this respect, as they can easily overstrain the usual coping abilities and defense mechanisms of childhood. Autosuggestion and hypnosis may become one of the ways in which traumatic influences can be channeled into dissociative states (Putnam 1995).

About 10% of adults in the general population have high scores on scales of hypnotizability (Hilgard 1986). Even though individuals suffering from pathological dissociation are usually also highly hypnotizable (Frischholz et al. 1992), the converse is not true – a high degree of hypnotizability does not necessarily imply the presence of pathological dissociation.

Thus the epidemiological correlation between the DES, for example, and hypnotizability is only modest (Kihlstrom et al. 1994). Hypnotizability, as a "trait" variable, is also highly correlated with other personality traits, such as a tendency toward losing oneself and other self-altering experiences ("absorption"; Roche and McConkey 1990) or a particular inclination toward fantasy and imagination ("fantasy proneness"; Lynn and Rhue 1988; Rhue and Lynn 1989). Like hypnotizability, these personality traits do not indicate that a psychopathological condition is present, but they may be part of a complex defense or coping mechanism. The autosuggestion or autohypnosis model for dissociation should thus be understood provisionally as no more than a metaphor or clinical heuristic in need of further empirical testing (Putnam and Carlson 1998).

4.3.2 Models of Causation for Various Dissociative Symptom Clusters

The controversy concerning the connection between the dissociative disorders in general and exposure to trauma also dominates the discussion of the etiology and pathogenesis of dissociative amnesia. Practically all systematic studies and reviews reveal a high, or very high, association between this entity and multiple traumatic experiences. Coons and Milstein (1992), for example, found multiple causative factors in a series of 25 patients with severe intrapsychic stress and conflict: child abuse (60%), marital discord (24%), deviant sexual behavior (16%), suicide attempt (16%), criminal behavior (12%), death of a near relative (4%), running away (4%), or unknown (16%). A total of 72% of the patients studied had had major traumatic experiences in their own early development: sexual abuse (52%), physical abuse (40%), emotional neglect (16%), or abandonment (12%). The influence of traumatic experiences on many different aspects of memory thus rightly occupies a central position in the discussion of causal factors of dissociative amnesia.

It is important to distinguish episodic-autobiographical from semantic-procedural memory. The first system, which consists of spatiotemporally organized autobiographical experiences with a special connection to the self as participant or observer, appears to be preferentially affected in cases of dissociative amnesia (Kihlstrom 1990). This episodic memory may manifest itself in either an explicit or an implicit form. While a person with dissociative amnesia is unable to recollect a specific event intentionally in verbal form, his or her behavior may implicitly reveal an unambiguous connection to it. The same individual has no deficit of semantic-procedural memory (Schacter and Kihlstrom 1989).

It is significant that traumatically induced memory disturbances in the above sense are not uncommonly accompanied by recurring intrusive thoughts, images, dreams, and emotions that are clearly related to the original traumatic episode (Horowitz 1976). Patients with dissociative amnesia may also react with intense affect to seemingly neutral stimuli without consciously understanding their emotional meaning or being able to place them explicitly into the context of the prior trauma (Loewenstein 1996).

Clinical studies of traumatized war veterans, war prisoners, and adults who suffered massive abuse in their early development reveal that exposure to trauma and dissociative amnesia may also be associated with neurobiologically demonstrable changes in hippocampal structures, possibly as a result of excessive glucocorticoid activity. Hippocampal volume loss documented by magnetic resonance imaging (MRI) is significantly correlated with dissociation scores and with the symptom cluster of "numbing," as well as with avoidance in PTSD (Bremner et al. 1995).

The same causal factors just discussed for dissociative amnesia are of basic importance in dissociative fugue. However, the origin of dissociative fugue is thought not to lie exclusively or primarily in prior trauma; a number of other important psychodynamic factors, particularly related to premorbid psychopathology and unfavorable family background, are also thought to play a major role. Some patients show considerable degrees of separation anxiety, depressive mood disturbances, suicidal and outwardly aggressive impulses, and primitive denial tendencies. Not uncommonly, the dissociative fugue has the nature of wish fulfillment, e.g. when the patient escapes from an unbearable marital situation. Often, particularly when a crime has been committed, the suspicion of simulation may arise, i.e. a more or less conscious attempt to lessen the patient's own guilt and accountability for his or her own actions. Fatigue, sleep deprivation, and heavy alcohol consumption may be predisposing factors. A fugue may also follow mild head injury (Berrington et al. 1956; Loewenstein 1996; Riether and Stoudemire 1988).

Numerous models have been developed to explain dissociative identity disorder. Each emphasizes a different aspect of the multifactorial causation of this complex pathophysiological phenomenon. According to one pragmatic clinical model, the etiology and pathogenesis of dissociative identity disorder are a developmental sequence involving several steps (Braun 1993; Kluft 1996; Mollon 1998; Putnam 1995):

- A *capacity for dissociation* is considered essential. This is not yet a psychopathological phenomenon in itself, but rather a psychobiological variable relating to general hypnotizability that is found to a limited

extent among the general population, is at its most pronounced in the early school years, and normally becomes less so with increasing age (see above).

- Constitutional factors, in combination with *early traumatic experiences,* may result in the persistence of this capacity into adulthood. A capacity for dissociation reinforced by autosuggestion and autohypnosis is a basic defense and coping mechanism for the channeling of overwhelming traumatic experiences. It is of etiological significance in this context that a reliable history of being severely abused in childhood can be obtained in an extremely high percentage of patients with multiple personality disorder. In addition to severe sexual and, in particular, incestuous traumatization, physical abuse, and continuous injury to the narcissistic equilibrium, it seems that the experience of loss of significant others in childhood, the direct observation of the death, suicide or other self-destructive acts of near relatives, and severe physical illness involving intense and prolonged pain can also play a pathogenetic role in this disorder.
- A further factor promoting the use of the dissociative mode for the processing of traumatic experiences is a *lack of compensatory social relationships* of a consoling or supportive nature after an exposure to trauma, with the result that the trauma is encoded not as a discrete, finite event, but as an ever-present personal reality.
- *Repeated, overwhelming traumatization* that the child is unable to integrate leads, by way of dissociation, to a compartmentalization of biographical memory. Many different factors, including life experiences of diverse types, individuals of major importance in the child's world (via introjection, internalization, and identification), imaginary playmates, or external influences (encouragement of role-playing, contradictory educational demands or reward systems, identification with a dissociative parent) prepare the intrapsychic nucleus for the generation and imaginative outfitting of alter egos. The final development of the adult psychopathology of multiple personality disorder is determined not only by interpersonal therapeutic factors, but also by sociocultural ones. Because of the repeated transformation and reprocessing of the original early childhood traumatic experiences, an adult suffering from multiple personality disorder is often unable to recollect exact biographical details without contamination by confabulations and misinterpretations serving a defensive function, so that a historical objectification of the events described may be impossible.

This clinical model is thus essentially oriented toward both trauma psychology and developmental psychology. It emphasizes the relatedness of dissociative identity disorder to PTSD but also requires consideration of the special developmental psychological, i.e. cognitive and affective condition, of the multiply traumatized child. This model implies that adults without developmental disturbances who have been exposed to severe trauma generally do not develop psychopathology analogous to multiple personality disorder, but rather develop the clinical syndrome of PTSD. A change of personal identity status through indoctrination and brainwashing differs from a traumatically induced change of personality (as we have been discussing) by having its own, particular dynamics and a different symptomatic configuration (Lifton 1976). The appearance of endemic discoveries of multiple identities in the context of questionable large-scale gatherings demands a further explanatory model in which uncontrolled group-dynamic processes, ideological manipulation, religious fundamentalism, and paranoid social criticism must all be considered major factors (Spanos 1994).

4.4 Treatment

Dissociative disorders are characterized by a high degree of variability of their most prominent manifestations, a broad spectrum of intensity, variable acuity versus chronicity, and a variable measure of psychiatric comorbidity. Although epidemiologic studies have reliably documented their high prevalence and thus the correspondingly high demand for treatment, no method of treatment has been empirically tested in systematic, controlled studies. This is true both of psychotherapeutic methods and of biological (particularly psychopharmacological) interventions. Principles of therapy discussed in the literature on this topic are often of a very general nature distilled from clinical practice, though there may be a narrower focus on specific treatment problems.

There is a consensus among experts that treatment must be planned and provided largely on an individual basis. Psychotherapeutic strategies are generally preferred to biological approaches. In view of the importance of severe trauma in the etiology and pathogenesis of both the simple and, in particular, the complex dissociative disorders, stress is placed on avoiding the danger of inducing further trauma through therapeutic measures.

The treatment of a comorbid psychiatric disorder is geared toward the therapeutic standard for that particular disorder, but must also be adjusted to the specific type of therapeutic interaction that patients with dissociative disorders require. A syndrome-oriented, mainly psychopharmacological treatment of this

psychiatric comorbidity may become a priority when psychiatric emergencies arise or when access to the patient is blocked by the comorbidity, meaning that the indicated form of psychotherapy cannot be performed.

4.4.1 Dissociative Amnesia and Dissociative Fugue

The goal of rapid restoration of the full ability to remember and integrate previously dissociated memories requires a secure and reliable treatment framework and is based on a stable therapeutic alliance. Cautious history-taking accompanied by repeated reassurance and encouragement of recollection can promote this therapeutic goal. It is essential to allow the patient to set the pace of the process of recollection, thereby giving him or her a feeling of control and power (Loewenstein 1995). Active involvement by the therapist is necessary for the safety of the patient if suicidal, parasuicidal, or outwardly aggressive crises occur during the process of recollection. Temporary hospitalization must be considered in such cases. Finally, the therapist and the patient must work toward a restoration of knowledge of personal identity and of the particular life circumstances that provoked the disorder. This always requires a confrontation with the inducing trauma and a focusing on, and working through of, existing conflicts.

It must be realized that patients with dissociative fugue most probably have a more complex psychodynamic situation at the root of their disorder. A tolerant approach toward their frequent feelings of shame and guilt about sexual conflicts, social misbehavior, marital discord, financial troubles, illegal activities, etc., is often necessary. Successful treatment requires a confrontation with and gradual integration, or sometimes even simple acceptance, of modes of behavior during the fugue episode that may markedly diverge from the patient's internal moral standards and from what the patient requires of him- or herself under other circumstances (Coons and Milstein 1992).

If major affective, psychotic, obsessive-compulsive, or anxious manifestations or manifestations of PTSD or of deficient impulse control should arise during the recollection of the traumatic events that induced the dissociative state, then differential psychopharmacological interventions are definitely indicated, and the therapist must devote the necessary attention to the treatment of amnesia (Friedman 1997). As a rule, the formerly dissociated information recollected during therapy must be discussed and reprocessed repeatedly in several sessions until harmonious integration is achieved.

Hypnotic techniques or an amobarbital interview may be of assistance in the treatment of dissociative amnesia and fugue and generally leads to remission of symptoms (Loewenstein 1995). The use of these modes of treatment requires even closer attention to the general therapeutic principles discussed above.

4.4.2 Depersonalization and Derealization

The therapeutic approach to patients with primary depersonalization and derealization disorders is based on the same general principles. Treatment begins with psychoeducational instruction of the patient regarding the nature of the often very distressing symptoms, training in the recognition of possible inducing stimuli, and detailed information about the different forms of treatment available.

The patient can be taught specific techniques for the alleviation of symptoms right away (Steinberg 1995):

- *"Grounding" or reorientation techniques*: The patient is instructed, if depersonalization occurs, to make physical contact with the objects in his or her familiar environment, to touch them and concentrate on the sensations this produces, and to speak his or her own name and location and other positive features of the environment out loud, thereby producing a supportive effect, which results in increased self-confidence.
- *Distraction techniques*: Deliberate absorption in a pleasant activity, such as an intense conversation with a trusted person, can break the vicious circle of negative thoughts and emotions that generally accompanies an experience of depersonalization.
- *Controlled dissociation*: The patient is systematically instructed to raise or lower the intensity of the feeling of depersonalization voluntarily whenever an episode occurs. This allows the patient to regain a feeling of control over the dissociative symptom, which the individual usually experiences as overwhelming in the face of his or her own helplessness and powerlessness.
- *Creative visualization*: The patient is instructed to visualize with the "inner eye" some positive recollection, pleasant place, or familiar and reassuring situation as vividly as possible, thus fending off the depersonalizing experience.

Hypnotic techniques are sometimes used with success (Spiegel 1988). Cognitive strategies play a major role in the treatment of cognitive distortions, which regularly accompany traumatically induced depersonalization (Briere 1992). Modified psychodynamic techniques concentrate on depersonalization as a pathological defense mechanism leading to a fragmented perception of the self and of objective reality. A therapeutic position grounded in ego psychology and object-relation theory appears to be advantageous

(Grotstein 1981). A classical psychoanalytical treatment setting, involving a suspension of the visual modality during the therapeutic interaction, is contraindicated in most cases of chronic depersonalization (Cattell and Cattell 1974).

Extremely varied psychopharmacological strategies have been applied in the treatment of depersonalization syndromes. Although symptoms of depersonalization in the context of other primary disorders generally improve when the underlying disorder, e.g. depression or anxiety, is treated, the results obtained to date in the treatment of primary depersonalization disorder are contradictory and unconvincing. The neurobiological conception of depersonalization as a disturbance within the spectrum of obsession and compulsion (Simeon et al. 1995) and the associated hypothesis of serotonergic dysfunction suggest a role for the use of selective serotonin reuptake inhibitors. Hollander et al. (1990) reported promising initial experiences in an open study with fluoxetine and fluvoxamine. Empirically controlled studies, however, are not yet available. The same is true of the use of clonazepam (Stein and Uhde 1989) and the theoretically intriguing use of opiate antagonists, such as naltrexone, as a form of treatment for depersonalization and self-injury (Winchel and Stanley 1991).

4.4.3 Dissociative Identity Disorder

The psychotherapy of patients with dissociative identity disorder is generally time-consuming and fraught with frequent setbacks. These usually result from the therapist's attempts to identify and work through the often extremely traumatic experiences lying at the root of the disorder. It has been stated that two essential prerequisites for the successful treatment of such patients are an orientation toward the treatment model of post-traumatic disorders and an adherence to the principles of dynamic psychotherapy (Gabbard 1994).

The primary therapeutic goal of integration and unification of the individual alter egos in a single personal identity cannot always be achieved in reality. Harmonization of the internal tension between the individual personalities, without actual integration, may represent the outer limit of what therapy can achieve. In still more complicated cases, even this much is impossible, and therapy focuses on helping the patient by supporting him or her in an attempt to solve current problems and cope with the difficulties of the present living situation.

Kluft (1995) stresses the necessity of planning treatment in three basic phases, in each of which a different aspect of therapeutic technique is emphasized:

1. The phase of security (supportive interventions, ego reinforcement, empathy)
2. The phase of recollection and grief (post-traumatic treatment model)
3. The phase of connection (traditional psychodynamic treatment principles)

A safe therapeutic atmosphere and the creation of an informative and strengthening relationship based on trust – a reliable and durable therapeutic alliance – are preconditions for undertaking further therapeutic steps. It is necessary to establish contact with the alter egos that express themselves even in this early phase, to make a contract with them against premature termination of therapy, suicidal acts, self-destructive behavior, and so forth, to promote communication between the personalities, and to reduce the burden of symptoms as much as possible. Through the process of history-taking, the therapist can make acquaintance with the different personality states and begin to understand their essential characteristics, origins, and mutual relationships.

In this early phase, special symptom-oriented therapeutic strategies play an important role. They may be accompanied by a directed, highly cautious application of hypnosis, and they may be supported by differential psychopharmacotherapy. In this early stage of the therapeutic process, the therapist must not aim at forced recollection. If the therapist and patient do not succeed in establishing a secure basis for the first phase, active trauma work must not be embarked upon, as it will regularly be accompanied by the appearance of extreme affect and disorganizing recollections.

Colrain and Steele (1991) list the factors that must be considered as contraindications to the uncovering of dissociated memories in long-term psychotherapy:

- Early therapeutic stage
- An unstable therapeutic alliance
- Current or continuing abuse
- Current, acute external life crises
- Advanced age, severe physical handicaps, and/or terminal disease
- Lack of ego strength, including severe borderline and psychotic states or massive regression
- Uncontrolled, abrupt alternation of the different alter egos
- Uncontrolled flashbacks
- Severe conflicts and lack of cooperation in the alter ego system
- Severe primary alexithymia
- Temporary factors: imminent absence of the therapist, transitions in the patient's life cycle

Dealing with traumatic memories requires a high degree of empathy, a sense of the patient's ability to

deal with the associated stress, and a feeling for the maximal amount of confrontation that the patient can tolerate. A simple working off of the associated extreme affects is rarely therapeutically effective. The success of therapy depends on its being embedding in a stable therapeutic relationship, in which all of the patient's reports of experienced trauma, even if they are scarcely credible, are accepted as representing the patient's subjective reality and are taken as a kind of alarm signal communicated to the therapist. Likewise, a knowledge of the forms of possible recollections, especially visual flashbacks, somatized sensations, or blatantly staged behaviors, is essential. Recollections of this type may be based on a kernel of truth in some segment of the patient's prior biography, but they are certainly not always a simple copy of what was actually experienced, and they may indeed be considerably transformed.

The complexity of the defense process in these patients' recollection work becomes obvious when the information provided by different alter egos is contradictory, illogical, and bizarre and when confabulations fulfill the basic need for a defense mechanism rather than contributing to the discovery of the truth. In this stage of treatment, the therapist must not assume the task of clarifying the actual truth through insistent history-taking. Though the therapist must occasionally be highly active and engaged, particularly when suicidal, outwardly aggressive, or disorganized crises occur, he or she must also attempt to preserve as neutral a position as possible when receiving information from the patient. It is important both for the protection of the patient and for the maintenance of the therapist's own professionalism to prepare the patient for the possible, and even probable, appearance of unpleasant, traumatic memories and to adhere to the principle of informed uncertainty (Appelbaum and Gutheil 1991) with respect to the subjective reality that manifests itself in them.

Fascination and over-engagement on the part of the therapist often accompany the beginning of psychotherapy with such patients. This initial enthusiasm is just as often followed by repeated disappointment, exhausting setbacks, and feelings of confusion over the further course of treatment. Kluft (1996) describes the most common reaction patterns of the therapist as follows:

- Retreat into personal inaccessibility, skeptical assumption of the role of a detective for the objectification of historical truth
- The conviction that an "ordinary" therapeutic setting is deleterious to this extremely traumatized patient and that only "love" – in manifold variations, all of which violate therapeutic boundaries – can achieve a therapeutic benefit
- Assumption of the role of an advocate with the patient as client, urging the patient to pursue a legal remedy for the experienced injustice
- Counter-identification of the therapist with the patient and development of post-traumatic stress symptoms in the therapist

Highly regarded experts report that the intermediate phase of therapy is especially unlikely to proceed in a linear and predictable way. There are many obstacles along the path to an integration of the extremely different components of the patient's personality. A cohesive personal identity in relation to a biographical narrative formed by the patient in collaboration with the therapist often cannot be achieved and, when achieved, is rarely complete. The learning of new coping skills to deal with current life problems without resorting to dissociative defense mechanisms is a therapeutic goal of equal importance to the basic reconstruction of the patient's personality.

As a rule, the treatment of patients with dissociative identity disorder should follow a multimodal design. A pragmatic approach to therapy involves the application not only of techniques of cognitive analysis, but also of hypnotherapeutic strategies, temporary hospitalization, art therapy, and syndrome-oriented pharmacotherapy (Putnam and Loewenstein 1993). The few available results from follow-up studies of patients treated in this type of therapeutic setting are quite encouraging (Ellason and Ross 1997).

5 Conversion Disorders

5.1 Definition and Clinical Features

A conversion disorder involves a loss or alteration of neurological function that may cause a neurologic disease to be suspected, but that actually cannot be adequately explained in this way. A temporal relationship between the onset of physical symptoms and a psychosocial stress or intrapsychic conflict is required as part of the definition of a conversion disorder. The constellation of symptoms is not under conscious control, nor is it a culturally sanctioned response pattern, and it is not limited, in the syndromal sense, either to pain or to sexual dysfunction. The concept of conversion disorder in both ICD-10 and DSM-IV is restricted to such pseudoneurological disorders and thus differs from the symptomatologically much broader concepts found in older texts. The clinical forms of conversion disorder are characterized by pseudoneurological symptoms affecting voluntary

movement, sensation, and state of consciousness – the latter in the form of non-epileptic (psychogenic) seizures (Martin 1995).

One subtype of conversion disorder includes disturbances of motor function. The most prominent type of disturbance is a weakness or paralysis that usually affects the extremities, only rarely the neck or the trunk, and practically never the face or the tongue (Pincus 1982).

Symptoms appearing to arise from affections of the extrapyramidal system, such as tremor (Koller et al. 1989), dystonia (Marsden 1995), or dyskinesia (Williams et al. 1995), are much more difficult to evaluate. Even though the expressive nature of such disturbances, in relation to extremely problematic interpersonal interactions or psychosocial stress, may at times be unmistakable, the possibility of an underlying organic process must always be considered (Cunningham Owens 1990).

A number of characteristics of psychogenic disorders of gait and stance may be very helpful for their identification as a conversion syndrome (Brandt et al. 1994), particularly the following:

- Spontaneous fluctuation of stance and gait that may often be provoked by distraction or suggestion
- Marked slowing of movement, as in a slow-motion film
- A typical gradual increase of the amplitude of sway in the Romberg test, after an initially steady stance
- A "flat-footed walk on ice," marked by careful rolling of the foot with reduced movement in the ankles and knees, as on slippery ground
- Extremely uneconomical body posture or sudden giving way of the hip and knee joints, with catching of the body, usually without falling
- Frequent accompanying psychomotor expressive symptoms, such as a pained or strained facial expression, moaning while grasping the leg, mannered hand posture, or hyperventilation

Dysphagia ("globus hystericus"), aphonia or dysphonia, and urinary retention are other symptoms that may appear, albeit rarely (Kellner 1991).

A second subtype of conversion disorders includes disturbances of sensory function: the lack of any sense of pain may be quite impressive. Testing of the sense of touch is extremely problematical, as it is not very reliable even under normal clinical circumstances. Reported hypesthesia or anesthesia must therefore be carefully investigated; gross violation of known anatomical boundaries is a relatively reliable indicator that the disorder is psychogenic rather than neurological. Another typical finding is hemihypesthesia or hemianesthesia affecting the entire body, with strict respect of the midline (Toone 1990).

The sensory subtype also includes visual field defects or blindness as well as deafness (Newman 1993).

A significant innovation in DSM-IV is the inclusion of certain hallucinations in this diagnostic category. These misperceptions are identified as pseudohallucinations by the lack of other psychotic signs and by otherwise intact reality testing. More than one sensory modality may be affected. The perceived content of the hallucination is often of a naïve or fantastic character (Martin 1995).

A further subtype includes non-epileptic seizures; sensory deficits or symptoms may also occur. There are several typical clusters of clinical features that suggest, but do not unambiguously indicate, that a seizure is psychogenic (Savard and Andermann 1990):

- A psychogenic seizure may either start suddenly or develop gradually.
- Not uncommonly, quasi-auras involving nausea, vertigo, dyspnea, and headache may be reported to significant others, whose presence in the room obviously promotes the occurrence of a seizure. Seizures usually occur in a familiar environment at home, and very rarely at night.
- The seizure pattern itself is highly variable; it may be either uni- or bilateral, and it may include tonic, clonic, tonic–clonic, or non-purposeful high-amplitude motion components. Seizures are often accompanied by dystonic body postures, of which a dramatic, though rare example is the classical "arc de cercle"; other, striking accompanying movements include rhythmic pelvic thrusts and random patterns of movement of the upper and lower extremities, with thrusting and biting.
- The facial expression displays a broad spectrum of dramatized primary affects. Vocalizations may either precede or accompany the seizure.
- Patients are usually able to avoid painful positions or self-injury during the seizures. Self-destructive behavior may be present, however, as an expression of severe psychopathology of the personality. The rarer cases of urinary and fecal incontinence accompanying pseudoseizures are to be regarded in the same light.
- Dilated pupils indicate increased sympathetic tone, while cyanosis is the result of breath-holding.
- Geotropic eye movements are an interesting sign: passive movement of the head always causes a deviation of the eyes toward the floor and away from the examiner.
- Psychogenic seizures usually last significantly longer than epileptic seizures, for more than 2 min on average, and not uncommonly proceed to a prolonged pseudo-status epilepticus. Psychogenic sei-

zures also tend to occur more frequently than epileptic seizures, often several times a day.
- An essential requirement of the diagnosis is that the electroencephalogram (EEG) is normal during and between the seizures.

Major problems of differential diagnosis arise when a patient has both genuine epilepsy and psychogenic seizures. Psychogenic seizures are not exclusively of the major hysterical type, but may also manifest themselves as absence episodes, psychogenic syncope, fugue states, or stupor. These clinical entities illustrate the continuous transition between the conversion disorders and the dissociative disorders (Kihlstrom 1994).

Although the modern psychiatric classification systems rule out the diagnosis of a conversion disorder when sexual dysfunction or pain occurs as the single dominant symptom, these may indeed be important accompanying symptoms of conversion disorders. The same is true of a number of other somatoform disturbances of autonomic function or of sleep (Kapfhammer et al. 1992).

Supposed symptoms of conversion may instead turn out, on further investigation, to be prodromal signs of a misdiagnosed or initially not objectifiable neurological or neuropsychiatric illness. Now that sophisticated diagnostic techniques, including neuroimaging and neurophysiological testing, are available, such misdiagnoses are not likely to be as frequent as was suggested by the now classic study by Slater et al. (1965), which revealed a staggeringly high rate of misdiagnosis that was subsequently revealed during follow-up (Crimlisk et al. 1998; Mace and Trimble 1996). However, misdiagnoses are not at all rare, particularly at the time of the initial manifestation of disease (Cloninger 1987; Fishbain and Goldberg 1991; Jones and Barklage 1990; Watson and Buranen 1979).

A thorough listing of coexisting psychopathological symptoms revealed that conversion syndromes may accompany psychiatric disorders of extremely varied types; a particularly high frequency of such syndromes in patients with affective illnesses was emphasized, though they may also occur in schizophrenics (Slater et al. 1965, Ziegler and Imboden 1962). In a prospective study of neurological patients with conversion symptoms, Kapfhammer et al. (1998a) emphasized the important distinction in the differential diagnosis between a conversion disorder and a somatization disorder or artificial disorder. These diagnostic subgroups differ considerably with regard to the dynamics of disease course, psychiatric comorbidity, self-destructive motifs in illness behavior, psychosocial impairment, utilization of medical care, and associated socioeconomic cost.

5.2 Epidemiology

The collection of accurate data on the prevalence and incidence of conversion disorders is complicated by a number of methodological difficulties. These involve not only the varying theoretical conceptions of conversion and correspondingly inconstant diagnostic boundaries, but also the thoroughly heterogeneous groups of subjects and/or patients investigated, as well as the extension of the period of time in question to the subjects' entire lifetime, rather than a more reasonable restriction to the moment of investigation (Toone 1990). Obviously, prevalence figures obtained in patient populations are highly dependent on the particular outpatient or inpatient setting in which the investigation is carried out:

- Studies of lifetime prevalence performed in Scandinavia and the United States suggest that approximately 0.5% of the general population suffers from conversion symptoms (Ljungberg 1957; Weisman et al. 1976).
- It appears that only very few patients with conversion disorders present for treatment in outpatient psychiatric or psychotherapeutic practices. Stefansson et al. (1976) reported a figure of 15–20/100,000.
- Ford (1983), on the other hand, estimated the percentage of patients with conversion disorders among those in general medical facilities as being much higher than this (20%–25%).
- At the National Hospital (Queen Square), London, a specialized neurological facility, the rate of conversion disorders remained relatively constant at 0.85%–1.55% over several decades (Trimble 1981).
- In a psychiatric consultation service in a large general hospital, the frequency of conversion disorders over a period of several years was just over 4% (Kapfhammer et al. 1992, 1998a).
- The importance of sociocultural factors is revealed by the much higher prevalence figures obtained in Third World countries (Murphy 1990; Nandi et al. 1992).

Although a number of reports in the literature indicate a higher frequency of conversion disorders in subjects of lower educational and socioeconomic status, as well as in rural areas or in preindustrial societies (Folks et al. 1984; Jones 1980), skepticism is nonetheless warranted with regard to oversimplified conclusions of this type (Kapfhammer et al. 1992). Women seem to be over-represented in all studies available to date, though men very often develop conversion symptoms after accidents in the workplace or in military settings (Allodi 1974). All age-groups may be affected; the peak incidence is between the ages

of 20 and 40 (Kapfhammer et al. 1992; Tomasson et al. 1991).

5.3 Etiology and Pathogenesis

There are several models for the pathogenesis of the conversion disorders, among which psychodynamic concepts play the most important role. According to an early psychoanalytical formulation (Freud and Breuer 1895), conversion symptoms result from major conflicts of inner drives, which may be traced back to traumatic experiences of family interaction in early life. The memory of these experiences must be repressed and thereafter remains unconscious. In later life, however, the occurrence of analogous conflicts may result in their reactualization. In order to avoid a reliving of these highly affectively charged experiences, they are repressed again and then somatized. The physical symptoms represent, in symbolic expression, a compromise solution between drive impulses and defense. This conflict resolution by means of conversion constitutes the primary gain derived from the conversion symptom. The assumption of the illness role that the conversion symptom makes possible also provides the patient with a socially mediated secondary gain, which leads to a reduction of both internal and external stress. Empirical clinical observation has revealed that a subgroup of conversion patients – in particular those with psychogenic seizures – did indeed suffer a high rate of physical and sexual abuse in early childhood (Alper et al. 1993).

Over the ensuing years, there was considerable refinement and modification of the original psychoanalytic position, which was essentially a concept of hysteria. At first, drive conflicts arising from sexual traumatization at an oedipal stage of development were held to be essential for the generation of conversion states, but the range of possible conflicts became much wider thereafter, to include aggressive impulses, narcissistic regulation of self-esteem, problems of separation and individuation, and grief after loss. Ego-psychological studies showed that a fully developed symbolic representation is not present in all cases of conversion; depending on the structural level of intrapsychic processing and the depth of regression, less well developed forms of physical expression may predominate. In the current psychodynamic conception, conversion is an independent problem-solving strategy for eliminating a multiplicity of intrapsychic, interpersonal and social conflicts by means of identification with a certain illness role. This conflict-resolution mode is not connected to any particular personality structure (Mentzos 1980; Hoffmann 1996).

These modern psychodynamic conceptions are entirely compatible with the learning-theoretic approach, according to which classically conditioned and/or operant-conditioned physical reactions can be applied in the guise of symptoms of illness in order to deal with particularly stressful or conflict-laden situations:

- The importance of learning in this model becomes evident when we consider the large percentage of patients who themselves work in clinical facilities, are married to or friendly with hospital personnel, or have people with phenomenologically very similar symptoms in their immediate familial and social environment (Kapfhammer et al. 1992).
- Medico-sociological theories on the illness role and illness behavior also apply in this model context (Mechanic 1962; Pilowsky 1990). These theories also emphasize a learned pattern of behavior for eliminating emotionally stressful situations by means of excessive focusing on physical sensations and symptoms, as well as an assumption of the illness role and care-seeking behavior in medical facilities, which may take different forms in different individuals.

While psychoanalytical approaches generally presuppose a categorical unconsciousness of the motives underlying the generation of conversion symptoms, there is, in more recent theories, a dimensional conception of the patient's insight into these motives. Unconscious or automatically learned motives occupy one pole of this continuum, which, however, also includes other types that are much nearer to conscious awareness – even, at the opposite pole, motives of an interpersonal manipulative character (Ford and Folks 1985; Miller 1988).

According to an early theory that was advanced mainly by psychoanalytical authors, a hysterically structured personality was considered an important prerequisite for the development of conversion symptoms under the influence of typical conflict situations. Alarcon (1973) listed a number of descriptive features of this hysterical primary personality, i.e. histrionic behavior, emotional lability, dependence, overexcitability, egocentrism, seductive behavior, and suggestibility.

This personality type, supposedly conferring a predisposition to conversion formation, was also excellently described in the ego-psychological depiction by Shapiro (1965) of the impressionistic cognitive style, with openness to fleeting perceptual impressions, diffuse memory, and imprecise factual knowledge on one hand, and marked receptivity to unconscious symbols and affectualization on the other. From a clinical perspective, however, it must be pointed out that a hysterical personality is by no means a necessary precondition for the development of a conversion syndrome. Rather, systematic studies of personality

typology among conversion patients have revealed a multiplicity of different personalities, displaying not only histrionic, but also predominantly passive, dependent, and depressive traits (Chodoff and Lyons 1958; Folks et al. 1984; Toone 1990).

Painstaking clinical, and particularly neurological studies of patients with conversion syndromes have revealed a frequent association with coexisting major organic, primarily neurological, abnormalities (Folks et al. 1984; Marsden 1986; Merskey and Buhrich 1975; Merskey and Trimble 1979; Ron 1994; Roy 1977). Organic brain disorders may either predispose to the development of conversion disorders or serve as models of illness for the social learning process. A vivid illustration of the latter is the frequent simultaneous appearance of epileptic and non-epileptic seizures; non-epileptic seizures have been diagnosed in as many as 25% of patients with epilepsy (Ramchandani and Schindler 1993). This coexistence may be found in epileptic patients with early acquired brain damage and secondary cognitive deficits. Frontal lobe injuries with resulting impairment of attention and planning mechanisms also seem to predispose to the development of conversion disorders (Ron 1994; Spiegel 1991).

Several neurophysiological and neuropsychological hypotheses may further contribute to the understanding of conversion processes. Ludwig (1972) and Whitlock (1967) postulated that a corticofugal inhibitory mechanism for afferent impulses and a disturbance of attention function are fundamental to the generation of conversion. In accordance with the early formulation of hysteria by Kretschmer (1923) as a resorting to instinctual motor templates, including extreme forms such as the "movement storm" or "feigned-death reflex," in response to shocking affective experiences, these authors also described reactions to disaster as increasingly regressive modes of dealing with otherwise intolerable stressors. These regressive behaviors contribute to a defenseless and helpless pose and also form an obstacle to mature judgment of reality; this results in a psychological barrier being created, thus closing out the social situation or inner conflict that is perceived as dangerous. At the same time, the patient's freedom to direct his or her attention to any object desired is blocked by concentration on the physical symptom. This phenomenon is clearly related to the clinical sign of "la belle indifférence."

It may be that limited coordination of information between the two cerebral hemispheres plays a role in this process, as suggested by clinical observations of an increased frequency of conversion symptoms on the left side of the body (Bishop et al. 1978; Galin et al. 1977; Stern 1974).

Neuropsychological findings also suggest a hemispheric dysfunctionality of this type. Flor-Henry et al. (1981) demonstrated not only bifrontal changes, but also functional disturbances primarily in the nondominant hemisphere, in a group of patients with frequently recurring conversion symptoms. In their neuropsychological study, they reported a significant inhibition of verbally coded images and a simultaneous, marked affective incongruence. These experimental findings were reminiscent of psychoanalytical conceptions of an impressionistic cognitive style or of affectualization (Shapiro 1965). Observations of psychopathologically relevant changes in the presence of focal brain lesions, such as hemineglect (anosognosia or hemiplegia) with involvement of the nondominant parietal cortex, or anosodiaphoria (uncritical cheerfulness and denial of deficit) with right frontal brain damage, may provide a basis for future neuropsychological models of certain psychopathological abnormalities in conversion disorders, such as "la belle indifférence" (Cutting 1990).

5.4 Treatment

Patients with conversion disorders are very often first seen by neurologists. The first therapeutic measures should also be undertaken in this medical setting. A detailed physical examination is essential, including whatever additional diagnostic tests are indicated. It is important to communicate the findings clearly to the patient. They must be interpreted in an empathic, accepting, and not degrading manner that takes the patient's own conception of the illness into account.

Clinical experience reveals that hospitalized patients with conversion disorders quite frequently respond positively to a multiplicity of nonspecific suggestive measures (Baker and Silver 1987). When the conversion disorder takes a chronic course, patients also often learn to derive benefit from empathetically conducted physiotherapeutic exercises (Delargy et al. 1986). It remains unknown, however, whether these therapeutic measures alone can lead to persistent, long-term benefit, particularly if the underlying psychosocial or psychological problem has not been addressed.

It is clear that any psychiatric illness underlying conversion symptoms must be recognized and properly treated. In such situations, the syndrome-oriented application of differential psychopharmacotherapy is indicated (Kapfhammer 1995).

Behavior-therapeutic and cognitive-therapeutic approaches in acute clinical care have the advantage that a clearly structured treatment plan can be worked out with the patient, and the rationale for each step of the treatment can be precisely and intelligibly explained. Important elements of this process include, above all, attention to central cognitive convictions regarding the somatic symptoms, sensitization with respect to the

effects of attention and body perception, direct discussion of stress-inducing personal problems, reduction of avoidant coping strategies and promotion of more promising alternative strategies, physical activation, and reinforcement of "normal behavior." Important contact persons must then be included in the treatment process to allow the therapist to identify and alter the many forms of social reinforcement that result from and, in turn, serve to maintain the patient's illness behavior.

Lazarus (1963) reported the results of multimodally structured behavioral therapy in 27 patients suffering from conversion disorders. After an average of 14 sessions, a good or complete remission of symptoms had been achieved in 71% of the patients. Teasell and Shapiro (1993) emphasized that behavior-therapy techniques, and operant conditioning in particular, are associated with a high probability of recovery, even in chronic conversion disorders.

In a psychodynamically oriented therapeutic approach, an attempt is made to understand central conflicts and affective states as indicators of a disturbed experience of the self and the outside world and to recognize the unconscious dimension of the production of the disorder in the framework of the physician–patient relationship. Conversation with the therapist enables most patients with conversion disorders to gain a meaningful causal understanding of their condition with regard to current conflicts and psychosocial stressors. The conversion symptoms often have many different levels of reference, which can be talked through by the patient and the therapist in focal therapy, with resulting benefit (Daie and Witztum 1991; Viederman 1995). In individual cases, long-term psychoanalytic treatment can also be recommended. The indication depends on the patient's suitability for this particular treatment structure and, above all, on what the patient expects from it (Ford 1983).

Controlled studies on the treatment of conversion disorders are still lacking. Thus an overall assessment of the different types of treatment, ranging from hypnosis to family therapy, cannot provide any recommendation regarding standard modes of differential therapy.

Major changes in treatment are necessary, however, when a careful evaluation by differential diagnosis of conversion syndromes results in their reclassification as conversion disorders, somatization disorders, or artificial disorders (Kapfhammer et al. 1998a,b).

Somatoform Disorders

1 Unexplained Physical Symptoms

The simple descriptive term "unexplained physical symptoms" (which is the ICD-10 primary care alternative to somatoform disorder) is to be preferred to some of the other labels that have been widely used, such as "hypochondriasis" in a general sense, "functional symptoms", "functional overlay" and "somatization". The term "somatization" is widely used to describe these patients, but it is best regarded as a psychological process rather than a category. It has been variously defined; one widely quoted definition is "a tendency to experience and communicate psychological distress in the form of somatic symptoms and to seek medical help for them" (Lipowski 1988). This is unsatisfactory in that it contains several distinct elements and it also implicitly assumes a process in which psychological distress is expressed as bodily symptoms. The term "somatization" is currently used in at least three different ways: (1) high levels of medically unexplained symptoms, (2) somatic preoccupation or worry about illness and (3) the somatic presentation of traditional psychiatric disorders (Kirmayer and Robbins 1991).

Although the association with a range of psychiatric disorders has repeatedly been shown, patients with medically unexplained symptoms have never been satisfactorily accommodated in either medical or psychiatric classifications. As a result, physicians and psychiatrists have used different terms in diagnoses. Physicians have tended to use "syndrome descriptions" which reflect in their special interests, e.g. irritable bowel, fibromyalgia, chronic pelvic pain. This has recently been usefully modified by the development of operational syndrome definitions such as those used for chronic fatigue syndrome (Wessely et al. 1998) and irritable bowel.

Psychiatrists, on the other hand, have focused on the associated psychological symptoms and have tried to use standard psychiatric diagnostic categories together with the recent and still ill-defined group of somatoform disorders. This grouping was introduced in DSM-III for conditions in which physical complaints are more conspicuous than psychological ones and is now widely used. In ICD-10, it is grouped as a part of "neurotic, stress-related and somatoform disorders" (F40–F48) and is defined as follows: "the main feature of somatoform disorders is repeated presentation of physicals symptoms, together with a persistent request for medical investigations, in spite of repeated negative findings and reassurances by doctors that the symptoms have no physical basis". It includes several subcategories with traditional names as well as new groupings; it is unfortunate that there are considerable differences between ICD-10 and DSM-IV.

In everyday clinical practice, it is best to formulate clinical problems according to the physical syndrome, course and disability and the presence of any associated psychiatric disorder or disorders.

1.1 Epidemiology

In the general population, unexplained physical symptoms severe enough to cause distress and some limitation are extremely frequent. For example, a North American report found that 41% of subjects reported back pain in the previous 6 months, 26% headache, 17% abdominal pain, 12% chest pain and 12% facial pain. Many of these complaints were long-standing, recurrent and associated with some limitation of activities. As in other studies, the greater the number of physical complaints, the higher the proportion suffering from current and lifetime psychiatric disorder (Von Korff et al. 1988). There are few cross-cultural differences in overall prevalence, although patterns of types of symptoms vary from country to country (Kirmayer et al. 1994; Simon and Von Korff 1991).

In primary care, at least a fifth of all new presentations are of unexplained physical symptoms (Goldberg 1995). These are of many types, but among the commonest are abdominal pain, chest pain, musculoskeletal pains, fatigue and headache (Kroenke and Mangelsdorff 1989). Most of the symptoms are transient, but a proportion are persistent and associated with significant disability and very considerable use of medical resources. Medically unexplained symptoms are frequent in many general hospital outpatient clinics and especially so in the selected population referred to pain clinics. Follow-up studies suggest that negative investigation fails to reassure many clinic attenders and that this is especially so in those assessed as having high health anxiety. Non-specific diagnoses are most frequent among general hospital inpatient discharge diagnoses (Mayou et al. 1991). In a series of Danish case register studies, Fink has documented the extensive medical and surgical resources used by a small number of people who have multiple admissions to hospital for which no physical diagnosis is recorded (Fink 1995).

1.2 Aetiology

Aetiology has been viewed from various standpoints – psychodynamic, psychiatric disorder, behavioural,

cognitive. These explanations are not mutually exclusive; it is probable that the aetiology is often multicausal (Kellner 1991; Barsky and Klerman 1983). Current models emphasize the importance of attribution or cognitive interpretation of bodily sensations. This interpretation may be affected by cultural and illness belief factors or by personality and other individual psychological factors (Mayou et al. 1995), as illustrated in Fig. 1.

The model implies that pathophysiological mechanisms cause bodily perceptions which are then interpreted and that subjective symptoms and disability are determined by a process of attribution, or cognitive interpretation. This in turn is determined by the patient's recent and lifetime illness experience and by aspects of personality and current mental state. Once symptoms have occurred, maintaining factors will inevitably include the reactions of other people, family, friends, acquaintances and especially doctors, and secondary psychological factors, such as anxiety, which may reinforce the underlying pathophysiological processes and the attribution of meaning. There is very considerable evidence about each aspect of this model, and it is useful to examine these in turn.

A very large number of possible minor pathological and physiological causes have been described, and they include the physical consequences of psychiatric disorder, especially anxiety (Sharpe and Bass 1992). These include the following:

1. Major pathology
2. Minor pathology
3. Physiological processes
   a) Sinus tachycardia and benign minor arrhythmias
   b) Effects of fatigue
   c) Hangover
   d) Effects of overeating
   e) Effects of prolonged inactivity
   f) Autonomic effects of anxiety
   g) Lack of sleep

Recent research has consistently shown evidence that illness experience, remote and recent, appears to predispose to and precipitate medically unexplained symptoms:

- Childhood illness
- Family illness and consultation in childhood
- Childhood consultation and school absence
- Physical illness in adult life
- Experience and satisfaction with medical consultation
- Illness in family and friends
- Publicity in television, newspapers, etc.
- Knowledge of illness and its treatment

It is not surprising, and indeed may be even appropriate, that past experience should affects subjects' interpretation and concern about symptoms which may be medically minor but may, in fact, be of considerable individual significance.

There has been extensive research on understanding the role of individual perception and interpretation of symptoms in experimental studies in populations with and without physical disorder (Pennebaker and Watson 1991) and in clinical studies (Barsky 1992; Mayou et al. 1995). These have resulted in health belief, attribution and cognitive models that combine the roles of personality variables, attention and health beliefs (Cioffi 1991). They result in two separate, but related, aspects: amplification/minimization and misinterpretation. Cognitive behavioural formulations emphasize the central significance of health anxiety and of the reinforcing effects of its physiological, cognitive, affective and behavioural consequences (Salkovskis and Clark 1993). It is evident there are no real differences in the psychological mechanisms of symptom perception whether the underlying cause is attributable to major pathology or to physiological processes or trivial pathology. The aetiology of physically unexplained symptoms differs from that of the impact of physical illness only in the proportion of causation attributable to psychological variables.

There is very considerable complexity in a psycho-

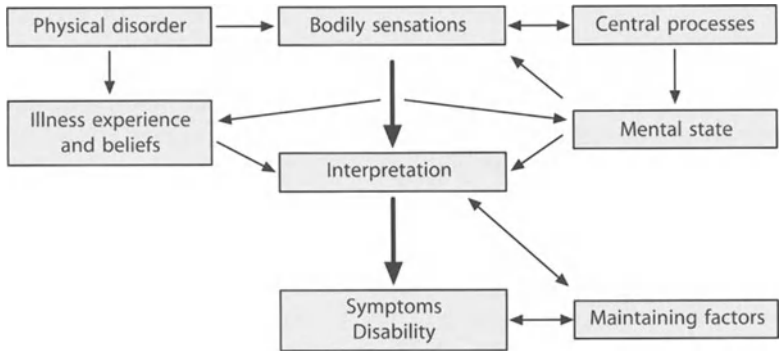

Fig. 1. Model of the aetiology of unexplained physical symptoms

logical and psychiatric literature which uses varying terms, each of which has been used in many different ways. They refer to:

- Vulnerable personality – individuals differ widely in their tendency to health anxiety about minor bodily sensations and a small extreme subgroup may be diagnosable as suffering from a hypochondriacal personality disorder.
- Psychological reaction to acute or chronic stresses – the general worry and stress may result in bodily symptoms of autonomic arousal and in a general increase in health anxiety and a tendency to misinterpretation.
- Psychiatric disorder – although not invariably associated with disabling and persistent unexplained symptoms, it is usual when symptoms are severe, multiple or recurrent and accompanied by disability and disease conviction.

Psychiatric disorder is important in the aetiology of chronic unexplained symptoms, but there are many people whose physical symptoms are due to psychological processes but who do not suffer from diagnosable psychiatric disorder. They may benefit from psychological or psychiatric treatment. Many have sub-threshold disorders (Janca et al. 1995). The uncertainties that have always surrounded the conditions now collectively referred to as somatoform disorders has meant that there has been great variation between national systems of classification, criteria and terminology.

There have been numerous studies of the association between psychiatric disorder and unexplained symptoms. There is a strong association between the number of physical symptoms and psychiatric disorder. The range of diagnosis is wide. In primary care, adjustment disorder is the commonest diagnosis, but affective and somatoform disorders are also frequent. The WHO Primary Care Study suggests remarkably similarities in all the participating countries (Üstün and Sartorius 1995). In secondary care, affective disorder and panic and other anxiety disorders predominate but, as in other medical settings, there is considerable co-morbidity with somatoform disorders.

A Canadian study which examined patterns of somatization in 685 patients attending family medicine clinics (Kirmayer and Robbins 1991) found that 26% met criteria for at least one of three definitions of somatization: (1) numerous unexplained physical symptoms, (2) illness worry or hypochondriasis, and (3) somatic presentations of major depression and anxiety. Most patients met criteria for only one of these three types of somatization, suggesting three distinct groups.

Once established, the symptoms and associated distress may be perpetuated by secondary physiological, behavioural or cognitive processes as well as by a number of social factors, including the reaction of others. There is substantial evidence that the behaviour of doctors may make problems worse by failing to provide explanations, by giving information which is inconsistent or ambiguous or by over-investigation. Simple reassurance following negative investigation is often ineffective (Howard and Wessely 1996), especially in people who are prone to suffer health anxiety as a feature of their personality.

1.3 Assessment

Psychological factors should always be considered from the beginning of the assessment in any patient with persistent and unexplained physical symptoms. Early assessment of psychological and social factors and awareness of the possibility of negative physical investigation enables the doctor to pursue physical and psychological care in parallel. The general principles of assessment are as follows:

- Consider psychological factors from outset
- Appropriate physical investigation to exclude physical cause
- Clarify psychological and physical complaints
- Understand patient's beliefs and expectations
- Identify depression or other psychiatric disorder
- Identify psychosocial problems

Past history may provide evidence of previous episodes of unexplained physical symptoms or of a psychiatric disorder. It is important to enquire about mood and anxiety symptoms and also to question patients about their beliefs about the nature and meaning of their symptoms (Marple et al. 1997).

There is a tendency for non-specialists to pursue excessive physical investigation, often in response to demands from patients and their families. This should be avoided as it often creates problems becoming less and less effective and leading to further requests for investigation and reassurance. Investigations should be chosen for good medical reasons and, if negative, the results need to be clearly explained and discussed. It has repeatedly been found that straightforward reassurance that findings are negative is only transiently effective in those who have high usual levels of health anxiety. Indeed, repeated reassurance may exacerbate problems.

On completion of investigations, it should be possible to make a formulation of the causes in terms of the aetiological model in Fig. 1, which can be the basis of treatment, whether this is simple explanation and reassurance or specialist psychological treatment. Treatment of any underlying physical causes and modification of any of the evidence in the model is

valuable, but the central themes of treatment are usually the management of psychiatric disorder and the modification of inappropriate interpretation.

1.4 Treatment

Improved treatment of unexplained, somatoform, symptoms has two elements. In view of the very large numbers of patients who are disabled and who use very considerable amounts of medical care, the main emphasis will need to be on simple ways of improving general medical care:

1. Measures to improve recognition, explanation, advice and avoidance of iatrogenic problems in routine medical care; good early treatment by non-specialists can prevent unnecessary investigation and long-term iatrogenic disability.
2. The role of specialist services in assessment and treatment and also supervision and training of other disciplines involved in care.

Consideration of the interaction of minor physical and psychological factors from the outset enables the doctor to avoid all the difficulties that arise from presenting patients with sudden change from an apparently physical to a psychiatric explanation. The doctor can show that the presenting symptoms are accepted as real, familiar and deserving of treatment. Reassurance that there is not a serious or sinister underlying physical disorder must be accompanied by an explanation and specific advice which meets the patient's anxieties. With the majority of patients in primary care, it is unnecessary to raise issues of psychiatric diagnosis, although it is often important to discuss the ways in which everyday psychological factors have an important role in *all* medical problems.

Follow-up review and discussion and the involvement of a close relative can be useful. Goldberg et al. (1989) described a model of what they refer to as "reattribution", which they have used successfully to train primary care doctors to manage unexplained physical symptoms. This has three important elements: making the patient feel understood, changing the agenda and making the link to psychological distress.

The general principles of treatment can be summarized as follows:

- Emphasize symptoms are real and medical care is appropriate
- Minimize/control physical care
- Offer explanation and discuss
- Discuss role of psychological factors in all medical care
- Treat primary psychiatric disorder
- Agree treatment plan

In the past, referral to psychiatrists for patients with persistent disabling symptoms has often been unhelpful, because many patients do not suffer from the types of psychiatric disorder seen in mental illness services. However, there is very considerable evidence that standard treatments of anxiety and depression and psychological treatments especially adapted for particular clinical problems can be highly effective. Unfortunately, they are neither widely used nor available at present. The main reasons for referral to psychiatrists or to other specialists are:

1. For help in diagnosis
2. For comprehensive assessment and advice on management
3. To provide specialist treatment

Since many patients find psychiatric explanations unacceptable and are reluctant to attend clinics which they see as treating mental illness, it is essential that referring doctors have a good working relationship with the psychiatrist or psychologist and are willing to explain the nature of the referral to the patient. Patients who have confidence in their primary care doctors or physical specialists are much more likely to accept referral if it is seen as involving a colleague of their own doctor and if they are assured that there condition is seen as real, familiar and deserving of medical treatment.

1.5 Specialist Treatments

The more fully that specialist treatment can be integrated with routine physical care, the more likely patients are to find the treatment acceptable and helpful. The general principles and procedures for specialist treatments need to be adapted and overall treatment plans formulated to take account of the presenting symptoms. For example, cognitive behavioural treatment has been shown to be effective in the treatment of a number of syndromes, including general medical symptoms (Speckens et al. 1996), chronic fatigue (Sharpe et al. 1996), non-cardiac chest pain (Mayou et al. 1997) and irritable bowel. The detailed treatments are directed towards the rather different symptoms, limitations and cognitions of each of these common problems. The therapist must be familiar with the medical issues and with the particular procedures, self-help materials and with other elements of treatment that have been shown to be effective.

The specialist, with knowledge of both physical and psychological aspects of somatoform symptoms, is better placed than the primary care doctor or general hospital physician to assess aetiology and to provide

formulations to the patient of the causes of the symptoms and the way they are being managed. Many patients are reassured by meeting a confident, sympathetic doctor who asks about their worries, accepts the symptoms as being real and deserving of treatment, finds them familiar and is able to discuss practical treatment plans.

Major depressive illness is an important cause of unexplained physical symptoms, and standard antidepressant treatment is required. Patients who are sceptical of the importance of psychological causes of their complaints are often reluctant to take antidepressant medication and are worried about its side-effects. The general principles of all treatment – careful explanation, the involvement of relatives, the support of other doctors – are fundamental to dealing with such concerns. It is also important to choose an antidepressant whose side-effects are least likely to cause problems and to provide the patient and family with a complete explanation.

Although, in general, antidepressants can only be expected to be effective where there are psychological symptoms of depressive disorder, there is evidence that a number of pain syndromes in which depression is not conspicuous respond to antidepressants.

Cognitive behavioural treatment adapted from methods which have been shown to be successful for anxiety disorders have now been demonstrated to be effective in medical outpatients (Speckens et al. 1996) with a number of specific types of physical symptoms, such as some chronic pain, non-cardiac chest pain (Mayou et al. 1997) and irritable bowel, as well as with the somatoform syndromes such as hypochondriasis (Warwick et al. 1996; Clark et al. 1998).

Individual and group psychotherapies have been widely used. They appear to be most effective when directed towards helping the patient establish an understanding of the origin of the symptoms and the ways in which changes in understanding and behaviour can lead to improvement (Guthrie 1995).

In the minority of patients with long histories of multiple symptoms, effectiveness of specific treatments is limited. Management has to be directed towards simplifying medical treatment so as to provide a consistent plan which can be agreed with the patient by a single doctor. It is frequently possible to very considerably reduce medical resources being used, to avoid the complications of excessive and contradictory care by a number of people and to achieve the improvement of the functional status and well-being of patients and their families. The techniques are considered more fully below in the section on somatization disorder.

With complicated chronic pain and other symptoms, treatment may involve individualized programmes of physical, psychological and social elements. It is difficult to evaluate such programmes, but they do appear to be helpful in outpatient and also in inpatient treatment (Main and Benjamin 1995).

2 Somatoform Disorders

Somatoform disorders were introduced as a category in DSM-III as a means of bringing together a number of traditional categories with recently proposed new groupings. The classification was seen as provisional, but has been little changed in DSM-IV. ICD-10 included a similar category but with significant differences in the sub-categories, which are shown in Table 1.

Although both classifications are intended to be provisional, they are often treated as having greater validity than was claimed by those who devised the criteria. The whole concept requires critical review (Murphy 1990; Janca et al. 1995). A major difficulty is the lack of applicability to a number of non-Western countries who do not share the mind/body separation which characterizes Western medicine (Kirmayer et al. 1994; Lee 1997). There are other significant problems:

1. There is considerable overlap with other major psychiatric disorders (especially anxiety).
2. The clinical descriptions of the specific psychiatric disorders are largely derived from hospital-based experience and are not readily applicable to the large number of people with functional complaints

Table 1. Categories of somatoform disorders in ICD-10 and DSM-IV

ICD-10	DSM-IV
Somatization disorder	Somatization disorder
Undifferentiated somatoform disorder	Undifferentiated somatoform disorder
Hypochondriacal disorder	Hypochondriasis
Somatoform autonomic dysfunction	No category
Persistent pain disorder	Pain disorder associated with psychological factors (and a general medical condition)
Other somatoform disorders	Somatoform disorders not otherwise specified
No category	Body dysmorphic disorder
No category	Conversion disorder
Neurasthenia	No category

in the community and primary care. Many of these have sub-threshold emotional problems.
3. Disabling, medically unexplained symptoms can occur in the absence of psychiatric diagnosis (especially in primary care).
4. Diagnostic criteria are based on a mixture of principles – aetiology, symptom counts, consultation, response to medical treatment.
5. The more precise sub-categories are only appropriate for a minority of subjects.
6. Many patients are classified in residual categories based on unexplained presenting symptoms.

The remainder of this chapter describes the main categories of somatoform disorder in ICD-10. The ICD category of neurasthenia is described in a separate chapter (Chap. 8, this volume), and conversion disorder, which is included with the somatoform disorders in DSM, is also discussed elsewhere in this book.

There have been few major epidemiological studies of somatoform disorder or of its sub-categories. General population studies of somatoform disorders have focused on patients with multiple symptoms (Simon and Von Korff 1991). Research in primary care has found somatoform disorders to be frequent among consecutive attenders, and there is often co-morbid affective or anxiety disorder. The most detailed evidence is provided by the WHO Primary Care Study, which has provided findings from centres in 14 countries (Üstün and Sartorius 1995). In contrast to the frequent claims that somatoform disorders are most frequent in non-Western cultures, it is apparent that there are relatively few differences between the wide range of countries in this project (Gureje et al. 1997a).

Table 2 summarizes findings from a Danish primary care study which demonstrates the marked differences in using ICD-10 and DSM-IV (Fink et al. 1999). DSM-IV is dominated by undifferentiated somatoform disorder and somatoform disorder not otherwise specified (NOS); in contrast, in ICD-10, undifferentiated somatoform disorder is less common and the highest prevalence is for the descriptive category of autonomic dysfunction. In both systems, the more precise categories of somatization disorder and hypochondriasis are relatively uncommon. Co-morbid psychiatric disorder was present in about half the cases.

Table 2. Somatoform disorders in a Danish primary care study of consecutive attenders (%) (adapted from Fink et al. 1999)

	ICD-10	DSM-IV
Somatization disorder	6	1
Undifferentiated somatoform disorder	7	27
Pain disorder	8	8
Hypochondriasis	4	4
Autonomic dysfunction	14	–
Neurasthenia	4	–
Conversion disorder	–	3
Somatoform disorder NOS	–	27

2.1 Hypochondriasis

The history of the term "hypochondriasis" extends over many centuries. In the twentieth century, it has had a relatively general lay meaning and a more precise psychiatric meaning, which has usually emphasized an excessive preoccupation with having a physical disorder. Hypochondriacal concerns occur in many psychiatric disorders, but there has been considerable argument about whether there is a primary syndrome. There is substantial overlap with anxiety, depression and somatization disorder. Definitions emphasize the cognitive and behavioural elements of misattribution of bodily sensations, disease conviction and reassurance-seeking (Côté et al. 1996).

DSM-III attempted to provide definitive criteria, and these remain largely unchanged in DSM-IV; ICD-10 is similar (see Appendix A). The main problem in diagnosis is that the criteria depend heavily upon the patient having sought help and having been appropriately investigated and reassured. In fact, there is evidence that many patients with unexplained physical symptoms have not had any convincing explanation and that reassurance may have been ambiguous or, indeed, even anxiety-provoking.

Hypochondriasis has been said to be relatively common in medical outpatient clinics with considerable psychiatric co-morbidity (Barsky et al. 1992). The WHO Primary Care Study reported that ICD-10 hypochondriasis was rare, with a prevalence of 0.8%, but that a less restrictively defined disorder had a frequency of 2.2% (Gureje et al. 1997b). Patients with this abridged hypochondriasis often had co-morbid major depression and generalized anxiety disorder and described considerable psychiatric ill-health and functional disability. There were no differences in rates between the 14 countries in the study. The key factor in the proposed abridged diagnosis is removal of the criterion of "persistent refusal to accept medial reassurance". The findings of this large study are consistent with other evidence that our current criteria are inadequate to define a syndrome characterized by health anxiety or disease conviction. The wider concept is also supported by accounts of *sub-threshold* and *transient* hypochondriasis in medical populations (Barsky et al. 1990).

The aetiology of hypochondriasis has generally been discussed in the terms discussed above for medically unexplained symptoms. However, three issues deserve particular attention:

1. *Is hypochondriasis a depressive disorder?* Kenyon (1964), in a widely quoted, large case-note study of patients diagnosed in a specialist psychiatric hospital, concluded that hypochondriasis was always secondary to another syndrome, usually depression. More recent research on representative populations has consistently supported the idea of a primary syndrome characterized by bodily preoccupation and conviction of disease.
2. *Is hypochondriasis a personality disorder?* It has been argued that hypochondriasis is often a lifelong problem of attitudes and behaviour (Tyrer et al. 1990). Although this may well be true for a subset of patients, it is probably more common for the syndrome to be episodic, with clear onset in adult life.
3. *Cognitive behavioural explanations.* Salkovskis and Clark (1993) have examined the role of cognitive explanations of panic disorder and hypochondriasis and conclude that both disorders result from a persistent tendency to misinterpret bodily changes as indicating catastrophic harm. Despite the overlap between the two syndromes, they suggest there are differences in terms of the perceived imminence of the catastrophe, the role of safety-seeking and the nature of some of the beliefs and assumptions upon which misinterpretations are based. Overall, the cognitive explanations fit in well with the concept of hypochondriasis as a subgroup of the whole spectrum of anxiety disorders in which health anxiety is especially prominent.

Treatment of hypochondriasis follows the general principles described earlier in this chapter. Associated depression should be treated with antidepressants. The disease conviction and misinterpretations seem to respond to a variety of individual or group psychotherapy or behavioural treatments. Although these treatments appear at first sight rather varied, they share the common aim of trying to enable the patient to have a clearer understanding of the origin of the symptoms and to answer specific worries and anxieties. This informed reassurance and explanation appears to be substantially more effective than straightforward reassurance that findings, examinations and investigations are all negative.

There have been several uncontrolled evaluations of treatment on populations of patients satisfying diagnostic criteria for hypochondriasis. Warwick and colleagues (1996) have reported an inpatient randomized controlled trial of intensive cognitive behavioural treatment. There were significant benefits in the treated group compared with those on the waiting list, benefits which were maintained at 3 months.

Anxiety and avoidance due to the fear of contracting a disease, e.g. human immunodeficiency virus (HIV), is know as *disease phobia* (Bianchi 1971) or illness phobia. There is no agreement as to whether this is best classified as a subgroup within hypochondriasis or within specific phobias. It is probably very similar to that of other specific phobias. Fears on injury, blood and dental treatment are common examples.

Dysmorphophobia, excessive concern about bodily appearance, is included with hypochondriasis in ICD-10, but is classified as a separate somatoform disorder, body dysmorphic disorder, in DSM-IV (Phillips and Hollander 1996). The ICD formulation has the advantage of emphasizing the probable similarity in psychological aetiology to those described for hypochondriasis, while DSM emphasizes the descriptive syndrome.

The epidemiology is unclear. The condition is uncommon, but probably more frequent than case reports and highly selected series have suggested. The rather few reports from less selected populations give a truer picture of a range of concern about appearance. Concern about appearance may be a symptom of a number of psychiatric disorders, including schizophrenia and delusional disorders.

Patients with dysmorphophobia often feel that they have not been taken seriously by doctors, and their feelings of grievance exacerbate their distress. Their complaints deserve careful assessment and collaboration between physicians and surgeons on the one hand and psychiatrists and psychologists on the other. In this way, it is possible to identify those who may respond to surgery or other physical treatment and those for whom specific psychiatric care may be useful.

Treatment is often difficult. Antidepressant medication can be effective in those with symptoms of depression. Plastic surgery or other physical treatment is often effective in those who have relatively precise dissatisfactions and realistic expectations of what may be achieved. Such treatments are ineffective and, indeed, are contraindicated in those who have vague complaints, especially those who have concerns about several parts of the body and who have histories of previous failed treatment. Cognitive behavioural treatment has been reported to be successful in a small number of subjects.

2.2 Somatization Disorder

Somatization disorder was introduced in DSM-III to describe a chronic condition characterized by numerous changing physical symptoms over a period of

many years. The precise formulation arose from a programme of research on a syndrome that was originally alleged to be a form of hysteria and was given the name Briquet's syndrome (Guze et al. 1986). The syndrome is now rightly separated from hysteria, but has somewhat different criteria in DSM-IV and ICD-10 (see Appendix B). There is a high degree of psychiatric co-morbidity, and personality disorder is common. The severity and the very considerable chronicity required to make the diagnosis suggest that there may well be advantages in considering the syndrome as a form of personality disorder (Speckens et al. 1995).

The definition depends on an entirely arbitrary cut-off based on symptom counts. While the syndrome defined in this manner has high reliability, there is little evidence that it has true validity and that it can be separated from similar syndromes with somewhat fewer physical complaints or with different patterns of complaints. It has been argued that there would be advantages in a broader definition (abridged somatization disorder). The prevalence of this suggested disorder is considerably greater than somatization disorder and may have some provisional practical utility (Escobar et al. 1989). However, there appears to be little justification for its arbitrary separation from undifferentiated somatoform disorder. As originally defined, somatization disorder is uncommon, between 0.1% and 0.4% in the United States (Simon and Von Korff 1991). It has a similar prevalence in all countries and cultures (Gureje et al. 1997a).

It is generally agreed that treatment of somatization disorder is difficult and that it is probably best directed towards control of symptoms and medical care rather than cure. Smith and colleagues (1986, 1995) have demonstrated in a series of important studies that provision of very simple advice to doctors treating patients with somatization disorder which suggested controlling medical care appeared to be effective in reducing consultation and health care costs, although there was little effect on their measures of patient outcome. It seems unlikely that such a simple procedure will be adequate in the majority of patients. However, it does illustrate the importance of controlling medical care, offering regular appointments with a single physician and trying to achieve more positive and instructive aims.

Clinical experience suggests that the following measures are beneficial to patients and their families and can improve the satisfaction of those treating them and reduce health costs:

- Simplify medical care
- Treat any co-existing psychiatric disorder
- Clarify psychosocial problems and tasks with patient
- Offer to see patient at regular, fixed intervals
- Negotiate treatment plan with patient and family
- Consider written contact

2.3 Undifferentiated Somatoform Disorder

Many patients present with features of more than one somatoform disorder and do not easily fit into any single category. Those who have multiple unexplained symptoms but are sub-threshold for somatization disorder are included in undifferentiated somatoform disorder. The very large size of this group indicates the failure of the sub-classification of somatoform disorders.

This has resulted in proposals for the abridged somatization disorder described above or for a new category of multi-somatoform disorder (Kroenke et al. 1997). Alternatively, it may be argued that categorical definition is unhelpful and that it would be preferable to look in terms of dimensions of symptoms, behaviour, attributions and disability (Janca et al. 1995). The lack of validity for a large residual category means that treatment must follow the general principles outlined earlier in this chapter, and expectations of success would be appropriately modest in those with chronic multiple or recurrent symptoms.

2.4 Somatoform Autonomic Dysfunction

Unlike DSM-IV, ICD-10 has a sub-category for those disorders whose symptoms appear to arise from overactivity of the autonomic nervous system. There is a sub-division according to the bodily system which is predominantly affected. Four features should be present:

1. Persistent troublesome symptoms and autonomic arousal
2. Additional symptoms referred to a specific organ or system
3. Preoccupation and distress about the possibility of serious disorder that does not respond to reassurance
4. No evidence of significant disturbance of structure or function of the organ or system

Although it is alleged that this syndrome can be differentiated from generalized anxiety disorder and from hypochondriasis, clinical experience suggests that this is not so. Epidemiological studies have found it to be a relatively large but residual category corresponding to some extent to the residual categories of DSM.

2.5
Persistent Pain Disorder

This category (referred to as "pain disorder associated with psychological factors" in DSM-IV) depends upon preoccupation with pain which causes significant distress or impairment and which appears to be due in substantial part to psychological factors (King and Strain 1996). The criteria require no judgement about the aetiological role of the psychological factors and is therefore a diagnosis of exclusion of other primary psychiatric disorder and of medical explanations. It describes a single diagnostic presenting problem rather than a psychiatric syndrome in any conventional sense.

While the category is an admission of our current lack of understanding, it may have some operational value in clinical practice. However, it separates consideration of patients who attend pain clinics for predominantly musculo-skeletal complaints from all other somatoform symptoms.

Treatment of chronic pain must reflect the multiple factors which are likely to be important in the formulation of aetiology in any individual patient. Treatment plans should include management and underlying physical problems, treatment of associated depression or other primary psychiatric disorder and cognitive behavioural measures to modify pain behaviour and perception and reduce disability. It is generally important to involve close relatives. More severe and chronic pain problems may require multidisciplinary treatment programmes (Wilson and Gil 1996; Main and Benjamin 1995).

2.6
Current Status

Review of the overall category and of its component sub-categories, suggests that somatoform disorders should be seen as a provisional operational classification with uncertain boundaries and sub-categories (Janca et al. 1995). They are in many ways residual descriptive categories for those who do not have conspicuous psychological symptoms. Present specific categories derive from historical formulations as much as from research and clinical experience. A worryingly high proportion of subjects are classified in non-specific or undifferentiated categories.

Increasing awareness of the inadequacies of our current concepts of somatoform disorder should not lead us to underestimate the value of having had provisional operational criteria applicable to very large numbers of people suffering disabling clinical problems. The present criteria, recent research and very considerable clinical experience point the way to improved classification. It is probable that this should be multidimensional so as to cover the type of clinical syndrome, the nature of underlying beliefs and health anxiety, course and severity.

Appendix A: ICD-10 Research Diagnostic Criteria for Hypochondriacal Disorder

A. *Either* (1) persistent belief, of at least 6 months duration, of presence of a maximum of two serious physical disorders; *or* (2) persistent preoccupation with a prejudged definite disfigurement.
B. Preoccupation with the belief and symptoms causes persistent distress and interference with personal functioning.
C. Persistent refusal to accept medical reassurance.
D. Exclusion of schizophrenia and mood disorder.

Appendix B: ICD-10 Research Diagnostic Criteria for Somatization Disorder (Abbreviated)

A. A history of at least 2 years' complaints of multiple and variable physical symptoms that cannot be explained by any detectable physical disorders.
B. Preoccupation with the symptoms causes persistent distress and leads the patient to seek repeated (three or more) consultations or sets of investigations ... In the absence of medical services ... there must be persistent self-medication or multiple consultations with local healers.
C. There is persistent refusal to accept medical reassurance that there is no adequate physical cause for the physical symptoms.
D. There must be a total of six or more symptoms from a list, with the symptoms occurring in at least two separate groups. [List of fourteen symptoms categorized as gastrointestinal, cardiovascular, genitourinary, skin and pain]

CHAPTER

8

S. Wessely

Neurasthenia

The first difficulty felt by anybody who enters on the study of neurasthenia is caused by the wide divergence of views held by the medical authorities both as to its nature and causation. (Cobb 1920)

1 Historical Development

Neurasthenia was originally described by the New York neurologist George Beard in 1869 (Wessely 1996), although some believe that the unfashionable midwest psychiatrist Van Deusen has an equal claim. No matter, over the next 30 years the concept enjoyed extraordinary, albeit not universal success across Europe and America. Bumke (1925) wrote that there was no instance in the history of medicine of a label having the impact of neurasthenia. Hundreds of journal articles and textbooks appeared between 1870 and 1900, and numerous doctors and clinics devoted themselves to the care of neurasthenic patients, not least because as an illness of the newly successful middle classes, it was associated with substantial income.

However, by the early part of the twentieth century, neurasthenia was in retreat. There were a number of reasons for this. Its pathological basis was called into question by the new science of neurophysiology, and it was no longer a socially exclusive illness. The interest shown by neurologists and physicians waned, and as more and more were convinced by the role of psychological factors, this interest was transferred to psychiatry, with the inevitable loss of prestige and revenue. Treatment shifted; in place of the much hyped "rest cure" (*Rastkur*) came the realisation that not only did enforced rest fail to cure, it probably was itself a cause of disability. The new psychiatric classifications of depression and anxiety gained credibility as rapidly as neurasthenia lost it (see Wessely et al. 1998).

It is ironic that neurasthenia has fallen into disrepute in the country of its birth, the United States, while it has taken hold in China and South Asia and has never left the former Soviet Union. Its history in China is particularly instructive. It was introduced into Chinese thinking probably in the 1920s, almost certainly due to the influence of American medicine. It was called *shenjing shuairuo* (nerve weakness) and was successful probably because the concept of depletion of nerve energy was compatible with the older tradition of Chinese medicine (Lee 1998). Its apogee was reached under the Communist regime, in the 1950s and 1960s. Seminal studies by Arthur Kleinman in the 1970s (Kleinman 1982) suggested that this was now the principal socially acceptable way for people to express psychological distress - hidden under a somatic disguise.

Since the end of the Cultural Revolution, the changing political and economic climate has, however, led to a decline in the use of the term "neurasthenia". Something similar can be observed in Japan, where the concept of neurasthenia was extremely popular until recently and was largely applied to patients who would now be diagnosed as anxiety disorders or hypochondriasis (Kitanishi and Kondo 1994). Another usage in Japan is as a euphemism for schizophrenia (Munakata 1989), since Japanese society has a particular abhorrence of serious mental illness.

2 The Neurasthenia Syndrome

What was, and what is, neurasthenia? The answer depends upon when and where the question is asked. A Victorian physician and follower of Weir Mitchell or Beard would answer that it is an organic disease of the nervous system, resulting from a system giving way under the pressures of modern life. A psychiatrist following the lead of Bleuler and Kraepelin would say it is a mild form of depression. A modern Western psychiatrist would hardly recognise the word, while a primary care doctor in the modern non-English speaking world would reply that it is a stress-related disorder characterised by fatigue but with little or no depression. Finally, some modern doctors would say it is an old term for the condition that we now call "chronic fatigue syndrome" (CFS) and whose physical aetiologies we are rediscovering after years of psychiatric neglect.

DSM-IV, the bible of American psychiatry, ignores neurasthenia and treats it as a "waste basket category", largely the result of failure to diagnose more conventional diagnoses. In contrast, ICD-10, more avowedly international, allows neurasthenia a place (F48.0). Confusion still remains over the status of "post-viral fatigue syndrome", which, under a virtually identical case definition, is listed as a neurological disorder (G93.3). Subsequent clarifications by the World Health Organization (WHO) made it clear this was a political compromise to allow all doctors to code for a fatigue syndrome, whether or not they considered it a psychiatric or neurological condition.

Neurasthenia is defined in ICD-10 (F48.0) as follows:

A. It must include one of the following:
   - Persistent and distressing complaints of feelings of exhaustion after minor mental effort
   - Persistent and distressing complaints of fatigue and bodily weakness after minor physical effort

B. At least one of the following symptoms must be present:
   - Muscle aches and pains
   - Dizziness
   - Tension headaches
   - Sleep disturbances

- Inability to relax
- Irritability

C. Symptoms are not relieved by rest, relaxation or entertainment
D. Minimum duration 3 months
E. Not associated with organic brain syndromes, mood, panic or generalised anxiety disorders

Hence there are many neurasthenias, but one thing every conceptualisation of neurasthenia has in common is that it is an illness of fatigue and fatigability. At the heart of the neurasthenia is the complaint of fatigue, precipitated by minor physical or mental effort. This fatigue is a subjective experience, one inaccessible to direct measurement. As such, it should be distinguished from the neurologist's use of fatigue as an objective failure to sustain force (as in myasthenia gravis) or the neuropsychologist's use of fatigue as a failure of mental performance. As the Victorians knew, and we are rediscovering, while a neurasthenic patient complains of abnormal physical and mental fatigue, objective tests of muscle or brain are essentially normal. Instead, what is being experienced is a sense of increased effort – that everyday tasks can be performed, but at the expense of an unpleasant sensation of increased physical or cognitive effort (Lawrie et al. 1997).

Neurasthenic patients clearly experience increased effort in everyday physical and mental tasks, reflected in sense of painful muscle exertion, and painful cognitive processing. This increased effort is not the result of increased neuromuscular or metabolic demands (a Victorian concept), nor does it result in any substantial decline in actual muscle or cognitive performance. The result is a mismatch between patients' evaluation of their physical and mental functioning and the external evidence of any consistent deficits. The basis of this disorder of effort must remain speculative, and the perception of effort is a complex topic, but I assume it is because the sufferer needs to devote more attention, or even energy, to processes that the rest of us perform automatically, be it muscular exertion or mental concentration (Lawrie et al. 1997).

3 Prevalence

Chronic fatigue is common – indeed, it is second only to headache in most community services. Wherever one looks, between 20% and 40% of the population answer yes to the question "do you feel tired all the time?". Women invariably out number men. Thus a U.K. study finding that 20% of men and 30% of women complain of being tired all the time, all day and every day for the past month, can be taken as typical of a large literature (Wessely 1995). Chronic fatigue is relatively unaffected by age – it is rare before puberty but is, if anything, more common in younger age-groups.

Because neurasthenia is defined as more than just chronic fatigue, it is less common. Exact prevalences are crucially dependent on definition. Hence on the Swedish island of Lundby, deservedly a mecca for psychiatric epidemiologists, the lifetime prevalence of "fatigue syndrome" was 33% for women and 21% for men. The point prevalence of neurasthenia in Zurich, as reported by Jules Angst, is lower, but still substantial. Again, women were affected more commonly than men. If more stringent criteria are used, the prevalence naturally falls, particularly when co-morbid psychiatric disorder is excluded (see below), but it is worth remembering that there is no study that reports that neurasthenia is less common than such familiar disorders as schizophrenia or obsessive compulsive disorder. Neurasthenia is a public health issue.

Perhaps the best estimates of the prevalences of pure neurasthenia comes from the WHO Primary Care Study (Ustun and Sartorius 1995). The prevalence of neurasthenia ranged from a high of 3.7% (Manchester) to a low of 0.3% (Athens and Bangalore). Whether or not these represent true differences or alternatively differences in illness behaviour, recognition and methodology cannot be answered; however, what is clear is that there are relatively large numbers of people presenting in primary care who fulfil the diagnostic criteria for neurasthenia – indeed, it is the third most common mental disorder encountered in that setting (Ustun and Sartorius 1995).

Simply because there is an operational definition of a condition gives no information on its nosological status. The principle criticisms of the neurasthenia concept come from two sources. The first is the relationship between neurasthenia and the symptom of fatigue. The second is the relationship between neurasthenia and other psychiatric disorders. As already described, wherever it has been studied, chronic fatigue emerges as one of the most common symptoms experienced in the community. Like all symptoms, it is dimensionally, and not categorically, distributed. Fatigue is part of the human condition, as is chronic fatigue. If we study the distribution of fatigue-related symptoms in the population, a normal distribution is found (Pawlikowska et al. 1994). There is no point of rarity, and no clear division between the normal and the abnormal. An appropriate analogy would be with blood pressure – we all know that there is no unique illness called "high blood pressure", nor a diastolic

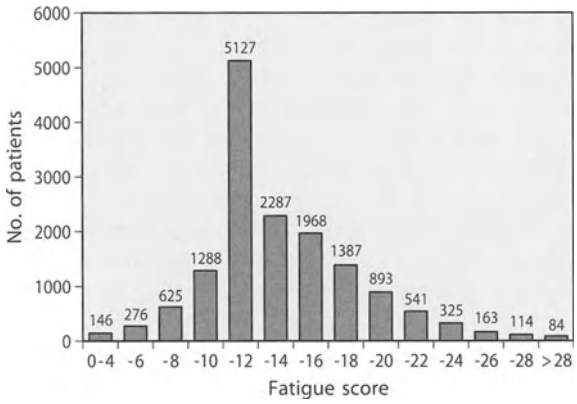

Fig. 1. The distribution of fatigue in the community. (From Pawlikowska et al. 1994)

reading which separates normal from abnormal. Instead, there is a gradient of risk, with no clear delineation between normal and high. Yet that does not invalidate the importance of high blood pressure, nor its association with morbidity, and the need for doctors to treat it. The same is true of fatigue/neurasthenia (Fig. 1).

4 Aetiologies

We have not really progressed since Kraepelin divided neurasthenia into congenital and acquired. Hence on the one hand we have a long series of studies claiming that neurasthenia results from some form of toxic insult, be it infection, trauma or chemical insult. Neurasthenic syndromes have been described in those recovering from Epstein Barr virus infection, people with prolonged influenza, those exposed to organic solvents or organophosphate pesticides, patients with mild head injuries and in Vietnam veterans possibly exposed to Agent Orange, among others. All of these suggest that neurasthenia may be a non-specific response to insult. Longitudinal studies in which data is collected prior to the onset of illness are rare and are confined to the field of post-infectious neurasthenia, but those that have been conducted suggest that prior psychological symptoms increase the vulnerability to subsequent neurasthenia after an infective trigger.

This model, in which pre-exposure to psychological or social variables explains some of the post-exposure outcome, is not unique to the relationship between insults such as viral infections and the development of neurasthenia/chronic fatigue. We found the same to apply to viral meningitis, in which the contribution of the precipitating infection was more substantial, but the combination of previous psychiatric disorder and viral meningitis was particularly associated with the onset of CFS. Similar results have been presented to explain the transition from acute to chronic back pain, from herpes zoster to post-herpetic neuralgia, from acute gastroenteritis to irritable bowel syndrome, from head injury to the post-concussional syndrome, from trauma to post-traumatic stress disorder (PTSD) and to explain the development of post-surgical fatigue (see Wessely et al. 1998).

5 Neurasthenia and Other Psychiatric Disorders

There are few psychiatric disorders that are not associated with chronic fatigue. It would be tedious to list all the studies that show that fatigue is a common, and often the most common, symptom of depressive disorders – it is simpler to state that I know of no exception. Fatigue is also part and parcel of all of the anxiety disorders, is frequent in eating disorders and can be associated with virtually any psychotic or organic mental disorder. Given that much the same comment can be made about the role of fatigue in medical disorders, it is for that reason that fatigue is not a subject which attracts much interest among doctors, who are aware of its non-specificity, and that the presence of fatigue is not helpful in the matter of diagnosis. It is interesting to note that the general public sees things very differently – for them, fatigue is a very important symptom indeed (Dohrenwend and Crandell 1970).

Given the importance of fatigue in neurasthenia and its ubiquity elsewhere, virtually every study notes the overlap between neurasthenia and the common psychiatric disorders. For example, in Chinese Americans, the annual prevalence of neurasthenia was 6.4%, but fell to 3.6% when co-morbid conditions were excluded (Zheng et al. 1997). In Australian primary care, the prevalence of fatigue syndrome was far higher (25%), but again two thirds were classified as cases of psychiatric disorder (Hickie et al. 1996). In the Zurich studies, 79% of the cases of neurasthenia were associated with depression and/or anxiety (Merikangas and Angst 1994). Much the same can be said of CFS – a considerable proportion of patients, especially in specialist settings, also fulfil criteria for recognised psychiatric disorders, but invariably somewhere between a third and a half do not. If we follow Occam's Razor and try not to create more categories than is necessary, it remains true that a category resembling neurasthenia is essential.

The relationship between neurasthenia and psychiatric disorders appears to be predictable, whether or not it is neurasthenia or CFS that is studied. In general, neurasthenic subjects experience more psychiatric

distress than normal subjects, but less than those with well-defined psychiatric disorders such as depression. On the other hand, they usually score as highly, and occasionally higher, on measures of somatic symptoms. Much the same applies to CFS.

Longitudinal studies confirm the overlap between neurasthenia and psychiatric disorders, but also show that the two are independent. Fatigue is certainly a well-known prodrome to depression (Dryman and Eaton 1991), but studies from London, Zurich and Australia suggest that "pure" fatigue syndrome is not particularly associated with subsequent depression; in other words the interchange between chronic fatigue/neurasthenia and depression is due to the large contribution made by co-morbidity – neurasthenia/fatigue and psychiatric disorder in the same person – but a pure neurasthenic syndrome is relatively stable and is not inevitably followed by depression.

The links between depression and neurasthenia are a partial explanation for the over-representation of women in studies of fatigue, neurasthenia or CFS. However, although one or two studies find the excess in women to be entirely accounted for by depression, most do not. Adjustment for mood disorder reduces, but does not eliminate, the excess in women, which is more likely to be related to some common social and biological confounders.

In conclusion, there is now persuasive evidence that neurasthenia is associated with, but not the same as, depression or anxiety. There is no evidence that it is a discrete disorder, however, with a clear division between normal and abnormal fatigability; it is instead a question of degree.

6
Chronic Fatigue Syndrome

Neurasthenia had largely vanished by the 1960s from Western medicine and psychiatry, and with it the interest in fatigue states. These were revived in the 1980s by the emergence in the English-speaking world of what became known as CFS, an illness to all intents and purposes indistinguishable from neurasthenia as originally proposed by Beard and Mitchell. Given the close overlap between the concepts, it is not surprising that 97% of those attending a CFS clinic in Wales fulfilled criteria for neurasthenia (Farmer et al. 1995). Likewise, a soon to be published comparison of neurasthenia and CFS in Chinese American and Causasian inhabitants of Los Angeles showed that neurasthenia in the ethnic Chinese and CFS in the Caucasians were strikingly similar, although the explanations each group gave for their illness could hardly be more different (Lin et al. 1996). Nevertheless, one should beware of equating all the diagnoses of neurasthenia with CFS; as currently used in South Asia, for example, neurasthenia is not the same as CFS and is more characterised by complaints such as headache, insomnia and tension (Lee 1998).

The emergence of CFS in the last decade has been accompanied by an upsurge of interest in the biological basis of the syndrome, an interest not seen when neurasthenia was seen as a solely "psychiatric condition". Much of this activity has not led to any consistent insights, but one area relevant to this contribution has been comparisons between the neurobiological associations of the major psychiatric disorders and those of CFS. These have emphasised the similarities between, for example, major depression and CFS, but also the differences. Hence the sleep abnormalities commonly found in severe depression are not normally encountered in the "pure" fatigue syndromes. Likewise, the well-known pattern of an overactive hypothalamic–pituitary–adrenal axis, with high cortisol levels which do not drop after dexamethasone challenge, has not been found in CFS, and instead a mild pattern of hypocortisolaemia has been reported by most, but not all, groups. As in major depression, the significance of these observations remains unclear, partly reflecting difficulties with sample choice and size and also the fact that major depression itself is a far from homogenous concept.

7
Management

When neurasthenia burst onto the European medical scene at the end of the nineteenth century, the first treatment proposed was the Weir Mitchell rest cure – sufferers were treated with diet, massage, rest and isolation from work and family. The readers of this volume may like to note that it was in Germany that the rest cure found its most ready acceptance. Playfair's book was available in German in 1883, only a year after its publication in English, and a German edition of Weir Mitchell was available by 1886, reviewed by Freud in the following year. Large numbers of "retreats", private clinics and rest homes appeared across Central Europe between 1880 and 1900 (see Wessely et al. 1998). It was financially vital to the neurologist, since, as one of them wrote in 1894 (Ziemssen 1894), the neurologist should not "undertake a thoroughgoing course of this sort of treatment unless in a private institution". Fortunately, the author continued, "we have in Germany an abundance of good private institutions." The rest cure became the most commonly used treatment for nervous disorder across Central Europe and America. It "provided the

raison d'être for the clinic, since isolation could not by definition be procured at home, nor could the expensive apparatus of electrotherapy". As Shorter (1990) points out, "physicians in these competitive, profit-making clinics were happy to comply with the patients' desire for face saving (organic) diagnoses, and made great use of such expressions as ... chronic fatigue and neurasthenia".

However, several reasons can be identified for the fall of the rest cure, and ultimately of the diagnosis neurasthenia itself. The illness was no longer the exclusive province of the rich and successful. The rest cure not only did not work, it seemed to make people worse, and even to condemn them to the life of a chronic invalid. When it did work, this was more due to the charisma of the doctor than to any inherent property of the treatment. Neurasthenia itself shifted from being seen as an organic disease of the central nervous system to a psychological disorder best managed by the new analytically inspired psychiatry. The rest cure disappeared.

It was revived under the auspices of the emergence of CFS in the 1980s. Popular and even some professional texts praised the virtues of rest as the best form of management and warned of the dangers of excessive exercise, where "excessive" could mean virtually any activity involving more than minimal effort. Common sense and a knowledge of physiology could have pointed out the dangers of this approach, but sadly it was several years before this indeed happened. In the next section, I shall outline our new thinking on the subject, another example of "back to the future".

8
Cognitive Behavioural Approaches to Chronic Fatigue Syndrome/Neurasthenia

In this section, I will outline in a little more detail what I see as the most promising practical approach to the problem of neurasthenia/chronic fatigue, drawing in particular on the cognitive behavioural model of symptoms and the use of cognitive behavioural therapy (CBT) in treatment.

The treatment of CFS has been a mess, although signs of a return of common sense are now visible. For many years, sufferers were given no advice or help except exhortations to rest, "live within your limits" and wait for the medical breakthrough. Not only was there no evidence that this is helpful, but such advice ignored a vast literature stretching back many years concerning its adverse effects. Perhaps in consequence, a series of outcome studies made gloomy reading (Joyce et al. 1997).

However, the situation may now be improving. Firstly, the rather dispiriting prognostic studies all refer to patients seen in specialist centres. In these studies, the strongest predictor of poor outcome was the strength of attribution of symptoms to a solely physical cause. However, we have shown that patients with CFS in primary care are not characterised by such intense illness beliefs and also do not correspond to the "Yuppie flu" stereotype. It is plausible that such patients have a far better prognosis. Secondly, outcome studies refer to the situation without treatment, perhaps because many suggested either that no treatment was possible or alternatively promoted ineffective treatments (Wilson et al. 1994).

Several groups have suggested an alternative model for understanding CFS (Wessely et al. 1991; Surawy et al. 1995; Sharpe et al. 1997). At the heart is the message that whatever triggers CFS may not perpetuate it. For example, an ordinary viral infection may *precipitate* fatigue which, for the majority of the population, is resolved when a normal recovery is made. However, on rare occasions, the presence of *perpetuating* factors (such as psychosocial stressors, rapid deconditioning, failure to rest adequately or concurrent depression) may delay or impede recovery. Fatigue then becomes chronic, persisting long after the departure of the original trigger and maintained by new variables. These include the following:

1. The effects of inactivity: Prolonged rest is effective in the short term, but counterproductive in the medium and long term. With the passage of time, more symptoms and greater fatigue will continue to occur at progressively lower levels of exertion. Inactivity therefore sustains symptoms and increases sensitivity to them. Several studies have shown that coping with symptoms by avoidance behaviours is associated with worse disability.
2. Inconsistent activity: Many sufferers that we encounter are not persistently inactive (although some end up that way). Instead, excessive or prolonged rest is followed by a burst of activity, which, compared to the preceding level of inactivity, is often "too much, too soon". This pattern may also be reinforced by the sense of frustration often encountered in sufferers and perhaps also by pre-existing personality and lifestyle factors. Many patients have attempted sudden increases in activity and find that they culminate in exhaustion, for which the inevitable response is further rest. This "stop and start" pattern means that, while extremes of disability are often avoided, sufferers are unable to build up a sustained level of recovery. This pattern often leads to the characteristic complaint of CFS sufferers that any activity must be "paid for" later by further pain and fatigue. Delayed fatigue

and myalgia are well-recognised physiological phenomena that occur between 24 and 48 h after any exertion in excess of a person's current (and not previous) fitness.

3. Illness beliefs and fears about symptoms: These can influence disability, mood and behaviour in any illness. In CFS, unhelpful and inaccurate illness beliefs, reinforced by occasionally ill-informed media coverage, include fear that any activity which causes an increase in fatigue is damaging or impossible, that "doing too much" causes permanent muscle damage, that CFS is due to a persistent virus or progressive immune disorder, that CFS is irreversible or untreatable and that rest is the only remedy.
4. Symptom focusing: Increased symptom focusing is also noted in CFS (Ray et al. 1995). Concern about the meaning and significance of symptoms (which are often interpreted as "warning signals") is heightened by the unpredictable nature of CFS. Increased concern leads to heightened awareness, selective attention and "body watching", which can then intensify both the experience and perceived frequency of symptoms, thereby confirming illness beliefs and reinforcing illness behaviour.
5. Emotional consequences: Of whatever cause, depression and anxiety are strongly associated with fatigue and muscle pain, impaired memory and concentration, and reduced activity.

I and many of my colleagues have suggested that CFS may be better understood (and hence treated) by focusing on these and other possible perpetuating factors and the many ways in which they interact in self-perpetuating vicious circles of fatigue, behaviour, beliefs and disability (Wessely et al. 1991; Sharpe and Chalder 1994; Surawy et al. 1995). This is illustrated in Fig. 2.

Such models have been associated with the development of two styles of rehabilitation. The first, based on a simple exercise avoidance/deconditioning model, is graded exercise. Recent clinical trials indeed confirm this is both safe and effective (Fulcher and White 1997; Wearden et al. 1998). However, the benefits of exercise are not related to increasing physical fitness and instead may be more linked to improved confidence and self control – in other words the gains may be behavioural rather than physiological. Exercise can also be difficult to "sell" to the patient and, if carried out in an over-enthusiastic or uncontrolled fashion, can be counterproductive – patients who exercise too aggressively will develop fatigue and myalgia, with a consequent reactivation of illness fears and loss of confidence in the physician.

The other treatment strategy is CBT. This does involve specific exercise regimes, but is a more collaborative and cautious method of exploring the role of conscious beliefs in determining behaviours and of collaborating on a series of behavioural experiments aimed at reducing the inconsistent activity patterns so characteristic of CFS, before embarking on a behavioural programme to reduce avoidance behaviours and gradually increase activities. Two randomised controlled trials confirmed the efficacy of this approach, which was also associated with better compliance than simple exercise programmes (Sharpe et al. 1996; Deale et al. 1997).

In conclusion, the exact form of rehabilitation for chronic fatigue/neurasthenia remains unclear and is probably not a crucial issue anyway. Exercise programmes are safe and effective, but compliance may be a problem. More behavioural programmes, emphasising consistency in activity rather than exercise per se, may be less of a high-risk strategy, particularly if combined with some form of cognitive intervention

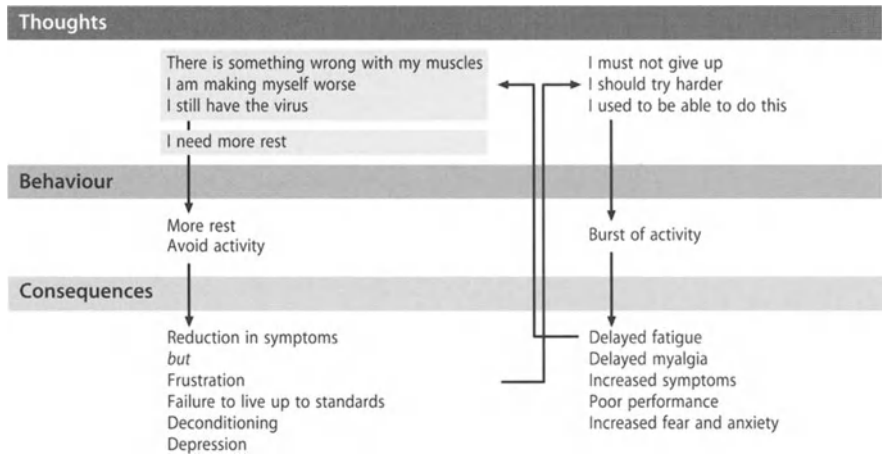

Fig. 2. Perpetuation of chronic fatigue syndrome

designed to provide a rationale for treatment. The aim is to reduce the stimulus-driven method of coping adopted by most chronic sufferers, in which the day to day, and even hour to hour, variation of symptoms guides what activity is undertaken, by a programme in which rest, sleep and activity are managed by timetable, and not in response to symptoms. Improvement, in which activity slowly increases and fatigue reduces, will happen, but may take weeks and months (Sharpe et al. 1996; Deale et al. 1997). Overall, providing psychological support, reducing disability and encouraging activity is the core of good clinical management (Wilson et al. 1994). In contrast, we can be clear that, of all the myriad of treatments proposed for chronic fatigue/neurasthenia, prolonged bed rest is one of the few that can be guaranteed not to work.

9 Drugs and Neurasthenia

The role of pharmacotherapy remains less clear (Wessely et al. 1998). At present it seems safe to assume that where depression appears to be a prominent feature, antidepressant are indicated. However, in the case of "pure" neurasthenia, the evidence is equivocal. Several good trials have failed to show benefit from selective serotonin re-uptake inhibitors. Whether or not this represents sample selection, or alternatively a defect in serotonin metabolism that is the opposite of that found in major depression, remains unclear. Clinical experience and some controlled trials from the related field of fibromyalgia suggest that tricylic antidepressants, given in doses not thought to be effective in patients with mood disorder, may help sleep, fatigue and pain and should be encouraged. Finally, there is preliminary evidence of benefit from monoamine oxidase inhibitors, something which also acts as a timely reminder of the overlap between neurasthenia and atypical depression.

10 Conclusion

I conclude that, despite all its difficulties, the concept of neurasthenia remains a valid one for psychiatrists and epidemiologists alike (Hickie et al. 1997). However, I doubt that there is a single cause of neurasthenia, any more than there is a single cause of high blood pressure. I doubt that one factor, be it psychosocial, viral or immunological, will satisfactorily explain anything other than a minority of cases. Instead, like all psychiatric disorders, it is also certainly multifactorial. New evidence suggests that chronic fatigue/neurasthenia has a genetic basis, which is not unexpected. There remains a strong clinical case for assuming that exposure to certain infections, such as the Epstein Barr virus, play a role in initiating symptoms. It is tempting to assume, although difficult to prove, that differences in the way in which the body deals with such agents and the ability to mount and control an efficient immune response may play a part.

Regardless of the results of further neurobiological inquiries, there can be no doubting the important role played by psychological, social and cultural factors in the aetiology of neurasthenia. Previous experience clearly increases vulnerability to fatigue syndromes. Whether or not coincident life stress also plays a part remains uncertain, but it would be surprising if it did not. Subsequent events certainly play a crucial role in determining the eventual outcome. The person's own emotional make-up and coping strategies are important, as are the reactions of family, friends and the medical profession. It is variations at this sociocultural level that account for the many different interpretations and usages of the term "neurasthenia" across the globe.

CHAPTER

9

M.J. Kelleher, H.S. Keeley, D. Chambers, P. Corcoran

Suicide

1 Introduction

It is true to say that suicide is a feature of the human condition and has been present, although usually as a rare phenomenon, in all societies and at all times. Suicide and parasuicide together may be referred to as "suicidal behaviour". Parasuicide or deliberate self-harm will be dealt with in the next chapter, but the two topics overlap considerably and, to avoid repetition, issues which may be relevant to both areas may only be dealt with in one.

2 Definition

Defining suicide is by no means as easy as it would first appear. Deaths may be divided into natural and unnatural, or internal and external causes, which is the division used for statistical purposes. How each individual death is categorised depends on many factors, including who is making the decision, in what circumstances, for what purposes, the subjective definition of the words used and how carefully intention is assessed. Many definitions have been used in the past, and the one given below is that recommended by the World Health Organization (WHO 1992):

Suicide is an act with a fatal outcome, which the deceased, with the knowledge and expectation of a fatal outcome, had himself planned and carried out with the object of bringing about the changes desired by the deceased.

The definition of suicide has three elements; *intention,* potential *lethality* and *fatality* of outcome. Only the last is certain but, even here, doubt may creep in if the person lives for a long time before eventually dying, e.g. on a life support machine. Lethality may also give rise to confusion, as in the case of someone who dies from an overdose of a small amount of medicine to which he or she is particularly sensitive. However, establishment of intention causes the greatest difficulty.

3 Legal Definitions and Statistics

A narrow legal definition of intention requires evidence in words, either written (as in a suicide note) or spoken to another, who is prepared to give evidence. If the coroner hears a case before a jury, he may seek such evidence. The decision made is to be in keeping with the criminal law, i.e. beyond reasonable doubt. As many cases cannot match this level of certainty, they are unsatisfactorily left as *undetermined* as to whether death was accidental or purposefully intended. This is the situation as it applies in England and Wales. Other jurisdictions use a balance of probabilities approach which, drawing on evidence from a number of sources, allows a verdict of suicide to be made for statistical purposes even in the absence of proof beyond reasonable doubt. In the Republic of Ireland, where this approach is adopted, the ratio of undetermined death to suicide has fallen to 0.04 for both genders. The male and female ratios in England and Wales have risen to 0.46 and 0.71, respectively (Kelleher et al. 1996). In an examination of 16 countries between the years 1974 and 1991, Neeleman and Wessely (1997) found that the ratio of undetermined death to suicide had increased in only two countries besides England and Wales, namely, Belgium and New Zealand. This situation has important implications for research and for meeting national health targets.

4 Variations in Suicide Rates

At present, about 1% of deaths in Britain and Ireland are due to suicide. In the younger age-groups, the relative proportion of these deaths is much higher because deaths due to other causes are so infrequent. In many Western countries, suicide and road traffic accidents are the most common causes of death in men aged 15–24 years (WHO 1997).

Few, if any, administrations over-estimate their suicide rates. The tendency is to under-estimate. This may occur at a local level where obvious suicides are sometimes misclassified in an attempt to spare the feelings of the bereaved. Defective bureaucratic procedure can also cause misclassification at a national level and at an international level, if the returning of statistics to the WHO is given a low priority. Variation in official recording practices is probably the most important single reason why suicide rates vary between countries and over time. Douglas (1967) questioned and doubted what could reliably be gleaned from such figures. However, most researchers today accept that official statistics are of value in estimating likely differences or trends in rates, especially if examined over time and with the proportions of alternative verdicts taken into account (Sainsbury and Jenkins 1982).

5
Religious and Civil Sanctions

There have been great variations in the religious attitude to suicide in different European countries. Christian churches have strongly condemned suicide since the time of Augustine, who, as a part of his ideological war against the Donatists, stated that the suicide of Judas was a more heinous crime than the betrayal of Christ. This contrasts with the Old Testament, which reports suicides in a very matter-of-fact way, without condemnation (Barraclough 1992). From the time of Augustine to the Reformation, the suicide rate in Europe is considered to have been very low. This was so among both Christians and Jews. Islam subsequently adopted the condemnatory Christian and Jewish attitude to suicide (Umri 1987). After the Reformation, the suicide rates began to rise, which has been attributed to the loss of an all-embracing religious purpose which "inspired all aspects of life" (Masaryk 1970). The effect of such influences can be seen in the official attitude to suicide. France decriminalised suicide at the time of the Revolution, but it was not decriminalised in the United Kingdom until 1963 and in the Republic of Ireland in 1993. However, long before these dates, civil and religious sanctions had been effectively abandoned.

The greatest probable effect of official condemnation, whether religious or civil, is to increase the morbidity and suffering of the bereaved as well as obfuscating the magnitude of the problem, thereby making research and prevention more difficult. It has been found that countries with religious sanctions against suicide return significantly lower rates of suicide to the WHO for both males and females. Countries with religious sanctions also return less complete data, strongly suggesting the likelihood of under-recording (Kelleher et al. 1998a). However, religion may have a genuinely inhibitory effect on the expression of suicide. Durkheim found that Catholics and Jews had lower rates of suicide than Protestants, which he explained in terms of *integration* (Durkheim 1952). More recently, Stack and Wasserman (1993) found that frequency of church attendance would appear to be the discriminating factor rather than religious allegiance itself. From a clinical and sociological point of view, in risk assessment, meeting others and forming social bonds is more important than the specific church that the person attends.

The effect of religion is as relevant to children as to adults. A recent South African study revealed that none of the Muslim children in a multi-denominational school had reported experiencing suicidal behaviour among family, friends or peers, whereas such experiences were reported by children from the other denominations, namely Hindu, Christian and traditional African (Pillay 1995).

6
Cultural Issues

Examination of the suicide rates of the 27 European countries which report mortality statistics to the WHO reveals that 23 of them experienced an increase in suicide over the period from 1960 to 1985. There were relatively large increases in Northwest and Central Europe, while rates decreased in Mediterranean countries (Diekstra 1989). This strongly suggests the influence of socio-cultural difference and change. The values associated with each culture may reflect differently on suicide, in that the strength of condemnation may vary.

European countries with a higher quality of life have higher suicide rates than countries that are not as stable economically and indeed have large areas characterised by poverty (Inglehart 1990). By quality of life, we refer not only to economics but also to psychological well-being as measured by "values and attitudes" studies (World Values Study Group 1994).

This may be explained in terms of a greater sense of community and stronger social bonds in countries characterised by widespread economic disadvantage. In plain terms, it is not as bad to be oppressed or depressed in areas with a strong sense of community, sharing the same type of problems, as in countries whose populations enjoy greater wealth and general well-being. The isolation and sense of hopelessness that accompanies marginalisation may be accentuated in such societies.

However, those who have claimed that the rising suicide rate is an inevitable by-product of industrialisation have yet to explain the recent reduction in the male suicide rate in Japan and Finland. Variations in rates are undoubtedly associated with different stages in the economic development of a society, but factors such as national, cultural and ethnic identity are also crucial in determining the rate of suicide.

7
Youth and Developmental Factors

Rates of suicidal behaviours show a distinct escalation at adolescence. Developmental changes that occur at this time partly explain how this may come about. Erikson (1963) describes this period as a stage concerned with the formation of identity. Physical,

sexual, social and emotional developments bring the adolescent further into the social arena of the adult with associated new responsibilities. From a cognitive perspective, cognitive errors and distorted thinking, as in Beck's concept of the triad of negative thoughts about self, others and the future, are central in the genesis of suicidal ideation. Developments in adolescent thought processes mean that they tend to think more in hypothetical terms and less in terms of concrete and immediate experience, i.e. they are less inclined to accept things as they are and more to consider how they could be. As the adolescent struggles through the developmental phases inherent in the formation of an identity, he or she may develop depressive symptoms, especially hopelessness, which has been found to be a powerful predictor of suicidal behaviour (Beck et al. 1985).

Adolescents have been described as being caught between two worlds, their need for independence conflicting with dependency needs and a desire to be part of a family. Richman (1986) has developed a family systems approach to the treatment of suicidal adolescents. This approach is based on the premise that disturbance in the family structure and an inability to accept change or contain crises promote suicidal acting out. This and other similar theories stress the importance of parental psychopathology and other, often unconscious, dynamics within a pathogenic family system that may result in a child being driven to self-destruction (Berman and Jobes 1991).

This is also a key time for risk-taking behaviour of all types and, in particular, experimentation with alternative life-styles and behaviour. Adolescents' thoughts also tend to be egocentric, and they believe that their intentions, motives, behaviour and personality are scrutinised by the people around them, which may lead them to rebel (Mussen et al. 1990). Youth subculture is associated with groups who reject mainstream opinions, embracing instead anti-establishment art forms and modes of expression. The mods, rockers and punks of previous decades were examples of subcultures whose deviance was reinforced by media portrayals and the creation of moral panic among other elements of society. The glorification of death in general and of suicide, in particular of iconic figures in these subcultures, may have a potentially destructive effect on their members. Media representations of youth culture suggest that negativity and ambivalence with regard to life and death is encouraged.

Homosexuals and those with gender identity disorders are subgroups at increased risk of suicide. A majority of suicide attempts by homosexuals occur during their youth, and gay youth are said to be two to three times more likely to attempt suicide than other young people, possibly as a result of peer rejection and social isolation. In the United States, they comprise 30% of completed youth suicide annually (Gibson 1989).

8
Age and Gender Variations

For most of the Western world, the female suicide rate is about one third that of males. There are a few countries, however, where the female rate actually exceeds the male – a significant example being the People's Republic of China (Canetto 1997). Ethnic and regional studies within different countries reveal other exceptions. For example, among the Maring people of Papua New Guinea, suicide is only associated with women, whereas among the Gainj of Papua New Guinea, it is confined to married women (Healy 1979). In the Deganga region of India, more than two thirds of suicides are women (Banerjee et al. 1990). Death from suicide among the Aguaruna of the Peruvian Amazon region is especially common among women and young men (Brown 1986). In England and Wales, mortality by suicide among immigrants of Indian origin is higher among women than men (Raleigh et al. 1990). When mortality data are examined by age and gender, we find additional exceptions to the preponderance of males among the casualties of suicide. For example, for those aged 15–24 years, female suicide mortality rates exceeded rates in males in several Asian and South American countries (Barraclough 1988). It is important to recognise that international comparisons of gender ratios can only be considered to be reliable if we assume that recording practices within each jurisdiction are consistent for both males and females. This may not be a valid assumption and should be borne in mind when weighing up the evidence.

Again, as with variation in overall international rates, socio-cultural influence is suggested by these gender variations. In most of these countries, women occupy a subordinate position in the social structure, with poor life chances. For young females, particularly in countries of low economic development, the tendency to turn to prostitution and use of illicit drugs is dangerously high. This becomes even more of a risk in countries where the sex industry has become accepted as economically necessary. The suicide rate of young females is, in turn, adversely affected.

The previous examples suggest that women in particular social and economic circumstances may be equally affected by suicide, but the fact remains that, in general, there are protective factors which are more relevant to women, particularly in the West. These factors include a tendency to prioritise family and child-related concerns, which has been found useful in

differentiating between suicidal ideators and parasuicides (Linehan et al. 1983).

Indeed, in keeping with the idea of protective factors for females, socio-cultural influence in the Republic of Ireland is suggested by a ratio of male to female suicide of 7:1 for 15- to 24-year-olds, and recent figures indicate that this ratio is increasing. This may be related to improved social conditions for young females in Irish society, which is reflected, for example, in the fact that in 1995/1996 there was a majority of females in third-level education for the first time in the history of the state.

Studies focusing on female participation in the labour force (FPLF) have made similar findings. It would appear that in countries where FPLF is relatively new and not readily accepted, male suicide rates are adversely affected. The explanation offered is that FPLF conflicts with traditional cultural values by undermining the cultural interpretation of masculinity. The point is also made that males are more likely to have their wife as sole confidante (McGrath et al. 1990; Veroff et al. 1981), and thus they suffer a sense of loss if their wife decides to participate in the labour force (Stack 1998).

Increased FPLF has implications for female suicide rates as well. Professional women tend to acquire the suicide rates of their male colleagues, perhaps a reflection of the increasing similarity of their roles (Boxer et al. 1995). In addition, women in the past were conservative in their choice of method of suicide, many dying as a result of overdose. In recent times, they are inclined to choose more violent methods such as hanging, which was so rare that in the past pathologists were instructed to regard such an event as murder until proven otherwise (M. Bolster, personal communication).

A further factor which may be seen as protective for females is the ability to cope with and accept emotions and feelings better than males. In association with cultural stereotyping, men may be less aware than women of their emotional distress. Even if they are aware, they may be less likely to express it either to themselves or to others, and this may have a fatal outcome. While this ability may have some physiological basis, it is encouraged and maintained by social reinforcement and the resultant phenomenon of the "self-fulfilling prophecy".

Age, as a correlate of suicide, is equally significant in suicide research. Recent years have seen a change in the age profile of suicide victims in most European countries. Traditionally, the old were more at risk than the young. The profile of the elderly, retired, socially isolated man who is precipitated into suicide by some kind of loss event, usually bereavement, still holds true to some extent (Kelleher et al. 1997a). However, many countries, including England and Wales (Charlton et al. 1992), Norway (Rettorstøl 1993) and Ireland (Kelleher et al. 1995), have seen a marked increase in suicide among young men in the last 30 years or so. In Ireland, the suicide rate in 15- to 24-year-old males increased by over 80% (from 13.5 to 24.5 per 100,000) between 1989 and 1996. As changes in recording practices have had a limited effect, the rise is most likely to be due to social and attitudinal changes. The exact identification of these changes is a different matter.

None of the specific explanations that have been postulated for the increase in Ireland appear convincing. Change in illness patterns is unlikely to be sufficient, because there is no evidence that psychological illnesses such as depression have increased sufficiently in either frequency or severity to explain the increase in young male suicide. The rise in substance abuse has been suggested as an explanation of this trend (Neeleman and Farrell 1997), but this appears to be unlikely when we consider the reported increase in rural areas (Dudley et al. 1992; Kelleher et al. 1997b), where hard drug abuse is less common (An Garda Síochána 1996). It should again be emphasised that the rise in suicide rates among young males is part of an international trend. Most industrialised countries, with the exception of Japan, are reporting such changes. The matter must therefore be viewed as being an international problem requiring cross-national, as well as local, research and co-operation, if it is to be adequately addressed.

9
Psychological Autopsy Studies

One of the best tools available for the investigation of suicide is the psychological autopsy study. It involves investigating the suicide victim's background by means of interviews with his or her close relatives, medical doctors and others who would have been in contact. In the case of young people, peers are often not contacted because of the fear of inducing modelling behaviour and because of difficulties with consent. Various such studies have been done, recently by Foster et al. (1997) and in the past by Barraclough et al. (1974), among others. These have identified 90% or more of suicides as being mentally ill. Depression is the commonest illness found and is present in about two thirds of cases. It is particularly common among women, present in over 80% of cases in an Irish study (M.J. Kelleher et al., unpublished work). Alcohol is related to both depression and suicide. Some history of alcohol abuse is present in over half of the male suicides in the above Irish study. It may be used in

moderate amounts in the run-up to the act of suicide, particularly by young men. The consequences of many years of heavy drinking predispose to suicide, particularly in middle-aged and older men.

10
Study of Suicide Notes

Another potentially useful tool to help us understand the psychological processes underlying a person's decision to die by suicide is the systematic study of suicide notes. While Schniedman (1996) acknowledges that the study of suicide notes provides valuable insights into the suicidal mind, he stresses that it is important that they be set in the context of the person's background and experiences. This is particularly important when we consider notes left by younger people who die by suicide, which tend to be more centred on the here and now and often show signs of "magical thinking". Posner et al. (1989) analysed the notes left by 17 individuals who died by suicide between the ages of 10 and 20 years from a psychoanalytical perspective and found that the most prominent themes were those of love, ambivalence and aggression turned inward. A reason that was often given for the suicide was that of a feeling of being a bad person.

11
Suicide and Physical Illness

There is evidence that certain physical illnesses carry a higher risk of suicidal behaviour than others. Much of this association is undoubtedly due to high co-morbidity rates between these illnesses and depression, especially with neurological conditions such as multiple sclerosis and parkinsonism, and has been documented with certain types of stroke. A high risk of suicide also occurs in conditions such as Huntington's chorea and the muscular dystropies, where there is a long, chronically progressive downward course of the illness with no available hope of cure. Suicidal behaviour also occurs in the context of a diagnosis of acquired immunodeficiency syndrome (AIDS) or related illnesses and is part of the complex physical and psychological changes that happen in this situation.

There are other less dramatic associations, however, and the presence of chronic pain, especially back pain, can be a factor in suicidal behaviour, either by itself or in combination with other stresses. It is often easy to forget to ask about depressive symptoms or to accept them as "natural" in circumstances where the person is chronically disabled. However, they are treatable and their alleviation can be a great relief to the patient. The presence of depressive symptoms is also associated with requests for euthanasia, and adequate support and treatment of the person may encourage them to re-examine their situation in a more positive light.

12
Suicide and Mental Illness

12.1
Depression

Depressive illness is, as stated above, the commonest diagnosis among women who kill themselves. Unlike men, many of these women will have been formally diagnosed and treated for their depression. The greater willingness on the part of women to identify and accept treatment for their psychological distress may be part of the reason why their rates have not risen in most countries. However, advances in medical treatment for depression up to now do not seem to have affected the overall rise in suicide rates in developed countries, although this situation may now be changing (Montgomery et al. 1995). In cases of suicide, it is common to find anxiety co-morbid with depression, and a subgroup of adolescent suicide cases has been described who show evidence of anxiety, perfectionism and distress at times of change (Shaffer 1988).

12.2
Schizophrenia

Among mental illnesses, one of the most devastating is schizophrenia. It is sometimes not fully appreciated that schizophrenia has a comparatively high association with suicide occurring in between 10% and 15% of patients. In fact, suicide is the commonest cause of death in this condition (Mortenson and Juel 1993). Early age of onset, maleness, severity of condition, negative symptoms, return of insight and loss of status are all contributing factors. The commonest correlate, however, is the concurrent presence of depression (Schuwall and Siris 1994). The increased use of new atypical anti-psychotic medications may be associated with a decrease in suicidal behaviour in this group.

12.3
Personality Disorder

Personality disorder, particularly when associated with aggressiveness and impulsivity, may culminate in

suicide. The commonest types of personality disorder associated with suicidal behaviour are those of dysocial, borderline and impulsive types (Kaplan and Sadock 1991). These types of personality problems are often associated with very dysfunctional backgrounds. The association between borderline personality disorder and a reported history of having been sexually abused in childhood has been noted in the past (Waller 1993). Indeed, it has been emphasised that a history of child sexual abuse should be regarded as one element in a matrix of adverse experiences that increase the individual's vulnerability to greater levels of psychopathology and suicidal behaviour (Mullen et al. 1993). The dynamics of this include both a need for and an inability to maintain supportive relationships associated with unrealistic demands and an explosive, disproportionate response when let down.

12.4 Substance Abuse

Drugs, whether prescribed or illicit, may have an association with depression, suicidal behaviour and suicide. Some hypotensive agents, including calcium channel blockers and some anti-parkinsonian drugs, may cause depression and give a sense of hopelessness. The use of street drugs, including ecstasy, amphetamines, cocaine and heroin, may be followed, on occasion, by parasuicidal acts and, less frequently, by suicide itself. Hawton et al. (1993) found that substance misuse is the best predictor of eventual suicide. A recent article suggests that the rise in young male suicide may be associated with higher levels of substance misuse (Neeleman and Farrell 1997).

12.5 Suicide Among Recently Discharged Psychiatric Patients

In recent years, it has been noted that there is a substantial increase in suicide among those recently discharged from psychiatric hospitals, greater in the first few weeks but remaining elevated for several months (Goldacre et al. 1993). Many factors may contribute to this, including worsening of illness, dissolution of support structures, inability to get or retain a job and return to previous bad habits such as non-compliance with treatment and abuse of drugs or alcohol. In general, the problem seems to lie in the inability to function adequately in society following a psychiatric admission. Studies indicate that suicides occurring both during hospital admission and in trial discharges and early post-discharge outpatient treatment are increasing, but are still relatively rare occurrences and as such are difficult to predict. More active treatment of high-risk patients may therefore help. Questions regarding procedures on discharge assessment will be addressed later.

13 Biochemical Theories

Many biological theories have been advanced in explaining suicidal behaviour. Among the proposed substrates, the most enduring links have been found with the brain neurotransmitter serotonin. Serotonin abnormalities have been linked to suicidality across psychiatric diagnoses (van Praag 1991). Abnormalities in the serotinergic system have been found in the frontal cortex of suicide victims (Mann et al. 1986). It has also been found that those suicide attempters who eventually died by their own hand had a markedly lowered level in their cerebrospinal fluid (CSF) of the serotonin by-product 5-hydroxy-indole-acetic acid (Nielsen et al. 1994). The link between impulsivity and aggression has been highlighted by, among others, Asberg et al. (1986) and Coccaro (1989), who suggested that reduced central serotonin activity might predispose to a lowered threshold for aggressive responses to noxious stimuli rather than for unprovoked aggressive behaviour. Suicide, especially by violent means, is viewed in this context as a form of auto-aggression (Brent et al. 1993). Abnormal platelet serotonin aggregation may identify a subgroup of suicide attempters at high risk of repeating and perhaps of eventual death by their own hand. This is only one potential marker, and many others, including the levels of cholesterol and the soluble receptor of the human lymphocyte growth promoter interleukin-2, have also been advanced (Engelberg 1992; Nassberger and Traskman-Bendz 1993).

14 Genetics

If there is a chemical basis to suicidal behaviour, then these are likely to be reflected in genetic differences between cases and controls. There is evidence that this is so for suicide from twin and adoption studies (Roy et al. 1995; Schulsinger et al. 1979; Wender et al. 1986). Family studies of suicide attempters also show that their relatives have an increased frequency of suicide attempts (Egeland and Sussex 1985; Brent et al. 1996). Candidate genes investigated so far have been those associated with serotonin, principally polymorphisms of the rate-limiting enzyme tyrosine hydroxylase (Abbar et al. 1995; Nielsen et al. 1994). On the basis

of a detailed review of the literature, Brent et al. (1994) concluded that there was a strong family relationship between the transmission of suicidal behaviours and the tendency to impulsive aggression. However, results so far have been conflicting, and it is not currently possible to determine the exact manner in which such biological factors might alter a person's predisposition towards suicidal behaviour. What is likely is that this research will not result in a simple blood test dictating a management choice, but rather that biological factors will be added to psychosocial variables, rather as family history is considered at present, when it comes to the assessment of future suicidal risk. Some researchers have attempted to form models incorporating biological, social and psychological factors in order to explain the process or processes.

15 Prevention

A major problem in suicide prevention is the non-usage of services by those at risk. This is particularly so in males, where one study found that only half had been seen by a general practitioner or a psychiatrist in the year before death compared to 86% of the females (M.J. Kelleher et al., unpublished work). It has been proposed that suicide awareness programmes in schools and colleges would help prevent suicide in the young. Opinions differ on this, however, some fearing that such programmes are at best ineffective and at worst might be associated with an increase in suicidal behaviour. The wisest approach in the present state of knowledge is one of case identification within schools, either through the better education of teachers in such endeavours or perhaps, though less convincing, through surveys of the student population. The effectiveness of postvention support programs in sensitive settings, such as schools, has become a contentious issue and great care is needed to prevent glorification of the victims, which may only encourage further modelling.

The Defeat Depression Campaign, instituted by the Royal College of Psychiatrists in the United Kingdom, is an attempt to increase public awareness of psychiatric illness in general and depression in particular. It may have, as one outcome, a reduction in suicide by those who attend general practitioners and medical services. This was the experience reported in the Gotland study, where general practitioners were given extra training in the signs and symptoms of depression (Rutz et al. 1989). In this case, the effect was only temporary; however, more recent research has suggested that advances in the pharmacological treatment of depression may result in a fall in rates of suicide (Isaacson and Bergman 1998).

Prevention, in the short-term at least, will be enhanced by limiting access to methods. Such limiting would include the barring of hand-guns and restrictions on gun licences in general; the change from coal to natural gas; the restriction of the availability of poisons; the limitations of over-the-counter purchase of medicines which may be harmful in overdose; and better prescribing habits by doctors.

16 Response

The aftermath of suicide may be devastating for relatives. Only in recent years has it been appreciated how great the trauma can be. Such bereaved people may need counselling, and the Canadian Task Force (1994) recommends that, to succeed, bereavement postvention programmes should be part of a comprehensive package that includes prevention and intervention components, affiliated with the existing mental health services. However, suicide survivors are no more likely to have a complicated or pathological bereavement reaction than others who were bereaved unexpectedly or tragically (Murray-Parkes 1987). Nevertheless, the grief response differs because of the social issues associated with a suicide death. A search for meaning and crisis of values is a common part of all bereavement reactions but especially occurs after a suicide. Another difficulty is the lack of social supports perceived by suicide survivors. Sometimes this is a real problem associated with stigma, but it can happen that the bereaved fail to identify potential sources of support, simply because they feel that the pain of their loss is too great to be helped by others. Self-help groups can be invaluable in this situation, and allied with professional involvement, they can help the bereaved to integrate their experiences into a comprehensive framework.

Death by suicide is usually perceived as violent, regardless of the method used, and the act may have been directed aggressively against the bereaved person. Survivors can have difficulty with their feelings of anger and guilt that may be denied or displaced onto services or people who are seen as having failed to prevent the death. Such reactions can also lead to the development of secrets or myths that distort communication within the family and set the seeds for later difficulties, including further suicidal behaviour. The other, most striking, reaction seen with suicide survivors relates to their need to search for clues to the reason for the suicide. This preoccupation with the

question "why" may never completely leave the bereaved. If there is a strong element of denial, then the survivor may look for evidence that the death was not a suicide. Sometimes illness supervenes, requiring treatment in its own right. The prescription of medication, however, is not a panacea and should be limited to specific indications. It may, perhaps rightly, be construed by the bereaved as a distancing or a medicalisation of what are often normal features of the grief process.

Certain groups of survivors have particular needs and reactions. For example, children may be "protected" from the truth about a suicide, but this may lead them to develop disturbing fantasies about death and the deceased. They may also be unable to express their guilt, anger and worries. These worries often centre around the idea that they are somehow responsible for the death. They should be encouraged to attend funeral rituals and to discuss their feelings in an open manner, using age-appropriate language. Adolescents can react to a suicide with intense feelings of guilt, and this can impair their development of self-esteem, leading to difficulties, e.g. with substance abuse. They are also very vulnerable to modelling behaviour and may decide, through identification with the deceased, that they are "fated" to die in the same manner. People with learning disabilities also form a discrete group whose needs may not be adequately recognised and met, especially by care staff, who may not recognise the contribution of bereavement to behavioural problems (Hollins and Esterhuyzen 1997).

Sometimes, professional carers are sorely affected (Grad 1996). Many, especially general practitioners who are more isolated and those in a psychotherapeutic relationship with the deceased, have significant bereavement reactions which they may find difficult to express. Each should be given an opportunity to discuss and effectively deal with their responses. Nothing should be said or done that would unnecessarily add to their distress. However, if the suicide occurs within a service, the matter must be investigated. This should be done compassionately and efficiently. The scape-goating of individuals ought not to be the aim, although, sometimes, blame may have to be attached where duty clearly is not honoured. More frequently, the system itself requires review so that similar events might be avoided in the future.

In the aftermath of suicide, evidence may have to be given before a coroner's court. This is traumatic for both the survivors and the professional involved. For the survivors, it is often the first occasion on which they will have had contact with the court system. Unfamiliarity with the system and fear of ridicule may prevent them from participating properly in the process that would otherwise provide an opportunity to clarify some outstanding issues. For the professionals, reports have to be written and sometimes evidence given in court. Preparation for this should be a mandatory part of training for all health care workers. Despite the legalities, suicide is, ultimately, a matter of choice and, as stated earlier, no longer a criminal offence. By the same token, those who look after the suicidal should not have to work in fear of being branded professionally negligent in the event of a suicide, provided they have taken reasonable care. The prevention of suicide should not be seen as carrying the same burden of responsibility as a death directly caused by medical neglect.

17
Euthanasia and Physician-Assisted Suicide

The moral dilemma regarding physician-assisted suicide (PAS) and euthanasia is being increasingly debated. In euthanasia, the doctor ends the patient's life, whereas in PAS, the patient ends his or her own life with either advice or medications provided by the physician. In the Netherlands, where the practice is illegal, but not prosecuted provided specific criteria are fulfilled, women are more likely to choose euthanasia and men to die by PAS (van der Maas et al. 1996).

An unresolved question is whether euthanasia as a way of dying will become more popular in the years ahead. For a short time, the Northern Territories of Australia legalised PAS. The Australian Senate repealed this law in March 1997. In July 1997, the American Supreme Court ruled that citizens do not have a positive right to demand assisted suicide (Churchill and King 1997). A survey of the 51 member countries of the International Association for Suicide Prevention disclosed that in 12 countries, out of 49 respondents, active euthanasia was reported as occurring and in 29 countries, passive euthanasia occurred (Kelleher et al. 1998b). While some regard the distinction between active and passive euthanasia as being blurred or non-existent, there is an important clinical difference between discontinuing a treatment or failing to start one (passive euthanasia) and giving an injection calculated to stop the heart (active euthanasia). Psychiatrists individually and their governing bodies collectively will, in time, have to address the implications of these difficult subjects. In the Netherlands, it is now acceptable practice to terminate life on the grounds of psychological pain and suffering. It is not acceptable anywhere else.

18 Conclusion

Suicidal behaviour, whether fatal or non-fatal, is a fact of life that must not be glamorised, ignored, stigmatised or underestimated. Everyone is a potential victim, either directly or indirectly through contact with a suicide or suicide attempter. There already exists an international body of researchers who are working together in an attempt to better understand the phenomenon of suicide. The ultimate aim of this research is the formulation of effective prevention programmes that will reduce the suicide rate internationally or at the very least halt the almost universal increase in suicide.

Any problem faced by society must be brought up from the depths of social stigmatisation in order for the key issues to be dealt with on local, national and international levels. It is easy to turn a blind eye to the adversities of problems such as suicide, but as long as individuals and societies do so, a clear strategy for prevention will prove difficult to execute. The important issue is to remain focused and to continue to cooperate in the international attempt to prevent suicidal behaviour.

Parasuicide

1 Introduction

Having discussed suicide in the previous chapter, the present chapter addresses the related topic of parasuicide, which is being increasingly recognised as a major public health problem. Parasuicide is one of the strongest risk factors for both repetition and eventual suicide and, as such, the topic requires serious consideration. Given that the suicide attempt rate is at least ten to 15 times higher than the actual suicide rate (Böhme 1994), the scale of the problem has important implications for the provision of health services and thus needs to be addressed as a priority in its own right. Parasuicide has been identified as one of the Health For All targets by the World Health Organisation (WHO Regional Office for Europe 1985).

2 Definition and Nomenclature

Because of the overlap between those who attempt and those who complete suicide, there is a problem of definition and nomenclature in suicidology.

Stengel (1952) identified epidemiological differences between people who died by suicide and the survivors of an apparent suicidal act. Stengel believed that suicidal intent was essential in both groups, so that those who survived were failed suicides (Stengel and Cook 1958). Subsequently, this notion that a degree of suicidal intent was evident in all suicidal behaviour was contested. Kessel and Grossman (1965) proposed the terms "deliberate self-poisoning" and "deliberate self-injury" to replace "attempted suicide" as it was recognised that "most attempted suicides had performed their act in the belief that they were comparatively safe". Although these terms assumed that a desire to die was not present, they did imply that the behaviour was not accidental. This terminology of deliberate self-poisoning and deliberate self-harm was rejected by Kreitman and Philip (1969), as it neglected the "very real association that exists between attempted suicide and completed suicide". Kreitman and Philip (1969) introduced the concept of "parasuicide" to describe "an event in which the patient simulates or mimics suicide, in that he is the immediate agent of the act which is actually or potentially harmful to himself". Kreitman stated that this type of patient was not usually addressing himself to the task of self-destruction. These terms, i.e. deliberate self-harm and parasuicide, are sometimes used to describe a similar population in clinical practice. In this chapter, we refer to parasuicide as defined in the tenth version of the International Classification of Diseases (World Health Organisation 1992):

> An act with nonfatal outcome, in which an individual deliberately initiates a non-habitual behaviour that, without intervention from others, will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognised therapeutic dosage, and which is aimed at realising changes which the subject desired via the actual or expected physical consequences.

The definition includes acts that are interrupted before the actual self-harm occurs, but excludes acts of self-harm by people who for whatever reason are unable to understand the meaning or consequences of their action. This term was introduced because of the difficulties associated with the retrospective assessment of the intent of a particular attempt and the need for an all-inclusive general term for epidemiological studies and statistical analysis. It encompasses a diverse population which includes a small but significant proportion of failed suicides who are usually older and more often choose potentially fatal methods. From a clinical point of view, it is often both possible and necessary to distinguish between a failed suicide and a minor episode of deliberate self-harm with low intent. This distinction is one of the most important functions of the psychiatric assessment and carries both service and treatment implications.

3 Epidemiology of Parasuicide in Europe

No country in the world has national figures for parasuicide. In 1986, the WHO Regional Office for Europe appointed a Working Group to consider the possibility of establishing a collaborative European study of attempted suicide. The WHO/EURO Multicentre Study of Parasuicide was proposed and started in 1989 in 16 research centres across Europe. Given the scale of the problem and the logistics involved in national-level studies, it was decided to adopt a multicentre approach whereby the research would be carried out in defined catchment areas. At present, there are 26 centres involved, and this number continues to grow as new centres are established in Eastern Europe.

The study covers two broad areas of research – the monitoring of trends in the epidemiology of parasuicide (the Monitoring Study) and follow-up investigations with a view to predicting future suicidal

behaviour (the Repetition Prediction Study). The Monitoring Study has four main purposes (Platt et al. 1992):

1. To use local case-registers to monitor parasuicide in defined catchment areas
2. To estimate the true incidence of medically treated parasuicide using standardised definitions and case-finding criteria
3. To identify sociodemographic risk factors significantly associated with parasuicide
4. To ascertain variations in patterns of treatment

As a prerequisite to the study, the catchment areas had to be described in detail. This work identified wide variation between the centres on three levels: (1) the structure and provision of health services, (2) social, cultural and demographic factors and (3) the extent to which they are representative of their respective countries (Bille-Brahe et al. 1996). Despite these limitations, the use of standardised methodologies across a large number of centres (4,591,000 total population) has meant that the WHO/EURO Study constitutes the largest pool of specific data about suicide attempts in the world.

Figure 1 indicates the average person-based suicide attempt rates from the participating centres for 1989–1992. There is wide-ranging fluctuation in rates between the centres. While the centres from Southern Europe are associated with low rates, it is difficult to make further generalisations. Based on these data, an "average" European rate of parasuicide for persons aged over 15 years would be 140 and 193 per 100,000 for males and females, respectively (Schmidtke et al. 1994b).

Average age-specific rates for the period 1989–1992 are shown in Fig. 2. For each age-group, the female rate exceeds that of the males. Whereas the highest rate among females is for those aged 15–24 years, the male rate peaks among those aged 25–34 years.

For the period 1989–1993, a total of 22,655 episodes made by 17,486 people were recorded. The commonest method used was self-poisoning (80% of females and 64% of males). Over 40% of the individuals had made previous attempts, and an average of 15% made further attempts during the study period. The female to male ratio, previously thought to be in the region of 2:1, has been diminishing over the years (Schmidtke et al. 1994a). In Ireland, it has been close to parity for a number of years, whereas the Helsinki Centre reports rates in males that are slightly higher than those in females (Lawlor et al. 2000).

Important differences emerged between the attempters and the local general populations. The category with the highest proportion of attempters over the whole study period was that of single people. The rates of being single do diminish with increasing age, as might be expected, but 23% of those older than 25 years were divorced or separated. As a corollary, an

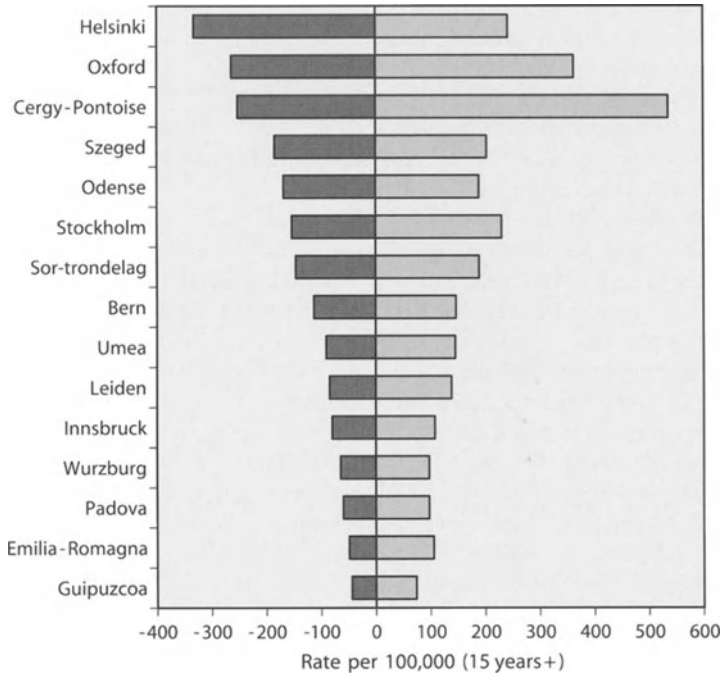

Fig. 1. Average person-based suicide attempt rates for the participating centres, 1989–1992. *Dark boxes*, males; *light boxes*, females. (Reprinted from Kerkhof et al. 1994 with the editor's permission)

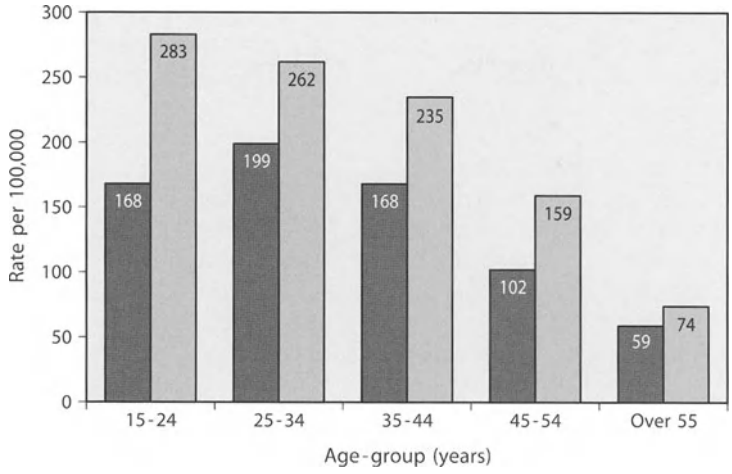

Fig. 2. Average age-specific parasuicide rates, 1989–1992. Data from the WHO/EURO Parasuicide Monitoring Study participating centres, 1989–1992. *Dark boxes*, males; *light boxes*, females. (Kerkhof et al. 1994)

average of 27% of the males and 20% of the females were usually living alone. Another interesting result was that 9% of the males and 6% of the females had changed their living conditions shortly before the attempt. This was usually a change from a socially stable living situation to living alone or in an institution (Schmidtke et al. 1994b).

4 Social Variables

It has been indicated that there is a strong independent association between suicidal behaviour and unemployment (Platt 1984). Compared with the general population, suicide attempters more often belong to the social categories associated with social destabilisation and poverty (Schmidtke et al. 1996). The rate of parasuicide in a particular area is socially determined and is greatest in urban areas of social deprivation (Morgan et al. 1975; Daly et al. 1986; Kelleher et al. 1996). There are many inter-related sets of disadvantages in these high parasuicidal areas, including overcrowding, poor education, high unemployment rates and low rates of ownership of domestic property. However, the best predictor of the rate of parasuicide in an area is the local unemployment rate which, of course, is correlated with the other measures of disadvantage (Kelleher et al. 1996).

The length of educational training required to obtain full-time employment has increased in Western Europe, so that a third-level qualification is required in many cases. This inflation of the credentials required in order to work contributes to the difficulties encountered by early school-leavers. Remaining in education can be protective against suicidal behaviour (Kelleher 1998a). Data from the WHO/EURO Monitoring Study indicates that 57% of parasuicides had only a low level of formal education, whereas only 12% had completed education to the highest level (Schmidtke et al. 1996). Given the relationship between unemployment and suicidal behaviour, the effect of educational disadvantage greatly increases the likelihood that a person will be unemployed for most of their potentially productive lives and therefore be at greater risk of engaging in suicidal behaviour. It is important to recognise that the impact of being out of work is not just due to material deprivation. The unemployed, especially married men, are denied the opportunity to undertake roles which are deemed appropriate by society and are excluded from valued categories of experience associated with employment. Social support, whether emotional understanding or practical aid, will help to reduce distress, but it is important that it is not viewed as a panacea. In the absence of measures intended to increase the individual's sense of control over their own life, social interventions may have the effect of reducing the patient's autonomy even further, which has negative results for both those giving and receiving aid (Whelan 1993).

5 Personal Risk Factors

While the precipitant for a suicide attempt is often an inter-personal difficulty, contrary to previous opinions, parasuicidal patients have had multiple personal

handicaps with which to cope (Keeley et al. 1999). In general, parasuicidal patients also have poor coping skills, which would make them more vulnerable to the effects of potential stressors (Linehan et al. 1987). A person who attempts suicide tends to give a story of many problems building up, one upon another, leading to the perception that they cannot be resolved. These may include a strong family history of mental illness and addictive behaviour, childhood stresses, including physical and sexual abuse, poor education and leaving school early, especially if male. A recent study which followed up a cohort of deliberate self-poisoners in Ireland (Kelleher et al. 1999) found that deliberate self-poisoning was associated with high levels of individual psychopathology, as shown in Table 1. Personal psychopathology interacts with the social pressures, including relationship difficulties and loss events, leading to a perceived absence of any choice other than suicidal behaviour.

Furthermore, a sense of powerlessness increases distress both by its demoralising effect and also by inhibiting adequate coping. There are indications from the European data presented above that a reduction in social stability, e.g. being thrown out of home, is associated with suicide attempts. The absence of supportive relationships and overwhelming social stresses are negative prognostic signs. A diagnosis of schizophrenia or substance misuse can be seen as indicating a high risk of repetition, especially for men (Roy et al. 1984; Deykin and Buka 1994). Other authors have attempted, with varying degrees of success, to form models incorporating biological, social and psychological factors in order to explain the process of suicidal behaviour (Maris et al. 1992). One possible model, based on Irish data, is shown in Fig. 3.

Table 1. Personal psychopathology of deliberate self-poisoners (Kelleher et al. 1999)

Diagnosis	Males (*n*)	(%)	Females (*n*)	(%)
Psychoses	3	4	7	6
Personality disorder	29	38	31	28
Alcohol abuse	53	70	20	18
Substance abuse	21	28	12	11
Other	9	12	13	12
Adjustment reaction	7	9	35	32
Affective disorder	25	33	54	49
Anxiety states	3	4	1	1
Affective disorder with anxiety states	5	7	12	11

5.1 Biological Factors

There is also evidence that there is a chemical basis to suicidal behaviour. Much of this information is dealt with in the suicide chapter, but a brief synopsis will be given here. One of the most robust findings in biological psychiatry is that discovered by Asberg et al. (1976), who found that those suicide attempters who eventually died by their own hand had a markedly lowered level in their cerebrospinal fluid (CSF) of the serotonin by-product 5-hydroxy-indole-acetic-acid (Asberg et al. 1986; Nielsen et al. 1994). This was felt to correlate with Mann's finding of abnormalities in the serotinergic system in the frontal cortex of suicide victims (Mann et al. 1986). These results are also reflected in more recent genetic work. A detailed review of the literature by Brent et al. (1994) concluded that there was a strong family relationship between the transmission of suicidal behaviours and the tendency to impulsive aggression. Family, twin and adoption studies (Roy et al. 1995; Schulsinger et al. 1979; Wender et al. 1986) indicate that the relatives of suicide attempters have an increased frequency of suicide attempts (Egeland and Sussex 1985; Brent et al. 1996).

5.2 Suicidal Ideation

Because suicidal thoughts, at a superficial level at least, may occur in many young people, they cannot be considered either statistically abnormal or reflecting mental illness in the absence of other evidence. One study from an Australian university found that 62% of students reported suicidal ideation, while 7% reported past attempts (Schweitzer et al. 1995). Other studies also indicate high rates of ideation among students (Mishara et al. 1976; McKey et al. 1993; McAuliffe 1998). It is important, however, to distinguish between a person's consideration of self-harm as *an* option – which may enhance their sense of control and freedom – and a person who is perturbed and feeling constricted, who views self-harm as the *only* option (Shneidman 1996).

Thus suicidal ideation becomes significant in young people when acting on these thoughts seems to be the only solution. It is at this point that there is a serious risk of attempting suicide. Across diagnostic categories, where ideation is concomitant with high levels both of hopelessness about the future and helplessness in coping with it, suicide risk is particularly high. Also

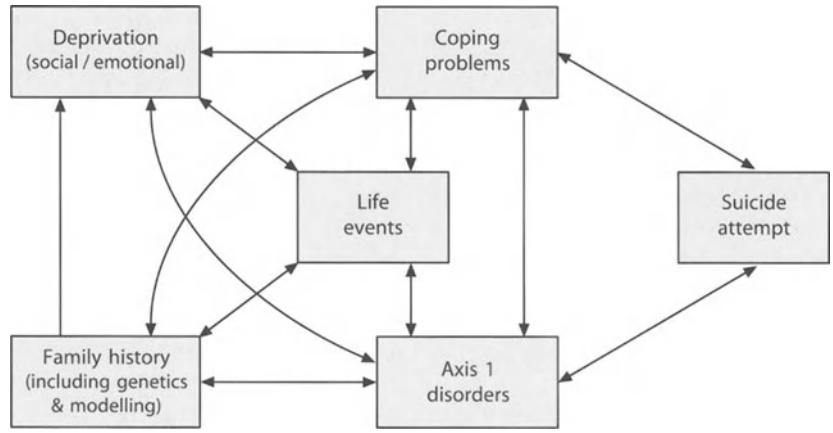

Fig. 3. Social and familial pathways to suicidal behaviour

in the absence of psychopathology, ideation with a plan is an important risk factor for completed suicide. Brent et al. (1993) found that adolescent suicide victims were significantly more likely to indicate suicidal ideation with a plan in the week prior to their deaths. In fact, when compared with demographically matched controls, 77% of the suicide victims in their study were known to have had ideation compared with none of the control group. Ideation is also a key precedent to parasuicide. In one prospective community study of adolescents (Andrews and Lewinsohn 1992), 87% of those who had a history of attempted suicide also reported prior suicidal ideation.

Linehan et al. (1987) argue that suicide ideators as a control group are "clinically significant" because of the following:

1. Suicides and parasuicides emerge from a population of suicide ideators.
2. Clinicians have to distinguish between patients who express suicidal intention but do not go on to parasuicide, and those who will engage in parasuicidal behaviour.

In summary, although there are problems in extrapolating from suicide ideators to parasuicides, ideation provides a useful preliminary measure of suicide intent and risk. In terms of conversion, where suicidal thoughts progress from conceptualising suicide as one solution to the only option, planning may become a logical step and therefore enquiring about preparation for the act remains a useful assessment tool.

5.3 Psychiatric Illness

Psychiatric diagnoses were collected in five centres of the WHO/EURO Monitoring Study. These clinical diagnoses were made by psychiatrists using Chap. V of the ICD-9 system of classification. Only 33% of attempters were given a diagnosis in these centres. It is unclear why the remaining 67% were not diagnosed. Obviously, cases that did not meet the ICD-9 criteria were not accorded a formal psychiatric diagnosis, but it is likely that variation in access to psychiatric assessment was a major factor. Twenty-one per cent of both sexes were given the diagnosis of "adjustment disorder or abnormal reaction to stress". This indicates that the most relevant precipitant to the episode was a response to an external stress, rather than personal psychopathology. The next most common diagnosis, for men, was abuse of substances, including alcohol, at 18%; the second commonest diagnosis for females was "neuroses and personality disorders without neurotic depression" at 22% and "neurotic depression" at 21% (Schmidtke et al. 1994b).

For some attempters, the prognosis is abysmal, with many repeating the behaviour (Kelleher et al. 1999). A total of 15%–20% of those who have a history of deliberate self-harm will repeat the behaviour (De Moore and Robertson 1996), and about 1% of adults go on to take their lives within 12 months of an attempt (Hawton and Fagg 1988). The psychiatric diagnoses for those who had made more than one suicide attempt in the WHO/EURO study (Schmidtke et al. 1994b) differed from the first-evers. More male repeaters had a diagnosis of addiction (23% vs. 14%), and there were more diagnoses of schizophrenia (14% vs. 4.5%). The most significant difference for females was that "adjustment disorder" was diagnosed in 30% of first-evers and in 17% of repeaters.

Given that a significant number of parasuicides (especially males) present with a diagnosis of "addiction", it is important to examine the link between suicidal behaviour and alcohol misuse. Alcohol dependence plays a causal role in 25% of all suicide cases

(Murphy and Wetzel 1992). Among adolescents, alcohol misuse has been shown to predict seriousness of suicidal attempts (Beautrais et al. 1996) and completed suicide (Shaffer et al. 1996). Alcohol may lower brain serotonin, thereby disposing to suicide by reducing impulse control (Sellers et al. 1992). Fombonne (1998) demonstrated a linkage between the rapid rise in young male suicidal behaviour and alcohol misuse over a 20-year period in a sample of London adolescents. The link between alcohol usage, altered serotonin neurotransmission and suicidal behaviour may be an important mechanism in the induction of parasuicide.

The previous chapter discussed the relationship between suicide and mental illness, in particular the relationship between depression, schizophrenia, personality disorder, substance abuse and suicide. Again, it is worth stating that the use of street drugs such as ecstasy, amphetamines, cocaine and opiates may be followed by parasuicide. This may involve the serotonergic brain system (Steele 1994). There is a strong relationship between severity of substance misuse (in terms of the drug chosen and method of administration) and risk of non-fatal suicidal behaviour (Garrison 1993). Substance misuse is associated with a seven-fold greater risk of attempting suicide (Deykin and Buka 1994). It is also more likely to lead to a more lethal outcome in suicidal behaviour, as more violent methods are chosen (Neeleman and Farrell 1997). According to the WHO/EURO study, the relationship between personality disorder and parasuicide is most pronounced in females, especially those who repeat. Most studies dealing with personality disorder and suicidality show a high degree of these disorders in people who commit self-destructive acts, particularly the borderline and impulsive subtypes. It is also likely that personality disorder interacts with other comorbid factors, such as substance misuse, depression and alcoholism (Casey 1989).

Although suicide is the leading cause of death in schizophrenia, with lifetime estimates of 10%, it may not be commonly realised that 40%–55% of individuals with schizophrenia attempt suicide (Roy et al. 1984). In those people with schizophrenia who attempt suicide, males are as common as females (Wilkinson and Bacon 1984). Less is known about the specific risk factors associated with suicidal behaviour in schizophrenia, as most research has focused on risk factors in depression. Suicide attempts occur early in the course of schizophrenia. Given that the short-term suicide risk varies over the course of schizophrenia, and that it is extremely difficult to predict the long-term risk, parasuicide in schizophrenia must be rigorously assessed.

Barraclough et al. (1974) found a current diagnosis of depression in 70% of completed suicides. Issacson and Rich (1997) found that depression occurred in at least half of all deaths by suicide. In another study, Foster et al. (1997) found an overall rate of depression of 36% with over double the incidence among women (60%) as among men (29%). In the WHO/EURO study, neurotic depression was diagnosed according to ICD-9 criteria in 21% of all women who attempted suicide. Kelleher et al. (1999) also stressed the relationship between deliberate self-poisoning and affective disorder with 33% of male ($n = 83$) and 54% of female ($n = 111$) self-poisoners presenting with a diagnosis of affective disorder (see Table 1). While suicidal ideation is a recognised symptom in depressive disorders, parasuicides appear to represent a different sociodemographic population to completed suicides, although a degree of overlap exists.

6
Suicidal Behaviour in Institutions

6.1
Psychiatric Hospitals

Given the high prevalence of individual psychopathology which is obviously present in psychiatric hospitals and in spite of the best efforts of medical and nursing staff, suicidal behaviour does occur in psychiatric hospitals. When it does happen, it sometimes occurs in clusters (Taiminen and Helenius 1994). The factors that discriminate between the suicidal and non-suicidal in hospital populations may differ from community ones. Self-burning is one type of self-harm that appears to be more common among in-patients, especially females with a history of personality disorder (O'Donoghue et al. 1998). The current ethos of open door units and increased patient autonomy has the effect of making it more difficult to restrict access to inflammable clothing and matches, etc. The situation regarding the frequency of suicide among recently discharged psychiatric patients has already been discussed in the previous chapter. Briefly, it has been noted that there is a substantial increase in suicide among those recently discharged from psychiatric hospitals, which is greater in the first few weeks but remains elevated for several months (Goldacre et al. 1993). The problem seems to lie in the inability of the individual to function adequately in society following a psychiatric admission. The difficulty in returning to full social functioning is associated with social stigma and perceived loss of a meaningful role in society.

6.2 Prisons

A more detailed description of prison psychiatry is outlined in Chap. 17 (Vol. 1, Part 2) and the following is therefore only a brief description regarding suicidal behaviour in prisons.

Official concern was expressed at the high and apparently increasing rate of suicidal behaviour in prisons in the United Kingdom and Ireland in the early 1990s. There are some indications that the increase has levelled off, but the U.K. rates are five to six times higher than in the general population (Dooley 1990). To some extent, this is to be expected as the population in prison mainly consists of young men who are all undergoing major stresses just by virtue of their incarceration. There is also a high incidence of substance abuse and dysfunctional family background within the prison population, all of which would predispose to difficulties in coping with stress. A U.K. report found that suicide attempts in prison were more likely to occur in the early stages of imprisonment. Over 25% of suicides occurred within 1 month and over 50% within 3 months of incarceration. The majority of prison suicides were by individuals on remand (Crighton and Towl 1997). Procedures mainly aimed at increasing communication both within prison and between prisoners and the outside world have been introduced in an effort to reduce the degree of helplessness felt by prisoners (Dooley 1994). Policies aimed at increasing the proficiency of prison staff in dealing with the problem have also been instituted, e.g. by establishing suicide awareness groups within the prison.

6.3 Schools

Clusters of suicidal behaviour among young people in a particular area or school are most often attributed to the Werther or contagion effect. The term "Werther effect" was coined by Phillips (1974), based on the character of a young man in Goethe's 1774 novel *The Sorrows of Young Werther* who killed himself. This effect may result from media accounts of a celebrity suicide or personal ties and emotional identification with a person who attempts or dies by suicide. For instance, much has been made of copycat suicides following the death of the rock singer Kurt Cobain. It is likely that those already at risk are most likely to be affected and that the contagion tends to influence their choice of method and the setting. This can lead to an apparent increase in completed suicide if the attempter changes to a more lethal method, e.g. hanging or guns, in imitation of the celebrity. Clusters may also surround the unexpected death of a high-profile student in a school, and again those already emotionally vulnerable are most at risk (Gould et al. 1990). Prevention of such clusters may best be managed by combining case identification of those most at risk with general measures involving promotion of mental health status and reduction of stigma and bullying, rather than by specific suicide intervention packages (Kelleher 1998b). The latter programmes may have the effect of glamorising suicidal behaviour and have been found, in some cases, to result in outbreaks of deliberate self-harm among students (Callahan 1996). The issue of school postvention programmes will be further discussed later.

7 Intervention

On first consideration, there appears to be a continuum from suicidal ideas, whether fleeting, recurrent or more persistent; to impulsive and more detailed planning; to attempts of varying severity; culminating in suicide itself. However, this is not necessarily true, and many people may make a serious attempt without ever having previously thought about suicide. Undoubtedly, others have given prior consideration to the decision, sometimes on and off, over many years. No one knows, however, what the gateway factors are from one level to the next.

Presumably there are a mixture of inducing and inhibiting issues. In such an apparently incoherent field, chaos theory may be invoked as an explanatory hypothesis. Reid (1998) indicates that chaos theory can be relevant to psychiatry. In particular, he describes a model of the possible effects of psychosocial stressors in bipolar illness. Perhaps this model can be applied to the understanding of parasuicidal behaviour. Chaos theory refers to the seemingly random type of variability that can arise in a non-linear system. Although appearing random, the behaviour of an object in such a system can be modelled. Parasuicidal patients inhabit a vulnerable psychosocial system, as indicated from the WHO/EURO Monitoring Study. In such a vulnerable and unstable psychosocial system, a stressor, if it has sufficient amplitude, may drive the system into sustained chaotic dynamics. A stressor may therefore produce a long-lasting effect, with subsequent episodes apparently not linked to any precipitant and appearing to rise spontaneously. This might help to explain the apparent reduced importance of external stressors as precipitants in subsequent episodes, noted in the WHO/EURO study (Schmidtke et al. 1994b).

7.1 Assessment

Intervention after an act of parasuicide presents a host of problems that must be addressed. The policy of the Royal College of Psychiatrists (1996) in the United Kingdom is that such cases should be psychiatrically assessed, particularly if the event results in admission to a general hospital. Table 2 gives a schema for some essential elements in the assessment of suicidal risk following an act of parasuicide.

In general, assessment must include the diagnosis and establishing the reason for the attempt; severity of illness if present; likelihood of repetition of suicidal behaviour in the short term; discussion with an informant if available; decision with regards to disposal once safe to discharge from general hospital, which may be as psychiatric in-patients, psychiatric out-patients or referral back to a general practitioner.

Assessment of suicidal risk that is based on risk factors alone is not sufficient. Risk assessment in suicidal patients involves determining the balance between risk and protective factors (Appleby 1997). Ringel's pre-suicidal syndrome (1976) may also inform assessment. First described in 1958, there are three distinct elements, namely, constriction, inhibited aggression turned towards the self and suicidal fantasies which relate to a specific state of mind that may lead to suicidal acts. Knowledge of the above factors can facilitate earlier awareness of serious suicidal intent, rendering earlier intervention possible. The use of validated psychological scales may aid in decision-making. Beck's Suicide Intent Scale is a 15-item questionnaire, which is administered by the clinician to an individual following an act of attempted suicide. It has been consistently validated as a measure of the seriousness of intent to die (Beck et al. 1974a; Beck and Lester 1976) and provides a means of assisting a clinician in assessing suicidal risk. Hopelessness (i.e. a negative

Table 2. Assessment of risk in parasuicides

Task	Questions	Indicators of increased risk
Establish the patient's suicide intent at the time of the attempt	Did he or she wish to die? Did he or she plan the act? In choosing the method, did he or she expect to die? Did he or she seek help following the act?	Evidence of planning, e.g. selecting isolated location Evidence of a final act, e.g. suicide note Method with a high perceived lethality Absence of help-seeking following the act
Determine if there is a continued risk of suicide; he or she should be asked direct questions	Does he or she still express a wish to die? How does he or she see the future? What has changed for him or her? Do risk factors still outweigh protective factors?	Hopelessness Lack of remorse Ambivalence about the future Past history of suicidal behaviour
Establish if any psychiatric illness is present; he or she may require formal psychiatric evaluation	Does he or she have a history of psychiatric illness? Is he or she being treated for psychiatric illness? If yes, could his or her treatment regime/compliance be improved? Does he or she have a family history of psychiatric illness?	For depression, presence of agitation, insomnia For alcoholism, presence of social isolation, depressed mood For personality disorder, presence of sociopathic or borderline subtypes For schizophrenia, being male, young, chronically ill For neuroses, presence of panic attacks
Establish the coping skills/resources available to him/her	Did he or she experience a recent loss? Does he or she have interpersonal difficulties? Does he or she live alone? Does he or she have family or community support? Is he or she physically ill? Does he or she have financial, employment, housing or legal worries?	Bereavement/loss Marital/relationship difficulties Older age, male sex Social isolation Physical/psychiatric illness Unemployment Criminal record
Decide on the level of intervention	Have the medical/surgical complications of the act been treated? Does he or she require psychiatric treatment? Will he or she accept treatment voluntarily? Does he or she require compulsory admission? If he or she is being discharged, has an emergency contact number been provided?	Compulsory admission In-patient treatment Poor compliance

view of the future) is the cognitive feature which is most consistently related to suicidal ideation, intent and completion in adults (Beck et al. 1990). The Beck Hopelessness Scale (Beck et al. 1974b) is a 20-item self-report questionnaire which assesses the level of "negative view of the future" held by the patient. It has a high false-positive rate, which needs to be kept in mind (Beck et al. 1990). It has to be stressed, however, that these scales act as an aid to assessment and do not substitute for a detailed psychiatric evaluation.

In high-risk cases, admission to hospital is the preferred option. Compulsory admission may have to be considered. Ideally, this is best avoided as it may mean prevention in the short term but may result in hostility towards the service should suicidal ideas return later. Hospitals should have a protocol for managing suicidal patients that maximises observation while minimising intrusion. The level of supervision must be graduated to the degree of perceived risk. Good therapeutic relationships at nursing and doctor level are essential.

7.2 Aftercare

Aftercare, i.e. after acute medical treatment, varied considerably across the WHO/EURO centres. Perhaps surprisingly, the commonest type of treatment offered between all centres was in-patient (50% of females and 53% of males), then out-patient treatment (19% of males and 22% of females), and no treatment was recommended for 16% of both sexes. In-patient treatment was recommended slightly more often for those who made more than one attempt, whether male or female. It must be pointed out, however, that this contradicts more recent findings which suggest that out-patient treatment is the more likely next stage of care. For example, Hawton et al. (1997), in an examination of deliberate self-harm in the Oxford region of England, report that in-patient care accounted for only 10% of the aftercare provided following assessment ($n = 738$). It is suggested here that the reason for such a discrepancy between studies may relate to the demographic characteristics of the samples in question. Furthermore, variations in service provision, i.e. supply factors, may determine the type of service provided to parasuicidal individuals. As one example of such differences, acute assessment is carried out by trained social workers in the United Kingdom, whereas it is performed by psychiatrists in Ireland. The absence of proven interventions (as discussed below) may account for such variations in clinical practice.

Because the problems of individual parasuicidal patients may be multiple, a team approach is essential (Kelleher et al. 1999). To this end, referral for assessment to a variety of mental health professionals, including social workers, psychologists and nursing personnel, could be made at the discretion of the consulting clinician, taking into account the individual circumstances.

The social needs of some parasuicidal patients may be enormous. Often low stress tolerance is conjoined to situations that are themselves very stressful. The parasuicidal person may be the only outward sign of a very dysfunctional domestic unit with other disturbed members, including dependent children. Social work intervention may be essential to unravel the social and other problems, including, where appropriate, the provision of case work care (Gibbons et al. 1978). However, it may be that the effect from social work intervention is stronger in females than males. There is a strong case to be made for the attachment of a social worker to each accident and emergency department so that all those presenting with deliberate self-harm will have the opportunity for assessment.

In a study examining the experience of suicide in the lives of 100 college students, Keeley and Kelleher (1998) found that friends and family were most popular as sources of help, but perhaps more significantly almost 50% did not know where they could turn. In response to a more specific question on the type of organisation they thought would provide acceptable help, 47% of the students suggested the Samaritans, while, with the exception of one student, medical services were never suggested. Three per cent mentioned the college services, but 40% were unable to make any suggestions. It appears from this information that the statutory services have a marketing problem when it comes to making their services acceptable to the young.

7.3 Specific Interventions

The efficacy of cognitive behavioural therapy has been demonstrated in selected populations in several research studies, some of which are ongoing (Linehan et al. 1987; McLeavey et al. 1987). Its place in routine clinical practice is not yet assured. Part of the difficulty is the various exclusion criteria that apply and, even more importantly, inadequate compliance by the target population. Other proposed intervention treatments include the Green Card study, as suggested by Morgan et al. (1993). This involves giving suicide attempters a card which increases their awareness of the extent of services to which they might have access without having to harm themselves. This approach has been piloted and has been found to be very acceptable to the patients, but it suffers from problems with acceptance

by clinicians and the lack of a sufficiently large sample to give a proper statistical indication of its benefits. A systematic review of the effectiveness of controlled intervention trials in deliberate self-harm has been published recently, and it concludes that there is a need for larger trials of treatment. The only significantly effective treatments identified in the review were depot flupenthixol in multiple repeaters and dialectical behaviour therapy (Hawton et al. 1998). This report confirms the high degree of uncertainty as to which forms of treatment are most effective.

7.4 General Practice

Management of parasuicide exclusively by general practitioners is considered unusual in Europe (Platt et al. 1992; Fitzsimons et al. 1997). The extent to which it happens depends on the structure of the health services in the country under study. Estimates range from 7% in Ireland (Fitzsimons et al. 1997) to 13% in France (Platt et al. 1992) and 20% in England and Wales (Kennedy and Kreitman 1973). There is some evidence that cases that are managed by the person's general practitioner, with or without the additional hospital services, may have a lower repetition rate than those managed by the hospital services alone. It is likely that general practitioner treatment might reduce the high level of non-compliance with aftercare of suicide attempters, whether because of their increased understanding of the person's social situation or because of reduced stigma and ease of access. Such a change in treatment would require increased resourcing and training of general practitioners, including the provision of community-based psychiatric back-up, but could have positive implications for hard-pressed casualty and other general hospital departments.

7.5 Voluntary Services

It is the voluntary services that are often the first to recognise a particular social need. The policy of the Samaritans and other "befriender" groups is that the volunteer does not influence or intervene in people's decisions to take their own lives unless specifically asked to do so (Befrienders International 1995). They therefore provide emotional support as opposed to professional directive counselling, unless the client requests referral. This implies limitations in the Samaritan's role, but on the other hand it also means that some clients may be more likely to contact somewhere where they will not be forced to do something that they do not want – even if it is perceived as good treatment and ensures that a separate identity is maintained.

The 12 member states of the European Union were surveyed in a study by Befrienders International (1995). The number of contacts per suicide varied widely between centres, with the United Kingdom/Ireland having the highest and Denmark the lowest. This may be related to the number and accessibility of centres. Germany, next to Denmark, has the second lowest number of contacts per suicide, but unlike Denmark it cannot be accused of having fewer prevention centres. A possible explanation offered is that the wide variety of services available can lead to reduced clarity about their perceived function. Numerous centres in Denmark have become professionalised, and this may discourage people who do not believe they have a psychiatric problem or fear being diagnosed with one. This last feature is particularly important to the nature of the service offered by the Samaritans and might indicate a need for befriender organisations to retain their independence from the statutory services if they are to continue to appeal to younger age-groups.

7.6 Helplines

Third-party callers provide a potential avenue for reaching high-risk groups who do not directly approach health services, particularly males, and young parasuicides who do not want to be referred for more specialist care. It was found that in the first year of a hotline launched in Geneva (Perret-Catipovic 1999), most callers were family members or friends of young suicidal people. There were equal numbers of calls concerning potentially suicidal males as females, although the parasuicide ratio in Switzerland is four females for every one male. In recognition that, in addition to mental health professionals, many other people have a role to play in preventing suicide, the gatekeeper intervention training programme was developed in Alberta, Canada, for the purpose of developing the intervention skills of a large range of professionals, volunteers and people who by virtue of their work have the opportunity to help people in distress. It has been evaluated positively in several studies (Bagshaw 1988; Crookall and McLean 1986; Tierney 1988).

7.7 Prediction of Repetition

As previously stated, within a year of an attempt, about 1% of adults die by suicide (Hawton and Fagg

1988). Predicting future suicide with any degree of accuracy is, at present, beyond clinical skill. In one large-scale study using what was regarded as the best clinical predictors such as previous attempt, serious mental illness and admission to a mental hospital, it was found that the likelihood of predicting suicide over a succeeding 5-year period was as infrequent as three times out of a hundred (Pokorney 1983). However, most clinicians do not need to engage in this relatively long-term type of prediction. Instead, the challenge is to decide whether the patient is suicidal at the time of examination. Such a judgement is based on two things, the clinician thinking about it and the patient telling it. What the patient says is of paramount importance, as words make intention explicit. Because suicide can occur in virtually any psychiatric condition, no examination should be considered complete without asking about such intentions, often best introduced after establishing through careful examination a good clinical relationship, by enquiring about the future. Most patients are happy to unburden themselves of self-destructive pre-occupations to an understanding physician. If an attempt has been made or an intention has been disclosed to an informant, the matter should be discussed with the patient. Absence of supportive relationships, isolation and social stresses perceived by the patient as being beyond his or her capacity are negative prognostic signs. In particular, a change from a stable to an unsettled social situation may precipitate an attempt (Schmidtke et al. 1996).

Accurately identifying those at high risk of repeating parasuicidal behaviour in the future could have service benefits, because special provision could be made to prevent such a recurrence. As clinical predictors seem insufficient, some other approaches are being investigated. A prediction mechanism based on a computer model, designed for use by nursing and other paramedical staff, was found to discriminate between those who repeated parasuicide and those who did not do so (Corcoran et al. 1997). Presently this model is being tested and refined further in a prospective study by triage nurses working in accident and emergency departments.

8
Prevention of Clusters

8.1
School-Based Suicide Prevention Programmes

As discussed above, there has been considerable debate about school-based efforts to tackle suicidal behaviour in students. Some of them are of questionable efficacy and safety (Hazell and Lewin 1993). An alternative and perhaps more sensible approach has been to train teachers as gatekeepers to detect emotional problems and suicidal risk in students and refer them as appropriate, using available community resources, e.g. professional and voluntary mental health bodies (Canadian Task Force on Suicide 1994). An appropriate ethos might be to focus on positive aspects by learning coping skills that will be helpful in future crises.

8.2
Community-Based Programmes

Guidelines for programmes aimed at the prevention and containment of suicide clusters have been drawn up by the Center for Disease Control (1994) in Atlanta. The main aim of the guidelines, which must be generic by their very nature, is to have identifiable and prepared figures within the community to co-ordinate responses and to deal with the media so that panic, rumour and innuendo are reduced to a minimum. They stress the importance of using existing resources within the area and the necessity of adapting any strategy to cope with the local cultural climate.

9
Conclusion

Parasuicide prevention might well learn from the public health approach to heart disease where a change in diet, more exercise, reduction in weight, cessation of smoking and moderate drinking were found to be of such importance. A difference is, however, that in heart disease the focus was on the individual, whereas a public health approach to the prevention of parasuicide would have to focus more on social issues. The rates of parasuicide might well fall if the deprived received better education from the earliest age, including better education of the parent(s), especially as many are young, inexperienced and deprived (Kelleher et al. 1999). Children, particularly males, should be retained within the educational system. Over-crowding could be alleviated by providing adequate housing, allowing more personal space and thereby reducing the likelihood of constant confrontation. Better employment prospects are likely to reduce parasuicide, as are reduction in the use of alcohol and avoidance of the misuse of drugs (Proudfoot et al. 1997; Neeleman and Farrell 1997). The positive outcome of reduction in the use of alcohol can be seen in the former Soviet Republics, where a

restriction on alcohol during *perestroika* coincided with a sharp decline (35%) in suicide (Wasserman and Värnik 1998).

The Finnish were one of the first people to attempt to approach suicide prevention from the point of view that treatment of suicide attempters is only the tip of the iceberg in a problem whose roots reach far down into the structure of society. The obvious conclusion from this is that in order to attempt to adequately address this problem, it is necessary to make changes to our societies in ways that may conflict with deeply and sincerely held views. Another implication of their approach is that it is essential to have accurate information about all aspects of the problem, and research is therefore important at all levels of society. Internal evaluation of the strategy (Hakanen and Upanne 1996) indicates that it was successful overall in mobilising professionals both in health and non-health service sectors nationally to take responsibility and to further develop suicide prevention in practice. In addition, they reached their central strategic aim of evolving co-operation across professionals and sectors. During the implementation phase of the project, suicide frequency fell by 9% below the initial increasing rate, but Beskow et al. (1999) can only report that the strategy *may* have contributed to this reversal. The Finnish strategy makes seven main points and it is appropriate to end two chapters devoted to the problem of suicidal behaviour with their impressive insights (Tuipale 1993).

According to the strategy of "Joint Responsibility for Suicide Prevention", the rising suicide rate can be reversed if:

- Everyone who has attempted suicide receives as effective help as possible.
- Depression is recognised and the person offered all the support he or she needs; everyone suffering from serious depression should receive appropriate and effective treatment.
- We can prevent alcohol being used as the universal solution to problems, and find better means of supporting efforts to cope.
- Mental and social supports are enhanced within the treatment of somatic illness.
- A person in a life crisis receives appropriate support from friends and relatives, and from professionals when necessary.
- The risk of youngsters becoming alienated from life can be avoided, and individuals running a risk of suicide are guaranteed the possibility of coping and improving their self-esteem.
- The cultural climate in Finland, including the education system, becomes more relaxed and permissive, and less guilt promoting, stigmatising and punitive than it tends to be at present. It needs to promote belief in life, resourcefulness, self-esteem, initiative and mutual support.

Personality Disorders

Translator: A. Rodón

1 Introduction

The fascination and risks inherent in psychiatric pathology lie in the complex nature of psychiatric disorders, which is characterized by an intricate interplay of somatic functions, learning processes, acquired attitudes, and situation-specific influences. This is particularly evident with accentuated personality constitutions which conceptionally, nosologically, and diagnostically transcend and touch on various disciplines: the broad range between the healthy condition and a pathological development, between successful adaptation and dissocial development, and between constitutional temper and character variants and psychiatric illness. Moreover, the field dealing with deviant personalities is susceptible to misinterpretation in terms of anthropology, sociopsychology, and criminological policy: instead of as a physician, the psychiatrist can be perceived as an instrument to implement law and order tool. This is particularly important when dealing with dissocial behavior, which is why, in *Der Mann ohne Eigenschaften* ("The Man Without Qualities"), Musil warned our profession against becoming the backup angel of justice.

It was with the statement "Do We Need Personality Disorders?" that Tölle (1986) opened the relevant chapter in the previous, third edition of *Contemporary Psychiatry* (in German). With critical reserve toward the classification systems emerging in the Anglo-American countries at the time, he went on to outline the topic according to the German-speaking tradition, e.g., following Kretschmer and Kurt Schneider. Regarding nosological criteria, Tölle distinguished three groups of abnormal personalities, of which one resembled the psychoses (hyperthymic, paranoid, and schizoid forms), one was equivalent to character neuroses (hysterical, anancastic, depressive, in part schizoid, but also sensory disorders), and the last consisted of sociopathic or antisocial personalities. As the chapter by Hoffmann (1986) in the same book shows, despite attempts at integration using concepts from psychological and character neuroses, an incompatibility remained between the theories of neurosis and psychopathy which arose almost simultaneously nearly 100 years ago.

Personality disorders have now become well accepted and moved into the foreground of psychiatry and psychotherapy, both in science and in the doctor's office. In particular, the introduction of separate personality registration on the so-called axis II using DSM-III (APA 1980) and the subsequent editions DSM-III-R (APA 1987) and DSM-IV (APA 1994) stepped up research and publication worldwide, leading to the inception of professional journals and scientific societies devoted solely to the field of personality disorders. Today, the flood of theoretical concepts and therapeutic methods is immense and almost impossible to organize. Due to the heterogeneous nature of the subject matter, the outline which follows shows redundancies and hazy spots which at present can be avoided neither by empirically determinable criteria nor by conceptional and definitional classifications.

2 Definitions of Terms

The term "personality" is one of the most dubious words in our language. On the hand, it refers to an ethical, pedagogic value judgment, as when we say that someone has a strong personality or is a person of character. All people are persons, to be sure, but not everyone has a strong personality, which, according to Binder in the first edition of *Contemporary Psychiatry* (1964), is distinguished by a conscious, sustained exercise of thought and will. The concept of personality includes the terms temper and character, where temper refers more to the basic vital traits, while character encompasses long-range attitudes.

Using the terminology of psychiatry and psychotherapy, we will now define personality as the sum of all psychological characteristics and behaviors which lend a human being his or her unique, distinct individuality, these all being contained in aspects of perception, thought, emotion, will, and interrelationship with others. On the other hand, a personality disorder occurs if, due to degree and/or a particular combination of psychopathologically relevant features in any of these areas, there is considerable suffering and/or lasting impairment of social adaptativeness (Saß 1987).

Psychiatry and psychology have different conceptional views regarding classification and description in this field. Psychiatric thinking aims at distinguishing personality disorders according to nosological, typological, and characterological aspects. The various personality disorders are to be grouped in units distinct both from each other as well as from what is seen as normal. Methods used in depth psychology and developmental psychology, such as the psychoanalytical theory of personality, avoid a strict classification and instead depart from the assumption that all patients will show a specific disorder pattern if the biographically relevant events and influences are correlated with the development of the self.

This led to the interpersonal and sociodynamic methods used in clinical psychology, which place

greater weight on the interpersonal and interactive part of personality development, and also of personality disorders, as well as the biosocial learning theories, which take biological, intrapsychic, and environmentally specific social influences on personality disorders as their starting point (Millon 1969). Such models complement our more psychopathological concepts in interesting ways; Fiedler (1998), for example, approached personality disorders from a cognitive-behavioral direction and regarded them as personality-caused interaction disorders, and Schmitz (1999) employed a dimensional concept of dysfunctional personality styles conforming to psychoeducative aspects.

3 History of the Concepts of Abnormal Personality

3.1 French Schools of Thought

With his concept of a *manie sans délire*, Pinel (1809) pioneered scientific treatment of abnormal personality and was the first to delimit it as a nosological unit. The decisive characteristic feature was an impairment of the affective functions without a concomitant impairment of the intellect. One of his patients showed clear emotional instability and dissocial tendencies, two features that are also central to modern diagnosis. Pinel considered poor upbringing and a perverted, unrestrainable disposition as possible causes, thus giving rise to the nature versus nurture controversy, which remains current to this day. Esquirol's (1938) monomanias also show many features which are now seen as personality disorders, particularly alterations of will and emotions but not of intelligence. Unfortunately, the concept was abused insofar as perfectly circumscribed behavioral disorders came to be seen as syndromes, such as pyromania, cleptomania, erotomania, or homicidal monomania, a problem which remains rooted in modern classification systems and has led to forensically relevant misunderstandings, as in the assessment of culpability.

Particularly successful was the theory of degenerations as pathological deviances from the normal due to harmful environmental influences and heredity, severity progressing from one generation to the next and eventually leading to extinction (Morel 1857). The concept presented by Magnan and Legrain (1895) of a regular succession of certain syndromes, above all the *dégénérés supérieurs*, who showed affective peculiarities but normal intelligence, would be of significance for the future study of psychopathology. Magnan postulated a discordant interaction between the cerebrospinal centers which upset the psychic balance of the degenerate and caused a special sensitiveness. Ideas of an imbalance and a fragility due to the nervous system kept recurring in theories on abnormal personality until Dupré's *Doctrine des Constitutions* (Dupré 1925), in which he proposed the concept of a *deséquilibration mentale* in the sense of congenital psychopathic degeneration. These ideas were later combined with those from social Darwinism in many countries, where they gave rise to misguided notions about "unworthy life," but which in Germany led to the gravest consequences (Binding and Hoche 1920).

3.2 Anglo-American Traditions

In 1812, the American physician Benjamin Rush described patients with antisocial/dissocial behavior without intellectual losses, a condition which he termed "moral alienation of the mind." Prichard's (1835) concept of "moral insanity" had a similar impact in England. The increasing emphasis on individuals who showed amoral, socially harmful behavior and delinquency led to the question of whether these people were responsible for their actions. This collided with attempts at integrating "moral insanity" into a psychiatric nosology with a legalistic orientation. Later, the concept presented by Henderson (1939) of the unadapted or aggressive psychopath found its way into the Anglo-American notion of a personality disorder determined mostly by antisocial traits. The British Mental Health Act currently includes the term "psychopathic disorder" in the sense of abnormally aggressive and irresponsible behavior, a definition that has been under fire for decades (Lewis 1974).

Cleckley's monograph *The Mask of Sanity*, originally published in 1941 (Cleckley 1976), greatly influenced the American notion of psychopathy and led the way for the now important concept of the antisocial psychopath (Hare 1970, 1991). The concept of abnormal personality was also influenced by the pioneers of psychoanalytical character research, Meyer (1903) and Freud (1908). In a groundbreaking paper, Alexander (1928) distinguished between primarily self-syntonic psychopaths, whose neurotic acting out disturbs mainly those around them, and secondarily self-syntonic neurotics, who are usually their own victim.

3.3 Schools of Thought in the German-Speaking Countries

Koch (1891–1893) first employed the term "psychopathic inferiorities" for a "psychic border region" (inferiority here is closely connected with the concepts

of degeneration and must be seen somatopathologically rather than as a value judgment). He did distinguish between innate and acquired psychopathy, but classified most forms as innate psychic impairments. Beginning in 1883 and throughout the various editions of his textbook, Kraepelin developed the concept of psychopathic condition in the sense of today's understanding of abnormal personality. The concept of psychopathic personality was mentioned for the first time in the seventh edition (Kraepelin 1903/1904), where it appeared in the context of dissociality. Constitution typologies followed later, including the sketches by Kretschmer (1921) as well as other systematic typologies, e.g., the layer theory by Kahn (1928), Schultz (1928), and Homburger (1929) and the reaction typologies by Kretschmer (1921) and Ewald (1924).

As a result of Kurt Schneider's classic monograph *Die psychopathischen Persönlichkeiten* ("The Psychopathic Personalities"), originally published in 1923 (Schneider 1950a), the systematic typologies lost importance and a descriptive, analytical approach without a sociological perspective was favored. Kurt Schneider defined abnormal personalities as variations or deviations from a vaguely imagined but not precisely definable average and proceeded to point out the psychopathic personalities as such, whose abnormality causes suffering to themselves or to society. He distinguished ten types of psychopathic personality: hyperthymics, depressives, those suffering from insecurity (subdivided into anxious and obsessive–compulsive types), fanatics, show-offs, those showing mood instability, explosiveness, lack of feeling, avolition, and the asthenics. His teachings have had a decisive influence on all later concepts of personality disorder.

4 The Example of the Borderline Syndrome

As "a border region or no-man's-land" (Saß and Koehler 1983), the borderline symptom still resembles its mostly vague and poorly defined historical forerunners from which the path has led into the relative clarity of the currently used classification systems for personality disorders. In a more general form, Hughes (1884) first spoke of a "borderland" regarding unusual conditions. "Borderline" was first used as a distinct nosological term by the psychoanalyst Stern in 1938, who applied it to patients showing both psychotic and neurotic characteristics. In its eventful development leading up to today's borderline personality disorder, four theoretical currents are evident (Herpertz and Saß 1999a).

1. The first casts the borderline disorder as a subschizophrenic disorder. Kraepelin (1903/1904) already described an intermediate between pathological mental conditions and individual eccentricities, which he called a border region with undeveloped cases, *formes frustes*, of dementia simplex. Similarly, Bleuler's diagnostic category of latent schizophrenic cases included cases of peculiar, odd, eccentric individuals (E. Bleuler 1911). The Bleuler-based concepted presented by Hoch and Polatin (1949) of pseudoneurotic schizophrenia was to have serious consequences, also for psychoanalysis.
2. The second current characterizes borderline disorder as an emotionally unstable "subaffective" disorder bordering affective illness. Such a syndrome was first described by Bonet (1684) as *folie maniaco-mélancolique*. Beginning with the fifth edition of his textbook, Kraepelin described "constitutional irritations" within the psychopathic conditions. Following in the footsteps of Kraepelin, contemporary authors interpreted the borderline disorder as cyclothymic temper (Akiskal and Akiskal 1992). Kurt Schneider (1950a) included the hardening of these personalities with the emotionally unstable and explosive psychopaths.
3. The third current characterizes borderline disorder as disturbed impulse control (Clarkin et al. 1993; Herpertz and Saß 1997). This goes back to the old illness concepts of an impulsive disorder of the will (Berrios and Gili 1995). Forerunners were the *fureur sans délire* of the Swiss psychiatrist Matthey (1816) and the monomanias of Esquirol (1838), which Kraepelin grouped under "impulsive insanity." In the typology of Kurt Schneider (1950a), impulsive personality traits also fall into the category of emotionally unstable and explosive psychopaths (Herpertz and Saß 1997).
4. The fourth current, which at the moment is receiving much attention, characterizes borderline disorder as a post-traumatic stress disorder as first described in DSM-III following observations on Vietnam veterans. Up to one third of all patients meeting the DSM-III criteria for borderline disorder also showed signs of a post-traumatic stress disorder (Coryll and Zimmerman 1989). However, multiple traumas are also seen in other psychiatric illnesses (Zanarini et al. 1997), and some patients meet the criteria of borderline disorder without reporting any severe traumatic events from their childhood.

Taken together, it is evident that the rather large category of borderline syndromes evolved from a number of different forerunners and served as a diagnostic wastebasket for difficult patients. Often, it

was not used to designate any specific personality disorder, but, incorrectly, also in cases where psychosis was suspected, i.e., to conceal the physician's own diagnostic uncertainty. The decisive breakthrough needed to bring order and clarity was not to be made until the paper by Spitzer et al. (1979), who introduced the dichotomous division into emotionally unstable or borderline personality disorder on the one hand and borderline schizophrenia or schizotypal personality disorder on the other (Saß and Koehler 1983). In current diagnostic research, the borderline personality disorder has become one of the empirically best documented conditions and now serves as an example for the entire group of personality disorders.

5 Personality Disorders in the Modern Diagnostic Systems

Today's concept of personality disorder has abandoned the old controversy of neurosis (which is seen as being more acquired) versus psychopathy (which is regarded more as inherited). In the relatively assumption-free, descriptive classification systems, "personality disorder" now functions as a neutral collective term for all dysfunctional personality variants. Essentially, the modern definitions of personality disorder which appear in ICD-10 and DSM-IV go back to Kurt Schneider, since a personality disorder is diagnosed when a personality is inflexible and maladapted and this leads to clinically relevant suffering or impairment in the social, professional, or other important functions.

According to the DSM-IV and ICD-10 research criteria, diagnosis follows an operational description with a formulation of explicit inclusion and exclusion criteria in a polythetic algorithm. There is some overlap, however, since many people meet the criteria of several personality disorders. This overlap of different disorder categories is termed comorbidity, even though "joint occurrence" would be preferable, particularly with personality disorders of unclear morbidity. The so-called comorbidity often represents a methodological artifact, since identical criteria appear in the list of features of several personality disorders. The question also arises of whether the feature descriptions and the cutoff (threshold) values indicated in the criteria allow a reliable and valid assignation (Saß 1986; Herpertz et al. 1994). Furthermore, in the case of concomitant axis I disorders, a diagnosis of a comorbid personality disorder – which should only be made by means of peculiarities in the patient's medical history which existed prior to the disorder in question – would have to be uncertain (see Chap. 20, Vol. 3, Part 1; Chap. 24, Vol. 3, Part 2).

A further problem is posed by the persisting differences in terminology and concept between the classification systems, as the comparative differential typology in Fig. 1 shows. Thus, the schizotypal and narcissistic personality disorders of DSM-IV do not appear in ICD-10; instead, ICD-10 groups schizotypal disorders under schizophrenia, and the criteria for the

Kraepelin, Kretschmer K. Schneider, ICD-9	ICD-10	DSM-IV

Explosive, emotionally impoverished Moody Needing recognition ∅	Dissocial Emotionally unstable { - Borderline type / - Impulsive type } Histrionic ∅	Antisocial Borderline Histrionic Narcissistic	B
Insecure Weak-willed Obsessive-compulsive	Insecure Dependent Anancastic	Insecure Dependent Obsessive-compulsive (Passive-aggressive)	C
Depressive Asthenic Hyperthymic Cyclothymic	∅ ∅ ∅	(Depressive) ∅ ∅ ∅	+

Fig. 1. Personality disorders in the classical typology and in the modern classification systems. ∅ suggested research criteria; + "subaffective" forms

narcissistic personality disorder are found under those for the paranoid type. On the other hand, ICD-10 includes an emotionally unstable personality disorder which is divided into an impulsive type and a borderline type. In DSM-IV, the latter appears as an independent form of the borderline personality disorder. Moreover, the diagnostic threshold values also differ, with the result that prevalence rates are higher when applying ICD-10. These discrepancies between the systems make it difficult to compare studies and complicate routine diagnosis.

By now, the great variety of criteria in the modern classification systems has made operationalized diagnosis so complex as to make systematic classification a major undertaking. Moreover, diagnosis of personality is met by several relatively specific hindrances (Bohus et al. 1999). Thus, criteria for the diagnosis of personality disorders deal with subtle phenomena which must be seen from a larger chronological perspective. There can be considerable discrepancies between a patient's self-assessment and the opinion of significant others or visitors due to self-syntonia or self-dystonia. For this reason, a patient's self-assessment is of little diagnostic help, and the physician must often rely on information from other people. Thus, when using the *Aachener Merkmalsliste zur Erfassung von Persönlichkeitsstörungen* (AMPS; Aachen List of Features for Assessing Personality Disorders), we relied on quite diverse information, including a diagnostic interview with the patient, the case history, behavior observation, and a chronology of the course of illness from the patient's file (Saß and Mende 1990). For the difficult task of assessing premorbid personality disorders by analyzing case histories, special biographical inventories are recommended (von Zerssen 1994a). Table 1 shows the standardized examination procedures for assessing personality disorders which are currently available in the German-speaking countries.

6 The Five-Factor Personality Model and Its Relation to Personality Disorders

The advantages of the category-based or typological approaches currently used in psychiatry are their simple conceptualization, communicability, their wide distribution, and a general human tendency to perceive and decide in terms of categories (Saß 1986). Unfortunately, these advantages are offset by serious shortcomings. The validity of a category-based or typological model is compromised by frequent multiple diagnoses which are a result of the polythetic set of criteria. Many of the cutoff points seem arbitrary, and features falling only a little below this limit are ignored, thus leading to a relatively low interrater reliability in the diagnosis of personality disorders.

Since many psychologists dealing with personality disorders are of the opinion that a medical category-based diagnostic system cannot do justice to behavioral disorders, the concept of personality disorders is still not used in many areas of clinical psychology. Instead, such psychologists attempt to represent the various personality disorders with a dimensional personality trait model. Individuals are not classified using a category-based or typological system, but instead the various disorder features are assigned a position according to intensity in a multiaxial dimensional space. For the transition from healthy to disturbed personality, they favor a continuity model. The forerunners of dimensional models in psychiatry originate from, among others, C.G. Jung (1921), who introduced the introversion/extroversion dimension, and Kretschmer (1921), who described the dimensions of schizothymia and cyclothymia. Eysenck's (1952) influential dimensional personality model uses factor analysis to reduce the number of possible personality features to the three dimensions extroversion (sociability, activity), neuroticism (emotional instability), and psychoticism (impulsiveness, aggressiveness). Cloninger et al. (1994) also made important contributions to empirical personality research with his biopsychological personality theory, on the basis of which he developed four temper dimensions (harm avoidance, sensation seeking, reward dependence, perseverance) and three character dimensions (self-directedness, cooperativeness, and self-transcendence).

Fiske (1949) introduced a five-factor personality model, known in the English-speaking world as the Big Five (Costa and McCrae 1990). According to this model, there are five robust personality factors, i.e. neuroticism, extroversion, openness to new experiences, sociability, and conscientiousness. Von Zerssen (1994b) also includes piety as a sixth dimension and defines the sociability factor by its contrary pole, aggressiveness. The disadvantages of category-based operationalization are mostly avoided by a dimensional model, and empirical comparison of the two approaches suggests that the dimensional model is superior, at least as far as research is concerned (Rutter 1987; Widiger and Costa 1994).

Varying opinions of the dimensionality of personality disorders, as well as of the relationship between personality dimensions and personality disorders, also depend on which statistical tests are employed (Pukrop et al. 1998). Correlations are calculated, usually indirectly, using factor analysis assuming orthogonal dimensions factors, which are assigned on both a clinical and an intuitive basis. Recently, facet theory has been suggested to analyze the correlation between personality disorder and personality dimensions by

Table 1. Examination procedures for assessing personality disorders (after Bohus et al. 1999)

Type of examination	Instrument	Diagnosis systems	Source of data
All personality disorders			
Self-assessment	Personality Diagnostic Questionnaire (PDQ-R)	DSM-III-R/DSM-IV	P
	Screening Test for Co-morbid Personality Disorders (STCPD)	DSM-III-R	P

means of a similarities matrix between an a priori established semantic frame, the definitions system, and an empirical data structure, whose contents correspond to this system of definitions. Using this facet theory model, we empirically tested the structural similarity correlations between personality dimensions and personality disorders, confirming the continuity model and finding a meaningful relation between personality disorders and personality dimensions (Saß et al. 1995; Herpertz et al. 1997b).

7 Epidemiology, Course of Illness, and Prognosis

According to German and American studies, 3%–10% of the general population meet the diagnostic criteria for a personality disorder (Reich et al. 1989; Zimmerman and Coryll 1990; Maier et al. 1992). Compared to values seen in earlier personality diagnosis, these numbers are rather high. However, simply meeting

these criteria need not imply that the individuals are so dysfunctional and impaired as to require treatment.

Personality disorders occur more often in urban than in rural populations and tend to be more frequent in socially weaker populations. The overall sex ratio for all personality disorders is the same here, although some of them are seen more frequently in women, e.g., dependent and borderline personality disorders, while others are found more commonly in men, e.g., antisocial personality disorder (Merikangas and Weissman 1986; Weissman 1993). While these differences in frequency could indicate real gender differences, the confounding influence of social stereotypes and gender roles should not be overlooked.

Prevalence rates are much higher among nonselected psychiatric patients. After the first classification systems appeared, clinical studies found surprisingly high frequencies for personality disorders of 50%–80%, while more recent studies reported average prevalence rates of 40%–60% (Mellsop et al. 1982; Saß and Mende 1990; Oldham et al. 1992; Herpertz et al. 1994). Random samples in forensic psychiatry yielded prevalence rates of up to 80% (Dilling et al. 1984; Merikangas and Weissman 1986; Saß 1986). In a wide-scale international World Health Organization (WHO) study (Loranger et al. 1994), 39.5% of 716 psychiatric patients examined showed at least one personality disorder according to ICD-10, where individual prevalence rates fell between 15.2% (anxious personality disorder) and 1.8% (schizoid personality disorder).

The idea that personality disorders are permanent was always a part of the concept of abnormal personality and is also found in the ICD-10 and DSM-IV diagnostic guidelines. However, many authors criticize the postulate of temporal stability of personality disorders and stress the importance of situational factors. Instead of continuity and contextual independence, many cases probably exhibit a long, slowly changing course (Loranger et al. 1991). Recent overviews of empirical studies on the stability and changeability under pharmacological or psychosocial therapy partly confirm and partly refute earlier assumptions, considerable changes being observed especially with depressive forms (Sanislow and McGlashan 1998; Grilo and McGlashan 1999).

Clinical experience has shown that increasing age and decreasing vitality tend to attenuate hardened personality traits. This applies especially to those personality traits which seriously impair social functioning, such as inconstancy, dissocial behavior, autodestructiveness, and impulsiveness. Other traits can harden with advancing age, above all obstinacy and rigidity. Despite all their fundamental stability, personality disorders show more flexibility and adaptability than was earlier supposed. The degree of behavioral oddities depends on the particular situation and the demands to be met during the period of life in question, and developmental challenges can lead to a crisis. Thus, an anxious personality in early adulthood, faced with establishing autonomy, making decisions, and finding a meaning in life, will suffer acutely from its deficient social competence, a dependent or depressive personality will most likely suffer when having to cope with a loss or separation, while a histrionic personality will have great difficulties compensating age-related losses in looks and vitality.

Generally speaking, the risk of suicide is three times higher for individuals with a personality disorder than for the general population, with borderline, narcissistic, and antisocial personality disorders showing the highest numbers. These groups also show the highest degree of psychosocial impairment, with deviant actions, decreased capacity for work, and deficient skills at establishing dependable interpersonal relations. The latter is otherwise seen only in paranoids and schizoid personality disorder, with their severe tendency for social isolation. Still, catamnestic examinations over relevant periods of 10–30 years have shown sufficient social integration in two thirds of the patients even in these subgroups of severely disturbed, emotionally unstable personalities. The grave social dysfunction seen in borderline personality disorder and the repeated autodestructive actions, especially early in life, often lead to prolonged inpatient stays. Individuals with an anxious, dependent, or obsessive-compulsive personality disorder will confide in the family doctor, and occasionally in a specialist, but only with the onset of additional symptoms which warrant inpatient hospital treatment, such as anxious, dependent, or obsessive–compulsive personality disorders require. Individuals with other personality disorders, e.g., schizoid and paranoid forms, are unlikely to seek help by themselves.

The prognosis will depend on the particular type of personality disorder, any eventual comorbidity, and the degree of severity. Further prognostic factors are psychostructural maturity and the level of psychological and social functioning. In a catamnesis of 539 inpatients in the Federal Republic of Germany, Tölle (1966) found that about a third each managed their own life in a favorable, compromising, or unfavorable way, respectively. Histrionic, obsessive–compulsive, dependent, and insecure personality disorders had a good prognosis; despite an often difficult and drawn-out course of therapy, success has also been reported for borderline and narcissistic personality disorders. Prognosis is less favorable for schizoid, paranoid, and, notably, antisocial personality disorders. Prognostically favorable characteristics are motivation, trust in others, flexibility, and insight into one's own role in difficulties with interpersonal contact. Cases are com-

plicated by concomitant illness, especially addiction and affective disorders. Thus, the mortality rate for patients with personality disorders and substance abuse is three times that of patients with a single personality disorder (Bohus et al. 1999).

8 Basics of Therapy

The therapy of personality disorders employs psychotherapy, therapy with psychopharmaceuticals, and sociotherapeutic treatment. An important development in recent years has been the integrated, interdisciplinary approach (Saß and Herpertz 1999). Generally, the treatment of personality disorders requires time, as it involves the gradual reshaping of deep-seated characteristics pertaining to life, health, and social behavior. Crisis management becomes necessary if these personality traits generate problems or social conflict. It may be helpful if the patient's partner (spouse or family) can be involved. The choice of therapy will depend on the particular personality disorder and its degree of severity, as well as any concomitant psychiatric illness. The physician must always make a careful psychopathological and physical examination to detect any complicating somatic or psychiatric illness and to assess the need for medication. Psychotherapy relies mainly on supportive talks and behavioral techniques, to a lesser extent also on depth psychology and analytical therapy. In recent years, cognitive methods have gained much attention in the treatment of personality disorders, with differential indication and differential psychotherapy having become increasingly elaborated (Fiedler 1999). As far as the patient is concerned, this involves concrete, prototypic interactive disorders. Psychological and sociotherapeutic strategies can be used as complementing measures, e.g., to improve the patient's social situation or to initiate rehabilitation. Regardless of the method chosen, the establishment of a reliable, regular, and confidential therapeutic relationship is vital, as it provides the basis for one of the most important general therapeutic factors, which is the possibility of corrective emotional experiences. In addition to individual therapy, group therapy is increasingly being used now, but the patients must be compatible (Schmitz 1999; Rennenberg and Fydrich 1999).

The aim of pharmacological therapy, which is gaining in importance, is to influence the biological disposition toward dysfunctional behavior and perception. The theory can be traced back to Kraepelin and Kretschmer, who held that abnormal personality features are incompletely formed, weakened forms, or *formes frustes* of the two main groups of endogenous illnesses. This is why the psychopharmaceuticals used to treat schizophrenic and affective psychoses are also employed in the therapy of (probably) related personality disorders in order to reduce the neurochemical vulnerability to affective and cognitive dysfunctions. Pharmacological treatment is not an alternative, but merely a measure intended to support psychotherapy, although in some cases psychotherapy is only possible under the influence of stabilizing medication (Saß et al. 1998; Kapfhammer 1999; Kapfhammer and Rothenhäusler 1999). There is danger inasmuch as psychopharmaceuticals can lead to unrealistic expectations, chronic complaints about side effects, or parasuicidal actions. The possibility of supportive medication should be explained to the patient prior to the beginning of therapy. Possible detrimental effects which might carry over into the doctor–patient relationship also need to be considered. Sedatives should be approached with care, as their prolonged use can interfere with a patient's quality of life and, particularly, the ability to work. Utmost care must be taken to avoid dependence, and, except for acute crisis management, the use of benzodiazepines is particularly inadvisable for the treatment of personality disorders, which by definition have a long course of illness.

9 Individual Personality Disorders

The following section is based on the two main international classification systems. Due to the international preeminence of Anglo-American research, DSM-IV plays the leading role, but as the official diagnosis encoding system used in the German-speaking countries, ICD-10 will also be of great practical relevance as of January 1, 2000. A comment will be added wherever there is more than a slight divergence between the two systems. Further viewpoints regarding individual personality disorders will be dealt with in their own sections, which are also detailed here (e.g., Beck et al. 1993; Schmitz et al. 1996; Fiedler 1998; Bohus et al. 1999; Saß and Herpertz 1999). The section devoted to each personality disorder is divided into the historical development of the concept, a description of the clinical picture, diagnosis and differential diagnosis, prevalence, etiopathogenetic aspects, and therapy.

Since the first publication of DSM-III (APA 1980), a personality disorder has been assigned to one of three superordered clusters. Cluster A consists of personality disorders characterized by odd, eccentric behavior, i.e. the paranoid, schizoid, and schizotypal personality disorders. Cluster B consists of personality disorders characterized by emotional, dramatic, or moody

behavior, i.e., the antisocial, borderline, histrionic, and narcissistic personality disorders. Cluster C consists of personality disorders which can, in Kurt Schneider's terms, be described as anxious, fearful, or asthenic, i.e., the avoidant-insecure, dependent, and obsessive-compulsive personality disorders.

However, this cluster method, which was retained from DSM-III through to DSM-III-R and DSM-IV, has not yet been well validated empirically and is based mainly on descriptive similarities. On the whole, research by Saß et al. (1995) on a cohort of psychiatric patients with personality disorders using hierarchical cluster analysis confirmed the DSM grouping, as did research by other authors (e.g., Morey 1988), although the obsessive-compulsive personality disorder seemed to fit Cluster A better. This would seem plausible characterologically, as obsessive-compulsive subjects are characterized by rigidity, energy, perseverance and by emotional distance, similar to the other disorders in Cluster A.

9.1 Cluster A (Odd and Eccentric Personality Disorders)

9.1.1 Paranoid Personality Disorder

History

The term "paranoid personality disorder" describes a proximity to delusional (paranoid) disorders as well as to paranoid schizophrenia, but manifestations usually remain below the threshold of psychotic disorders. Paranoid features in the sense of odd personality features are mentioned in Kraepelin's textbook as "pseudo-grouch" (*Pseudoquerulant*) and "cantankerous," and Kretschmer (1921) referred to them as "expansive personalities." Kurt Schneider (1950a) mentioned the active and unrestrained nature of the fanatic and belligerent person, but also the quiet, eccentric, unrealistic, and purely fantastic forms in subdued fanatics.

Description

According to DSM-IV, individuals with a paranoid personality disorder show a pattern of distrust and suspicion, reading malevolence into the motives of others. This affects their perception not only of their friends' and their partner's loyalty and credibility, but also harmless comments and everyday behavior of people whom they come into contact with. People with a paranoid personality disorder quickly react to perceived insults with excessive force, counterattacks, and/or long-lasting enmity. They are especially sensitive about failure and supposed discrimination and are easily insulted, emotionally rigid, persevering, and belligerent, while at the same time appearing humorless and emotionally blunt. Typically, they attach exaggerated value to certain personal or imagined complexes, which can causing them to quarrel with others. Mistakes are usually blamed on others.

Typical Thinking

"I can't trust anyone," "they're trying to manipulate and exploit me," "they want to humiliate or annoy me" (Beck et al. 1993).

Differential Diagnosis

According to DSM-IV, the paranoid personality disorder is distinguished from the delusional disorder with paranoid delusion by the clearly delimited, persistent, and unrealistic delusions shown by the latter. The paranoid personality disorder, on the other hand, often shows a very real vicious circle of self-fulfilling prophecies, since the persistent distrust easily leads to information really being withheld or denied, which in the patient's mind confirms the suspicions. Occasionally, and especially during stressful times, a patient with a paranoid personality disorder may experience a loss of reality control for brief periods lasting from minutes to hours similar to that seen in psychotic episodes.

One of the special forms described by German authors is the (retiree) grouch. Sometimes, complex personalities – belligerent persons with a secret wound, a "thorn in the side" – develop a "fighting paranoia" (Kretschmer 1921). These "fighting paranoids" can be forensically important not only when they pester and insult courts and authorities, but also when they tend toward acts of violence, and extreme cases may need to be committed to an institution. Ideational fanatics follow an overvalued idea which they rank above everything else and may, depending on the times and circumstances, attain great religious or political significance or commit warlike terrorist acts and even induce others to commit (mass) suicide. In their biosocial personality theory, Millon and Davis (1996) distinguished five types of paranoid personality disorders: paranoid-narcissistic, paranoid-antisocial, paranoid-compulsive, paranoid-aggressive, and passive-aggressive and the decompensated form, the latter with schizophrenic tendencies.

Prevalence

According to studies employing DSM-IV, 0.5%–2.5% of the total population, 2%–10% of psychiatric outpatients, and 10%–30% of psychiatric inpatients showed paranoid personality disorders. Of a group of 291 outpatients with personality disorders, 22% showed a paranoid personality disorder according to DSM-III-R (Morey 1988). Using the International Personality Disorder Examination (IPDE), Loranger et al. (1994) found 2.4%, a clearly lower ratio. Regarding comorbidity with other personality disorders, the commonest are narcissistic personality disorder (2%–75%), borderline personality disorder (0%–100%), insecure personality

disorder (8%–86%), and passive-aggressive personality disorder (17%–53%) (Bernstein et al. 1993).

Etiopathogenesis
Seen psychoanalytically, delusion with projection plays a prominent role, at least with pronounced paranoid symptoms. The patient wards off conflict with his or her own aggressive impulses by transferring them onto others and perceiving them as persecution. Seen from a cognitive perspective, these paranoid patterns of behavior are an attempt at dealing with feelings of shame and humiliation. Paranoid individuals usually see themselves as being inadequate, incomplete, and useless, and so others are blamed for problems and difficulties in order to counteract these unpleasant feelings (Beck et al. 1993). Genetic findings are etiologically important, as the prevalence of paranoid personality disorder is higher among relatives of chronic schizophrenic patients and of patients with a delusional paranoid-type disorder (Kendler et al. 1984).

Therapy
See Sect. 9.1.4.

9.1.2 Schizoid Personality Disorder

History
Observing relatives of schizophrenic patients, E. Bleuler (1911) noticed that, even though they themselves had no psychotic illness, they did show certain behavioral peculiarities such as social isolation or a peculiar way of communicating and, like Kraepelin (see Sect. 4), suspected a transitional form with fluid borders between schizoid character and latent schizophrenia, with its typical thought disorders and social dysfunction. This led Kretschmer (1921) to hypothesize a continuum between premorbid personality features and schizophrenic illness, i.e., a transition from schizothymic temper to schizoid type and to psychosis. Bostroem (1926), on the other hand, disagreed with Kretschmer's hypothesis of a continuously rising degree of severity along a uniform schizoid dimension up to schizophrenia and held that, in this case, the development of specifically schizophrenic symptoms should be possible to predict from the oddities of an individual's character.

Description
The chief characteristics of the schizoid personality disorder are indifference and an inability to develop close emotional attachments to others, seclusiveness, and a reduced capacity for emotional experience and expression. Individuals with a schizoid personality disorder are shy, reserved, and seemingly indifferent to both praise and criticism. Bleuler vividly described schizoid persons as rigid, impenetrable, dry, and cold, as odd cranks, reserved eccentrics, cool and inwardly highly sophisticated aristocratic types, or scatterbrained, indifferent, and emotionally blunt odd fellows. Descriptions in Kraepelin's textbook are similar: he also noticed that dementia praecox patients often were particularly quiet and withdrawn as children.

Typical Thinking
"I feel better when I'm alone," "relationships confuse me," "I don't care what others think about me" (Beck et al. 1993).

Prevalence
The schizoid personality disorder seldom appears in a clinical setting, and prevalence lies well below 1%. According to field studies in the United States (Kalus et al. 1993), prevalence in the general population is 0.5%–1.5%. Regarding familial clustering, there is a higher prevalence of schizoid personality disorder among relatives of schizophrenic patients or those with schizotypal personality disorder.

Differential Diagnosis
The most difficult distinction to be made is that from mild forms of autism and Asperger's disorder, which also show reduced social contact, but tend to be noticed much sooner (see also Chap. 7, Vol. 3). The latter also show stereotyped or ritual behavior, motor mannerisms, and a narrowing of interests. Otherwise, schizoid personality disorder can also show brief psychotic episodes lasting a few minutes to a few hours when under stress, whereas in delusional disorders and schizophrenia these phenomena are permanent. In order to be able to make a diagnosis of schizoid personality disorder, the personality abnormalities must be present before and after the psychotic episode.

Regarding the other personality disorders, there is some overlap of symptoms with the schizotypal and the paranoid personality disorder, such as social isolation and affective narrowing, but the schizoid form lacks the cognitive losses and distorted perception of the schizotypal disorder, nor does it show the increased distrust and paranoid ideas typical of the paranoid personality disorder. It is important to distinguish it from the avoidant-insecure personality disorder, which also shows social isolation, but which in this case is due to social fear overriding a wish to engage in social contact. Schizoid individuals have little desire for social intimacy and therefore prefer to withdraw from it.

Etiopathogenesis
Regarding correlations to the schizophrenic spectrum, more psychological abnormalities were found around schizophrenia, but no significant increase in schizoid or schizotypal personality disorders. Nor is there an obvious familial clustering of personality types among relatives of schizophrenic patients which would point

to a homogenous schizoid dimension, but rather a quite heterogeneous set of abnormalities. In large-scale, albeit retrospective studies, Huber et al. (1979) and M. Bleuler (1972) found no clear premorbid schizoid personality features in two thirds and one half of the patients, respectively. Prospective high-risk studies also failed to show any significantly pronounced schizoid traits in children who later developed an illness of the schizophrenic spectrum compared to children who remained psychiatrically unremarkable (Parnas et al. 1990). On the other hand, von Zerssen (1994a) also noticed definite schizoid traits in patients showing personality disorders combined with high neuroticism. Generally speaking, although a survey across the schizophrenic spectrum revealed no close ties between schizophrenia-like premorbid personality traits and the severe forms in the sense of a specific schizothymic-schizoid-schizophrenic dimension, a clustering of general characteristics indicating mental susceptibility to disorders could be observed.

Seen psychoanalytically, schizoid individuals have particular difficulties expressing fear and enmity, which may be due to a troubled early mother–child relationship (Fairbairn 1940). Likewise, Arieti (1955) postulates that schizoid personalities develop a primarily defensive structure as a consequence of early problems, the patients being so sensitive to rejection as to repress the value of a relationship. Behavioral explanations also stress problems in dealing with feelings in the context of interpersonal relationships (Turkat 1990). The biosocial learning theory of Millon and Davis (1996) holds that pampering and protective parents teach their children to avoid stress. Lacking interpersonal experience, they are ill-equipped for handling conflicts and sticking them out, which further favors withdrawal and isolation.

Therapy

See Sect. 9.1.4.

9.1.3 Schizotypal Personality Disorder

History

The relationship of schizotypal personality disorder to schizophrenia is similar to that listed for the schizoid personality disorder. We would also like to refer to the history of the borderline syndrome, which has always included some "subschizophrenic" syndromes (see Sect. 9.2.2), as well as the schizophrenic spectrum and the borderline schizophrenia described in Danish family and adoption studies (Parnas et al. 1990).

The concept of "schizotypy," to which research by Hoch and Polatin (1949) on pseudoneurotic schizophrenia also contributed, was developed by Rado (1953) in the sense of a "schizophrenic genotype." In DSM-I (APA 1952), the schizoid personality disorder still included the now separate schizotypal and insecure personality disorder. Millon (1981) distinguished between schizoid-schizotypal and insecure-schizotypal personality variants. Spitzer et al. (1979) finally clarified the issue with their operational criteria for schizotypal personality disorder.

Description

The schizotypal personality disorder is characterized by even stronger deficits in establishing interpersonal contact than seen in the schizoid disorder. Furthermore, it shows peculiarities of perception, thinking, and behavior, disorders of attentiveness, selective attentiveness, and filtering of stimuli, cognitive gliding, and increased association via unusual selection and rating of information. Regarding language, there are unclear or strange expressions and incorrect use of words, though not to the point of associative loosening and incoherence. These individuals are loners, uncomfortable in the company of others, and do not have a good grasp of the usual means of communication such as eye contact, body language, etc. In addition, they show a pronounced fear of social situations and actively avoid them. People with this disorder often develop magic thinking, belief in the occult, and superstitions. They also tend to show odd behavior, as in their choice of dress and movement.

Typical Thinking

"I'm extremely uncomfortable when strangers talk to me," "when other people are talking, they probably have known each other for a long time and don't want me around," "I don't belong there" (Beck et al. 1993).

Differential Diagnosis

Due to close symptomatological and pathogenetic correlations to the schizophrenic spectrum, ICD-10 groups "schizotypal disorder" under schizophrenic and delusional disorders, and its symptoms overlap with those described for schizophrenia simplex in ICD-10. When distinguishing schizotypal personality disorder from social phobia in a differential diagnosis, it is important that individuals suffering from social phobia gradually relax when in contact with others, whereas those with a schizotypal personality disorder become increasingly uneasy. The schizotypal personality disorder is distinguished from schizophrenia, delusional disorder, or affective disorder with psychotic features by its lack of hallucinations and delusions. When distortions of thinking and perception occur, such as erroneous interpretation of coincidences, of comments by others, or of situations, individuals with a schizotypal personality disorder do not rigidly cling to them as do those with delusional disorders. However, similar to the paranoid and the

schizoid personality disorders, there can be brief psychotic episodes, especially when under stress. On the whole, the most difficult distinction to make is that from schizophrenia simplex or the residual type, and it should be borne in mind that it is not always possible to exclude a past schizophrenic episode with acute symptoms.

A differential diagnosis is particularly difficult in children showing social isolation, eccentric behavior, and unusual language. When making a differential diagnosis, it is important to consider autism or Asperger's disorder, as well as specific speech and communication disorders. Regarding other personality disorders, there are close similarities to the paranoid and schizoid personality disorder and further to the avoidant-insecure, narcissistic, and, above all, borderline personality disorder, which can also show psychosis-like symptoms, but is characterized by a completely different pattern of affective reactions and shows a different social behavior, social withdrawal, and avoidance of close friendships occurring only rarely.

Prevalence

According to DSM-IV, the disorder appears in 3% of the general population. There is a familial clustering inasmuch as schizotypal personality disorder tends to be commoner in first-degree relatives of schizophrenia patients, and a slight clustering of schizophrenia or other psychotic disorders has been observed in relatives of those with schizotypal personality disorder. However, the course of schizotypal personality disorder as defined in DSM-IV only rarely shows a transition to schizophrenia or another psychotic disorder.

Etiopathogenesis

Since the Danish high-risk studies on twins and adopted children, the schizotypal personality disorder is considered to be closely related to disorders at the core of the schizophrenic spectrum (Kendler et al. 1984). Family studies on schizotypal index subjects yielded corresponding findings (Battaglia et al. 1995). The hypothesis of schizotypal personality disorder as the expression of a genetically determined susceptibility to schizophrenia is supported by schizophrenia research employing biological markers, such as disorders of eye movement when following an object, disorders of attentiveness and information processing, and some abnormal social behavior.

Continuing Rado's (1953) search for a genetic component of schizophrenia, Meehl (1990) postulated an "integrative neural defect" which he called "schizotaxia" and which he saw as the only inherited factor. Individuals showing this trait were designated schizotypal or schizotypic, a term distinct both symptomatologically and theoretically from the purely descriptive DSM-IV term. Meehl believed schizotaxia to arise out of four central behavioral traits of schizotypal patients: cognitive gliding as the mildest form of the schizophrenic thought disorders; aversion toward interpersonal relationships and social fear due to a conviction of not being lovable; anhedonia with pronounced, general, and persistent impairment of the capacity for joy; and, lastly, a distinct ambivalence. The much-employed schizotypy questionnaire by Chapman et al. (1976), which is based on Meehl's concept of schizotaxia, encompasses 97 items for the three dimensions physical anhedonia, distorted perception, and magic thinking.

9.1.4 Therapy of the Cluster A Personality Disorders

Establishing an open, trusting doctor–patient relationship is of the utmost importance in psychotherapy. This relation can then be extended to relationships with others. In doing so, the considerable fear of closeness and commitment – which is also the reason why those with schizoid or schizotypal personality disorder in particular seldom seek out treatment by themselves – should never be forgotten. More usually, it is either because other people near them have taken the initiative or because there are further, strong fears, depression, or social difficulties which cause them to seek help. The distrust, the readiness to take offense, and the latent aggressiveness of patients with paranoid personality disorder require the therapist to have a great deal of patience, flexibility, and empathy. When treating patients with schizoid personality disorder, the main difficulties in establishing a therapeutic relationship are due to the fearful detachment, the inability to make contact, and the stunted affect.

Paranoid personality disorder should be treated using behavioral therapy. In view of the distrust and touchiness, care should be exercised when making references to the patient's background or psychodynamic interpretations. It is important to bear in mind the patient's tendency for erroneous interpretation of situations, the friend/enemy mentality, and specific styles of acting and interacting. Cognitive therapy requires considerable time before trust is established and the pathological thinking can be approached and dealt with (Beck et al. 1993). It is further important to improve the patient's psychosocial skills and structure his or her immediate social environment.

When treating schizoid personality disorder, the main goals are improving the patient's capacity for perception and for experiencing life more fully. This can be done using sensory, body awareness, and emotional refinement exercises. Behavior therapy should aim at training social skills and dealing with fear in social situations.

A similar approach is used for the schizotypal personality disorder, although patients tend to show cognitive distortions in thinking and in judgment, especially in interpersonal emotional situations. A combination of cognitive and behavior therapy is recommended for detecting and identifying automatic thinking and its underlying assumptions (Beck et al. 1993). The personality awareness of these patients is characterized by the belief that they are largely responsible for situations. Appropriate behavior can be shown in role-playing (acting out) and practiced in exercises involving social situations.

There are no strictly controlled studies on the pharmacological treatment of paranoid and schizoid personality disorders (Saß et al. 1998). Due to the similarities to schizophrenia shown by the schizotypal personality disorder, neuroleptics can be employed, especially with stronger schizophrenia-like symptoms, particularly since the recent atypical drugs cause fewer and less severe side effects. Concomitant depression, fear, agitation, or exacerbation of paranoid tendencies can be dealt with using symptom-oriented psychopharmacological therapy in all three disorder types. Anhedonia and lacking motivation have often been treated with tricyclic antidepressants and monoamine oxidase (MAO) inhibitors, but the new selective serotonin reuptake inhibitors (SSRI) should also be considered, although there is the danger of excessive dynamic activation and hence of causing a psychotic episode.

9.2 Cluster B (Emotionally Unstable Personality Disorders)

9.2.1 Antisocial Personality Disorder

History

The meshing of the concepts of abnormal personality and social deviance was treated in detail in the section on the history of ideas (see Sect. 3). The socially deviant personality forms are now given different diagnostic criteria, i.e., antisocial personality disorder (DSM-IV) and dissocial personality disorder (ICD-10), also called "psychopathy" by Hare (1970, 1991). The differentiation of personality disorders from pure dissociality without additional psychopathological peculiarities is of importance, especially in forensic psychiatry. This requires a distinction into more pathic and more dissocial abnormal personality variants (Saß 1987), thus yielding the following differentiation:

1. Personality disorders occur in individuals who suffer from their psychopathological peculiarities and/or whose social life is impaired by these peculiarities. Their symptoms resemble those of psychiatric patients in the strict sense.
2. Moreover, some of these individuals show a potential for conflict, as their social behavior is marked by deviance and delinquency and is evidently related to psychopathological abnormalities. Due to the close correlation between social deviance and psychopathological abnormalities, the designations antisocial personality disorder (DSM-IV) and dissocial personality disorder (ICD-10) would seem justified.
3. Some individuals show a clear and persistent disposition for deviant and delinquent behavior without psychopathologically relevant abnormalities throughout their life. This criminologically important core group corresponds to the "psychopathy" described by Hare (1970, 1991) in the strict sense: it usually shows a "dissocial character structure" (see below) and can now also be defined quite well biologically (Herpertz and Saß 1999b).

Only by means of a differentiation such as this can forensic questions of culpability, prognosis, and therapy (Saß 1987) be settled. On no account should we speak of a personality disorder when dealing with recurring social deviance and delinquency, as shown by chronic repeat offenders or professional criminals, since this diagnostic term can lead to erroneous connotations of an illness-like disorder.

Description

According to DSM-IV, the main characteristic of the antisocial personality disorder is a permanent and deep-seated tendency to infringe on and abuse the rights of others. Empirically, the "dissocial character structure" (Saß 1987) of these individuals shows the following: little introspection and self-criticism, lacking empathy, coldness, egotism, an exaggerated sense of entitlement, a paradoxical idea of adaptation, and weak or faulty social norms. Their behavior is marked by impulsiveness, unreliability, weak commitment, and an absence of guilt feelings.

Typical Thinking

"Other people are weak and deserve to be exploited," "if I want something, I'll do whatever is necessary to get it," "we live in a jungle where only the strongest survive" (Beck et al. 1993).

Differential Diagnosis

The DSM-IV definition of the antisocial personality disorder causes great difficulties when making a diagnosis, as can be seen from the rather high frequency of this diagnosis, the temporal stability of the diagnosis, insufficient consideration of symptom intensity, and the large overlap with the symptoms of substance abuse (Cunningham and Reidy 1998; Herpertz and Saß 1999b). Thus patients scoring high on Hare's (1991) psychopathology checklist also show a worse psychosocial adaptation and more attempts at

suicide in their case history (Anderson et al. 1999). Despite a continued development of the concept since DSM-III, the description in DSM-IV still lists only criminal and socially harmful behavior patterns without considering indicators of a deep-reaching personality dysfunction going beyond mere criminal acts. A further point of criticism is that insufficient attention is given to gender differences, as studies on antisocial personality disorder in women have shown that early onset of antisocial behavior in young girls shows only a weak correlation with antisocial behavior in adult women (Rutherford et al. 1999).

When making a differential diagnosis, an exclusion criterion is antisocial behavior occurring exclusively in the context of schizophrenia or a manic episode. On the other hand, an antisocial personality disorder often occurs together with conditions caused by psychotropic substances, in which case both diagnoses must be made. Regarding other personality disorders, the antisocial personality disorder is closely related to the narcissistic personality disorder, though the latter does not show tendencies for impulsiveness, aggressiveness, or cheating. There may be a partial overlap of symptoms with the histrionic, the borderline, and the paranoid personality disorder, although as a rule these do not show such lasting antisocial behavior.

Prevalence

Reports of prevalence are strongly influenced by spot checks and gender. In the general population, prevalence is about 3% for men and 1% for women. In clinical institutions it can be 3%–30%, with clearly higher values for addiction treatment centers or prisons. Studies on antisocial personality disorder (DSM-IV) in prison inmates gave a prevalence of 70%–100%, which would suggest that the category is too general (Widiger et al. 1996), whereas a study using Hare's psychopathy checklist (1991) on various forensic populations in prisons or psychiatric clinics revealed a diagnostic prevalence of 25% for psychopathy (Herpertz and Saß 1999b).

First-degree blood relatives of individuals with antisocial personality disorder show a higher prevalence of this disorder than the general population. Furthermore, there is a familial relation to somatization disorder and disorders linked to psychotropic substances, with somatization disorder being commoner in women. Studies on adopted children suggest the existence of a genetic component as well as environmental factors, since adopted children tend to resemble their biological rather than their adoptive parents regarding antisocial personality features, but the adoptive family also influences development toward antisocial behavior. The disorder can diminish in vitality with advancing age, usually from the 40th year of life onward.

Etiopathogenesis

The longitudinal study carried out by Robins (1966) on 500 difficult children showed that the best predictor for a later antisocial personality disorder is the extent of antisocial and aggressive behavior in childhood and adolescence. Rutherford et al. (1999), however, did not find general deviations from norm- and role-conforming behavior in young and adolescent girls to be reliable predictors of antisocial personality disorder in adults, but rather for antisocial traits in the strict sense of psychopathy (Hare 1970, 1991). Genetic studies on twins and adopted children suggest hereditary factors (Nigg and Goldsmith 1994). Constitutional risk factors (temper) include above-average body size, sensation seeking, and fearlessness (Raine et al. 1998). Impulsiveness also proved to be a strong predictor for an early onset of stable and pronounced delinquency (Tremblay et al. 1994). Psychophysiological risk factors for antisocial personality disorder are mainly weak electrodermal reactions in anticipation of danger or punishment or when reacting to it, indicating a low conditionability by fear and deficient avoidance behavior, while reward-related stimuli leads to a strong activation (Arnett et al. 1997).

Neurotransmitter research in the past 10 years has aimed at identifying the role of disturbed central serotonergic processes in aggressive and antisocial personalities. Regarding 5-hydroxytryptamine, which is important in behavior regulation, genetic research data indicate a relation between an "LL" genotype and impulsive-aggressive tendencies (New et al. 1998). Furthermore, central catecholaminergic activity (Coccaro et al. 1991) and testosterone (Virkkunen et al. 1994) have also been suggested to play an important role in aggressive behavior.

Therapy

Due to the pronounced aggressiveness and criminality of individuals with antisocial personality disorder, therapy is of great significance, not only for the individuals themselves, but for society at large. So far, however, results of the most varied programs have been disappointing, with similar results for the core group of psychopaths according to Hare, although for the more neurotic forms, psychodynamic and behavior therapy may offer hope. Of course, the typical behavior pattern seen in antisocial personality disorder – low frustration tolerance, impulsive behavior, short-term (immediate gain) rather than long-range thinking – is highly unfavorable for therapy. These individuals are very unreliable both in interpersonal and in therapeutic relationships. They usually do not seek psychotherapy of their own accord but on the urging or orders of others, as by court order or due to confinement in prison or a forensic psychiatric institution. Therapy is hampered by the institutional

setting and a possible tendency on the part of the patient toward manipulation and malingering, and Shapiro (1965) concluded that "psychopathic dishonesty and lying" and impulsiveness greatly limit the therapeutic possibilities in patients showing dissocial behavior.

Results of the sometimes more behaviorally, sometimes more psychodynamically oriented therapy programs for individuals with antisocial personality disorder cannot be assessed with certainty yet. Multimodal, well-structured treatment programs with cognitive and elements of behavioral therapy have tended to show positive results, whereas general group or liberal environmental therapy and unstructured psychodynamic and client-oriented sessions tend to be ineffective and may even be detrimental to prognosis (Andrews et al. 1995; McGuire et al. 1995; Müller-Isberner and Cabeza 1999).

9.2.2 Borderline Personality Disorder

History

The section on borderline syndromes (see Sect. 4) gives a description of the historical thought currents dealing with the heterogeneous "borderland." The current diagnosis of borderline personality disorder, first formulated in DSM-III (APA 1980), is based largely on the paper by Spitzer et al. (1979). Forerunners were the aggressive type of the passive-aggressive personality disorder in DSM-I (APA 1952) and the explosive/epileptoid personality disorder in DSM-II (APA 1968). Since it first appeared in DSM-III, the concept was not changed fundamentally, except that in DSM-IV (APA 1994, 1996) the original eight characteristics were complemented by the item "passing stress-caused paranoid ideas or severe dissociative symptoms."

Description

Because of its great clinical and theoretical relevance, the four most important symptom complexes of the borderline personality disorder are detailed here (Herpertz and Saß 1999a).

As experiments (Herpertz et al. 1997a) have shown, the affective instability derives from an overly sensitive reaction to low-grade but emotionally relevant stimuli, a high affective intensity, and a proneness to quick affective changes. The high affective reactivity leads to sudden, short-lived bursts of extreme mood swings. Clinically, it is further suspected that the affective excitement gradually fades away over a prolonged period of time (Linehan 1993). The affective outbursts take place under certain conditions which can almost always be elicited with the patient under behavioral and situation analysis, e.g., real or imagined experiences of abandonment and rejection. In addition, closeness is often seen as threatening. These typical situational triggers are due to an unresolved ambivalence between a need for attachment and a fear of loss of autonomy (Fiedler 1998).

Especially characteristic of borderline personality disorder is a alternating lifelong pattern of impulsively inflicting harm to oneself or to others, including suicidal actions, self-inflicted wounds, bulimic binge-and-purge attacks, periods of excessive alcohol consumption, and temper tantrums and fights (Zanarini et al. 1990). Unlike antisocial personalities, most patients try to restrain or suppress their impulses. These attempts at control, however, are crude, inflexible, and not based on long-term, stable motives and values suitable for controlling affective impulses and sudden impulses to act. This leads to unpredictable swings between a tense holding back of affective impulses on the one hand and sudden outbursts on the other (Herpertz and Saß 1997). Predominant emotions are dysphoria, anxiety, and anger, and patients with borderline personality disorder can also suffer from chronic feelings of emptiness.

Furthermore, patients with borderline personality disorder are characterized by a highly unstable image and perception of themselves, which can also include aspects of gender identity and manifest itself in form of oscillations between heterosexuality and homosexuality, sometimes also as transsexuality. A lack of orientation and plans for the future in borderline personality disorder can interfere with the patients' attempts at building an identity and cause them to drop out and change jobs frequently, but also result in indiscriminate choice of social groups or partners.

A further, important area are the dissociative or (pseudo)psychotic symptoms, whose inclusion as characteristics of borderline personality disorder and whose influence on the validity of the diagnosis remain controversial (Gunderson and Zanarini 1987; Widiger et al. 1992). Brief paranoid ideas or hallucinations have also been considered pathognomic (Zanarini et al. 1990), but other authors warn against a renewed jumbling of the concepts of borderline and schizotypal personality disorder (Serban et al. 1987).

Typical Thinking

"The world is dangerous and evil," "I'm helpless and powerless," "I'm unacceptable by nature," "I can't control my feelings and impulses" (Beck et al. 1993).

Differential Diagnosis

Contrary to earlier definitions, in DSM-IV the borderline personality disorder does not lie on a spectrum with affective and schizophrenic psychoses, although affective disorders often occur together and brief paranoid and dissociative episodes can occur under stress. The genetic link between the major affective disorders and borderline personality disorder postu-

lated earlier has again been challenged (Baron et al. 1985; Gunderson 1994; Torgersen 1994).

When making a differential diagnosis, affective disorders are of great importance, and borderline personality disorder can often resemble a depressive episode. These are not so much long-lasting, autonomous mood swings as are seen in affective disorders, but rather more intense emotional reactions to stimuli (Cowdry et al. 1991). Regarding the other personality disorders in the emotionally unstable cluster, there is considerable overlap with the histrionic personality, which also shows a craving for attention, manipulative behavior, and sudden mood swings, but fewer self-destructive acts, ended relationships, and chronic feelings of emptiness and loneliness.

Earlier, a narrower view was taken of correlations to the schizotypal personality disorder and to schizophrenia. A detailed exploration will allow a differential diagnosis in most patients. Findings that suggest borderline personality disorder include the brief duration of psychosis-like symptoms, their occurrence in an affectively highly charged context, and their connection to individuals close to the patient with whom a conflict exists. Sensory illusions are usually pseudohallucinations, which are distinct from true hallucinations since the patient recognizes them as abnormal, but still feels unable to control them. Far commoner than (pseudo)psychotic symptoms are dissociative experiences, such as childish and dissociative amnesias, less commonly also depersonalization and hypnagogic states. Severe dissociative states are of great symptomatological importance in patients who have massive traumatic experiences in their history.

There are similarities with the paranoid and narcissistic personality disorders, as such patients may also react with anger to slight stimuli, but show a more stable identity. The antisocial personality disorder shows similar manipulative behavior, but tends to use it mainly to gain advantages, whereas borderline patients use it primarily to gain the affection of significant others.

In contrast to DSM-IV, the borderline type in ICD-10 corresponds to subforms of emotionally unstable personality disorders. Similar to the "excitable psychopath" of ICD-9, the borderline type was included rather late in the drafting stage. Despite much overlap with the DSM-IV borderline personality disorder, there are clear differences. Thus ICD-9 mentions no dissociative or paranoid experiences, and feelings of emptiness and fear of abandonment are mentioned only in the research criteria. Aside from the borderline type, the emotionally unstable personality disorder of ICD-10 includes the impulsive type, which is characterized by deficient impulse and affect control, high excitability, and a tendency toward violent and threatening behavior, particularly in answer to criticism or rejection. Such a differentiation into two subtypes is not without problems, since these describe different, especially gender-specific expressions of a basically impulsive and emotionally unstable personality (Herpertz and Saß 1999a).

Prevalence

A prevalence of about 2% is reported for the general population, 10% for psychiatric outpatients, 20% for psychiatric inpatients, and 30%–60% in clinical populations with personality disorders. A total of 70% of all borderline patients are female (Widiger and Weissman 1991). Frequency is five times higher among first-degree blood relatives than in the general population. A higher familial risk also exists for substance abuse, antisocial personality disorder, and affective disorders, with a close link to impaired impulse control. Especially in young adulthood, the disorder is characterized by persistent inconstancy and chronic instability, with loss of affect and impulse control, and there is a high risk of patients harming themselves, including suicide.

Etiopathogenesis

Interpersonal stressors, especially imagined or real rejection or abandonment, trigger intense basic affective reactions such as fear, anger, or despair, as could be shown in affect induction trials (Herpertz et al. 1999). Cognitive distortions such as dichotomous thinking and generalizations cause a further exacerbation of affect and affective dedifferentiation up to strong dysphoric affect, which can lead to self-injury or bulimic binging.

The central symptom of self-injury, seen particularly in female borderline patients, is often due to an attempt to reduce unbearable tensions (Herpertz and Saß 1994). These feelings lead to a quick reorientation and a suspension of body awareness disorder right up to analgesia. In many patients, the typical course of buildup and release of tension soon leads to a habit of self-injury via operative learning (Herpertz and Saß 1999a). The tension reduction model for self-injury has now become widely accepted (Favazza and Simeon 1995; Feldman 1988) and could be proven by laboratory measurements of psychophysiological parameters (Haines et al. 1995).

Psychodynamically, problems of emotion regulation in borderline patients were seen as a consequence of a disorder that had occurred early in their development, with an emphasis on the so-called primitive defense mechanisms, especially splitting. This is why borderline patients have great difficulty in integrating ambivalent or ambitendential perceptions and emotions.

The proximity to the post-traumatic stress disorder (see Sect. 4) which has been postulated for borderline

personality disorder rests on similarities between the two regarding trigger events such as sexual abuse, manhandling, or neglect in childhood, despite many methodological doubts and the currently much-discussed false memory syndrome (Ernst 1999). Frequencies of 30%–40% are reported for physical abuse in patients with borderline personality disorder, and 25%–70% for sexual abuse (Silk et al. 1995). Further parallels between borderline personality disorder and PTSD are functional abnormalities of the autonomous nervous system, generalization of fear, and difficulties in forming habits and in purging conditioned reactions.

Therapy

Aside from the basics of building a therapeutic relationship, improving psychosocial skills, structuring the psychosocial environment, and treating dysfunctional behavior patterns, special therapies have been developed for borderline personality disorder, of which the dialectic behavioral therapy (DBT) of Linehan (1993) enjoys great popularity at present. Systematic studies have yielded much empirical data for standardized treatment and for therapy control and follow-up, while therapy manuals for depth psychology have been prepared only recently (Kernberg et al. 1999). Herpertz and Saß (1999a) recommend an interdisciplinary approach to psychotherapy with an interpretation of cognitive, behavioral, and psychodynamic methods.

In DBT (Linehan 1993; Bohus et al. 1999), various dynamically hierarchized problem areas are treated systematically in separate stages. Therapy begins with the patient being informed about the treatment, giving consent, followed by motivation and analysis of the aims. The first stage of therapy consists in dealing with suicidal and parasuicidal behavior and with behavior harmful to the therapy and to the patient's quality of life, improving behavioral skills, consciously dealing with feelings, stress tolerance, and self-management. During the second stage of therapy, the post-traumatic stress disorder – which is routinely assumed to exist – is dealt with, while in the third stage the self-esteem is raised, and individual aims are developed and implemented.

According to cognition theory, borderline personality disorder usually shows rigid basic cognitive assumptions which cause a continued distortion of everyday information processing (Schmitz 1999). Dysfunctional schemes which act as self-fulfilling prophecies and thus impair self-control must be uncovered and dealt with by being placed in the proper context of the patient's biography. After dichotomous thinking has been eliminated, the continuum technique is applied: the patient is asked to give operational definitions of both extremes of a property, e.g., a person is trustworthy, as opposed to completely untrustworthy, and then to place actual people or relationships along the continuum thus defined (Beck et al. 1993).

Psychopharmacological measures can be used for acute crisis management when treating concomitant affective disorders, and long-term when seeking to improve impulse control, where SSRI are favored particularly. Recommendations for integrated pharmacological and psychotherapeutic measures are given by Kapfhammer (1999).

9.2.3 Histrionic Personality Disorder

History

The term "histrionic personality disorder" replaces the term "hysterical personality disorder" (Histrio was an actor in ancient Rome). According to Hoffmann and Holzapfel (1999), the historical forerunner of the histrionic personality disorder was the hysterical neurosis, which was always considered inconsistent and multifaceted, with conversion symptoms and dissociative phenomena in the foreground, and all descriptions have dwelled on the variety and diversity of the disorders (hysteria imitates disease). Otherwise, the term hysteria was abandoned as a category not only because of discrimination and labeling problems, but also because it could not be shown that hysterical symptoms, as originally postulated, occurred primarily in Oedipus conflicts. Kurt Schneider (1950a) described individuals with a tendency to dramatic, theatrical behavior, suggestibility, superficial and unstable affect, and a constant striving for esteem as attention-hungry psychopaths.

Description

The main characteristics of this personality disorder are a strong need for attention and recognition, suggestibility, and a tendency for affective instability and superficiality. Histrionic personalities have a sense for atmosphere, but also a tendency for dramatizing, falseness, and coquetry. They are largely unable to maintain a steadfast pursuit of goals and value orientation and are therefore inconstant, especially in relationships with other people and partners. Individuals with histrionic personality disorder seek to impress as something else and more than they are. Symptomatology and basic personality often show a dramatic bend, with a pronounced secondary hypochondria.

Typical Thinking

"If others don't like me or admire me, I'm nothing," "feelings and intuition are much more important than rational thinking and planning," "I get what I want if I dazzle or amuse others" (Beck et al. 1993).

Based on clinical observation as well as cluster and factor analyses, Millon and Davis (1996) distinguished five subtypes of the histrionic personality disorder:

- The theatrical types, who fascinate the opposite sex with their seductive skill and ability to slip into completely different roles
- The hypomanic types, who enthuse others with their lively, extroverted manner, but disappoint with their unreliability and irresponsibility
- The infantile types, who show a high affective instability and oscillate between dependent-childish and defiant-aggressive behavior
- The flattering types, who devote themselves to others in order to secure their recognition and love
- The cunning types, who employ superficial charm to manipulate others

Differential Diagnosis

Most important is the overlap with other personality disorders from the emotionally unstable cluster. According to DSM-IV, individuals with borderline personality disorder likewise seek attention, show manipulative behavior and changeable emotions, but characteristically also self-injury, outbursts of anger, chronic feelings of emptiness, and unstable self-image. The histrionic and the antisocial personality disorders share a tendency for impulsivity, superficiality, sensation seeking, egotism, seduction, and manipulation, but not the pronounced antisocial behavior coupled with gain seeking. There is overlap of the histrionic personality disorder with the narcissistic personality disorder inasmuch as both crave attention and recognition, but the latter lacks the emotional changeability and dramatic tendencies.

Clinically relevant, though uncommon (and usually preceding, less often following psychotic episodes of various origins), are the sometimes drastic "pseudo-hysterical" cases showing aggravation, conversion, dramaticism, and improper behavior.

Prevalence

A prevalence of about 2%–3% is reported for the general population and of 10%–15% for female in- and outpatients undergoing therapy. Women are clearly overrepresented, though less than with somatization disorders (Hoffmann and Holzapfel 1999). The prevalence in neurological clinics lies between 3.5% (Kapfhammer 1999) and 5.25% (Lempert et al. 1990). Conversion symptoms and histrionic behavior can occur throughout an individual's life, but more frequently in young adulthood, and lessening with advancing age.

Etiopathogenesis

Psychodynamically speaking, the typical personality traits are based on a "hysterical" form of resolving conflicts or of defense, the preferred mechanisms being repression and denial, which also cause the amnesias and perception disorders. There is affective shift and projection of unacceptable drives and impulses. According to Hoffmann and Holzapfel (1999), of etiopathogenetic significance are the increased tendency for identification and traits such as empathy, sensitivity, and theatrical skills, which can be positive, but also allow the individual to mimic a series of conditions. According to Nemiah (1995), dissociation – which Janet already considered to be closely related to psychasthenic and hysterical disorders – plays a central role, where hysterical mechanisms of repression, denial and hyperemotionality, identification and identity shift can favor a "consciousness-impairing" effect.

According to the biosocial learning theory (Millon and Davis 1996), constitutionally fixed traits of extroverted and lively children and the interactions in the early psychosocial environment play a role, e.g., frequently changing significant others with a strong but short emotional contact, leading to a style of communication geared toward affect and effect. Cognitive behavioral therapy places an emphasis mainly on special cognitive affect-assessing processes. According to Beck et al. (1993), upbringing during infancy is important in shaping the histrionic personality, fearful and threatening situations being mastered by outward appearance and skillful role playing. In relationships, the individuals seeks to adapt perfectly to the expectations of others, yet the role played lacks self-confidence and inner conviction and remains highly dependent on a social echo.

Therapy

Psychoanalysis sought to resolve the classical Oedipus conflict, but also attempted to improve a deficient self-image (Mentzos 1982). By interpreting transfer and countertransfer processes, the therapeutic relationship was supposed to deal not only with the Oedipus conflict, but also with desires for attention and care. Today, more importance is given to modification by behavioral therapy of cognitions and affects and their interactions in the typical histrionic behavior and interaction pattern. Patients tend to fashion a rather poor identity of themselves, often with regressive changes toward childhood, helplessness, misery, and the need for support.

Further aspects to be dealt with are the global, impressionistic thinking, the craving for attention, and the dependence on recognition. The physician–patient relationship is in constant jeopardy by the patient's dramaticism, which can extend into the erotic realm. In the long run, there can be great problems when it becomes necessary to adapt to and accept aging and loss of attractiveness.

9.2.4 Narcissistic Personality Disorder

History

In psychoanalysis, narcissism was at first closely connected to an early or pre-Oedipal disorder in the development of the ego. Hartmann (1972), Kohut (1977), and Kernberg (1976) later developed the object-relation theories further, which eventually led up to the concept of the narcissistic personality disorder, which was included in DSM-III in 1980 for the first time. Subsequent studies have not proven very reliable (Gunderson et al. 1991), and the disorder has not yet been officially introduced into ICD-10, appearing only in the appendix. However, standardized examination tools have improved reliability over the past few years (Cooper and Ronningstam 1992), and the narcissistic personality disorder continues to be listed in DSM-IV.

Description

According to DSM-IV, individuals with a narcissistic personality disorder have a basically fragile self-esteem and so on the one hand revel in fantasy and grandiosity, feelings of superiority, and disdain of others, and on the other are easily offended, thin-skinned, and highly susceptible to the opinions of others. Patients with narcissistic personality disorder tend to involuntarily exploit others, thinking that their own qualities and abilities entitle them to special treatment. There is an exaggerated sense of entitlement, lack of empathy, and a strong need for recognition and admiration. Further symptoms are feelings of emptiness and futility, weak identity, and distrust. With a clearly increased self-awareness and egotism, social discomfort and fear of negative opinions predominate. A particular problem is the tendency toward depressive crises and resolute suicidality following an imagined insult.

Typical Thinking

"No-one has the right to criticize me," "since I'm superior to others, I'm entitled to special treatment and privileges," "other people should be happy to satisfy my needs" (Beck et al. 1993).

Differential Diagnosis

It must first be decided whether the feelings of grandiosity are a trait of the personality or whether they are due to a manic or hypomanic episode or perhaps to substance abuse. Criticizing or offending persons with narcissistic personality disorder can trigger depressive moods of the severity of a major depression. If all the criteria are met, both diagnoses are to be made.

The areas of overlap with other personality disorders are important, especially those in Cluster B. The main feature distinguishing the narcissistic from the histrionic, antisocial, and borderline personality disorders, whose style also includes coquetry, coldness, and social claims, respectively, is the narcissistic feeling of grandiosity. Further differences are the relative stability of identity in the narcissistic personality disorder and the absence to a large extent of self-injury, impulsiveness, and fear of abandonment, which are typical of the borderline personality disorder. The antisocial and the narcissistic personality disorders are similar in their coldness, slickness, superficiality, exploitation of others, and their lack of empathy, but the narcissistic personality disorder usually does not show precipitated actions, aggressivity, or deception.

Prevalence

According to DSM-IV, the narcissistic personality disorder has a prevalence of 2%–16% in clinical populations and below 1% in the general population. It is seen predominantly in men, with about 50%–75% of patients being male according to DSM-IV. Features can appear especially in adolescence, but without developing into a full narcissistic personality disorder later. Similar to the histrionic personality disorder, individuals with narcissistic personality disorder often have considerable difficulties coping with aging and the physical, mental, and professional losses associated with it.

Etiopathogenesis

Kernberg (1970) saw the typical narcissistic grandiosity and exploitation as a consequence of an "oral anger" arising from an early, pre-Oedipal disorder of psychosexual libido development. Emotional deprivation was hypothesized as the cause, with the grandiosity and entitlement being an exaggerated compensation and protection for a damaged self-esteem. Kohut (1977) saw narcissism in a more positive light and considered it a stage of libido in the course of a normal development, with pathological narcissism only arising with arrested development, e.g., following traumatic experiences, disappointment by the mother, or insufficiently met emotional needs. On the other hand, there is no certain evidence for these psychodynamic models of the origin of narcissistic disorder, as might be given by proof of neglect during certain stages of development in infancy and childhood.

According to the biosocial learning theory (Millon and Davis 1996), the development of narcissistic characteristics is not due to neglect by the mother, but rather to parental overvaluing and rewarding grandiose behavior, thus leading to an inflated identity and self-esteem in the child. The cognitive theory (Beck et al. 1993) suggests dysfunctional ideas about the self, the world, and the future, which would lead to distorted assumptions about one's own importance. These individuals see themselves as extraordinary and hence entitled to concentrate solely on satisfying their

own needs. Such feelings of grandiosity can be reinforced by a corresponding echo from the environment.

Therapy

The character traits of the narcissistic personality disorder cause considerable problems interacting with others, which also complicates therapy. Due to their sense of entitlement and low empathy, narcissistic personalities are not very popular, either with those around them or with therapists. Psychotherapy is initially best carried out singly due to the social touchiness and low frustration tolerance of these patients, where the therapist must gradually find out how much confrontation coupled with support the patient can take. Any threat to the patient's self-esteem can cause exacerbations and setbacks, which may result in discontinuation of therapy, but particularly in serious suicidality.

The first step in cognitive-behavioral therapy is establishing a therapeutic relationship. During this time, the therapist's authority may be challenged by the patient, with competition, downrating, and depreciation being common. The main goals of the therapy should be directed at the major components of the narcissistic disorder, i.e., the grandiosity, exaggerated sensitivity to other's opinions, and lack of empathy (Beck et al. 1993). One difficulty in the therapeutic dialogue lies in the dialectic thinking of narcissistic individuals with their strict either–or categories, the identity oscillating between great superiority and total worthlessness. It is important to slowly relativize the circular interpersonal consequences of the patient's self-centered behavior (Fiedler 1998).

9.3 Cluster C (Anxious, Avoidant Personality Disorders)

9.3.1 Avoidant-Insecure Personality Disorder

History

The term "insecure personality" was applied by Millon (1969) to individuals who, out of fear and distrust, actively avoid others, while in the schizoid personality disorder a similar pattern of social deficiency is due more to a passive remaining at a distance out of disinterest and lack of social initiative. In the German tradition, Millon was preceded by the descriptions given by Kretschmer (1921) of a "sensitive character," especially the "insecure psychopath" of Kurt Schneider (1950a), which is related to the depressive type. While the designation "avoidant personality disorder" in the DSM system particularly refers to the avoidant behavior, the German translation underlined Kurt Schneider's aspect of insecurity (Saß et al. 1996). The ICD-10 term "anxious (avoidant) personality disorder" covers both aspects, the insecurity and the avoidance, but the criteria further list the need for affection and being accepted by others.

Description

The avoidant-insecure personality disorder is characterized by a great fear of rejection and the constant effort to avoid unpleasant feelings and situations where these could arise. Despite their strong wish for affection, individuals with avoidant-insecure personality disorder avoid social relations; they are insecure, shy, tense, and anxious. Their feelings of inferiority in social contact lead to a severe restriction of their social skills and roles.

Kurt Schneider (1950a) described how, out of insecurity, people with low self-confidence frantically try to appear overly secure or conspicuous, but still have a guilty conscience and always seek the fault for everything in themselves. The excessive self-criticism of the ethically overscrupulous person is seen in the sensitive type described by Kretschmer (1921), which can even develop into paranoia. According to Kurt Schneider, the feelings of guilt and insufficiency and the overwrought conscientiousness and cleanliness of insecure and sensitive individuals can lead to compulsions, as are characteristic of anancastic psychopaths, and may sometimes be accompanied by sudden attacks of anxiety and dizziness or palpitations.

Typical Thinking

"I should avoid situations where I call attention to myself and try to be inconspicuous," "the unpleasant feelings will get worse and get out of control," "I'd never live it down if people uncovered my insecurity" (Beck et al. 1993).

Differential Diagnosis

This personality disorder shows the strongest similarity to social phobia, an example of how difficult it can be to distinguish between axis I and axis II disorders, particularly since therapy is identical for both. The overlap is ultimately due to the general criteria for personality disorder, i.e., contrary to social phobia, the avoidant-insecure personality traits must be permanent and deep-seated and must manifest themselves in different situations. In differentiating it from social phobia, Millon and Davis (1996) pointed out that, in the avoidant-insecure personality disorder, the ambivalence of socially aversive behavior is the central aspect, as well as the low self-esteem and the desire for social contact. Social phobia patients, on the other hand, show more a pattern of avoidant behavior and a strong reaction to anxiety-triggering stimuli.

When making a differential diagnosis, it is important to keep in mind the other personality disorders located in the asthenic cluster. Common features are feelings of insufficiency, hypersensitivity toward crit-

icism, and a need for recognition, but in the avoidant-insecure personality disorder the main concern is avoiding humiliation and rejection, while the dependent personality disorder is characterized mainly by its need for being cared for.

It is unclear both theoretically and empirically how the avoidant-insecure and the schizoid personality disorders are related. There are contending notions: on the one hand, it is held that the schizoid personality disorder is a variant of a more general avoidant-insecure personality disorder (Reich and Noyes 1986) or that both are variants of one and the same personality disorder (Livesley and West 1986), and on the other hand that they are two perfectly distinct personality disorders (Millon 1981; Trull et al. 1987). Patients with schizoid or schizotypal personality disorder also show social isolation, but seem to be content with this and even prefer it, whereas those with avoidant-insecure personality disorder do have a need for social contact and suffer from their loneliness.

Prevalence

Comparing various studies, Widiger (1992) found a prevalence of avoidant-insecure personality disorder (DSM-III) of 5%–35% in psychiatric populations and of about 1% in the general population. Social phobia (generalized type), dependent personality disorder, and affective illnesses play a role in comorbidity.

The disorder often begins in infancy or in childhood, with shyness, isolation, and fear of strangers and new situations. Social relations marked by shyness and insecurity can also appear in adolescence and young adulthood. With increasing life experience, these traits sometimes decrease with age.

Etiopathogenesis

Both Siever and Davis (1991) and Millon and Davis (1996) postulate a genetic component of the avoidant-insecure personality disorder. According to the biosocial learning theory, the disorder is based on a combination of a biologically determined increased readiness for fear and special social experiences, such as a perception of insufficient fear regulation and poor social support when faced with demands (Millon and Davis 1996). Kurt Schneider (1950a) saw a proximity to affective disorders for forms with a pronounced depressive component.

Interpersonal etiology models can be traced back to Horney (1945), who considered an original feeling of anxiety an expression of helplessness in the face of a parental upbringing style, and to Sullivan (1953), who pointed to difficulties in regulating self-esteem. Avoidant behavior and social isolation would thus be consequences of a protection mechanism against increased interpersonal fear in a conflict between seeking closeness on the one hand and fearing it on the other. According to cognition theory (Beck et al. 1993), insecure patients have deep-seated negative views of themselves which originate in childhood and are due to rejection and criticism on the part of significant others. This leads to social avoidance behavior as a defense mechanism against being exposed by others. Thoughts are avoided which are conducive to dysphoria, discomfort, fear, and sadness.

Therapy

The establishment of a therapeutic relationship is complicated by the patients' low self-esteem and fear of being disappointed, rejected, and criticized. Individual therapy is recommended, using empathy, caring support, and recognition to help the patient gradually build confidence and develop a certain tolerance for social situations. However, behavioral therapy approaches in group therapy of insecure personality disorder have also been tried (Renneberg and Fydrich 1999). In patients presenting affective distemper, psychopharmaceutics may be used (Kapfhammer and Rothenhäusler 1999), but benzodiazepines, although popular because of their anxiolytic action, should be strictly avoided.

9.2.3 Dependent Personality Disorder

History

Descriptions of individuals showing dependence, helplessness, lack of willpower, and a need to lean on others already appear in nineteenth-century case reports of abnormal personalities, yet without defining a distinct type. Echoes of the modern personality disorder can be found in Kurt Schneider's (1950a) weak-willed, unstable, insecure, and asthenic psychopaths.

DSM-I (APA 1952) described the dependent personality as a passive-dependent subtype of the passive-aggressive disorder, but this form no longer appeared in DSM-II (APA 1968). It was not until Millon's biosocial learning theory (1969) that passive-dependent behavior was recognized as one of eight basic personality types and was later included in the DSM-III (APA 1980). This was due to empirical examinations which, using factor analysis, identified a dependence factor with elements of passivity, submissiveness, and low self-confidence (Livesley et al. 1990).

In the ICD system, dependent features were earlier included in the "asthenic personality disorder," and the first version of ICD-10 (1991) still included a "dependent (asthenic) personality disorder." It was not until the second ICD-10 edition (WHO 1992), in agreement with DSM-III-R, that the term "dependent personality disorder" was listed as a category of its own. Conceptionally, it is closely related to "neurasthenia," which appears in ICD-10 but not in DSM-IV.

Description

The dependent personality disorder is characterized by an overpowering feeling of not being able to conduct one's own life. With a self-image of helplessness and weakness, patients seek support in all situations, from others and especially from their partner. They with a dependent personality disorder are hardly willing to assume responsibility for themselves. In a relationship, these patients experience a constant fear of loss and abandonment, coupled with efforts to adapt and to yield. They further show a cognitive distortion known as catastrophizing, i.e., a fearful and exaggerated estimate of the worst possible consequences should the relationship end. Important complications, which often are the reason for seeking therapeutic help, include depressive mood, as frequently occurs in the face of a possible or actual loss of a relationship, and anxiety disorders resulting from similar situations. Furthermore, patients, especially women, often show somatic complaints such as conversion symptoms, hypochondriac fears, and somatization syndromes. If alcohol and other psychotropic substances are taken for relief, there is the danger of addiction due to these patients' tendency toward passive conflict avoidance. In their personal relations, people with dependent personality disorder are adaptable, friendly, and submissive and may show considerable social skills in imparting feelings of importance, strength, and superiority to partners whose support they seek.

Typical Thinking

"If left to myself, I'd be helpless," "I can't take decisions for myself," "I shouldn't do anything that could hurt those who support and help me" (Beck et al. 1993).

Differential Diagnosis

Even when the concept was still being developed, it was already a constant source of criticism that characteristics of dependent individuals are shaped by certain social roles and apply especially to women (Kaplan 1983). The criteria describe a submissive form of dependence which tends to be associated with women, while dominating forms of dependence, such as occur more commonly in men, are less often diagnosed as disturbed or pathological, especially by male therapists. In dominating dependent behavior, others are instructed to do the work or make the decisions. A diagnosis of dependent personality disorder is not warranted if the dependent behavior rests on cultural values and role expectations.

In a differential diagnosis, it is important to keep in mind that dependence can occur as a consequence of affective disorders, panic disorder, or agoraphobia. Distinctive characteristics are the early onset, the chronic course of illness, and a behavior pattern which is not restricted to episodes of one of these disorders, but which can be observed throughout the entire development of the personality.

Dependent behavior can also occur in personality disorders such as the histrionic one, but such patients are distinctly dramatizing, demanding, self-centered, dazzling, and superficial, while dependent persons are docile and modest. Feelings of insufficiency, hypersensitivity toward criticism, and a need for protection and affection also occur in avoidant-insecure personality disorder, but without the readiness of dependent individuals to entrust themselves to others and to rely on them. Insecure individuals, on the other hand, tend to withdraw and avoid contact. Patients with depression and anxiety disorder who in addition show a personality disorder often exhibit a combination of dependent and insecure features (Mavissakalian and Hamman 1988).

Prevalence

The prevalence of dependent personality disorder in the general population is estimated at 1%–2%, and in clinical populations at about 10%. In psychiatric clinics, this is one of the most frequently diagnosed personality disorders. On the average, the frequency in clinical groups is about 20% (Morey 1988; Blashfield and Davis 1993).

Etiopathogenesis

Psychodynamically, the cause of dependent features was sought in a maternal behavior marked by lavish affection and excessive concern, especially early in development (Freud 1908; Abraham 1925). The fixation in the oral phase during psychological development, with a desire for pleasure and being pampered, was thought to favor a dependent behavior with poor initiative and an insistence on being cared for by others (Levy 1966). Winnicott (1965) saw the manner in which dependent subjects establish relationships as a consequence of failed identity development with the formation of a false or lost "self," leading to a helpless-insecure need for support. According to Esman (1986), there are also latent inimical feelings for the partners, with the exaggerated friendliness and submissiveness being seen as a means of maintaining the relationship. Bonding theory assumes an anxiety-laden behavior which can be traced back to unpleasant experiences in earlier relationships, with a constant fear of loss (Bowlby 1977).

Seen from a cognitive-behavioral perspective (Beck et al. 1993), dependent patients fear independence and self-reliance, have only developed a low level of self-confidence, and see themselves as helpless and incapable of life. People who underestimate their own abilities and only develop and train them marginally are increasingly ready to and in need of securing the

help of others. Due to this lack of autonomy, thinking oscillates between total helplessness and dependence and total independence and isolation.

The biosocial learning theory of Millon and Davis (1996) and Bornstein (1993) links psychodynamic and cognitive-behavioral explanations. Dysfunctional learning originates from authoritarian or overprotective parents, discouraging independence and self-reliance and instead favoring the development of a personality which needs stronger partners for protection and security. The constant reinforcement cements the fear of making one's own decisions, the increasing insecurity prevents the development of interests and their implementation, and the fear of making decisions further aggravates the cycle of dependence. This also favors the development of an often comorbid anxiety disorder and depressive moods.

Therapy aims at improving self-confidence and independence. The compliance, friendliness, and reliability of dependent patients are very helpful in establishing a therapeutic relationship. However, in view of this dependent behavior, it is important to avoid creating a codependence between patient and therapist (Benjamin 1993). At the same time, the positive traits of a dependent personality, such as good social integration and considerable professional and academic achievement, must be protected (Bornstein 1993). This can make for a high sensitivity and great stability in mutually supporting partnerships. Cognitive and behavioral therapy (Beck et al. 1993) aim at improving decision-making ability and foster patients' confidence in their own skills, a clearer perception of their own interests and possibilities for their implementation, and a gradual detachment from protectors. Role-playing and assertiveness training are helpful, as is including the partner in order to relativize dependence-encouraging behavior. Aside from individual therapy, which these patients prefer, group therapy is also indicated, both to learn from the behavior of others and to reduce dependence on the therapist. Use of the newly learned skills in society is encouraged when, after conclusion of therapy, the patient attends follow-up sessions at increasing intervals to support a gradual detachment from the therapist and to bolster confidence in the (difficult) task of leading an independent life.

9.3.3 Obsessive–Compulsive Personality Disorder

History

Obsessive–compulsive abnormalities of personality were described by Esquirol (1838), who spoke of a *délire partiel* within a *monomanie instinctive*. Disturbed emotions and impulses were central to Morel and Dagonet's view of obsessive-compulsive phenomena (Berrios 1995), while in Germany Griesinger first presented a case history with obsessive–compulsive phenomena, with Westphal describing the underlying ideations in 1877.

Kurt Schneider (1950a) classed these disorders with anancastic or obsessive–compulsive psychopaths as a subcategory of insecure psychopaths. The obsessions/compulsions stem from deep-seated feelings of insufficiency and guilt. These individuals live in constant fear of neglecting something or causing some damage, and the particular ideas are firmly rooted in the individual's wishes, values, and biography.

Since Freud's fundamental book *Charakter und Analerotik* ("Character and Anal Eroticism") (Freud 1908), psychoanalysis has seen a close connection or transition between the "anal character" and the obsessive–compulsive neurosis with well-developed symptoms. However, even psychopathologically, obsessive–compulsive traits were considered a premorbid character structure whose symptoms can progress in times of stress and lead to a full-blown illness (Weitbrecht 1963).

Description

The main characteristics of the obsessive–compulsive personality disorder are conscientiousness, perfectionism, rigidity, solidity, and conformism, which can be overvalued to the point of adversely affecting professional productivity and interpersonal relationships. These subjects show severity, seriousness, and rigidity both with themselves and with others. This stiff, morally demanding and rule-minded behavior is stubbornly held to and forced on those close to the patient. The person's own feelings and those of others, humor, and joy are all seen as suspicious and threatening. Human beings, life, and the world are seen in a negative light, and the only meaningful things in life are seen as being work, toil, and fulfilling duties.

Basically, the qualities of obsessive–compulsive personalities – such as love of order, perseverance, punctuality, and thriftiness – are socially desirable, but can be negative when exaggerated. This is the case when anxiety, scruples, weakness in making decisions, painstaking exactness and meticulousness, and inability to distinguish what is important from what is not interfere with social functioning. Exaggerated caution due to an inability to make decisions and a fear of responsibilities likewise impairs social functioning.

Typical Thinking

"If I don't observe my principles 100%, I'll drown in chaos," "the world's a dirty mess, I'm the only one who's clean and organized," "I must keep my feelings under complete control" (Beck et al. 1993).

Differential Diagnosis

The most important differential diagnosis concerns the differentiation from the obsessive-compulsive disorder, which, in contrast to the above-mentioned psychoanalytical and psychiatric traditions, plays in important role in modern classification systems. Factor analysis has allowed obsessive-compulsive symptoms to be distinguished from the obsessive-compulsive personality, even though they may overlap (Coursey 1984). Although inconsistencies remain (Zaworka and Hand 1981), a spectrum covering the obsessive-compulsive disorder and the obsessive-compulsive personality disorder has not yet been confirmed empirically. Both disorders show a tendency toward rituals, rigid behavior, an inability to distinguish what is important from what is not, and an impaired emotional expression. However, obsessive-compulsive disorder patients need not always show an obsessive-compulsive personality, but just as often exhibit insecurity and fear of criticism or punishment. In obsessive-compulsive personality disorder, the patients do not see their own thought and behavior patterns as particularly absurd, self-dystonic, and painful. They manifest themselves along a broad spectrum of situations and are more generalized than the circumscribed symptomatology of the obsessive-compulsive disorder. There are indications that, during times of great stress, some symptoms of the obsessive-compulsive personality "fall apart" and lead to an obsessive-compulsive disorder similar to that described by Kurt Schneider (1950a).

Of great importance are the interactions between the obsessive-compulsive personality disorder and depression. The negative philosophy of life and the misery associated with it can lead to distemper under stress. On the one hand, obsessive-compulsive personality traits can intensify during depression or appear as disturbing for the first time, e.g., in form of depressive insecurity, anxiety, and difficulties in making decisions; on the other hand, obsessive-compulsive behavior can lead to difficulties, and hence to reactive depression, where obsessive-compulsive personality traits and depressive symptoms are closely interwoven.

The obsessive-compulsive personality disorder overlaps with Tellenbach's "melancholic type" found in about 50% of all endogenous depression patients (Tellenbach 1983). Patients of this type are usually conscientious, dutiful, and perfectionist. In relationships, they show a need for harmony and adaptability, thus showing both obsessive-compulsive and dependent features. Inherent obsessive-compulsive tendencies can also appear in the prodromal phase of schizophrenic syndromes in an attempt at halting psychotic disintegration (Lang 1981).

Regarding other personality disorders, the narcissistic personality disorder also shows a tendency toward perfection and an annoyance at others not being able to do anything right, but narcissistic individuals lack the self-criticism that is common and at times exaggerated in obsessive-compulsive subjects. Like obsessive-compulsive patients, the schizoid personality disorder also shows an evident formalism, but in the obsessive-compulsive personality disorder this follows from overvaluing work duties and rules, whereas the schizoid personality disorder usually shows a decreased capability for intimacy and for experiencing feelings.

Prevalence

The prevalence in the general population is estimated at 2%, while among psychiatric inpatients obsessive-compulsive personality disorder shows a prevalence of 6%–9%.

Etiopathogenesis

Lately, the relation of obsessive-compulsive disorders to an exaggerated toilet training which was started too early (during the "anal phase") and failed, as is hypothesized in psychoanalysis, has lost ground. Instead, Shapiro's (1981) three elements in the psychodynamic structure of obsessive-compulsive personality disorder are now cited (Hoffman and Holzapfel 1999): first, the emotional independence of individuals with an obsessive-compulsive personality constitutes an affective I-don't-need-anyone self-sufficiency, in sharp contrast to hysteric subjects; second, obsessive-compulsives avoid independent decisions so as not to make any mistakes; and third, they have a feeling of being driven, of constantly having an imaginary foreman looking over their shoulder and finding fault with everything they do. More recent psychoanalytic hypotheses postulate less an anal-aggressive drive, but rather interpersonal tension between obedience (another's decision) and autonomy (one's own decision).

Taking an interpersonal perspective, Sullivan (1953) described an underlying insecurity in interactions in obsessive-compulsive personality disorder which causes the individual to be extremely meticulous and careful in fulfilling general rules and norms. The cognitive perspective points out the formalistic thinking and the narrowing to conventions, rules, schedules, and hierarchical structures. Beck et al. (1993) described as typical the tendency of seeing things as good/bad or right/wrong, with a decreased capability for making more subtle judgments and tolerating ambivalence.

According to Millon's biosocial learning theory (1981), the tendency of obsessive-compulsive personalities to conform stems from an excessively controlled upbringing. Attempts at independence or at behavior outside of that prescribed are punished; the child cannot develop its own identity and internalizes the

strict norms of its parents and other significant individuals.

Therapy

Psychoanalysis now plays a minor role. Instead, obsessive-compulsive personality disorder is now treated using behavioral therapy. First, an allowance must be made for the patient's needs for order, reliability, and regularity. Learning relaxation techniques and autogenous and other training can also be useful. Due to their rigid behavior and their striving for control and perfection, obsessive-compulsive patients can be quite a problem in group therapy, which is why individual therapy may be indicated at first. The patients must try to put earlier learning experiences and their lifelong striving for perfection in perspective. According to Beck et al. (1993), a series of basic cognitive assumptions can be described which may help to modify the obsessive-compulsive restrictions of behavior and emotions. These include the notions that no mistakes are allowed, that mistakes mean failure, that mistakes bring about criticism, that patients must completely control themselves and their surroundings, that every details counts, and that without rules and rituals everything is lost. Further cognitive distortions of obsessive-compulsive personality disorder which must be addressed are the dichotomous thinking, exaggeration, and catastrophizing while overvaluing one's own imperfections and flaws, the inability to concentrate only on what is relevant, and the tendency to always think in terms of "should" and "must," i.e., putting moral norms and expectations before one's own ideas and wishes.

There are interesting psychopharmacological possibilities as therapeutic aides, particularly SSRI antidepressants (Kapfhammer and Rothenhäusler 1999).

9.3.4 "Subaffective" Realm

An important and special area closely related to Cluster C are the transitional forms between the affective accentuations of personality and affective illness (Saß et al. 1993; Herpertz et al. 1998). In DSM-IV and ICD-10, all relevant changes of mood and drive are encoded as belonging to the realm of affective disorders, e.g., dysthymic and cyclothymic. Nevertheless, in the criteria of these DSM-IV axis I categories, the chronic form of symptoms is highlighted, which fits more a trait than a state character. Where a lasting course of these deviations is observed, it would therefore make sense to diagnose them as personality disorders, as has now been taken into account in DSM-IV with the reintroduction of the category of depressive personality disorder in the appendix.

These types of personality abnormalities which could be termed "subaffective" have a long history in the German tradition (Herpertz et al. 1998). Kraepelin (1903/1904) first described constitutional distempers and constitutional restlessness as independent psychopathic conditions, later however as favorable dispositions or attenuated forms of depression, mania, agitation, and cyclothymia. Kretschmer (1921) justified notions of a continuum of mental illnesses and in the affective realm described fluid borders between cyclothymic character, cycloid personality, and manic-depressive psychosis. Kurt Schneider (1950a) included lasting changes of mood and drive which had not yet reached proportions of an affective psychosis in his typology of psychopathic personalities as depressive and hyperthymic forms. The asthenic psychopath, who is characterized by low vitality and psychological and somatic weakness, also shows some overlap with the permanently depressive personality type and further with the modern somatization disorder.

In modern American diagnostic research, Akiskal and Akiskal (1992) have described a broad bipolar spectrum with episodic and chronic subaffective forms of varying degrees of severity. Patients with a cyclothymic temper are moody and impulsive and show unpredictable behavior without meeting the criteria of a bipolar manic-depressive disorder, which etiologically would seem to be endoreactive behavior, as Weitbrecht (1963) also postulated earlier for "endoreactive dysthymia." The hyperthymic temper, whose forerunners were the hyperthymic psychopath of Kurt Schneider (1950a) and the manic type of von Zerssen (1988), characterizes patients with a tendency toward euphoria, who are enterprising, and who have a positive mood and self-image up to intermittent hypomanic episodes. Due to their high activity and efficiency, these individuals often are very successful professionally and require psychiatric help or psychotherapy only when symptoms are greatly exacerbated. Subjects with a depressive temper show a permanently depressed subaffective constitution, which corresponds to the optional depressive personality disorder in DSM-IV.

Despite its clinical plausibility, the concept of independent subaffective personality disorders has once again been strongly challenged by recent empiric research (Pepper et al. 1995; Rihmer 1999). Black and Sheline (1997) found that scores for personality disorders improved in depressive patients following psychopharmacological therapy. Empirically, the depressive personality disorder shows overlap especially with dysthymia and was linked to a poor prognosis for course of illness of affective disorders (Klein and Shih 1998). Similar to Angst (1988), Akiskal now also sees the subaffective personality disorders as mild, chronic, fluctuating subsyndromal forms of a primary affective illness with a stronger biological basis (Akiskal et al. 1997).

10 Outlook

Summarizing the current knowledge on personality disorders, a considerable heterogeneity can be seen both theoretically and empirically. There is no consensus either on the relationship between normal personality, accentuated personality, and full-blown personality disorder, nor on whether a more dimensional or a more prototype- or category-oriented recording method is best. There is controversy concerning the circumstances under which these conditions arise; in addition, knowledge on comorbidity and course of illness is not perfectly consistent, and therapy employs a variety of methods. In Germany, the psychiatric view of personality disorders meets with considerable criticism from clinical and differential psychology and – with some noteworthy exceptions (Fiedler 1998; Schmitz et al. 1996) – may even be ignored as a nuisance.

What does the future hold? Substantial developments are most likely to come from a combination of modern diagnostics and pathogenetic studies. Relevant questions currently concern the relationship between category-based and dimensional descriptions of personality, a hierarchization of the classification structure of disorder characteristics, overlap or distinction between normal and abnormal personality, differentiation of trait versus state characteristics, and not least the importance of genetic and nongenetic influences on the development of personality. A critical observation of the personality factors developed so far and their relation to the personality disorders reveals only poor agreement (Dyce and O'Connor 1998), but recent data point the way (Jang et al. 1996; Clark et al. 1997; Livesley et al. 1998). The hierarchically organized personality model appears well-founded, consisting of four broader higher-order traits, i.e., emotional dysregulation, dissocial behavior, inhibition, and obsessive–compulsiveness, plus 18 more specific lower-order traits. This four-factor solution does not, however, include the dimension "openness to experiences" which figures in many other personality models (Widiger 1988; Livesley et al. 1998).

One objection raised by Livesley et al. (1998) to the model is that individuals simultaneously showing schizophrenic or affective disorders are excluded. This marks a departure from many other studies and from the principles of DSM-IV, where the independent assignment of axis II diagnosis and axis I disorder was always considered very important. Thus it is likely that personality disorders which could show a relation to axis I disorders are underrepresented, which would warrant further research on clinical groups.

The Livesley factors are stable across clinical and nonclinical groups as well as pairs of twins, but otherwise support a general dimensional model, in which personality disorders do not differ qualitatively from normal personality variants, but are merely seen as maladapted extreme variants of general personality features. A systematic interpretation of category-based diagnosis of personality disorders and of the dimensional assessment of personality features might therefore be recommended, something which cannot be reconciled in a model of normal personality.

The current problems of personality research were essentially already presented by Kurt Schneider (1950a). *Klinische Pathologie* (1950b, "Clinical Pathology") advises caution, a recommendation which remains valid, and it therefore seems fitting to cite it at the end of this chapter: Personality disorders look like diagnoses, but this is really an unjustified analogy since individuals and personalities cannot be labeled diagnostically with the same precision as illnesses and their psychological consequences can. If anything, characteristics which stand out clearly can be described and highlighted, yet without having found any similarities to symptoms of illnesses. This emphasis follows certain perspectives, such as the patient's subjective condition, his or her perception of existence and life, and the conditions for development or specific difficulties in a certain sociocultural environment. In addition to the characteristics highlighted, the same individual has myriads of others, and it is easily overlooked that labeling a certain personality disorder may give the false impression that it refers to a person's whole psychological aspect, or at least the essential part.

Eating Disorders

1 Definition

The two major eating disorders are anorexia nervosa and bulimia nervosa. Substantial research and documentation are available for these disorders, which should be regarded as syndromes because they are not specific diseases with a common cause, common course, and common pathology.

Anorexia nervosa is a disorder characterized by weight loss, behavior directed towards losing weight, preoccupation with body weight and food, peculiar manners of handling food, intense fear of gaining weight, disturbance of body conceptualization, and amenorrhea.

Bulimia nervosa is a disorder in which the behavior of bulimia or binge eating is a predominant behavior. These individuals engage in some sort of compensatory behavior to counteract the potential weight gain from calories ingested during bingeing. They are also overly concerned about their physical appearance.

1.1 Diagnostic Criteria

The specific criteria for anorexia nervosa according to the *Diagnostic and Statistical Manual IV* (DSM-IV) are given in Appendix A (American Psychiatric Association 1994). Criterion A provides a guideline for determining the threshold which is considered "underweight," since there is no specific amount of weight loss associated with the other symptoms that constitute anorexia nervosa.

Anorectics demonstrate their intense fear of gaining weight by their intense preoccupation with thoughts of food and irrational worry about gaining weight. Criterion C describes the complexity of anorectics' disturbance of body conceptualization. Denial of illness is the hallmark symptom of this disorder. The last criterion is amenorrhea. There are two subtypes of anorexia nervosa: the bingeing/purging subtype and the restricting subtype. The latter is especially common in those who develop the illness under the age of 12.

The criteria for bulimia nervosa are more arbitrary and ambiguous compared with those for anorexia nervosa. There is no consensus on what constitutes a binge and how frequently bingeing must be in order to warrant a diagnosis of this disorder. Bulimic patients use a variety of behaviors to prevent weight gain; the most common is self-induced vomiting. Patients tend to estimate their worth in terms of body shape and weight. There are two subtypes of bulimia nervosa: the purging subtype and the nonpurging subtype. Appendix B gives the clinical criteria for bulimia nervosa.

1.2 Clinical Assessment

Current height and weight measurements are necessary for both anorexia nervosa and bulimia nervosa patients. Since there is no specific amount of weight loss associated with the other symptoms that constitute anorexia nervosa, criterion A of the diagnostic criteria merely provides a guideline for determining the threshold below which a person is considered "underweight." To determine a normal weight range for the patient, the clinician should consider the individual's body build and weight history. For children up to the age of 18, pediatric growth charts should be used. It should be noted that some children may not have weight loss, but still weigh less than their expected weight because they have failed to make weight gains while growing in height.

Many anorectic individuals deny their symptoms and are not motivated for treatment. Because of this, it is often necessary to interview family members or close friends to obtain an idea of their actual behavior. For example, they often deny an intense fear of gaining weight, but their behavior shows this fear by their intense preoccupation with thoughts of food and irrational worry about fatness. For example, they frequently look in mirrors to make sure they are thin and incessantly express concern about looking fat. They will take a great deal of time cutting up food into small pieces and rearranging food on their plates in order to eat less.

Anorectics' disturbance of body image is imbedded in a basic disturbed conceptualization of themselves. Anorectics tend to judge their self-worth predominantly by body shape and weight. Although some feel globally overweight, others realize they are thin but think certain parts of their body are too fat, particularly the abdomen, buttocks, and thighs. An overwhelming feeling of inadequacy and ineffectiveness is a core symptom of all anorectics. Their success at losing weight is an impressive achievement and boosts their self-confidence. This confidence and feeling of being in control of one area of their life augments the ability to deny the seriousness of the medical complications of their malnourished condition and thus enforces their belief that thinness defines their self-worth. Obsessive-compulsive behaviors often develop or become worse as the anorexia nervosa proceeds in severity. An obsession with cleanliness, an increase in cleaning activities, and compulsive studying are commonly observed in these patients. Perfectionistic traits are also common.

It is important to obtain a history of menstruation. In some adolescents who have never menstruated, the amenorrhea present is primary. Eating disorder patients, especially anorectics, are extremely unreliable about their menstrual histories. Many state they are

menstruating regularly because they do not wish to have the diagnosis of anorexia nervosa and they do not wish to be treated. Often, when these patients are hospitalized and observed carefully, it is obvious that they are not menstruating. In these patients, plasma levels of estrogen are low, as are levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This is caused by diminished secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus.

Many adolescent anorectics have delayed psychosocial sexual development, and adults often have a markedly decreased interest in sex with the onset of anorexia nervosa.

Most of the physiological and metabolic changes in anorexia nervosa are secondary to the starvation state or purging behavior. These changes revert to normal with nutritional rehabilitation and the cessation of purging behavior. In anorexia nervosa patients and bulimia nervosa patients who engage in self-induced vomiting or abuse laxatives and diuretics, hypokalemic alkalosis may develop. These patients often have elevated serum bicarbonate, hypochloremia, and hypokalemia. Patients with electrolyte disturbances have physical symptoms of weakness, lethargy, and at times cardiac arrhythmias. The latter condition may result in sudden cardiac arrest. Elevation of serum enzymes reflects fatty degeneration of the liver and is present in both the emaciated anorectic phase and during refeeding. Elevated serum cholesterol levels tend to occur more frequently in younger patients and return to normal with weight gain. Carotenemia is often observed in malnourished anorectic patients. Emaciation can also produce abnormalities in hematopoiesis, such as leukopenia and relative lymphocytosis.

Bulimia nervosa patients can have severe erosion of the enamel of their teeth, pathologic pulp exposures, loss of integrity of the dental arches, diminished masticatory ability, and an obvious unaesthetic appearance of their teeth. Parotid gland enlargement is associated with elevated serum amylase levels in bulimics who binge and vomit. The serum amylase level can be used to follow reduction of vomiting in purging patients who deny their vomiting episodes. Acute dilatation of the stomach is a rare emergency condition for patients who binge. Esophageal tears can also occur in the process of self-induced vomiting. This is usually accompanied by shock. Severe abdominal pain in the bulimia patient should alert the physician to a diagnosis of gastric dilatation and the need for nasal gastric suction, X-rays, and surgical consultation.

In bulimia nervosa and anorexia nervosa patients who vomit, ipecac may be used to induce vomiting. Cardiac failure can be caused by a cardiomyopathy from ipecac intoxication. This is a medical emergency that usually results in death. Symptoms of precardial pain, dyspnea, and general muscle weakness associated with hypotension, tachycardia, and electrocardiogram abnormalities should alert the physician to possible ipecac intoxication.

Patients who binge and purge, whether they be anorexia nervosa or bulimia nervosa patients, have a high comorbidity with major depression, alcohol and substance abuse, and other impulsive behaviors such as suicide attempts, self-mutilation, and stealing. Eating disorder patients may abuse amphetamines to decrease their appetite and lose weight. In summary, a good clinical assessment for an eating disorder patient must include specific inquiries into all of the core eating disorder symptomatology described above, as well as a comprehensive general psychiatric history because of the high comorbidity of these conditions with affective disorder, anxiety disorders, and substance abuse disorders. A serum electrolyte profile with amylase and liver enzyme levels is also essential. For eating disorder patients who have been ill for longer than 3 years, a measurement of bone density is important because of the high prevalence of decreased bone density in chronic dieting patients. This leads eventually to an increased incidence of fractures. It is important to remember that anorexia nervosa patients do not come into assessment and treatment willingly and that it is often necessary to obtain information from others in their environment (Halmi 1994).

1.3 Epidemiology

Conducting methodologically correct and meaningful studies of incidence and prevalence can be a serious problem. With a few exceptions, most of these studies on eating disorders have been conducted on restricted populations in very restricted areas of a country. Thus the true knowledge of incidence and prevalence of anorexia nervosa and bulimia nervosa within various countries is probably never known accurately. However, the studies mentioned below can give us an idea, which in some cases may be a close approximation to reality.

There has been a consistent increase in the incidence of anorexia nervosa in industrialized countries during the past three decades (Hoek 1993). For example, the most recent incidence study conducted in northeastern Scotland revealed that, between 1965 and 1991, there was almost a sixfold increase in the incidence of anorexia nervosa (from 3/100,000 to 17/100,000 cases). There are very few studies of the incidence of bulimia nervosa. In a large representative sample of the Dutch population in Holland, Hoek (1991) reported the incidence of bulimia nervosa as 9.9/100,000 per year during the period 1985–1986 and 11.4 during the period 1986–1989.

Prevalence studies of eating disorders are more abundant and easier to conduct. More recently, the prevalence of anorexia nervosa among young females in community populations has been estimated in a number of survey studies in countries such as England, Sweden, and Scotland. An average prevalence of anorexia nervosa in these countries, using strict diagnostic criteria, was 0.28% of young females (Hoek 1993).

Over fifty prevalence studies of bulimia nervosa conducted between 1981 and 1989 were reviewed by Fairburn and Beglin (1990). Those studies in which surveys and interviews were combined had a remarkably consistent prevalence rate of 1% for bulimia nervosa in adolescent and young adult women.

All studies show that eating disorders are rare among males. In clinical samples, the male to female ratio for eating disorders lies consistently between 1:10 and 1:20 (Hoek 1991).

Social and cultural factors are significant in influencing the prevalence and nature of eating disorders and dieting. The effects of the Western ideal of a slender body type have been particularly powerful. Individuals and groups who are exposed to this ideal seem to be at risk for developing an eating disorder (Crago et al. 1996).

Cross-cultural comparisons of anorexia nervosa and bulimia nervosa are fraught with the problems of correct translation of ideas and semantics. For example, in one study of Chinese patients, Lee et al. (1993) found they denied a fat phobia. However, 3 years later Lee et al. (1996) found that the majority of female Chinese undergraduate students reported feeling fat in their lower body. The authors conclude that a typically "Western" pattern of body dissatisfaction has overshadowed the traditional Chinese notions of female beauty based on the face. They further hypothesize that, in the context of a rapidly urbanizing Chinese society, this will predispose more females to weight control behavior and eating disorders. The major factors of self imposed weight loss or bingeing and purging behavior are of course present across all cultures and constitute the major criteria for the diagnosis of anorexia nervosa and bulimia nervosa. However, there may be subtle differences in the expression of these weight concerns across cultures.

1.4 Differential Diagnosis

For anorexia nervosa patients, it is important to ascertain that the patient has no medical illness that can account for weight loss. In rare circumstances, a patient may have both anorexia nervosa and a medical illness contributing to the weight loss. In such a situation, the diagnosis of anorexia nervosa is made by the positive criteria for anorexia nervosa, and both the underlying medical condition and the anorexia nervosa are diagnosed and treated as such.

Weight loss, peculiar eating behavior, and vomiting can occur in several psychiatric disorders. Weight loss frequently occurs in depressive disorders, which have several features in common with anorexia nervosa, e.g. feeling depressed, crying spells, sleep disturbance, obsessive ruminations, and occasional suicidal thoughts. However, a patient with a depressive disorder usually has a decreased appetite, whereas an anorectic patient denies the existence of an appetite. It is only in the severe stages of anorexia nervosa that the patient actually has a decreased appetite. The hyperactivity seen in anorexia nervosa differs from the agitated activity seen in depressive disorders in that anorectics' activity is planned and ritualistic, e.g. exercising programs, jogging, and cycling. The preoccupation with the calorie content of food, collecting recipes, and preparing gourmet feasts, which is typical of the anorectic patient, is not present in the patient with a depressive disorder. Unlike anorexia nervosa patients, those with depression do not have a fear of becoming fat or a disturbance in their body image.

Weight fluctuations, vomiting, and peculiar food handling may occur in somatization disorder. Generally, the weight loss in somatization disorder is not as severe as in anorexia nervosa, nor does the patient in the former disorder express a fear of becoming overweight. In addition, amenorrhea for longer than 3 months is unusual in somatization disorder.

Delusions about food in schizophrenia are seldom concerned with the calorie content of food. A patient with schizophrenia is not preoccupied with a fear of becoming obese and does not have the hyperactivity seen in an anorectic patient.

Chronic medical illnesses frequently associated with weight loss are Crohn's disease, hyperthyroidism, Addison's disease, and diabetes mellitus.

On rare occasions, a central nervous system tumor may be associated with bulimic behaviors. Overeating episodes also occur in the Klüver-Bucy syndrome, which consists of visual agnosia, compulsive licking and biting, an inability to ignore any stimulus, and hypersexuality. Another uncommon syndrome associated with hyperphagia is the Kleine-Levin syndrome, which is characterized by periodic hypersomnia lasting for several weeks.

2 Etiology and Risk Factors

A multidimensional model for conceptualizing eating disorders emphasizes the interaction of biological,

psychological, and cultural factors. Within each of these areas, research has identified factors that predispose, precipitate, or maintain the eating disorder.

2.1 Genetic Factors

Genetic factors include a genetic vulnerability or predisposition that could become manifest under adverse conditions, such as inappropriate dieting or emotional stress. The genetic predisposition could be a particular personality type, a tendency to susceptibility to psychiatric instability (especially affective or anxiety disorders), or a hypothalamic dysfunction.

In a series of 67 twin probands, Treasure and Holland (1989) found that the concordance for restricting anorexia nervosa was markedly higher for monozygotic (66%) than for dizygotic twins (0%). In a large population-based twin registry study, Kendler et al. (1991) showed that concordance for bulimia nervosa was significantly higher in monozygotic than in dizygotic twin pairs. In this study, rates of bulimia nervosa were found to be higher in individuals born more recently, giving a time cohort effect. In the first large uncontrolled study of siblings of anorectics, Theander (1970) found in a sample of 94 anorectic patients a risk of 6.6% for female siblings to be diagnosed with anorexia nervosa. In a large case-controlled design with rigorous methods of diagnosis, Strober et al. (1990) found a familial aggregation of anorexia nervosa and bulimia nervosa in the first-degree relatives of anorexia nervosa probands.

2.2 Neurobiological Factors

Most of the neuroendocrine changes in the eating disorders are directly due to dieting behaviors, weight loss, and other behaviors related to reducing caloric intake. These changes revert to normal with resumption of normal eating behavior and nutritional rehabilitation. A vulnerability for destabilization of some of the endocrine and metabolic mechanisms affecting eating behavior may influence the development of the full-blown eating disorder under stresses such as severe dieting. Increased corticotropin-releasing hormone (CRH) secretion in underweight anorectic patients and in normal-weight dieting individuals returns to normal with weight restoration. However, CRH is a potent anorectic hormone and may have a role in maintaining anorectic behaviors and initiating a relapse.

It is well established that the pituitary cells producing LH and FSH are understimulated in patients with anorexia nervosa because of hyposecretion of GnRH by the hypothalamus. Dysfunctions may be present in the neurotransmitter systems that influence GnRH release. There is considerable variability in the function of the hypothalamic–pituitary–ovarian axis in bulimia nervosa women. This is probably due to the fact that there is considerable difference in patterns of severe dieting and fasting in these patients. Some anorectic women remain amenorrheic for long periods of time (several years) after weight restoration. Studies have shown these women to be more psychologically disturbed compared to those that have a rapid resumption of menses.

It is well established that central serotonin pathways modulate feeding. Administration of serotonin antagonists produces increased food intake and subsequent weight gain; conversely, serotonin agonists decrease food intake. Kaye et al. (1991) found elevated cerebral spinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) levels in anorectic patients with long-term recovery compared with control subjects. Restricting-type anorexia nervosa patients are especially rigid, inhibited, ritualistic, and perfectionistic, and these are personality traits present in obsessive–compulsive personality disorder and to some degree in obsessive–compulsive disorder. It has long been speculated that serotonin system abnormalities are present in patients with this disorder, especially since their symptoms decrease somewhat with treatment using serotonergic antagonists. In the past year, three groups (Collier et al. 1997; Enoch et al. 1998; Sorbi et al. 1998) found that the -1438A 5-HT_{2a} allele was more common in anorectics than in controls. In two other studies, Campbell et al. (1997) and Hinney et al. (1997) did not find this to be true. An abnormality of serotonin functioning in anorectic patients may contribute to the development and maintenance of anorexia nervosa.

Both serotonin agonists and antagonists have been found useful as an adjunct treatment of anorexia nervosa. Cyproheptadine, a serotonin antagonist, has been shown to facilitate weight gain in anorectic patients. This drug most likely acts on hypothalamic appetite centers to decrease satiety and increase food intake. Clomipramine and fluoxetine (serotonin reuptake inhibitors) have been useful in preventing weight relapse in anorexia nervosa and may specifically target the characteristic obsessive–compulsive behaviors that are seen with food and weight control.

There is an association of low levels of CSF 5-HIAA with impulsive, suicidal, and aggressive behavior. Animal studies have shown that impaired serotonergic function leads to overeating and obesity. The bingeing and purging behaviors of bulimic patients are suggestive of impulse control and satiety-regulation problems. Several studies have reported impaired serotonergic function in bulimic patients. Specifically, bulimic patients have lower CSF 5-HIAA levels than

control subjects and blunted prolactin responses to meta-chlorophenyl piperazine (m-CPP) and to the serotonin agonist fenfluramine (Levitan et al. 1997; Jimerson et al. 1997). There seems to be enough evidence of serotonergic dysfunction in anorexia nervosa and bulimia nervosa patients to consider vulnerability in the serotonergic neurotransmitter system as a risk factor for the development of an eating disorder.

Norepinephrine facilitates eating in animals and has reduced functioning in both underweight and weight-recovered anorexia nervosa patients. This finding suggests that brain norepinephrine abnormalities may be a risk factor for the development of or relapse in anorexia nervosa.

Animal studies have shown a role for dopamine and opioids in modulating eating behavior and pleasure–reward responses to food. Anorexia nervosa patients have a reduced response of prolactin to chlorpromazine challenge and a growth hormone L-dopa challenge. This suggests that patients with anorexia nervosa have a defect in the negative feedback system in dopamine synthesis, such as impairment at the postsynaptic receptor site. Bulimic patients without a history of anorexia nervosa appear to have lower CFS levels of homovanillic acid and a less vigorous dopamine response to a clonidine challenge than bulimic patients with a history of anorexia nervosa. These findings suggest that abnormalities in the dopaminergic pathways could lead to decreased satisfaction after eating, which in turn may facilitate binge-eating behavior. The abnormal pleasure–reward response to food seen in both anorexia and bulimia nervosa patients could be related to dopamine and its role in self-stimulating or addictive behaviors.

Neuropeptides have a role in regulating satiety, appetite, mood, and neuroendocrine functions and thus may contribute to the pathophysiology of eating disorders. Opioid agonists increase and opioid antagonists decrease food intake in animals and humans. The opioid antagonist naloxone was found to decrease bingeing in bulimic patients, but the antagonist naltrexone decreased bingeing in bulimia patients only at doses high enough to produce hepatotoxicity. The opioids are linked with pleasure–reward systems, and it is therefore possible that bulimic patients are obtaining some relief from anxiety by bingeing–purging behavior, which may activate the opioid system.

Cholecystokinin (CCK) is secreted by the gastrointestinal system in response to food intake and provides signals to the brain via the vagus nerve. CCK both in the central nervous system and periphery promotes satiety. Both pre- and postprandial plasma CCK concentrations are normal in anorectic women. In some bulimics, there was an impaired plasma CCK response after a meal. It is likely that reduced CCK response is an epiphenomenon resulting from bingeing and purging behavior, since abstinence from these behaviors results in a normal CCK response.

Neuropeptide Y (NPY) and peptide YY (PYY) are found in the central nervous system and are potent endogenous stimulants to feeding behavior. Underweight anorectic women have elevated CSF NPY levels, which reduce to normal with weight rehabilitation. CSF NPY levels are normal in bulimic patients; however, CSF PYY levels are elevated after abstinence from bingeing and purging has occurred. These findings are somewhat puzzling. The elevated NPY levels in underweight anorectics are obviously not effective in getting the anorectic woman to eat. It may be possible that the elevated PYY levels in abstinent bulimics may be a factor contributing to relapse.

Vasopressin and oxytocin are neuropeptides from the hypothalamus; the former controls water-free clearance by the kidney and the latter promotes uterine contraction during parturition and milk production during the postpartum period. Oxytocin also appears to disrupt memory consolidation and retrieval, whereas vasopressin promotes the consolidation of learning. Oxytocin also inhibits vasopressin-induced release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. There are abnormalities in vasopressin secretion during hypertonic saline infusion in underweight and weight-restored anorectic patients and in bulimic patients. CSF vasopressin levels are high in underweight anorectic patients, and oxytocin levels are low. It is possible that a low level of oxytocin and a high level of vasopressin might work in concert to enhance the retention of distorted thinking and contribute to the anorectic patient's obsessional concerns about food. All of the above neuroendocrine findings and data are presented in a review article by Halmi (1995).

When the product leptin of the OB gene was identified, there was a rush to measure leptin levels in anorectic patients, since elevated levels of leptin were thought to cause weight loss. However, numerous studies have shown that leptin levels in anorectic patients correlate significantly with body mass index (BMI) and amount of adipose tissue. Thus emaciated anorectics have extremely low levels of leptin, which increase as patients gain weight (Eckert et al. 1998).

Because anorexia nervosa predominately starts during puberty (there is a bimodal peak for age onset at ages 14–15 and age 18), hypotheses have been generated associating endocrine changes at puberty with the cause of anorexia nervosa. Frisch (1985) hypothesized that a critical mass of fat tissue is necessary for normal gonadotropin effects and that an increase in fat tissue mass is associated with a weight increase at the time of menarche. Crisp (1984) developed the hypothesis that anorexia nervosa reflects an attempt to adapt to and

cope with maturational problems through the mechanism of avoidance of biological maturity. Crisp states that the reversal of the pubertal process is a psychological regression permitting avoidance of the self at a normal body weight. He noted that females who have an early menarche or who are mildly overweight are at a greater risk for developing eating disorders. Early menarche is usually associated with increased weight gain and change in body shape and can produce self-consciousness based on the obvious differences these young women show from their peers. This in turn can produce sensitivity to body image and an emotional vulnerability that makes them susceptible for dieting behaviors and the development of eating disorders.

2.3 Psychological Factors

Research on personality traits and psychiatric disorders in eating disorder patients is typically carried out after the eating disorder has developed. In some cases, studies have been done after patients have recovered from their eating disorder, but it has been difficult to determine whether personality features were a cause or a consequence of the eating disorder. Various studies of affective disorder in eating disorder patients have shown a lifetime prevalence rate of major depression that varies from 25% to as high as 80%. The evidence is less clear as to whether depression precedes and/or predisposes an individual to the onset of an eating disorder. At present, it can be said that major depression may precede, coincide with, or follow the onset of the eating disorder (Devlin et al. 1990).

High rates of anxiety disorders (36%–65%) have also been documented with anorexia and bulimia nervosa. Two studies found a lifetime prevalence of 65% (Halmi et al. 1991) and 60% (Toner et al. 1988) for anxiety disorders among eating disorder patients. Lifetime rates of an obsessive-compulsive disorder have varied from 26% to 44% in anorexia nervosa patients (Halmi et al. 1991; Toner et al. 1988). In a study of recovered anorexia nervosa patients, both Casper (1990) and Strober (1980) found that, compared to controls and to their sisters, anorectics with long-term recovery had greater obsessive-compulsive-like personality disorder traits. When assessed after the disorder, 23%–80% of anorectic patients received a diagnosis of personality disorder (Vitousek and Manke 1994). Restricting anorectics tend to receive cluster C (anxious-fearful) diagnoses (e.g. avoidant, dependent). By contrast, anorectic bulimics have an equal likelihood of receiving a cluster B (dramatic-erratic) personality diagnosis (e.g. borderline) or a cluster C one.

Diagnostic analyses have produced quite heterogeneous personality profiles of bulimia nervosa patients. It appears that no fundamental personality trait or traits have been identified as risk factors for the development of bulimia. Studies have shown the prevalence of personality disorders in bulimic patients have ranged from 21% to 77%, with diagnoses occurring most often in the dramatic-erratic cluster (cluster B). The rates of borderline personality disorder (BPD), in particular, have ranged from 2% to 47% (Wonderlich 1995). Most of the above psychological factors appeared to put individuals at risk for an eating disorder by increasing the likelihood that they will diet. Thus dieting itself is a major precipitating factor in the process of developing and maintaining an eating disorder.

It has been impossible to examine whether family conditions play an important role as risk factors in the development of eating disorders. Studies have been made of family interactions after patients have developed the eating disorders. In bulimic families, for example, studies have uncovered deficits such as lack of parental affection, negative, hostile, and disengaged interactions within the family, parental impulsivity, and family alcoholism and obesity (Strober and Humphrey 1987). Bulimic patients rate their families as conflictive, badly organized, noncohesive, and lacking in nuturance and caring (Wonderlich and Mitchell 1992). Anorectics perceive their families as stable, nonconflictive, cohesive, and with no lack of nurturance (Vandereycken et al. 1989). These patterns of interaction in the families of eating disorder patients are currently only descriptive and not explanatory.

Stressful life events may also be a risk factor for developing an eating disorder. There is controversy regarding the role of sexual abuse as a risk factor in the initiation of an eating disorder. Studies investigating the relationship between sexual abuse and eating disorders have produced highly discrepant results (Conners and Morse 1993). Overall, results suggest that approximately 30% of eating disorder patients have been sexually abused in childhood, and this figure is comparable to rates found in normal populations. Findings indicate that childhood psychological abuse in multiple forms increases the likelihood of lifetime comorbid axis I disorders and personality pathology among bulimic patients. A surprisingly low rate of sexual abuse has been reported among restricting-type anorectics relative to either bulimic anorectics or to normal-weight bulimics (Waller et al. 1993).

3 Course of Illness

The long-term studies of eating disorders are based on patient samples and do not include people who have eating disorders but do not get treatment. Therefore,

any generalization about the course of eating disorders can only be applied to patients who have presented for treatment. Long-term follow-up research indicates that the majority of patients with anorexia nervosa have ongoing problems with the illness (Eckert et al. 1995; Halmi et al. 1991; Theander 1985; Hsu and Crisp 1979). About one fourth recover from the disorder, one fourth stay chronically ill with no improvement, and about one half have partial improvement. Mortality rates at 10 years are 6.6%, and at 30 years are 18%–20% after presentation for treatment.

Since bulimia nervosa was first identified as a separate entity in 1979, there have been few long-term follow-up studies of this disorder. The majority of studies have had a 6-month to 2-years post-treatment follow-up. Keel and Mitchell (1997) reviewed 88 articles on the naturalistic and treatment follow-up studies of bulimia patients. Mortality rates for bulimia nervosa were estimated at between 0% and 3%. At a follow-up period of between 5 and 10 years, about 50% fully recover, while 20% continue to meet criteria for bulimia nervosa. Relapse poses a serious threat for bulimics, as about one third of recovered bulimics relapse within 4 years after treatment. About 20% of bulimics seem to sustain an unremitting bulimic illness.

3.1 Predictors of Outcome

In a 10-year follow-up study of 76 patients with severe anorexia nervosa, Eckert et al. (1995) established that those patients with partial recovery were more likely to have had bulimic symptoms at presentation for treatment with continuing bulimic symptoms through to the follow-up time 10 years later. In contrast, with the fully recovered patients, those with partial recovery expressed a greater preoccupation with weight and shape as well as being less well adjusted in their social, educational/vocational, and sexual functioning. Patients with an earlier age of onset recovered from the disorder more quickly. Some studies have found that a long duration of illness and very low weight at presentation for treatment are predictors of a bad outcome, and others have not found this to be the case. Most studies have found purging behavior to be predictive of a bad outcome.

In their review of research studies of bulimia nervosa, Keel and Mitchell (1997) concluded that personality disorders marked by problems with impulse control were associated with a worse prognosis in patients with bulimia nervosa. However, larger patient samples and longer-term follow-ups of bulimia nervosa patients are necessary to more accurately answer the questions regarding predictors of outcome in this disorder.

3.2 Standardized Assessments

The most reliable and accurate manner of making a correct diagnosis of anorexia nervosa or bulimia nervosa is by clinical interview using DSM-IV criteria. The structured clinical interview for DSM-IV axis I disorders and for personality disorders is a well-studied and frequently used semi-structured interview that is particularly helpful in establishing comorbid psychiatric disorders in eating disorder patients (First et al. 1995).

Two scales are especially useful for the documentation and measurement of the severity of core eating disorder symptomatology. The Eating Disorders Examination (EDE) is an interview for assessing current eating disorder symptoms and contains four subscales: restraint, eating concerns, shape concern, and weight concern. It also measures the frequency of binge eating and compensatory behaviors. The validity and reliability of the EDE have been well documented (Fairburn and Cooper 1984), and the instrument has been used extensively in treatment outcome studies of bulimia nervosa. The Yale-Brown-Cornell Eating Disorder Scale (YBC-EDS) is an eight-item scale assessing the severity of preoccupations and rituals common in the eating disorders. The YBC-EDS also has a set of six provisional items for assessing motivation for change. The eight-item scale and the motivational items have shown excellent reliability and convergent validity. The YBC-EDS is an easy-to-administer interview which is able to assess the severity of illness associated with the individual's unique eating disorder symptomatology (Mazure et al. 1994).

A pervasive feeling of inadequacy is common in both anorectic and bulimic patients. The Rosenberg Self-Esteem Questionnaire (RSEQ) is a ten-item self-report questionnaire with established validity and reliability and has been found in several studies to be a predictor of outcome for anorexia nervosa patients (Rosenberg 1979).

The Social Adjustment Scale (SAS) has a self-report version which assesses social functioning in several areas, including work, family relationships, social and leisure time, and economic functioning. It is widely used as a measure of general social functioning and has also been found to be a good predictor of outcome in eating disorder treatment studies (Weissman and Bothwell 1976).

Weight and height measurements are necessary for all eating disorder patients. From these measures it is possible to calculate the BMI (kg/m^2), i.e. weight in kilograms divided by height squared measured in meters. The BMI is widely used because it is a "standard score" of body mass. It is possible to set a

normal weight range across various countries and cultures by using this standard score as a measurement. Other medical assessments are discussed in the section on clinical assessments.

4 Treatment

The severity of illness will determine the intensity of treatment required for the eating disorder patient. Treatment levels range from a specialized eating disorder inpatient unit to a partial hospitalization or day program to outpatient care, depending on the weight, medical status, and other psychiatric comorbidity of the patient. Because most inpatients require intensive medical management and/or monitoring for suicidal and impulsive behaviors, controlled studies examining various treatment modalities are difficult to conduct and there have thus been very few of them. Medical management usually requires weight restoration, nutritional rehabilitation, rehydration and correction of serum electrolytes, and daily monitoring of weight, food and calorie intake, and urine output. Patients must be closely monitored for vomiting and drug abuse behavior.

Since patients with anorexia nervosa are resistance to and disinterested in treatment, there are very few outpatient controlled treatment studies. Open studies have indicated that a multifaceted treatment approach is the most effective, and this includes medical management, psychoeducation, and individual therapy utilizing both cognitive and behavior therapy principles. Controlled studies have shown that children under the age of 18 do better if they have family therapy. Nutritional counseling and pharmacological intervention can also be useful components in the treatment plan.

4.1 Pharmacotherapy

Medication is only a useful adjunct in the treatment of anorexia nervosa. The first drug used to treat anorectic patients was chlorpromazine. Surprisingly, there are no double-blind controlled studies to prove definitively its effectiveness in reducing core anorectic symptomatology and in inducing weight gain. Clinical experience has shown this medication to be particularly helpful in severely ill patients who are overwhelmed by constant thoughts of losing weight and have incessant behavioral rituals. Cyproheptadine in high doses (up to 28 mg/day) can facilitate weight gain in restricting-type anorectics and also has an antidepressant effect (Halmi et al. 1986). Some recent open studies indicate that fluoxetine may be effective in preventing relapse in anorexia nervosa.

Over a dozen double-blind, placebo-controlled trials of antidepressants, including desipramine, imipramine, amitriptyline, nortriptyline, phenelzine, and fluoxetine, have been conducted in normal-weight outpatients with bulimia nervosa. The dosage of antidepressant medication used was similar to that used for the treatment of depression. In all the trials, antidepressants were significantly more effective than placebo in reducing binge eating. In addition, the medication improved mood and reduced eating disorder symptoms, such as preoccupation with shape and weight. The abstinence rate from bingeing and purging in these studies was only 22%, which is disappointing. There are excellent reviews of these studies by Mitchell and deZwaan (1993) and by Walsh and Devlin (1992).

4.2 Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) principles can be applied in both inpatient and outpatient settings. CBT has not been systematically studied in anorexia nervosa patients. There have been a few controlled inpatient studies using behavior therapy, which was found to be effective in inducing weight gain. While effective in the short term, there are no data supporting the clinical effectiveness of behavior therapy as a sole treatment for anorexia nervosa. For a review of behavioral techniques in the management of anorexia nervosa, the reader is referred to Halmi (1984).

There are no large sample size, controlled studies of cognitive therapy in anorexia nervosa patients. Monitoring is an essential component of CBT. Patients are taught to monitor their food intake, their feelings and emotions, their bingeing and purging behaviors, and their problems in interpersonal relationships. Cognitive restructuring is a method patients are taught in order to identify autonomic thoughts and challenge their core beliefs. Problem solving is a specific method whereby patients learn how to think through and devise strategies to cope with their food-related and/or interpersonal problems. For a comprehensive review of CBT in the treatment of eating disorders, the reader is referred to Fairburn and Wilson (1993), Gardner and Bemis (1992), and Kleifield et al. (1996).

CBT is the first-line treatment for bulimia nervosa. It has been found to be the most effective treatment in over 35 controlled studies. About 40%–50% of patients are abstinent from both bingeing and purging at the end of treatment (16–20 weeks). Improvement by a reduction in bingeing and purging occurred in 70%–95% of patients. Another 30% of those who did not

show improvement immediately after treatment did show improvement to full recovery 1 year after treatment. In patients where depression was comorbid with bulimia, CBT was also found to decrease depression. For a review of these studies, the reader is referred to Mitchell and Raymond (1992). In bulimia nervosa patients, CBT interrupts the self-maintaining cycle of bingeing and purging and alters the individual's dysfunctional cognitions and beliefs about food, weight, body image, and overall self-concept.

4.3 Family Therapy

A controlled family therapy study by Russell et al. (1987) showed that anorectic patients under the age of 18 benefited from family therapy, whereas patients over the age of 18 did worse in family therapy than in the control therapy. There are no controlled studies of the combination of individual and family therapy. In actual practice, many clinicians provide individual therapy and some sort of family counseling for managing anorexia nervosa patients. A family analysis should be done on all anorexia nervosa patients who are living with their families. On the basis of this analysis, a clinical judgement can be made as to what type of family therapy or counseling is advisable. Family therapy is not widely used in the treatment of bulimia nervosa. This is probably due to the fact that most patients with bulimia nervosa are in their 20s and living away from their family of origin. There is a consensus, however, that families of younger patients should be involved in their treatment.

4.4 Medical Management

The medical management of inpatients is discussed under the general treatment heading. For the anorexia nervosa outpatient, regular weight monitoring is necessary. If there is any indication that the patient is purging, as with the bulimia patient, monitoring of serum electrolytes is important. Measurement of serum amylase is also useful in a patient who may be vomiting. For chronically ill patients, measurement of bone density will be an important indication of nutritional status and a risk indicator for the development of fractures.

The majority of patients with anorexia nervosa and bulimia nervosa are chronically inflicted with core eating disorder symptomatology of varying degrees of severity. While pharmacotherapy, CBT, and family therapy have produced effective interventions, they have not had impressive cure rates. Unlike substance abuse disorders or chronic medical illnesses such as diabetes, the eating disorders have elicited morbid curiosity but not empathy from sources funding treatment studies. Future treatment research needs to examine the combination of various treatment modalities and the sequential application of different treatments.

Appendix A. 307.1 Anorexia Nervosa

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g. weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of the expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D. In post-menarcheal females, amenorrhea, i.e. the absence of at least three consecutive menstrual cycles. (A women is considered to have amenorrhea if her periods occur only following hormone, e.g. estrogen, administration.)

Specify type:

- Restricting type: during the current episode of Anorexia Nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e. self-induced vomiting or the misuse of laxatives, diuretics, or enemas).
- Binge Eating/Purging type: during the current episode of Anorexia Nervosa, the person has regularly engaged in binge eating or purging behavior (i.e. self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Appendix B. 307.51 Bulimia Nervosa

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   (1) eating, in a discrete period of time (e.g. within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances

(2) a sense of lack of control over eating during the episode (e.g. a feeling that one cannot stop eating or control what or how much one is eating)

B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting or excessive exercise.

C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of Anorexia Nervosa.

Specify type:

- Purging type: during the current episode of Bulimia Nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.
- Nonpurging type: during the current episode of Bulimia Nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

CHAPTER 13

G. Kockott

Sexual Disorders

Translator: E. Taub

1 Introduction

Sexuality is a highly complex area of human behavior in which biological, psychological, and sociological factors all play a role simultaneously; the final result is a single, fused, unitary phenomenon that is, by nature, not exclusively biological, psychological, or sociological (Kinsey et al. 1948). The interaction of mental and biological factors is well known: according to the International Classification of Mental and Behavioural Disorders (ICD-10), sexual responsiveness is seen as a psychosomatic process. An example of this are varying social attitudes toward female sexuality, which range, even today, from acceptance in our culture to severe repression in some other cultures. It may be assumed that these differences in attitude cause differences in the sexual behavior of women in different societies.

In the late 1950s and early 1960s, Germany underwent a process of so-called sexual liberalization, which, fortunately, led to greater openness with regard to sexuality, but also to new norms, including norms of sexual performance, that created problems for many people. In recent years, the Western world has seen an increased prevalence of disorders involving diminished sexual pleasure, both in women and in men. Perhaps the cause is to be sought, at least in part, in the current sexual "oversaturation" by the mass media. An increase in disorders of sexual pleasure, specifically in women, has also been interpreted sociologically, in the light of the women's liberation movement, as a sign of women's resistance to continued male domination (Schmidt 1993).

The decision regarding which sexual behavior or behaviors to designate as deviant is very strongly influenced by sociocultural norms, which are highly divergent among different ethnic groups. Transvestitism is a paraphilia in Western culture, but transvestites are highly respected in other cultures, e.g. among some of the indigenous peoples of Southeast Asia. Among the Leptschas in India, sexual relationships are allowed between adult men and girls young enough to be legally protected from sexual contact in Western societies (i.e. below the so-called age of consent).

These sociocultural influences are taken into consideration in the international classification schemes. In the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) of the American Psychiatric Association (APA), it is recommended that clinical evaluation take account of the ethnic, cultural, and religious affiliation of the patient, as well as his or her social background, as these factors may influence sexual desire and the individual's expectations and attitudes regarding forms of sexual behavior (APA 1994).

The international diagnostic schemes, ICD and DSM, classify sexual disorders into three major types: functional sexual disorders, disorders of sexual preference (ICD-10) or paraphilias (DSM-IV), and disorders of sexual identity. These three types of disorder are discussed in the same order in both schemes.

Homosexuality, once regarded as a disorder in both schemes, is no longer listed as such in the DSM, from its third edition onward, or in the ICD, starting with its tenth edition. Homosexuality is now regarded as an alternative lifestyle that cannot be considered a disorder. It is therefore not discussed in this chapter on sexual disorders.

2 Functional Sexual Disorders

2.1 Definition and Classification

A functional sexual disorder is defined in DSM-IV as a disturbance in the course of the sexual response cycle or pain arising in the context of sexual intercourse (APA 1994). The term "sexual dysfunction" is used to designate those disorders for which a predominantly or exclusively physical cause is assumed, while impairments that are to be regarded as being of mental origin may be designated as functional sexual disorders (Sigusch 1996). The latter are defined more precisely as those impairments of sexual behavior and of the sexual experience, as well as of modes of physiological response, that make it difficult or impossible for both partners to have a satisfying sexual interaction, even though the necessary organic substrate is present, and there is no fixation on unusual sexual objects.

The causes of functional sexual disorders, particularly in older men, may range along a continuum from the exclusively physical to the exclusively mental, with a large intervening region of mixed or uncertain etiology. The diagnosis is frequently no more specific than the overarching category of functional sexual disorder.

The transition between healthy and impaired sexuality is a gradual one, because pathological abnormalities may appear in a given individual with varying frequency. There is also some variation in the limits of individual tolerance: one person may perceive a certain type of sexual experience as normal and unimpaired, while another may not. Two criteria therefore have to be fulfilled before a disorder can be said to be present:

1. A specific functional impairment exists.
2. The impairment leads to significant distress or interpersonal difficulties.

From the practical viewpoint of the therapist, it has proved useful to describe functional sexual disorders more specifically according to their form and content. In terms of content, disorders are classified by the phase of the sexual interaction in which they appear (Table 1), with reference to the sexual response cycle described by Masters and Johnson (1967). Formal descriptive criteria include the frequency of the problem (e.g. invariably present or only occasionally so), the circumstances and conditions of its appearance, and its duration and severity.

A diagnostic scheme for sexual problems such as that given in Table 1 has the advantage of providing precise and therapeutically relevant syndrome descriptions. At the same time, it serves as a set of guidelines for the evaluation of the patient.

A few formal characteristics of functional sexual disorders deserve special emphasis, because they provide clues to the diagnosis:

- *Primary versus secondary:* A primary disorder is one that has existed since the onset of sexual activity; a secondary disorder begins after an initial, asymptomatic phase. Secondary disorders sometimes have easily discovered causes.
- *Situation-dependent versus situation-independent:* Situation-dependent disorders occur only during certain sexual activities, e.g. only during attempted coitus, but not during masturbation. Situation-dependence is a very strong indication of a disorder of mental origin. Situation-independent disorders are those that appear during sexual activity of any kind, in which case a physical cause is more likely.
- *Partner-dependent versus partner-independent:* Partner-dependent disorders, i.e. those that occur only with a specific partner, are a very strong indication of difficulties with this partner alone.

2.2 Specific Disorders

Patients with *disorders of libido* have varying degrees of loss of sexual desire and loss of sexual interest, which may reach the extent of a marked aversion, leading them to avoid any situation with sexual overtones.

Table 1. Functional sexual disorders in the different phases of the sexual interaction (with ICD-10 and DSM-IV codes for disorders of nonphysical origin)

Phases	Disorders in men	Disorders in women
1. Appetite	Persistent and significant reduction of sexual desire (F52.0; 302.71)	
	Sexual aversion, disgust, anxieties (F52.1; 302.79)	
2. Arousal	Erectile disorders: strength and duration of erection inadequate for satisfactory sexual intercourse (F52.2; 302.72)	Disorders of arousal: intensity and duration of arousal inadequate for satisfactory sexual intercourse (F52.2; 302.72)
		Vaginismus: penile intromission impossible, or possible only with pain, because of paroxysmal constriction of the vaginal introitus (F52.5; 306.51)
	Painful sexual intercourse (dyspareunia): pain in the genital area during or immediately after coitus (F52.6; 302,76)	
3. Orgasm	Premature ejaculation: ejaculation before insertion of the penis into the vagina, upon insertion, or immediately afterward (F52.4; 302.75)	Difficulties with orgasm: orgasm never, or only rarely, achieved (F52.3; 302.73)
	Absent ejaculation: lack of ejaculation and anorgasmia, despite full erection and intensive stimulation (F52.3; 302.74)	
	Ejaculation without orgasm: ejaculation without pleasure and feeling of orgasm (F52.11; 302.70)	
4. Relaxation	Post-orgasmic mood abnormalities: irritability, inner unrest, sleep disturbances, depression, crying spells, abnormal sensations in the genital area, etc.	

These disorders are to be distinguished from various situations in which sexual interest may be reduced without any disorder being present. For example, sexual desire is physiologically lower in women in late pregnancy and in the post-partum period. Deliberate sexual abstinence, which the individual may impose on himself or herself for a wide variety of reasons, also does not count as a sexual disorder.

Disorders of libido affect women more often than men. In general, sexual disinterest has become a much more common diagnosis in recent years, as mentioned above in the Introduction.

In *disorders of male sexual arousal*, the penile erection either does not develop at all or is not strong enough or does not last long enough for satisfactory coitus to be achieved. Very often, penile tumescence is entirely adequate during foreplay, but diminishes markedly at the moment of attempted penetration; this is a strong indication of a psychological cause. If the erection is weak or of variable strength during so-called petting, or if it never occurs, and if this problem is situation-independent, i.e. also occurs during masturbation and involuntary morning erections, then a physical cause should be suspected. The opposite of this form of erectile disorder is priapism, an intense and long-lasting erection that may become painful. Priapism is now seen more commonly than it used to be as a side effect of a newly developed method of treatment, so-called intracavernous injection therapy (see Sect. 2.4.1).

In *disorders of female sexual arousal*, the so-called lubrication-swelling response normally occurring during sexual stimulation develops inadequately or does not occur at all. There are considerable individual differences in this response, but its complete absence is usually accompanied by a feeling of disappointment. Many women develop the usual physical responses to sexual stimulation but feel no subjective arousal. This is most likely to be interpreted as a form of defense against sexual experience. Isolated disorders of arousal are rare in women. They are often combined with disorders of libido and orgasm.

Vaginismus is an involuntary, reflexive contraction of the muscles of the pelvic floor and the outer third of the vagina which occurs during attempted coitus. Intromission of the penis usually becomes impossible. The contraction may be of variable intensity. In severe cases, even the insertion of a tampon or a gynecological examination is impossible. Most women with this problem are able to achieve normal orgasms through other forms of stimulation.

Pain during intercourse (*dyspareunia* or *algopareunia*) occurs very rarely in men. Pain is mainly felt in the glans penis. If no physical cause, such as phimosis, can be found, then this symptom is usually due to hypersensitivity of the glans or to an intense fear of the glans being touched.

Women suffer more commonly from pain during intercourse. This problem is usually due to a physical (gynecological) cause. The particular characteristics of the painful symptom are the key to the gynecological differential diagnosis. Dyspareunia may be the result of another sexual disorder, e.g. the absence of lubrication in the female under conditions of diminished or absent libido, or a disorder of arousal, may make the sexual act painful.

The various *disorders of ejaculation* may be divided into problems of timing and disorders in which the process of ejaculation itself is disturbed. Problems of the former sort should be classified as disorders of the male orgasm, because the timing of the experience of orgasm is abnormal, but the process of ejaculation itself is not. Such problems include the following:

- *Premature ejaculation (ejaculatio praecox, orgasmus praecox):* There is a gradual transition from sexual intercourse that is experienced as rapid, but not abnormal, to the disorder known as premature ejaculation. Premature ejaculation (or premature orgasm) in the male is best defined as a disorder in which the patient has little or no control over the temporal course of the process of ejaculation; he can no longer determine the moment at which ejaculation occurs.
- *Highly delayed or absent orgasm (male anorgasmia).* This symptom is rare; it may be an expression of psychological inhibition, or it may be caused by various medications, particularly psychoactive drugs, and alcohol. A delayed or occasionally absent ejaculation is a not uncommon and quasi-normal occurrence in advanced age.

Retrograde ejaculation (ejaculation into the bladder) and *ejaculation without orgasm* are due to disturbances of the process of ejaculation. These problems are rare and usually of exclusively physical origin, and we will therefore not discuss them any further in this chapter.

At most half of all women always or almost always reach orgasm during sexual intercourse. The degree of distress caused by the absence of orgasm is highly variable. Often, the occasional or even frequent absence of orgasm is not experienced as a problem.

We draw a distinction between *total* and *coital anorgasmia.* Women with total anorgasmia have never in their lives attained orgasm during any kind of sexual activity. They may describe varying degrees of sexual arousal without orgasm, but a feeling of dissatisfaction remains. These patients seem mostly to suffer from various anxieties connected to the experience of sexuality.

Women with coital anorgasmia may experience orgasm more or less regularly during masturbation, for example, but not during coitus. Despite their basic ability to reach orgasm, these women seem to suffer greater distress because of their problem than do women with other sexual problems. Orgasm during sexual intercourse is seen as the single right way to obtain sexual satisfaction. Fear of a type of loss of control often seems to play a role, i.e. the fear of "losing face" during the experience of orgasm. This may explain why the difficulty arises only in the presence of a partner.

Post-orgasmic mood disturbances are characterized by irritability, inner unrest, and lack of release of tension after sexual contact and are usually an expression of inadequate sexual satisfaction. The cause may lie in rejection of the partner or in a not yet recognized or accepted homosexual orientation.

We have seen that there is a marked difference between the functional sexual disorders of men and women. While such disturbances may be isolated problems in men, they are much more rarely so in women: the manifestation of a disorder is often the consequence, or sometimes the cause, of other problems. Only vaginismus seems to occur in isolation.

2.3 Causes

Published data on the relative frequency of organic sexual disorders and functional sexual disorders of mental origin are highly variable, especially with regard to male functional disorders. This is both because the patient samples in published studies are often not comparable and because sexual disorders may be of multifactorial origin.

Physical and mental causes often interact with each other in a "bundle of causes," in which case an either–or diagnostic decision cannot be reached. Thus the present author (Kockott 1981) found considerable anxiety regarding inadequate sexual performance among male diabetics with erectile dysfunction. The mental component added considerably to the sexual problems caused by diabetes. A group of investigators in France (Buvat et al. 1983) treated 23 patients who had erectile dysfunction and abnormal findings on pelvic arteriography, either conservatively with psychotherapy alone, or with arteriodilators, or with both. After 6 months of treatment, mild to marked improvement was found in all groups, including the group treated with psychotherapy alone. This example underscores the suspicion, often expressed in recent years, that a demonstrated organic pathology may not necessarily represent the single, determinative etiology of a sexual disorder.

An accurate establishment of the patient's past history and present symptoms by thorough history-taking remains the most important step in the differential diagnostic assessment of male sexual disorders, even now that new diagnostic techniques have been devised, such as the intracavernous injection test with Doppler sonography (see Sect. 2.4.1). A predominantly or exclusively mental cause is likely if the symptoms arose suddenly and then persisted in a situation-dependent manner. If it can be ascertained that problems with the patient's partner or other negative life events occurred at the same time as the onset of the disorder, then a psychogenic origin is still more likely.

The following rules of thumb may be kept in mind: Functional sexual disorders of younger men are usually largely or exclusively of mental origin, while physical causes are more likely to play a contributory role with increasing age and, in advanced age, may be the predominant etiology. Functional sexual disorders in women, as far as we are now aware, are usually of mental origin regardless of the age of the patient, except for dyspareunia. Interviewing the partner may be of great help in establishing the diagnosis. Partners can often recognize contributing mental factors more easily than the patients themselves.

2.3.1 Physical Causes

Sexual disorders occurring in connection with a physical illness may be caused by the illness itself, its sequelae, and/or the measures taken to treat it. The possibility of mental factors making a further contribution should always be considered (Schover and Jensen 1988).

The most common physical causes are vascular disorders (particularly in the male), neurogenic disorders, consequences of operations in the genital area, toxic influences (drugs, alcohol) and (less commonly) side effects of medications, and (very rarely) endocrine disorders.

Sexual disorders with physical causes, unlike psychogenic disorders, have specific manifestations depending on their cause: vascular disorders in the male predominantly lead to erectile dysfunction, while the rarer endocrine disorders lead to diminished libido. Local problems in women most often lead to dyspareunia.

Approximately 50% of men with diabetes mellitus have erectile dysfunction. It is debated whether diabetic women are also more liable to sexual disorders due to diabetes and its consequences. In most cases, diabetes-related erectile dysfunction is always present and is not associated with any major loss of libido. It appears independently of the severity or duration of diabetes. Its cause has not been unequivocally

identified, although there are extensive data to suggest that it is caused by diabetes-induced vasculopathy. The latter cannot be influenced by treatment of the diabetes itself. Acute diabetic crises may lead to the rare, transient erectile disturbances that are associated with a loss of libido; these can be alleviated by control of the blood sugar level. Erectile dysfunction may also be a psychogenic phenomenon in diabetic patients, a form of "self-fulfilling prophecy" that comes true because of the patient's strong expectation that it will happen.

In older men, arterial disease, hypertension, and cigarette smoking are risk factors for the development of erectile dysfunction of vascular origin. After a myocardial infarction, bypass operation, or mild stroke, 40%–70% of patients reduce their sexual activity and report diminished sexual interest, delayed orgasms, and erectile difficulties. Sexual problems are found particularly frequently in patients who feel very ill and are anxious about their prognosis. It may therefore be assumed that these patients' sexual interest is diminished both because of their general state of physical health and because of the depressive-anxious mental state produced by the experience of illness.

A number of neurological illnesses cause sexual disorders, usually in the form of disorders of arousal. These include disseminated encephalomyelitis, polyneuropathies of various causes, traumatic injuries of the spinal cord, and temporal lobe damage (alteration of sexual interest). In such cases, the neurological manifestations are usually much more prominent clinically than the sexual dysfunction.

Operations in the genital region may impair sexuality either by their direct physical effects or through the effects they may have on body image and body perception.

Transvesical prostatectomy often leads to retrograde ejaculation into the urinary bladder, while the experience of orgasm usually remains unimpaired. After retropubic prostatectomy, erectile disturbances may appear to a degree of severity corresponding to the radicality of the required surgery. They are, however, rarer than is often feared: approximately half of the patients in one study still had partial erections after the operation, and one quarter were sometimes able to achieve coitus (Schorsch and Spengler 1981).

Hysterectomy has no direct effect on sexuality. It may indirectly benefit the patient's sexual experience if she had still had residual fears of unwanted pregnancy before the operation. Understandably, it may affect sexuality negatively if the patient had still wanted to have (further) children. We have occasionally observed a severe depressive reaction, with impairment of the sexual experience, after hysterectomy, because the patients thought of themselves as no longer being complete women.

Mastectomy has a highly negative effect in approximately 50% of women in their feminine body experience. The great advances of plastic surgery in developing techniques of breast conservation and reconstruction will bring considerable relief to women undergoing mastectomy.

Approximately 50% of chronically alcoholic men have sexual difficulties of various kinds. The frequency of such difficulties in alcoholic women has not yet been investigated to the same degree of precision. Sexual dysfunction in such cases may have several causes. Alcohol reduces the serum testosterone level directly, alcohol-induced liver damage indirectly affects sex hormone production, alcohol-induced vascular changes may cause erectile dysfunction, and the personality changes brought about by alcohol abuse may create partnership problems that impair sexuality. The psychosocial effects of chronic alcoholism lead to further tension with the partner and family and may eventually cause the partnership to fail.

Medications, particularly psychoactive medications of various kinds, sedatives, anticonvulsants, and antihypertensive agents, cause sexual problems in many patients. There is hardly any medication for which no single case of an undesired, negative effect on sexuality has been described. For the great majority of these medications, no dose-dependence of the related sexual dysfunction has been established. It follows that other factors must play at least a contributing role. These factors may lie in the illness under treatment or in other areas yet unknown. The origin of sexual problems always involves an interaction of the medical treatment of the illness with the illness itself: 17% of untreated male hypertensives and 25% of treated male hypertensives suffer from erectile disturbances (a significant difference). Both of these percentages are significantly higher than the corresponding figure for the normal population (Bulpitt et al. 1976). The undesired effects of psychoactive medications are discussed in Sect. 3.

2.3.2 Mental Causes

Sexual disorders of mental origin, in contrast to those of physical origin, have no specific relationship to their causes: all currently known psychological causes have been found in all forms of sexual disorder. Furthermore, such disorders cannot be explained as the result of a single problem alone. A bundle of causes is usually at work, even more often than in disorders of physical origin, involving an interplay of personality traits, life experiences, provoking factors, and the individual dynamics of the symptom.

The causes of functional sexual disorders are mainly to be found in the following four areas: (1) intrapsy-

chic anxieties, (2) partnership problems, (3) learning deficits and lack of sexual experience, and (4) the self-fulfilling prophecy of performance anxiety.

From the psychoanalytic and psychodynamic viewpoint, psychogenic sexual symptoms are the result of a conflict between anxiety-producing drive impulses and the defenses against them. The development of sexual symptoms serves to stabilize mental equilibrium. Sexual symptoms are accepted as a means of avoiding the anxiety-laden "deeper" conflict. Arentewicz and Schmidt (1993) list, as the major types of anxiety, those related to drives, relationships, conscience, and sexual identity. By the latter, they are referring to the patient's uncertainty as to his or her own sexual role.

Partnership problems and sexual difficulties are closely related to each other. Each of these two types of problem frequently causes the other and can thereby reinforce itself. A sexual problem inevitably affects the patient's partner, while partnership problems often affect the sexual sphere, as it is an important part of communication within the partnership; such problems may, indeed, be displaced exclusively onto the sexual area. It may then be very difficult to discover the connection between this sexual disorder and the "covert partnership problem."

Arentewicz and Schmidt (1993) have described a number of typical partner-dynamic processes of this type:

- *Delegation:* The "normal" partner has an unconscious personal interest in the functional disorder of the affected partner. He or she may need the disorder to neutralize his or her own problems or to feel superior.
- *Arrangement:* The functional sexual disorder may be an arrangement between the partners for their mutual benefit. The motive may be a common defense against sexual anxiety, e.g. when the male partner of a woman with vaginismus has an erectile disorder.
- *Turning against the partner:* The functional sexual disorder is used as a weapon against the partner in a conflict over domination.
- *Ambivalence management:* Sexuality may become an important means of regulating the correct balance in a conflict between intimacy and distance. Excessive distance from the partner may be remedied by the intimacy of sexual contact, while, in case of excessive intimacy, greater distance can be achieved through a sexual disorder.

These partner-dynamic processes are usually first recognized only when the sexual problem has become the focus of psychotherapeutic treatment.

The expression "learning deficits and lack of sexual experience" refers to a lack of information about the forms of sexuality that are currently generally practiced and experienced. Traditional, but outmoded, ideas of female and male sexuality may contrast with the partner's expectations. A person's own lack of sexual experience may also cause problems.

Practitioners of the different schools of psychotherapy all ascribe a major role to anxiety in both the development and the maintenance of functional sexual disorders. Masters and Johnson (1970) emphasized the importance of performance anxiety. It is assumed that anxieties of this type prevent sexual arousal and inhibit the autonomic nervous system to such an extent that physiological arousal becomes impossible. This assumption is not entirely undisputed, as the evidence that anxiety is the most important factor in the maintenance of functional sexual disorders is derived mainly from clinical experience rather than from empirical data.

On the basis of his investigations, Barlow (1986) was able to show that men with normal and disturbed sexuality differ from each other in several respects:

1. Anxiety inhibits sexual arousal in sexually disturbed men, but often increases it in men without sexual disorders.
2. The demand for sexual performance increases sexual arousal in normal men, but it is a distraction and an impediment for men with sexual disorders.
3. Patients with sexual disorders often have negative feelings in situations involving sexual contact, while individuals with an undisturbed sexual life mostly report positive emotions.
4. In comparison to sexually undisturbed men, sexually disturbed men tend to underestimate their degree of sexual arousal.

From these empirical findings, Barlow derived a working explanatory model for sexual disorders of mental origin: according to this model, a process of cognitive distraction, interacting with anxiety, is mainly responsible for the appearance of sexual disorders.

Langer and Hartmann (1992) developed a clinically applicable model involving four levels of causation. On the level of dispositional factors, they posited psychophysiological vulnerability and ego-structural deficits. On the next highest level, they posited intrapsychic and partnership-related etiological factors. On the level of pathophysiological mechanisms, they posited psychodynamic processes, such as anxiety defense, and psychophysiological causes, such as elevated sympathetic tone, as well as cognitive elements, such as excessive self-observation and control. On a fourth level, they posited chronifying factors including, most importantly, specific anxieties of the types discussed above.

These various clinical experiences and empirical findings can be systematized and incorporated in

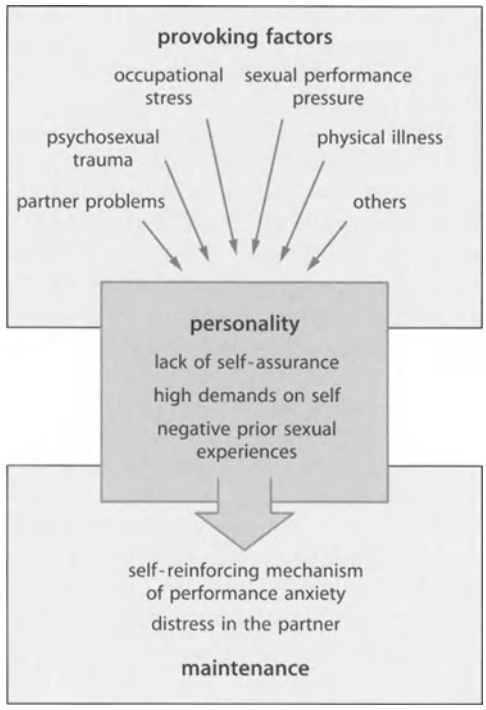

Fig. 1. Generation and maintenance of functional sexual disorders

a new theoretical viewpoint (Fig. 1). For ease of discussion, we will distinguish between the factors that provoke the disorder and those that maintain it. The connecting element is the patient's personality.

A single negative experience does not generate a sexual disorder in most cases, although an accumulation of unfavorable experiences in different areas of sexuality may do so. The provoking factors are thus not mutually exclusive, but rather additive or synergistic. The fact that one person may develop a sexual disorder after such negative experiences, while another may not, seems to be the result largely of personality variables and partly also of the partner's reaction and the patient's individual learning history. Research has yielded few firm findings with respect to the role of personality. A lack of self-assurance, low self-esteem, and a high emphasis on performance all have an unfavorable effect. As in Beck's model for the origin of depression (Beck et al. 1981), it may be assumed that life events result in a disturbance of sexuality primarily by reactivating earlier negative sexual experiences and the emotions connected to them.

Anxieties of expectation and performance always play a central role in the maintenance of functional sexual disorders, as does excessive self-observation (unless the sexual problem exclusively expresses a partnership problem). It is assumed, as a working hypothesis, that performance anxiety tends to increase by a so-called self-reinforcing mechanism.

The behavior-theoretic model is as follows: erotic situations involve the unfolding of a long chain of behaviors, which ends positively, under normal conditions, with a feeling of satisfaction and release of tension (Fig. 2).

When sexual behavior is disturbed (Fig. 3), the first, perhaps random occurrence of a functional sexual disturbance leads to performance anxiety. This anxiety prevents further normal function, which, in turn, heightens performance anxiety and leads to excessive self-observation, resulting in renewed failure.

Functional sexual disorders become firmly established through a mechanism of self-reinforcement, making them independent of the original causes that

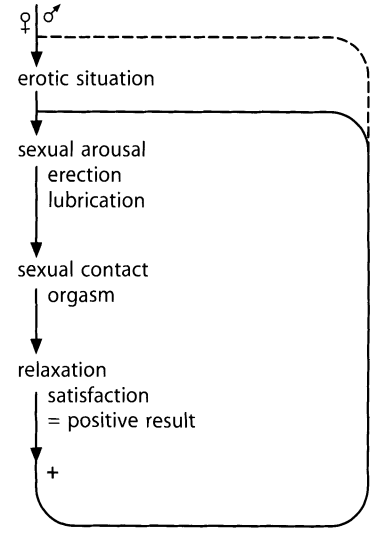

Fig. 2. Behavioral sequence of normal sexual behavior

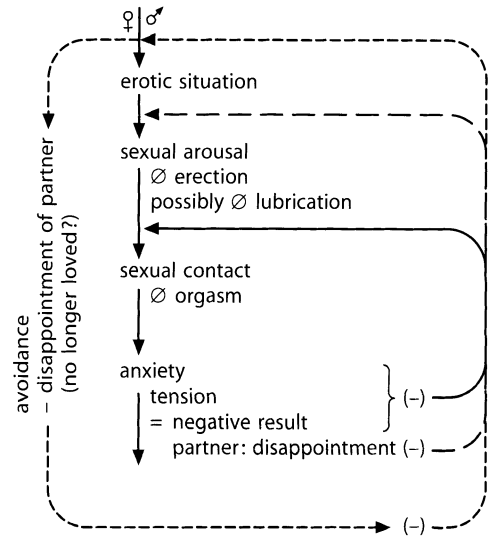

Fig. 3. Behavioral sequence of disturbed sexual behavior

provoked them; performance anxiety leads to their continued, functionally autonomous existence. Both the partner and the patient experience the disturbed sexual behavior as a disappointment. Because this disappointment further increases the patient's fear of failure, he or she begins to avoid sexuality as a means of fending off the undesirable situation. Avoidance brings the patient short-term relief, but the partner registers the patient's retreat from sexuality and relates it to him- or herself, perhaps concluding that he or she is no longer loved. Thus sexual problems open the way to partnership problems.

The foregoing is admittedly an oversimplified model of the complex mental causes of sexual disorders, but it has the great advantage of possessing explanatory power, while remaining easy for the patient to understand. This model can be used to explain the therapeutic process to affected couples and to make it clear why it is important to include the partner in the treatment.

2.4 Treatment

Not all sexual disorders require specific psychotherapy. A number of sexual problems come about merely because of lack of knowledge, absence of explanation, or a mistaken attitude toward sexuality that can be corrected by sexual counseling. Buddeberg (1996) provides an extensive survey of this topic that is relevant to clinical practice.

2.4.1 Physical and Pharmacological Treatment

When a functional sexual disorder has a predominantly physical origin, the therapeutic method of first choice is the treatment of the underlying physical illness. Frequently, however, there may be irreversible damage that will not respond to such treatment. In such cases, treatment must rely upon sexual counseling or on auxiliary pharmacological or physical measures, as will be discussed briefly in what follows.

The administration of sex hormones is appropriate only in the treatment of the rare endocrinological illnesses that are accompanied by documented androgen deficiency.

The new medication sildenafil (Viagra) has received a great deal of attention recently and will be discussed here in some detail. Sildenafil, a selective inhibitor of phosphodiesterase (PDE), has been on the market in the United States since March 1998 and in Europe since the autumn of 1998. Controlled studies have shown it to be remarkably effective in the treatment of erectile disorders of diverse etiologies.

We now know that, when the penis is in the resting state, the smooth muscle of its corpora cavernosa and arterioles is contracted, and the blood flow through the corpora cavernosa is minimal. The smooth muscle relaxes upon sexual stimulation, the flow of blood through the arterioles into the corpora cavernosa increases, and the draining veins are compressed between the corpora cavernosa and the tunica albuginea and thereby effectively sealed off. An erection results. Smooth muscle relaxation is mediated mainly by nitric oxide (NO), which is released by neurons and endothelial cells during sexual stimulation. NO, in turn, stimulates the production of cyclic guanosine monophosphate (cGMP), by activation of guanylate cyclase. In the human corpus cavernosum, cGMP is degraded mainly through the action of PDE-5. This is the point at which sildenafil acts. Sildenafil selectively inhibits PDE-5 and thereby slows the degradation of cGMP, leading to a prolongation and reinforcement of the relaxing effect of cGMP on smooth muscle and thus to longer-lasting and stronger erections. In accordance with this mechanism, sexual stimulation is a prerequisite for the effectiveness of sildenafil. Sexual stimulation initiates the development of an erection through the NO–cGMP mechanism, and the erection is then prolonged and strengthened by the slowing effect of sildenafil on the degradation of cGMP.

An improvement of erectile function is almost the only effect of sildenafil. The refractory period (i.e. the time after orgasm during which a new erection cannot occur) may be shortened; many men report more rapid ejaculations. The libido is in all likelihood not directly affected (elevated), but is certainly indirectly increased when a patient with erectile dysfunction has regained the ability to have an erection by using sildenafil.

Since its introduction, sildenafil has been tested in a number of controlled studies in different patient populations, including a total of more than 3000 men aged 19–87 years. Its effectiveness in patients with traumatic spinal cord injury and erectile dysfunction of mental origin is between 70%–80%, and in patients with severe diabetic disturbances and erectile dysfunction after prostatectomy, approximately 50%; the lower success rate in the latter groups is probably due to simultaneously existing nerve damage.

Sildenafil seems to be relatively safe to use. A few deaths have occurred in controlled studies, but the death rates were comparably low in the drug and placebo groups (0.45 versus 0.57 deaths per 100 patient-years) and were in fact lower than the expected death rate in this age-group in the general population (1.7 to 2.5 deaths per 100 proband-years), and the physicians conducting the studies found no connection between the deaths and the medication. Further deaths during treatment with sildenafil have been reported in the United States since its approval for use there. It is

not yet clear, however, whether these deaths were actually directly related to the use of sildenafil. A precise analysis of this matter is still urgently needed at present. The most recent studies show that sildenafil has no unfavorable hemodynamic effects in patients with coronary heart disease.

The major indications for sildenafil at present are erectile disturbances of physical origin, e.g. disturbances caused by diabetes and hypertension and in the aftermath of prostate surgery or traumatic spinal cord injury; severe erectile disturbance of uncertain origin in older men may also be an indication. Sildenafil is also effective against so-called psychogenic erectile dysfunction. It is theoretically conceivable that sildenafil helps men with erectile dysfunction of mental origin overcome their performance anxiety, which is often severe (see above). Sildenafil may thus be an important adjuvant treatment, i.e. a component of somatopsychotherapy. No data have been reported to date, however, regarding how treatment with sildenafil should be incorporated into psychotherapy or whether, when, and how the medication should be discontinued, etc. There are certainly other situations in which, despite an obvious mental cause of the disturbance, treatment with sildenafil is the only possible therapy, e.g. when there are partnership problems because of a psychotic illness in the spouse, but both partners strongly desire to preserve their marriage.

Sildenafil is, in all likelihood, not suitable for the treatment of disorders of libido (e.g. as a result of endocrinological or other illnesses, or the sedating effects of other medications), as our current knowledge indicates that this substance has no centrally stimulating effect.

Simultaneous treatment with sildenafil and nitrate-containing medications is absolutely contraindicated, as the mild hypotensive effect of sildenafil is considerably potentiated by nitrates, and dangerous hypotensive crises may result.

The following undesired side effects of sildenafil were described in controlled studies: flushing, headache, dyspepsia, occasional rhinitis or stuffed nose, and visual disturbances in the form of a bluish tint in the peripheral visual field. All of these side effects were said to be transient and of mild to moderate severity and remitted without specific treatment. The rate of termination of therapy because of side effects was almost equally low in treatment with sildenafil (2.5%) and placebo (2.3%). Alcohol mildly increases the hypotensive effect of sildenafil.

The effect of sildenafil is dose-dependent in the range between 25 mg and 100 mg, while increasing the dose to 200 mg or more does not increase the therapeutic effect. The effect sets in upon stimulation approximately 30 min to 4 h after the medication is taken. The manufacturer recommends that the drug be taken no more than once a day because of the possibility of increased side effects. As with all other modes of therapy for sexual disorders, it is strongly recommended that sildenafil be given in combination with sexual counseling, in which the patient's partner is included.

Nothing is known at present regarding possible problems associated with long-term use. Only a few long-term observations, involving treatment lasting up to 4 years, are now available. Physical dependence has not yet been observed. It is conceivable, but not yet demonstrated, that men might become psychologically dependent upon sildenafil.

The use of sildenafil alongside the psychotherapeutic treatment of psychogenic erectile disorders has not yet been tested systematically, and the views of psychotherapists on combination therapy of this type are highly divergent. Sildenafil might be useful for both diagnostic and therapeutic purposes if its use helps men with neurotic or partner-related conflicts to regain erections. Further difficulties and symptoms that are themselves due to the erectile dysfunction would then recede into the background. The neurotic or partner-related conflict would become clearer and thus easier to treat – or it would, perhaps, decline in importance once it became obvious that it did not, in fact, play the decisive role in causing the erectile dysfunction.

Our impression thus far is that the wave of prescriptions of sildenafil seen in the United States after its approval there is not being duplicated in Europe. Apparently, in the United States as in Europe, many men tried sildenafil for a time because of its status as a fashionable drug, and some will presumably continue to experiment with it in future. It remains to be seen whether sildenafil will have a lasting influence on human sexual behavior. We doubt it.

The World Health Organization considers sexual problems to be an impairment of an individual's health when he or she has a functional sexual disorder that causes suffering; such a disorder deserves to be considered an illness. This is the case for patients with the erectile disorders discussed above, for which sildenafil is a highly effective treatment. It follows that health insurance schemes should be required to assume the cost of such treatment. The indications for treatment should be established in a responsible manner by specialist physicians.

Controlled studies have shown that yohimbine hydrochloride is more effective than placebo in the treatment of disorders of libido in men and of erectile dysfunction. This selective, competitive α_2-adrenergic receptor blocker is thought to act centrally. Other so-called aphrodisiacs currently on the market are probably no more effective than placebo.

A number of antidepressants are said to possess a sexually stimulating activity in addition to their antide-

pressant effect. These claims are based on case reports. Such an effect was claimed for trazodone, for example, but could not be substantiated by a recently published controlled study. Reports of adverse side effects in the sexual area are far more common (see Sect. 3).

Vibrators are used in andrology as an aid in the obtaining of an ejaculate for diagnostic testing. A number of authors report the use of vibrators to treat total male anorgasmia, with occasional success. Their use as a therapeutic aid in women in the framework of so-called sex therapy is more common, but controversial among psychotherapists.

The injection of vasoactive substances into the corpus cavernosum of the penis induces an erection, which may ensue more or less rapidly and completely depending on the intactness of the corpus cavernosum and the blood vessels supplying it. This technique has therefore been in use for some time in urology as a diagnostic test for vascular abnormalities, in combination with Doppler sonography (intracavernous injection test). More recently, this technique has been put to use in the treatment of erectile dysfunction (intracavernous injection therapy).

The use of papaverine in the initial application of this technique often led to priapism, as did combination therapy with papaverine and phentolamine (though less commonly). Priapism must be alleviated within a few hours with a pharmacological antidote (vasocontrictor medication) or by surgical intervention to prevent permanent physical injury to the corpus cavernosum. Prostaglandin is currently used; this has resulted in hardly any cases of permanent erection, but complaints of local pain after the injection have become noticeably more frequent. Follow-up studies in recent years have documented high rates of discontinuation of treatment (as high as 60%), partly because of a regaining of spontaneous erections, but more commonly because of dissatisfaction with the mode of administration and disapproval by the partner. Thus informing and obtaining the consent of the partner are a necessary prerequisite for the initiation of this form of treatment.

This treatment is indicated in men with irreversible erectile dysfunction that cannot be treated successfully by other means. Its application is probably appropriate in combination with psychotherapy in men with erectile disturbances of mixed or uncertain origin in middle and advanced age. This mode of treatment will likely become much less common because of the success of treatment with sildenafil.

2.4.2 Surgical Methods

Penile prosthetic surgery has been practiced for more than 20 years. Three types of prostheses are commonly used. Silicone prostheses consist of two stiff rods that are inserted into the corpora cavernosa, thus producing a permanent erection. A second type of prosthesis, with flexible rods, leads to a type of permanent erection of intermediate stiffness. A third type consists of fluid-containing rods that can be hydraulically filled and emptied by means of a reservoir in the abdominal wall, so that an erection can be produced, and terminated, at will. The follow-up studies of patient satisfaction with this method of treatment that have been published to date were probably not carried out in representative groups of patients. Penile prostheses are currently considered a treatment of last resort for patients with a very strong desire for restoration of erectile function. The operation leads to permanent destruction of the corpus cavernosum. Prosthetic surgery has waned in popularity with the development of intracavernous injection therapy and, more recently, the introduction of sildenafil.

Surgical procedures involving the major pelvic arteries have often been reported to improve erectile function markedly as a positive side effect. The effectiveness of surgical procedures on vessels exclusively supplying the penis (usually the creation of an anastomosis) is disputed.

2.4.3 Treatment of Functional Sexual Disorders of Predominantly Mental Origin

The type of psychotherapy that should be used to treat a functional sexual disorder depends on the problem at hand. It may be necessary, in some cases, to use partner therapy, in which the sex-therapy aspect initially plays no role, or to use psychotherapy directed toward a personality disorder.

In a considerable number of patients, the mutual reinforcement of sexual and partnership problems is so strong that they can no longer be separated from each other. In such cases, sex-therapy and partner-therapy techniques are used in combination (Zimmer 1985).

The method of Masters and Johnson (1970) has proved effective for patients whose sexual problems are their most prominent symptoms. Treatment consists of a sequence of behavioral exercises that are to be carried out by the couple in between sessions with the therapist. The couple's experience with the exercises is discussed and evaluated in each session. In addition, attention is devoted to all other problems affecting the sexual area. Normal sexual behavior is gradually reconstituted in a series of intermediate steps of increasing difficulty, while other, symptom-specific treatments are concurrently applied. To treat erectile disorders, Masters and Johnson recommended the so-called "teasing method" (repeated, very brief insertion

of the penis into the vagina); to treat premature ejaculation, they recommended the "squeeze technique" (reduction of the urge to ejaculate by digital pressure on the penis); and, to treat vaginismus, they recommended the insertion of the patient's own finger or the insertion of Hegar dilators.

Treatment in the scheme of Masters and Johnson is always only one component of therapy of the couple as a whole – the "patient" is the couple. Sexual symptoms must be understood and treated on different levels. According to Schmidt (1996), the most important aspects to be considered include couple dynamics, the individual life histories of each partner, and the perspective of so-called symptom gain, as well as socio-psychological aspects (e.g. the striving for women's emancipation) that may be more or less important in individual cases.

Psychotherapy of functional sexual disorders with the inclusion of exercises, as described by Masters and Johnson, has been shown in several studies to be significantly more effective than psychotherapy without exercises.

Numerous further techniques have been proposed since 1970, and some have been scientifically studied, but the fundamental principles of therapy have remained the same:

- *Reduction of treating personnel and number of sessions:* It has been demonstrated in a number of studies that outpatient treatment in one to two weekly sessions with a single therapist is just as effective as quasi-inpatient treatment by a team of two therapists, as originally recommended by Masters and Johnson.
- *Group therapy:* The treatment of sexual problems in groups of couples with similar or different sexual disorders is just as effective as the treatment of couples separately.
- *Techniques for improving the sexual experience:* Exercises to promote physical self-awareness, practice with mechanical stimulation (e.g. the use of a vibrator when ejaculation is delayed), and the introduction of sexual fantasies have all been tested, with success.
- *Treatment of primary anorgasmia:* The technique of LoPiccolo and Lobitz (1972) has been found useful in the treatment of women with primary anorgasmia. In a program of nine sequential stages, women systematically learn to reduce their feelings of anxiety and inhibition with respect to their own bodies, to generate new, positive feelings and certain sexual capabilities, and to reach orgasm through self-stimulation.
- *Treatment of patients without partners:* Women without partners have been treated very successfully with the technique of LoPiccolo and Lobitz. No method for the treatment of men without partners has yet been adequately empirically tested. The most commonly used method at present is that suggested by Zilbergeld (1978), which mainly employs elements of self-confidence training to promote the ability to make contact with women, as well as a type of systematic desensitization that the patient carries out during masturbation to diminish sexual performance anxiety.

Therapists of different orientations have incorporated the techniques of Masters and Johnson into their own, individual theoretical frameworks and thereby developed variations of sex therapy that have been applied successfully in practice. Kaplan (1981) introduced psychodynamic and partner-dynamic aspects to sex therapy, as did the Hamburg group (Arentewicz and Schmidt 1993). Behavioral therapists use the individual techniques of Masters and Johnson selectively in individual treatment plans, according to the results of behavioral analysis. The model developed by Annon (1974, 1975) is an example of this kind of integration. In recent years, increasing attention has been paid to elements of cognitive behavioral therapy (Hawton et al. 1989).

Only a few studies have been performed on prognostic criteria for sex therapy. Thorough investigation of a large sample in England (154 couples; Hawton and Catalan 1986) revealed that a successful outcome of sex therapy is associated with the quality of the relationship between the partners, the strength of their motivation, and the extent of progress achieved in the first three therapy sessions. These criteria were basically confirmed in a later study of men with erectile dysfunction (Hawton et al. 1992).

The model of treatment devised by Masters and Johnson and its further development over the last 30 years have proved to be a major advance in psychotherapy. The present trend is toward combining sex therapy (also called "couples therapy") with the recently developed physical techniques (particularly intracavernous injection and oral medication), especially in older patients with sexual dysfunction of unclear or mixed etiology.

3 Sexuality and Psychosis

Psychotic illnesses alter patients' sexual behavior and experience. Even today, although the literature on this subject is rich in case reports and theories, data from controlled studies are scant.

Psychoses with sexual content are most frequently found among schizophrenics. The most common

thought disorders with sexual content include psychotic jealousy and delusions of being forced to engage in sexual behavior by others. These and similar delusions are probably present in 5%–20% of schizophrenics.

The most common perceptual disorders involve unpleasant sensations in the genital area, which are described by patients as burning, itching, hot, cold, or even as resembling an electric shock. The frequency of such sensations in the populations studied has been reported as being 30%–40%.

Sexual thought disorders and perceptual disorders are usually interpreted as a sign of regression accompanying a disturbance of sexual identity in psychotic patients, as a communication disorder, as an expression of sexual guilt feelings, or as a sign of anxiety connected to relationships.

Psychosis-related abnormalities of sexual behavior rarely take the form of very unusual sexual practices. They are primarily autoerotically oriented and are related, in their content, to sexual thought disorders and perceptual disorders.

Sexually deviant behavior occurs in psychotic patients as in nonpsychotic individuals. The reported data indicate, however, that sexual deviancy among psychotic patients is no more common than average. Psychiatric patients seem to be no more likely to be punished for sexual offenses than other individuals. There is also no reason to suppose that homosexual desires or behavior are any more common in psychiatric patients than in the normal population.

Schizophrenic patients seem to have less frequent sexual contacts than normal individuals and other psychiatric patients, both during acute episodes of illness and in the nonacute stage. The frequency of functional sexual disorders is estimated at 18%–60%, even after the resolution of an acute symptomatic episode.

The literature on the sexual activity of patients with affective psychoses and the frequency of functional impairments in this group is not extensive. The one finding that can be accepted as established is that the frequency of erections (including nocturnal erections) in depressive patients is lower during a depressive phase than at other times.

There is a surprising degree of variation in the frequency of sexual dysfunction and abnormalities of sexual activity reported in the literature. This is not just because of differences in study methods and in the definition of sexual problems, but also because of further factors affecting sexuality that these studies did not take always into account, including the patient's personality, premorbid sexuality, partnership situation, and psychopharmacologic treatment. Little is known about the effects of these additional factors. It does seem certain, however, that the sexual development of psychotic patients is delayed, as compared to that of normal individuals, even before the onset of acute manifestations of disease. This is particularly true of patients with schizophrenia (Nestoros et al. 1980).

Publications concerning the effect of psychopharmacological treatment on sexual experience have become more numerous only in recent years, but still largely concern single cases or small groups of patients. Controlled studies on this subject are rare, and, even today, the influence of psychopharmacological treatment on female sexuality is hardly discussed in the literature. Thus currently available data are inadequate to provide a representative picture of the sexual changes induced by psychoactive medications.

Three separate double-blind studies on small groups of patients demonstrated that neuroleptic agents diminish libido, delay ejaculation, and counteract erection (each effect was shown in a single study). If we consider the results of all of the uncontrolled case reports on this subject, the following rough picture emerges: phenothiazines may diminish libido, delay ejaculation (particularly thioridazine), and cause erectile dysfunction. In general, however, such changes are infrequently mentioned. There are a few reported cases of erectile dysfunction, delayed ejaculation, and diminished libido associated with butyrophenone treatment. Sexual disorders resulting from the use of other neuroleptics are only occasionally mentioned. The real frequency of sexual dysfunction is very likely higher than these published reports suggest. There are as yet no data concerning the so-called atypical neuroleptics.

The data on sexual side effects of the antidepressants are very heterogeneous. Well-controlled studies are rare but seem to show that functional sexual disorders are more common under treatment with antidepressants than under placebo treatment. According to Baier and Philipp (1994), the findings published to date suggest that different antidepressants may cause different, specific sexual problems depending on their particular pharmacological properties.

Sexual disorders seem to arise with increased frequency in association with the use of selective serotonin reuptake inhibitors; impairments of orgasm and ejaculation are the problems most commonly seen. In contrast, selective monoamine oxidase inhibitors and nefazodone seem to have much less of an effect on sexuality.

Our own study (Kockott and Pfeiffer 1996) of 158 psychiatric outpatients taking maintenance medication (100 schizophrenic and 58 depressed patients), and without evidence of acute or subacute disease manifestations, revealed that functional sexual disorders are common in psychotic patients. The patient needs to be asked about sexuality to discover such problems, because the patient will rarely report them spontane-

ously. Their frequency (47%) is much higher than in the normal population (approx. 10%) or than in a control group of outpatients treated for allergies (13.3%).

Disturbances of libido were the most commonly reported problem and were usually of multifactorial origin, according to expert clinical judgment. In the schizophrenic patients, an effect of the illness itself could be demonstrated. The sexually disturbed patients were somewhat "sicker" than others, although they were, on the whole, in very good mental condition. Psychosis seems to disturb sexuality considerably, as problems were present even in this significantly improved disease state. It was also shown that neuroleptic medication impairs sexuality, but its effect cannot be very large, because no significant association was found between the appearance of sexual disorders and the type, potency, or dose of neuroleptic medication given. Thus, in this study, the sexuality of schizophrenic patients was more impaired by the disease itself than by neuroleptic treatment.

4 Paraphilias

The terms "paraphilia," "sexual deviation," "perversion," "sexual variation," and "disorder of sexual preference" are used almost synonymously in the literature. Psychoanalytically oriented sexologists prefer the term "perversion" because of its prominence in the psychoanalytic theory of perversion; the term "disorder of sexual preference" was first introduced in ICD-10; and the term "paraphilia" has become usual in the English-speaking world through its use in the diagnostic manual (DSM-IV) of the American Psychiatric Association (APA).

On the level of behavior, a paraphilia or sexual deviation is best defined operationally as a sexual urge for an unusual sexual object or an unusual type of sexual stimulation.

4.1 Classification and Clinical Manifestations

Human sexuality is highly variable, both in the intensity of the experience and in its behavioral forms. As already mentioned in the Introduction, it is viewed differently in different cultures. Even within a single culture, views of sexuality may change rapidly. In the second (German) edition of this text, forms of sexual deviation were listed that are barely or not at all recognized today, such as saliromania, the urge to spray women with a fluid that the patient carries with him. In addition, sexual deviations are often given new names. Zoophilic behavior is called *Sodomie* (sodomy) in German-speaking countries today, while the same term in English also refers to homo- or heterosexual anal intercourse. The development of new technology leads to the appearance of new forms of deviation, e.g. erotophonia (the placement of obscene telephone calls to women who do not desire them), which, of course, appeared only after the invention of the telephone.

Decisions regarding what counts as a paraphilia or sexual deviation are thus highly dependent on both culture and time. The currently used international classification schemes for sexual deviations are valid only at the present time and are not fully applicable in non-Western cultures.

Gradual transitions exist from normal sexual fantasies and activities to sexual deviation. A paraphilia is present only when unusual sexual fantasies and/or activities are clearly predominant or exclusively present. According to Schorsch (1985), four levels of intensity can be distinguished:

1. A deviant impulse appears only once, or sporadically, in connection with a current conflict or a particular life crisis.
2. A deviant reaction becomes a repeated pattern of conflict resolution, without determining the patient's sexual orientation.
3. A stable, deviant orientation develops. Sexuality without deviant content cannot be experienced intensely or cannot be experienced at all (so-called fixation).
4. The stable, deviant orientation assumes a progressive course. Giese (1962) referred to this condition as *sexuelle Süchtigkeit* (sexual addiction) and described its characteristic manifestations as follows:
   a) An addiction to sensuality, in which specific stimuli take on a signal character
   b) Increasing frequency of sexually deviant behavior, with decreasing satisfaction
   c) A tendency toward anonymity and promiscuity
   d) The development of deviant fantasies and practices
   e) An "addiction-like experience" (*süchtiges Erleben*)

A fixed sexual deviation (levels 3 and 4) is characterized by the following:

- There is stereotypic, ritualized sexual behavior. The same form of sexual behavior is acted out again and again, and sexual satisfaction can only be obtained in this way.
- The partner becomes an object. The individual needs and sexual expression of the partner are of secondary importance and are accepted only when

they meet the expectations of the deviant. When they do not, they are perceived as disturbing. The partner is expected to play a specific role and is not allowed to be him- or herself. Shared experience remains entirely within the framework constructed by the deviant.
- The physical and mental satisfaction of orgasm is achievable only under the highly specific conditions characterizing the deviation, and not by ordinary coitus, which is thought of as a poor substitute for the deviant behavior.

Sexual deviations are not clearly delimited entities associated with particular abnormalities of personality, as was formerly assumed. They often appear, not in isolation, but in combination with other sexual deviations. For these reasons, there can be no generally applicable treatment program for exhibitionists or pedophiles, for example; the treatment must be individually tailored to the paraphilic patient.

The most common forms of sexual deviation are listed, with their usual international definitions, in Table 2.

4.2 Causes and Theories of Pathogenesis

The appearance of a sexual deviation in combination with a somatic or psychiatric illness is rare, and the nature of the relationship between the disorders is often unclear. An etiological relationship may be apparent in cases of mental debility or dementia. The exhibitionistic behavior of a feeble-minded patient may be a clumsy type of sexual advance that seems appropriate to the patient because he or she has never learned to do things differently. In demented patients, modes of sexual behavior may arise that are designated as deviant only because they do not conform to our current norms and conceptions of morality. In such cases, organic brain disease has impaired the patient's ability to control his or her own behavior in accordance with social convention.

An association of temporal lobe disorders with abnormal sexual behavior has been reported in a number of case studies.

There are a number of theories concerning the etiology and pathogenesis of sexual deviations, almost all of which are highly speculative.

The psychoanalytic theory of perversion has been repeatedly reformulated. In the recent literature (Morgenthaler 1974; Stoller 1979), the reparative aspect of sexual deviations is emphasized. Schorsch (1980) views the paraphilias as resulting from a severe problem of masculinity that is supposedly neutralized by the generation of the deviant symptom.

According to learning theory, on the other hand, sexual excitement in response to unusual stimuli comes about by way of classical and operant conditioning, both through sexual contacts and through fantasies

Table 2. Sexual deviations (paraphilias) and their classification in ICD-10 and DSM-IV

Sexual deviation	Characteristics	Classification	
		ICD-10	DSM-IV
	Recurrent, intense sexual urges, activities, and/or fantasies, present for at least 6 months, and involving:		
Exhibitionism	Exposure of the genitalia to unsuspecting strangers	F65.2	302.4
Fetishism	The use of inanimate objects (e.g., women's underwear)	F65.0	302.81
Pedophilia	Sexual activity with a prepubescent child or children, usually aged 13 or younger	F65.4	302.2
Transvestitism (transvestite fetishism)	The wearing of female clothing by a heterosexual man	F65.1	302.3
Voyeurism	The observation of unsuspecting individuals who are naked, in the act of undressing, or engaged in sexual activity	F65.3	302.82
Frotteurism	Touching and rubbing up against people who do not desire such behavior	F65.8	302.89
Sexual masochism	Real, not simulated acts of being humiliated, beaten, chained, or otherwise made to suffer	F65.5	302.83
Sexual sadism	Real, not simulated acts in which the mental or physical suffering (including humiliation) of the victim is sexually arousing for the affected person	F65.5	302.84
Zoophilia	Sexual activity with animals	F65.8	302.9
Erotophonia	Obscene telephone calls to unsuspecting or unwilling individuals	F65.8	302.9

during masturbation. In the view of Laws and Marshall (1990), human sexual behavior, including deviant behavior, develops according to the principles of "prepared learning," as laid down by Seligman (1970, 1971), i.e. under the influence of evolutionary, biological factors. This is thought to explain why not just any sexually neutral activity that happens to take place simultaneously with sexual arousal can become transformed into an independent source of sexual arousal.

In the theory of Money (1986), human sexuality develops through an interplay of biological and mental factors that influence the developmental process at particular times. This triad – biological factors, mental factors, and their taking effect during critical periods – is said to be decisive for the creation of sexual identity, sexual partner orientation, and the so-called "love-map," i.e. the sexual-erotic conceptual world of the individual. Money considers sexual deviancy to be a mechanism through which a sexual desire perceived as sinful is transformed into a "permitted" sexual pleasure.

4.3 Treatment

Paraphilias are not necessarily to be considered diseases that always require treatment. Deviants indeed suffer from their being different from others, but often less from the deviation itself than from the contempt and rejection that they perceive, or are actually subjected to, when their inclination becomes known. Thus counseling is often needed. Counseling may be the only therapeutic intervention required; the goal in such cases is to find an arrangement with which the affected individual and significant others can live.

Psychotherapy is the most important technique used to treat sexual deviations. It may be appropriate to combine psychotherapy with pharmacotherapy. Psychotherapy can often begin only after a reduction of libido by medication. Cyproterone acetate (CPA), a competitive testosterone inhibitor, is used for this purpose in Europe and Canada. Medroxyprogesterone acetate (MPA) is used with comparable effects in the United States, where CPA lacks government approval.

The clinical effect of CPA has been evaluated in many publications, but in only a single double-blind study. The findings may be summarized as follows: a daily dose of 100–200 mg leads to a diminution or elimination of sexual appetite after a period of 1–3 weeks. In addition, erectile function diminishes. Three weeks after the initiation of therapy, a reduction of the quantity of the ejaculate and a delay of ejaculation are usually reported. When high doses are given, a complete inability to obtain an erection or to ejaculate may result. Sexual fantasies and dreams become less frequent only in the ensuing months. CPA significantly lowers the testosterone level. The diminution of libido by CPA depends on the age of the patient and on the dose. Alcohol partially counteracts the effect. The response to CPA is highly variable among patients, but highly consistent in each individual patient.

Approximately one third of patients complain of side effects, such as fatigue, adynamia, and general reduction of performance, that appear in the second and third weeks of treatment and later resolve. A change of orientation of the sexual drive is never observed and is not to be expected by the therapist. When the medication is discontinued, the libido, erectile function, and ability to ejaculate become normal again within a few weeks. CPA is available in oral form or as an injectable solution, while MPA is available only in oral form.

The psychotherapy of patients with paraphilias is accompanied by a number of problems. Patients are often in a difficult social situation, and their motivation to undergo therapy may be highly ambivalent. Therapists assuming the treatment of a group of patients looked down upon by society may, at first, judge them not much differently. They must work to achieve a therapeutic posture. The therapist is also under pressure to succeed, even more so if the sexual deviation involves behavior injurious to others. The therapist may therefore become overcautious and institute modes of treatment that are either too rigid or too aggressive and are thus counterproductive to the goals of therapy. Because of these special difficulties, close psychotherapeutic supervision is necessary.

Research on this subject is in a highly fragmentary state. Controlled studies are rare; only a few are available in which the results of therapy are evaluated. The findings of such studies and other reports of clinical experience imply that the psychotherapy of sexual deviations is best performed according to the following guidelines:

- Psychotherapy must have a clear structure, and the boundaries of therapeutic behavior must be clearly set.
- Psychotherapy is often of a supportive nature at first; social problems must be addressed.
- Sexually deviant patients are highly variable in their suitability for therapy. The goals of treatment, forms of approach to the patient, and degree of depth must therefore be individualized. Thus the psychotherapist must not confine his or her approach to that of a single theoretical school. Integrative treatment programs that take psychodynamic and behavior-therapy concepts into account, and do not neglect pharmacological possibilities, seem to be most successful.

- A "cure" is only rarely achieved, but the patient can, at least, learn to keep his or her deviation under control and to develop a more suitable form of interpersonal communication, thereby improving quality of life.

The behavior-therapeutic approach, which has been applied by psychotherapists to a highly variable extent in the treatment of paraphilia, has four major emphases, which are independent of the type of sexual deviation (Kockott 1996). The different building blocks of behavioral therapy are used as needed to construct an individual treatment program for each patient:

1. *Covert sensitization:* The patient is instructed to think of the deviant behavior as vividly as possible. Once the mental image is clear, the patient is then told to change it suddenly and think of a particularly unpleasant experience, such as that of being surprised by a member of the family during the deviant behavior.
2. *Self-control methods:* The patient learns to distract himself or herself from deviant behaviors and to develop well-rehearsed alternative behaviors that are incompatible with the deviant behavior. For example, an exhibitionist might approach the woman to whom he desired to expose himself and, instead, ask her the time.
3. *Masturbatory saturation:* The patient masturbates to orgasm with normal sexual fantasies and then for a further time with deviant fantasies, until this activity becomes boring or unpleasant. This form of treatment is based on the learning-theory notion that normal sexual fantasies can be positively reinforced by the experience of orgasm, while deviant fantasies are extinguished, because they are no longer reinforced.
4. *Stimulus control methods:* The patient learns to recognize the situations in which the deviant behavior often occurs (e.g. unstructured free time, proximity to playgrounds) and changes his or her behavior to stay out of such situations as much as possible (by structuring free time, avoiding playgrounds, etc.).

All of the different aspects of the method of Masters and Johnson (1970) for the establishment of normal sexual behavior (see Sect. 2.4.3) can be used, depending on the individual circumstances, to develop or improve normal, nondeviant sexual behavior in sexually deviant patients. So-called "orgasmic reconditioning" is a further method. The patient is instructed to masturbate with his or her deviant fantasies at first and to switch to normal fantasies shortly before orgasm, making this switch earlier and earlier each time. The reinforcing effect of orgasm is then expected to reinforce, i.e. increase, normal masturbatory fantasies and extinguish, i.e. decrease, deviant fantasies. Although this method is often used, its effectiveness is disputed.

The usual methods of improving social skills, communication, and problem-solving behavior are applied (Margraf 1996), and the new modes of behavior that must be acquired are practiced by role-playing. For paraphilic men, stress is placed on improving behavior toward women in the social context and in the partnership, but also on improving the patient's view of himself.

Attention is increasingly being paid to relapse prevention. Several American treatment centers have taken up the relapse prevention model originally developed for alcoholism and adapted it for use in paraphilic patients. The patient is taught a number of coping strategies with which he can prevent a threatened relapse. He might, for example, carry an "emergency card" listing instructions for how to behave in an emergency and the telephone number of the treatment center.

4.4 Sexual Delinquency

Sexual delinquency is an illegal violation of the sexual autonomy of an individual, regardless of whether it is associated with a sexually deviant practice. Most sexual offenders are not paraphilic, but rather highly aggressive within the framework of normal sexuality (sexual assault, rape). Gradual transitions from nonaggressive deviancy to aggressive sexual delinquency do exist, but sadistically motivated sexual delinquency (involving a paraphilia) is rare.

Sexual delinquency creates two groups of individuals in need of treatment, the offenders and their victims. The experience of being assaulted or raped is always a trauma with major mental consequences, which have been termed post-traumatic stress reactions. Treatment is provided as in other forms of severe mental stress. Two behavior-therapy techniques are used in the treatment of women who have been raped: "prolonged exposure" and "stress-inoculation training" (SIT). Prolonged exposure is a less intense form of "flooding," while SIT is a package of treatments including muscle relaxation with controlled breathing, *Gedankenstop* ("thought stop") training, a "guided self-dialogue" in which incorrect perceptions are dealt with ("I am guilty of becoming a victim"), and "stress inoculation" in which coping strategies are developed and practiced by role-playing. A controlled study (Foa et al. 1991) showed that SIT had better results than prolonged exposure. For ethical reasons,

treatment with prolonged exposure is very rarely advisable in this patient group.

The psychotherapy of sexual offenders is particularly liable to the difficulties mentioned above in connection with the psychotherapy of paraphilic patients. The question of responsibility for possible further offenses also weighs heavily upon the therapist, who has the duty to maintain patient confidentiality, but must also find an acceptable way to prevent a relapse when the acute danger of one arises. Therapeutic "emergency measures" for use in crisis situations must be worked out with the patient in advance. If the patient is incapable of taking such measures to protect others, he must agree to protective measures on the part of the responsible government authorities.

The same general considerations apply to the psychotherapy of sexual delinquency as to that of paraphilia. Behavior-therapy methods to reduce or control sexually deviant behavior are generally not very successful in this patient group. A change of the patient's cognitive attitudes, however, is very important. Sexually aggressive offenders have extremely distorted ideas of their victims' experiences ("Women want to be raped," "Children enjoy having sex with me") and tend to use such ideas as a means of denying, or at least reducing, their responsibility for their own actions. To eliminate these cognitive distortions, the offender should be made aware of them and brought to understand the actual nature of the victim's experience, and the distortions should be changed by means of practiced role-playing. Cognitive restructuring sounds like a highly plausible therapeutic concept, but it is very difficult in practice. The effectiveness of these recommended modes of treatment has not yet been demonstrated.

Reports of primarily behavior-therapeutic treatment for sex offenders that have been published to date are mainly from Canada, the United States, and Germany. In the United States and Canada, inpatient treatment has been provided in prisons and forensic clinics for years. In Germany, there are only a few small units, in prisons and disciplinary institutions, in which sex offenders are treated. Intensive efforts are now underway to develop treatment programs that begin during the offender's incarceration and continue as outpatient therapy, because the danger of a relapse is especially great shortly after the offender is released.

There have been only a few properly controlled studies on the treatment of sexual delinquency (e.g. Schorsch et al. 1985; Marshall and Barbaree 1990). These studies do reveal, however, that sexual delinquency is treatable and that treatment reduces the rate of relapse. The success of treatment is mainly a function of the severity of the patient's psychopathology.

5 Gender Identity Disorders

The term "gender identity" denotes a person's feeling of being a man or a woman. Individuals with gender identity disorders suffer from a mismatch of their gender identity and their biological sex. The most important clinical variety of gender identity disorder is transsexualism, the persistent and complete mental identification with the opposite sex. Transsexualism will be discussed in detail below. There are also gender identity disorders occurring in childhood or adolescence or in the framework of other mental disorders, e.g. in schizophrenia.

Gender identity disorders have been described under a variety of terms, and connected with various different disease entities, since the early nineteenth century. The term "transsexualism" was first used by Hirschfeld in 1923, but entered common parlance only in the 1960s. A chapter on gender identity disorders, among which transsexualism is listed, first appeared in ICD-10. The term "transsexualism" was present in DSM-III-R, but was replaced in DSM-IV by the synonymous term "persistent gender identity disorder."

The major manifestations of transsexualism may be summarized as follows:

- *Constant and complete mental identification with the opposite sex:* transsexuals often describe this as a feeling of living in the wrong body.
- *Constant and intense discomfort with the specific features of one's own biological sex* (breasts, vagina, and menstruation in women; penis, testes, and facial hair in men): these features are totally rejected, and attempts are made to hide them by means of corsets or loose clothing or even to remove them physically; self-castration has been described.

Further symptoms resulting from these major manifestations include the following:

- The urgent *desire for sex change.* Transsexuals seek full legal and social recognition as members of the sex to which they feel they belong and actively seek sex-altering measures (hormonal treatment and surgery) as well as name changes and changes of legal status.
- The wearing of clothing associated with the opposite sex (*cross-dressing*) begins in childhood in some cases, but usually during puberty, when the mismatch between biological sex and mental gender identity becomes very obvious to the patient. Transsexuals strive, often successfully, to adopt the facial expressions and body language of the opposite sex and to work in occupations typically associated with the opposite sex.

The sexual partner orientation of male-to-female transsexuals is usually toward heterosexual men; in accordance with their perception of themselves as women, they do not view this orientation as homosexual. A few male-to-female transsexuals are sexually oriented toward female partners and perceive themselves as "lesbian." Female-to-male transsexuals seem to be almost invariably oriented toward female partners. There are also asexual individuals of both sexes.

The reported figures on the frequency of transsexualism are variable. The prevalence of the male-to-female variety is probably approximately 1:30,000, and that of the female-to-male variety approximately 1:100,000. The difference may have a sociocultural explanation. The female gender role is more flexible, at least in Western society; thus female-to-male transsexuals may find compromise solutions more easily than biologically male patients.

A responsibly performed differential diagnosis is of the utmost importance because, in severe cases of transsexualism, irreversible therapeutic measures are considered. The differential diagnosis must include the following disorders:

- *Homosexuality*, not accepted by the patient, accompanied by transvestitism: the homosexual, unlike the transsexual, basically accepts his or her biological body.
- *Fetishistic transvestitism:* A transvestite is sexually aroused by cross-dressing and does not identify permanently with the opposite sex.
- *Psychosis:* Transsexual symptoms in the framework of acute psychotic manifestations. These are only transient, and the other manifestations of psychosis are accessible to exploration by the therapist.
- *Early personality disorders*, particularly borderline pathologies, in which transsexual symptoms may appear transiently.
- *Conflicts of adolescence* with manifestations resembling transsexualism; these conflicts, too, are transient.

The essential criterion for the diagnosis of transsexualism is the complete and, above all, persistent mental identification with the opposite sex.

There is as yet no convincing explanation of the etiology of the transsexual syndrome. In children born of pregnancies supported with hormones of the opposite sex, behavioral alterations are found, including increased tomboyishness (in girls) or diminished aggressiveness (in boys), but never a disorder of sexual identity. Several authors have described electroencephalography (EEG) abnormalities in transsexuals, particularly in the frontotemporal region, but other authors have been unable to replicate these findings. Sociogenic and psychogenic etiologies are, to date, equally untenable. Sigusch (1996), who favors a psychogenic etiology, criticizes the "nosomorphic" view of transsexualism and compares it to homosexuality, which is no longer regarded as a disease state. He argues in favor of an analogous "de-pathologization" of transsexualism.

Practically all attempts to treat the transsexual syndrome with psychotherapy have failed. In the few reported cases of successful eradication of transsexualism by psychotherapy, the diagnosis of transsexualism was usually questionable.

In most cases, varying degrees of adaptation to the desired sex seem to be the most promising way to provide rehabilitation. The therapeutic procedure that has now gained international acceptance involves a series of therapeutic measures, provided over a period of years, that may culminate in a sex-change operation (Petersen and Dickey 1995). Therapeutic guidelines (so-called standards of care) for this procedure have been developed in several countries, including the United States and Germany (Becker et al. 1997).

The first step involves caring for and observing the patient for at least 1 year. The therapist tries to determine whether the transsexual desire remains stable and whether the patient can mentally accommodate a sex change. It has been found important to tell transsexuals repeatedly that the decisive therapeutic step is not the operation itself, but rather the preparation for it, which takes several years, during which the patient's ability to actually exchange gender roles is continually tested. The therapist also needs this period of time to check and consolidate the diagnosis.

The second step is the so-called everyday life test. The patient lives in the desired gender role fully, i.e. all day long, for at least 1 year. The patient must contend with the reactions provoked by the change in the social environment and determine whether the gender change has been successful.

If the patient has acquired a large measure of security in the new gender role, this may be further supported in a third step, the administration of hormones of the opposite sex. This treatment should be continued for at least 6 months before a sex-change operation. It enables the patient to experience the postoperative state before the (irreversible) operation is actually performed. Male-to-female transsexuals experience a decrease of libido, breast growth, and redistribution of subcutaneous fat, with an increased amount on the hips; while female-to-male transsexuals experience deepening of the voice, coarsening of the skin and facial features, and, in some cases, growth of facial hair.

If the first three steps have been successful, the fourth step is the sex-change operation itself. For male-to-female transsexuals, penectomy, castration, and the construction of a neovagina are usually performed. In individual cases, the construction of breasts by plastic

surgery may be necessary. For female-to-male transsexuals, bilateral mastectomy, oophorectomy, and (in some cases) hysterectomy are performed. The results of phalloplasty have been unsatisfactory to date; at present, so-called clitoral mobilization is usually performed instead.

After the operation, further treatment of the transsexual patient is still required, as both medical and mental difficulties may arise.

Pfäfflin and Junge (1992) summarized the results of a large number of follow-up studies of transsexuals who underwent sex-change operations. They concluded that the form of treatment consisting of the entire process of sex transformation is, indeed, effective. From the patient's viewpoint, treatment results in "alleviation of suffering and increased subjective satisfaction" in many different areas of life (partnership, sexuality, career, etc.).

From their review of the literature, Pfäfflin and Junge (1992) conclude that the following are positive prognostic factors for the further life course of transsexuals:

- Continued contact with a treatment facility
- Performance of the everyday life test
- Performance of hormonal treatment
- Counseling, or psychiatric or supportive psychotherapeutic treatment
- The sex-change operation itself and its quality
- Legal recognition of the sex change through a change of name and personal status

In Germany, the so-called Transsexual Law (*Transsexuellen-Gesetz*, TSG) was officially proclaimed in the Federal Legal Register[1] on 10 September 1980. The TSG provides that transsexuals may obtain a change of name and personal status through the responsible court authority. Before the name may be changed, it must be established, in two independently performed medicolegal evaluations, that the following requirements are met:

- The petitioner considers himself or herself as belonging not to the sex in which he or she was born, but to the opposite sex.
- He or she has felt compelled to live in accordance with this belief for at least 3 years.
- According to the current understanding of medical science, the petitioner's feeling of belonging to the new gender role will, to a high degree of probability, not change in future.

For a change of personal status, it is further required that the patient is not married and "permanently incapable of reproduction, and has undergone a surgical procedure to change his or her external sexual characteristics, through which a clear resemblance to the appearance of the opposite sex has been achieved." Because of the far-reaching nature of the legal decisions that are made on the basis of medicolegal evaluations, the evaluations themselves must be based on a very thorough examination of the petitioner. Guidelines for these evaluations have been developed recently (Becker et al. 1997).

Germany was the second country (after Sweden) to introduce specific legislation dealing with transsexuals. Since then, similar legal provisions have been made in other European countries, namely Italy, the Netherlands, and Turkey. In other countries, no special legislation was required, because the already existing laws were sufficient. The deciding bodies are either registry offices and comparable institutions (as in Austria, Denmark, Norway, some U.S. states, and Asia) or the courts (as in Belgium, Spain, France, and Poland).

Sleep Disorders

This work was partially supported by NIH grants 1K07 HL03640 and 1R01DA10682-01A2.

1 Introduction

There are a number of ways to classify sleep disorders, and indeed it may be some small comfort to the psychiatric community that our brethren in sleep research struggle with nosologic issues similar to those encountered when describing psychopathology. The International Classification of Sleep Disorders includes "dyssomnias" (intrinsic and extrinsic sleep disorders as well as those resulting from circadian rhythm disturbances), parasomnias (abnormal behaviors during sleep), and sleep disorders associated with mental, neurologic, or medical illness (ASDA 1997). DSM-IV describes primary sleep disorders, sleep disorders related to another mental disorder, and other sleep disorders, which include those associated with medical conditions or substance abuse (American Psychiatric Association 1994). This chapter is organized primarily on the basis of etiology and focuses on disturbances that are of most relevance to psychiatric practice; those wishing to see a broader spectrum or to obtain more detail are referred to major texts in the field (Mendelson 1987; Thorpy 1990; Poceta and Mitler 1998; Kryger et al. 2000). A detailed presentation of sleep disturbances in children, which is beyond the scope of this chapter, may be found in a recent compendium (Dahl 1996), and reviews have described the most recent findings in narcolepsy (Pelayo and Guilleminault 1998) and in sleep disturbance due to medications (Mendelson and Caruso 1998).

Let us begin with a reminder about a concept important to understanding sleep disorders in general. Since the birth of modern sleep research with the discovery of rapid eye movement (REM) sleep in the 1950s, there has been growing recognition that there are three states of consciousness: waking, REM sleep, and non-REM sleep. Each of these has a unique physiology, and indeed the physiology of REM is as different from the rest of sleep (non-REM) as the latter is from waking. Thus the regulatory mechanisms for thermal or ventilatory homeostasis found in major textbooks should be understood to be referring to processes that function when the individual is awake. It is almost as if a medical bookshelf should contain texts side by side: one for the physiology of wakefulness, and one (or even two) for physiology during sleep. Thus, while in a waking person exposure to increased ambient temperature will result in perspiration and increased ventilatory rate, and reduction in arterial oxygen saturation will cause an increase in minute ventilation, such responses are seen only very slightly if at all during REM sleep (Sullivan 1980; Parmeggiani 1980). This phenomenon explains a basic principle we will be dealing with in this chapter – that there are a number of illnesses based on pathophysiology which are manifest only during sleep. When awake, the pathophysiology is not evident, although some consequences, such as daytime sleepiness, may be. One of the best examples is found in sleep-disturbed respiration, with which we shall begin. After discussing this and another intrinsic disorder of sleep – periodic limb movement (PLM) disorder – we will describe delayed sleep phase syndrome, as an example of a circadian rhythm disorder, and then sleep disturbances due to causes extrinsic to sleep, including drugs and medical illness. We will conclude with comments about sleep in psychiatric illness, particularly depression, and two forms of insomnia which at this point are understood primarily in neuropsychological terms: psychophysiologic insomnia and sleep state misperception.

2 Sleep-Disordered Breathing

The historic roots of the understanding of sleep apnea lie in the late nineteenth century. Among those who first described sleep-disturbed breathing is S. Weir Mitchell, a neurologist important in the history of psychiatry for his rest cure for neurasthenia and for his advocacy of integrating psychiatry into the mainstream of medical research. In 1890, Mitchell described patients whose respiration was normal while awake, but who developed respiratory failure during sleep and would awaken with a sense of suffocation (Mendelson 1987); other contemporaries related upper airway obstruction to sleep disturbance and daytime somnolence (Lamacq 1887; Wells 1898). In more contemporary terms, a patient with uncomplicated sleep apnea is a person whose respiration when awake is fundamentally normal, but when sleeping develops full (apnea) or partial (hypopnea) periods of cessation of breathing. Depending on the definition used, the threshold for diagnosis is considered to be five or ten disordered breathing events (apneas and hypopneas) per hour of sleep (referred to as the apnea/hypopnea index). Most patients are unaware of having these events, although a bed partner may describe them. Typical complaints include daytime sleepiness, a sense that sleep is not restful, decreased libido, sexual dysfunction (Mendelson et al. 1990), and memory difficulties (Thorpy 1990; ASDA 1997). Some patients may report awakening with a sense of being unable to breathe, although reports of this nature should be evaluated in terms of a broad differential diagnosis including panic attacks, nocturnal asthmatic episodes, and nocturnal laryngospasm. The disordered breathing events may be

primarily obstructive (in which there is functional closure of the upper airway), central (representing a decrease in central respiratory drive), or mixed type. Obstructive sleep apnea (OSA) occurs more often in males than females by a ratio of perhaps 2:1. It tends to be an illness of middle life, although it can occur at any age, even in children, in whom there is a similar frequency in males and females. Associated features in adults include a history of snoring, obesity, and systemic hypertension. Patients with OSA have a higher rate of automobile accidents, presumably due to sleepiness, and those with an apnea/hypopnea index greater than 20 per hour have a somewhat higher mortality rate. Central sleep apnea can occur at any age, but is most common in the elderly. It, too, is more common in men than women, although after menopause this difference is reduced. A history of snoring is less common. The classical teaching is that OSA patients tend to complain of excessive sleepiness while central sleep apnea patients tend to complain of insomnia, although later studies suggest that this difference is less clear than was originally suggested (Mendelson 1995c).

As mentioned above, complaints of memory difficulties are common in OSA patients, and indeed cognitive deficits have been observed in various studies (Bedard et al. 1993). Whether treatment successfully reverses these deficits is not yet clear. One study has suggested that treated patients have improvement in long-term free recall or explicit memory (Mendelson et al. 1993), while others have shown persistent deficits in various measures even after continuous positive airway pressure (CPAP) therapy (Bedard et al. 1993).

There is evidence indicating that 20% of OSA patients currently have some form of depressive disorder using research diagnostic criteria (Reynolds et al. 1984), and the 5-year prevalence of major depressive disorder has been estimated to be 58% (Mosko et al. 1989). Some preliminary data suggest that patients with past or current treatment for depression have a significantly greater apnea/hypopnea index and total number of disordered breathing events and tend ($p < 0.06$) to have a lower minimum oxygen saturation than those with negative histories (Mendelson 1992). A later series of 199 OSA patients examined scores on the Minnesota Multiphasic Personality Inventory (MMPI) (Aikens et al. 1998). The depression scale was the most prominently abnormal scale, significantly elevated in 27% of patients, followed by hypochondriasis (22%) and hysteria (21%). The total number of MMPI elevations had a significant negative correlation with total sleep time, sleep efficiency, minimum oxygen saturation in non-REM sleep, and mean oxygen saturation in both REM and non-REM sleep. The depression scale itself did not significantly correlate with measures of sleep-disturbed respiration, although it was significantly related to total MMPI elevations. In summary, a range of symptomatology, including somatic concerns, emotional overreactivity, and other features, are often seen in OSA patients.

The original treatment for OSA was chronic tracheotomy, which, though effective, involves a major surgical procedure, requires chronic care, and is subject to various complications over time. Subsequently, uvulopalatopharyngoplasty (UPPP), which removes redundant tissue from the airway, was developed. Its advantages are that, when successful, it is a one-time procedure as opposed to other forms of treatment which require ongoing therapy; its disadvantage is that the success rate (which is highly dependent on the criteria employed) is in the range of 60%–70%, and it can also occasionally lead to complications, such as regurgitation of liquids or alterations in voice. Some centers perform specialized procedures including limited anterior sagittal mandibular osteotomy with genioglossus advancement, hyoid myotomy, maxillomandibular osteotomy with hyoid myotomy, or partial glossectomy (Powell et al. 1989; Douglas 1997). A relatively new procedure, the laser-assisted uvuloplasty (LAUP), has the advantage of being a more benign, outpatient procedure. Its effectiveness is still under investigation, but the evidence to date suggests that it is very useful for treating snoring in the absence of significant sleep-disordered breathing, but that there are little data to indicate that it is helpful for true OSA. Mechanical techniques such as tongue-retaining devices are also used, although their success rate is under investigation.

The most widely used treatment is CPAP, in which room air is introduced into the nose via a nasal mask or cushioned cannulae. It is very effective in the majority of patients. Its disadvantages are that it is a chronic treatment generally given for years and that there is often decreased compliance over time. Medical treatments at this point have been less successful. Among those that are used are protriptyline (which may increase tone of the genioglossus as well as reducing REM sleep) and medroxyprogesterone. Buspirone and fluoxetine have been used experimentally. (For all of the preceding compounds, these represent "off label" uses which are not specifically indicated in the American *Physician's Desk Reference.*) In clinical practice, this author's view is that the various medical approaches available at this time are best reserved for relatively mild cases or special situations such as for patients who are noncompliant or who refuse surgery or CPAP.

Ancillary treatments include weight loss, training to avoid sleeping on one's back, and avoidance of alcohol and other drugs which are respiratory depressants. Thus it is important to consider the possibility of sleep

apnea before administering many sedative/hypnotics to patients who may complain of poor sleep and, if features suggestive of the disorder (e.g. obesity, hypertension) are present, to obtain the services of a sleep laboratory. Drugs which are of particular concern for respiratory depression are the barbiturates. The older, long-acting benzodiazepines such as flurazepam may also exacerbate sleep-disturbed breathing; the newer, short-acting agents appear to be more benign in this regard.

In passing, it should be mentioned that one of Freud's more controversial colleagues was a Berlin otolaryngologist named Wilhelm Fliess, who believed that a number of psychiatric disorders, including depression, might be helped by operating on the nose. Although this idea has been held up to ridicule in some circles, in view of the possible association of sleep-disordered breathing with depressive symptomatology, with possible reversal after CPAP therapy (Millman et al. 1989), it may be that Fliess had more insight than he was credited for.

3 Periodic Limb Movement Disorder

Like sleep-disordered breathing, PLM is a disorder occurring primarily when the patient is asleep, with no specific manifestations in an awake patient. In this sense, it is referred to as a state-dependent motor disorder. PLM can be present in patients who complain of either insomnia or excessive sleepiness; in one case series of approximately 1700 patients in a sleep disorder center, it accounted for 13% and 6% of such cases, respectively (Mendelson 1997b). This is primarily a disorder of middle and older age and occurs equally in males and females. Typically, a patient has a normal neurologic examination when awake, and no evidence of seizure disorder on a waking or sleeping electroencephalogram (EEG), but when asleep has periodic movements of the limbs of which he or she is usually unaware. During a sleep study, these are manifested as movements in the anterior tibialis electromyogram (EMG), lasting 0.5–5.0 s, occurring approximately every 20–40 s. Often these are accompanied by brief evidence of arousal in the EEG (a K complex, alpha activity, or change to a lighter sleep stage). The most common diagnostic criteria is that there be at least five per hour. Clinically, these episodes are manifested as extensions of the big toe with dorsiflexion of the ankle, sometimes accompanied by knee flexion. In this sense, they are more reminiscent of a Babinski movement than a myoclonic jerk. The patient is usually unaware of the movements per se, but has a sense that his or her sleep is restless and unrefreshing. The bed partner, however, may be very aware of the movements, and hence it is often useful to interview him or her as well during a clinic visit.

The association of PLM with the subjective experience of poor sleep is not well understood, and indeed perhaps 6% of medical center staff with no sleep complaint meet the polygraphic diagnostic criteria (Kales et al. 1982). A later study of a clinical population complaining of either insomnia or excessive sleepiness found no correlation between the PLM arousal index (number of PLM associated with a brief EEG arousal, per hour of sleep) and subjective or objective measures of daytime sleepiness or a report of awakening refreshed or unrefreshed in the morning (Mendelson 1996). While the final answer is unclear, many clinicians believe that, although these movements can occur in people with no sleep complaints, there may be a subgroup in whom the associated arousals disturb sleep continuity to a degree that may correspond to a sense of having poor sleep.

The usual therapy for PLM has been low doses of clonazepam (Mitler et al. 1986), although compliance is often poor due to sedation; the shorter-acting temazepam (Mitler et al. 1986) and triazolam also may be used (Bonnet et al. 1990). The condition may be exacerbated by tricyclic antidepressants (Ware et al. 1984), and hence this possibility should be considered when a patient placed on these agents complains that sleep has worsened. It may occur transiently during withdrawal from barbiturates or benzodiazepines.

4 Restless Legs Syndrome

In contrast to PLM, restless legs syndrome (RLS) is a state-dependent sensory disorder. It is very different in another sense as well; while PLM is a polygraphically defined process in which the association with a subjective feeling of poor sleep is not entirely clear, RLS is primarily based on a subjective report, with minimal polygraphic evidence present. The typical history is of a dysesthesia, a "creepy crawly" or "pins-and-needles" sensation of the limbs, which occurs at rest and is relieved by movement. It is manifest as a sleep disorder insofar as patients have difficulty lying in bed to initiate sleep, but feel a need to get up and move around in order to dissipate this uncomfortable sensation. Although it can occur at any age, as with PLM it is most commonly a disorder of the middle and older years, but unlike PLM it is more common in females. It appears to have a higher frequency in patients with iron or B_{12} deficiency anemia and in patients with significant renal disease. It may also appear in pregnancy, usually after the 20th week of

gestation. Sleep studies reveal that most of these patients also have PLM (although only a small subset of PLM patients have RLS). Aside from this, there is little to be seen on polysomnography apart from increased motor movement artifact before sleep onset. It may be brought out by use of the forced immobilization test, in which a patient is immobilized on a stretcher for 60 min and sensory and motor events are recorded (Pelletier et al. 1992). The treatment of choice at this point is levodopa (Montplaisir et al. 1986), with use of bromocriptine (Von Scheele and Kempi 1990) in patients who do not respond well, although these are off-label indications for these compounds in the United States. The physician should check for, and treat, anemia. Many patients also develop anxiety or depressive symptoms which may require attention.

5 Circadian Rhythm Disorders: Delayed Sleep Phase Syndrome

Delayed sleep phase syndrome (DSPS) is a disorder in which the endogenous central nervous system (CNS) mechanisms for regulating the sleep/wake cycle operate in a stable but delayed phase relationship to the more typical times of waking and sleeping. In theory, it results from an inadequate ability of endogenous pacemakers to be reset by zeitgebers in the environment (primarily sunlight) to a typically scheduled 24-h day. A more extreme form of dysfunction, in which the pacemakers operate completely independently of the environment, such that the sleep/wake cycle tends to manifest the endogenous rhythm of approximately 25 h, is found in the much less common non-24-h sleep/wake syndrome. Patients with DSPS may present with a complaint of initial insomnia (Weitzman et al. 1981) or with difficulty with sleepiness in the morning. Onset is often in adolescence, and it is unusual to have symptoms appear for the first time after age 30. The data on the sex ratio are inconsistent, but it probably has approximately equal frequencies in men and women in the adult form. Typically a patient will describe being unable to fall asleep before 2:00 or 3:00 A.M. and then difficulty getting up before late morning. This may lead to problems with tardiness at school or work. There is often a history of use of sedative/hypnotics without much benefit, and this author has the clinical impression that many patients have been treated unsuccessfully for depression. Many patients have self-medicated with alcohol, and their sleep disturbance may be complicated by dependence.

A sleep study in DSPS usually reveals a very long sleep latency (time from the beginning of the recording until the patient first enters sleep), but then a relatively normal pattern, with minimal arousals. Thus this is a disorder of the timing, rather than the quality, of sleep. The original treatment for DSPS was chronotherapy (Czeisler et al. 1981), i.e. gradually moving the patient's time of sleep around the clock until his or her bedtime occurs at a more typical hour. In the short term, this is a fairly disruptive intervention, and compliance is often poor. A much more convenient therapy is to expose the patient to bright lights for 2 h in the morning, which phase-advances the sleep/wake rhythm to a more socially acceptable time (Rosenthal et al. 1990). In passing, it should be mentioned that there is one small case series of patients who became suicidal when given bright light therapy for seasonal affective disorders (Praschak-Rieder et al. 1997); the significance of this possible unusual association is under investigation.

6 Sleep Disturbance Due to Medications or Medical Illness

A wide range of prescription medications may result in disturbed sleep. The following may cause insomnia:

- CNS stimulants, e.g. dextroamphetamine
- β-Adrenergic agonists
- Steroids
- Calcium channel blockers
- Lovastatin
- Aminophylline
- β-Adrenergic blockers
- Thyroid preparations
- Cancer chemotherapeutic agents
- Fluoxetine

Other medications may cause daytime sleepiness, including the following:

- Sedative/hypnotics, particularly long-acting agents, e.g. flurazepam
- Phenytoin
- Disulfiram
- Tricyclic antidepressants
- Histamine-1 antagonists
- Centrally acting α-adrenoreceptor agonists

In psychiatric practice, a common dilemma is that patients may develop insomnia when placed on monoamine oxide (MAO) inhibitors or some selective serotonin reuptake inhibitors (SSRI), particularly fluoxetine. The ideal response is to lower the dose or discontinue the medication, but of course clinically this may not be possible. In that situation, low bedtime doses of trazodone may be added, although the

physician should be aware of rare instances of confusional states which may result.

It is also important to assess caffeine intake. In addition to caffeinated beverages, significant quantities are also found in a variety of nonprescription medications sold for a variety of reasons, including weight loss, headache, and menstrual discomfort. It is important to look for a present or past history of alcohol dependence. Even after a patient is "dry," sleep disturbances may persist for as long as 2 years.

Any medical disorder that causes pain or discomfort may of course disturb sleep, whether this be arthritic pain keeping an elderly patient awake or difficulty in breathing experienced by a congestive heart failure patient when lying down. In these types of patients, therapy is best directed at the underlying disorder rather than the sleep disturbance per se. Thus for the elderly arthritic patient, for example, the best remedy may be an analgesic rather than a hypnotic, and for the congestive heart failure patient a reassessment of the diuretic or cardiac medicines may be in order. The general principle, then, is to treat the underlying process whenever possible. This is true whether the fundamental difficulty is a medical problem or psychiatric disorder, as will be discussed in the next section.

7 Sleep in Depression

Sleep disturbance is reported by about 90% of patients with major affective disorder (Nelson and Charney 1980), and improvement in sleep has been interpreted by some to be one of the first signs of recovery (Mayer-Gross et al. 1960). A smaller group – perhaps 10% – complain of hypersomnolence, and these tend to be the bipolar or atypical depression patients. Sleep laboratory data indicate that total sleep and the amount of slow-wave sleep (stages 3 and 4) are reduced, while the number of awakenings during the night is increased (Mendelson 1987). Although theories put forth in the 1960s suggested a link between reductions in REM sleep and depression, the total amount of REM sleep is normal or only slightly reduced. A number of features of REM sleep are altered, however. It tends to occur earlier, often less than 60 min after sleep onset, a phenomenon known as a "short REM latency," which has been viewed by some investigators as a possible biological marker of depression. In addition, the first REM period is often longer, and characterized by more eye movements, than in controls. These changes have been interpreted in a variety of ways, and possible hypotheses have been that this reflects an alteration in the homeostatic regulation of sleep, a phase advance of a pacemaker regulating REM sleep, or increased cholinergic relative to noradrenergic activity (Mendelson 1987). Perhaps the most important point, however, is that a short REM latency is fairly sensitive, but not very specific, for depression, as it occurs in a variety of other conditions. Among these are obsessive-compulsive disorder, anorexia nervosa, drug and alcohol withdrawal, some instances of schizophrenia, divorcing women, and alcoholics with secondary depression. This has led some investigators to speculate that the short REM latency represents a marker of stress or illness severity rather than depression per se.

In practical terms, management of the sleep disturbance is best handled by aggressive treatment of the depression itself. There is little evidence to support the common practice of adding a benzodiazepine to the therapeutic regimen early in treatment. Usually a sedating tricyclic antidepressant or trazodone at bedtime provides relief during the period before the antidepressant effect is manifest. As mentioned earlier, a more difficult problem is the sleep disturbance which may result from MAO inhibitors and some serotonin reuptake inhibitors, which is best dealt with by dose adjustment or addition of a low dose of trazodone.

In passing, it should be mentioned that the sleep disturbance may not be merely an epiphenomenon of depression, but rather may in some sense be intimately related to the pathology. A variety of manipulations of sleep, including REM sleep deprivation, and partial or total sleep deprivation may effectively treat the constellation of depressive symptoms in a manner comparably effective as conventional therapies (Gillin 1983). The mechanism by which these treatments act remains to be elucidated. It is not clear, for instance, whether total sleep deprivation acts by altering circadian processes or whether it produces a nonspecific activation as opposed to a very specific improvement in depression. Although such techniques are very labor intensive and hence mostly of heuristic value, they do suggest a close relationship between disorders of sleep and affect. There are, of course, a wide variety of sleep disturbances in nonaffective psychiatric disorders, and the reader is referred to a recent thorough review (Kerkhofs 1997).

8 Chronic Insomnia

Many patients present with long-standing insomnia, but without evidence of major psychiatric or medical disorders, and do not manifest specific pathophysiology such as sleep apnea or PLM. These patients, who represent perhaps 20% of those seen in a typical sleep disorders center (Mendelson 1997b), are primarily

understood in neuropsychological terms. They are often divided into those with sleep disturbance manifest on the sleep recordings and in whom conditioned behaviors contribute to poor sleep (psychophysiologic insomnia) and those whose complaint of sleep disruption seems very disproportionate to the relatively mild changes found in their polygraphically measured sleep (sleep-state misperception insomnia). We will examine each of these in turn.

8.1 Psychophysiologic Insomnia

Of the two, psychophysiologic insomnia is by far the most common and is manifest by anxiety about not sleeping, which then in turn contributes to perpetuating the poor sleep. As in sleep-state misperception, it is more common in women than men; the typical age of onset is young adulthood, although patients are often not seen clinically until middle age. Phrased in behavioral terms, the typical patient has developed conditioned behaviors incompatible with sleep which become associated with the act of going to bed. The cues may be external (an association of the bedroom environment with a sense of distress about sleeping) or internal (a conditioned worrying about being unable to sleep). A typical story, which is not usually evident until after several visits, is that at some time in the past there was an emotionally traumatic event, such as an unhappy ending to a romantic relationship, which might be expected to lead to sleep disturbance in almost anyone. Typically, of course, a form of grief reaction occurs, and the sleep disturbance resolves along with the other signs of stress. These patients, however, seem to focus on the sleep disturbance rather than the reality issues; over time, the original trauma is sorted out, but the insomnia has taken on a life of its own. Clinically, it is characterized by difficulty going to sleep (as opposed to awakening during the night) and excessive worry about sleep. When questioned, the patient may report that he or she sleeps better when away from home (i.e. away from the stimuli associated with poor sleep) and that he or she can fall asleep when not trying (e.g. when watching television in the living room), but not when trying to sleep after going into the bedroom. The act of trying to sleep thus becomes a behavior which inhibits the ability to fall asleep.

8.2 Sleep-State Misperception

In sleep-state misperception, a patient who complains of chronic difficulty in going to sleep or awakening during the night is found to have relatively normal sleep as determined in the laboratory. The discrepancy between the patient's reported experience and the physiological measures has led to the hypothesis that this disorder results from the patient's misperception of his or her state of consciousness. An insight into this process comes from studies going back as far as the 1960s in which it was shown that many poor sleepers, when awakened by an auditory stimulus shortly after EEG-defined sleep onset, tend to report that they believe that they had been awake even though the polygraph indicated that they had been in non-REM sleep (Mendelson 1990). Later studies have indicated that, when such patients are given hypnotics such as triazolam or zolpidem, their reports of whether they had been awake or asleep become more consonant with the EEG (Mendelson 1993, 1995b); reports of having been awake or asleep in normal sleepers are not altered under these experimental conditions (Mendelson 1995a). An implication of these studies, then, is that hypnotic medications may not only increase the amounts of EEG-defined sleep, but may also alter the subjective experience of being asleep in some insomniacs.

Incidentally, it should be mentioned that there are also some patients with idiopathic insomnia, which typically begins in childhood and lasts throughout their lives. Both clinically and polygraphically, this may be mild or severe. The etiology is unknown, but presumably represents failure of sleep-inducing or -maintaining systems. When seen in childhood, there is often a history of birth complications, dyslexia, or hyperkinesis. In adults, there is often an overlay of suspiciousness, irritability, and dysphoric qualities, although there is no evidence of a higher frequency of major depressive disorder. Key elements of the history are that the sleep difficulty goes back to childhood and that the severity does not follow a temporal path parallel to periods of stress or emotional upset. In contrast, a diagnosis of sleep disturbance associated with depression, for instance, would require that there be a clear temporal pattern in which the sleep disturbance is coincident with clinical depressive symptomatology.

Although the processes which maintain the insomnia symptoms in some chronic insomnia patients are beginning to be understood (e.g. the conditioned behaviors incompatible with sleep in psychophysiologic insomnia), little is known about the underlying predisposing factors. One promising hypothesis suggests that there is a state of hyperarousal, as measured by heart rate, core temperature, and metabolic rate (Bonnet and Arand 1997).

8.3 Treatment

Both pharmacologic and nonpharmacologic treatments are available for the primary insomnias. The major sedative/hypnotics used are the benzodiazepines and the newer non-benzodiazepine γ-aminobutyric acid (GABA)A-benzodiazepine receptor agonists, including zaleplon, zolpidem and zopiclone, which have recently been reviewed (Mendelson and Caruso 1998). Unless daytime sedation is specifically desired, the shorter-acting agents are generally more appropriate. A recent review of reported adverse reactions to sedative/hypnotics during a 3-year period in a large teaching hospital indicates that most are mild and can be viewed as extensions of the therapeutic effect; the median frequency of reported adverse effects was 1 in 10,000 doses administered (Mendelson et al. 1996). In patients in whom traditional sedative/hypnotics are not effective, many clinicians use low bedtime doses of sedating tricyclic antidepressants or trazodone, although these are "off-label" indications in the United States. There has been a great deal of interest in the use of melatonin as a hypnotic; although this is an area in which there is not yet general agreement, this author's view is that there are very little data to support its use in insomnias which are not due to circadian rhythm disturbances (Mendelson 1997a).

Nonpharmacologic approaches to the primary insomnias are based on behavioral techniques (Mendelson 1987). Although they differ in their specifics, most have elements in common. These include documenting the amount of sleep, emphasizing self-management, encouraging the patient to take a more active stance, and helping the patient to see the sleep difficulty in the broader context of his or her waking life. Probably the two most widely used approaches are sleep restriction and stimulus control. Sleep restriction therapy (Spielman et al. 1987) is based on the notion that excessive time in bed helps perpetuate sleep disturbance, although the original cause may have been some other process. The technique is to make sleep more efficient by first shortening time in bed and then slowly increasing it; a 35-week follow-up study showed continued benefits as measured by total sleep, sleep efficiency, and waking time after initial sleep onset. The stimulus control technique (Bootzin and Engle-Friedman 1987), derived from operant conditioning principles, seeks to remove behaviors that are incompatible with falling asleep. Such behaviors include, for instance, having unhappy discussions with one's spouse in the bedroom, using the bed as a place to plan tomorrow's activities, or worrying about not sleeping. Thus the patient is instructed to strip the bedroom of all activities except sleeping and sex. The patient is told that if he or she is lying in bed unable to sleep, to get up and go into another room, and not return to bed until he or she feels able to sleep. After a 4-week treatment period, benefits have been reported to be maintained at 6-week follow-up (Puder et al. 1983). It should also be mentioned that medication and nonpharmacologic techniques are not necessarily incompatible. One study has indicated that patients who received a combination of behavioral therapy and triazolam were doing better in terms of total sleep and feeling rested in the morning 5 weeks after treatment compared to patients in monotherapy (Milby et al. 1993).

9 Conclusion

Sleep difficulties may be seen as symptoms of underlying processes that include intrinsic pathophysiologies of sleep, circadian rhythm disorders, medical or psychiatric illness, drugs, conditioned behaviors incompatible with sleep, or misperception of states of consciousness. For any given patient, the goal is to identify the underlying disturbance and provide a specific treatment.

CHAPTER

15

R.J. Hodgson, R. Budd, M. Griffiths

Compulsive Behaviours

1 Introduction

Many of the compulsive behaviours or behavioural addictions that are the focus of this chapter appear to fit the DSM-IV definition of impulse control disorders. This definition includes failure to resist an impulse, drive or temptation to perform some act that is harmful to the person or others; an increasing sense of tension or arousal before committing the act; and an experience of immediate pleasure, gratification or release when the act is initiated or completed. Compulsive behaviours such as compulsive buying or compulsive gambling also share many characteristics with drug dependence as well as with obsessive–compulsive disorders. However, in order to justify the use of the term compulsive behaviour rather than excessive, impulsive or addictive behaviour, there is a need to explain the use of the term compulsive.

It is tempting to suggest that there are compulsions that function to avoid distress, such as obsessive–compulsive disorders, and compulsions that function to achieve pleasure or gratification, such as compulsive buying or sexual compulsions. Certainly this distinction might apply to the initial stages of the development of the habit, but when a compulsion is full blown, the situation is more complicated. Although a sexual compulsion, for example, results in immediate pleasure, there are also occasions when the avoidance of preoccupation and frustration becomes more important than the achievement of gratification.

Thus a closer analysis leads to the conclusion that most compulsive behaviours have one characteristic in common, i.e. resisting an urge results in an unpleasant experience. This unpleasant experience could be called anxiety if a threat is involved, and frustration if there is a loss of an expected gratification (Table 1).

The following definition of a compulsive behaviour flows from this framework. It focuses upon the expected consequences of resisting the performance of an urge.

A compulsive behaviour is an active avoidance response. The avoidance is of intense, expected subjective experiences such as those associated with anxiety, frustration, guilt, anger or withdrawal symptoms. The other aspect of compulsion that needs to be emphasised is ambivalence. There is often a desire to carry out the compulsion and often a desire to resist.

Although this approach to compulsion applies to a wide range of behaviours such as drug use and obsessive–compulsive disorders, this chapter will focus upon the following disorders: compulsive gambling, compulsive buying, compulsive exercise, compulsive stealing, sexual compulsions and technological compulsions.

Table 1. Experiences associated with compulsive avoidance and compulsive appetites when behaviour is resisted or initiated after a long delay

	Behaviour resisted	Behaviour initiated after delay
Compulsive avoidance (e.g. OC disorder)	Anxiety	Relief of anxiety
Compulsive appetites (e.g. sexual compulsions)	Frustration	Relief of frustration

OC, obsessive–compulsive.

2 Compulsive Gambling

2.1 Definition

Compared to the other compulsive behaviours gambling, has been the subject of many academic and clinical publications, but the majority are speculative and do not provide definitive guidelines. Future epidemiological studies will be on a better footing thanks to the recent development of a reliable and valid method of identifying compulsive gamblers in community and clinical population.

The South Oaks Gambling Screen (SOGS) (Volberg and Steadman 1989) has been shown to be reliable and valid in identifying compulsive gamblers within a range of settings (Lesieur and Blume 1987). The SOG includes 20 items derived from the criteria published in the third edition of the *Diagnostic and Statistical Manual* (DSM-III), including the following:

- Gambled more than intended
- Have felt guilty about gambling
- Unable to stop gambling
- Others have criticised gambling

The 4-week test–retest reliability for SOGS is 0.71, and the internal consistency is 0.97. The correlation with a detailed clinical assessment based upon DSM-III-R is 0.94.

2.2 Prevalence

Estimates of the number of probable adult pathological gamblers vary from 0.2% to 1% in the United Kingdom (Dickerson 1974; Royal Commission 1978), 0.77% to 3.4% in the United States (Kallick et al. 1979; Culleton 1985; Sommers 1988; Volberg and Steadman 1988,

1989) and 0.25% to 1.73% in Australia (Dickerson and Hinchy 1988). These surveys have also indicated that pathological gambling is twice as common among males as it is among females, that non-whites have higher rates than whites and that those with poor education are more likely to be pathological gamblers (Lesieur and Rosenthal 1991).

As with many other excessive and dependence behaviours, availability is an important influence. For example, a study of prevalence across different states in the United States found that the number of opportunities to gamble at casinos, with slot machines, on sports and in teletheatres was associated with greater per capita incidence of Gamblers Anonymous chapters (Lester 1994). It is likely that the prevalence of excessive gambling will increase if opportunities to gamble continue to increase in many countries.

The acquisition, development and maintenance of pathological gambling is an area that is continually disputed. The exact causes and reasons for continuing gambling behaviour seem to be dependent upon the individual, but there also seem to be some general underlying factors and recurring themes. Problem gambling generally begins in adolescence and may start following a major life stress (Wolkowitz et al. 1985), e.g. the death of a parent or the birth of the first child. Such events may induce a need to escape from the problems of reality (Moran 1970). Prior to the age of 15, other predisposing factors may include serious family problems (e.g. divorce of parents), inappropriate school or parental discipline, exposure to gambling in childhood and/or adolescence (by family and/or peers) and even familiar emphasis on material symbols rather than savings (American Psychiatric Association 1980). According to Custer and Custer (1981), there are several "soft signs" of pathological gambling, including a higher than average I.Q., a lively and energetic personality, a predilection to taking risks, a lack of hobbies and interests, a low boredom threshold, episodic insomnia and "workaholic" tendencies.

As with all compulsive and dependence behaviour, it is important to recognise the heterogeneity of gambling. Firstly, there are many types of gambling, including the casino, cards, lotteries, horse and greyhound racing, bingo, gaming machines, dice, the stock market, games of skill and sports. Secondly, many types of people take many different routes into gambling and experience a range of consequences. Volberg and Steadman (1988), for example, identified two distinct groups of excessive gamblers based upon income. Lower-income gamblers were less likely to be white or male, had significantly lower levels of education and were more likely to have tried to stop gambling. They were less likely to have tried many types of gambling and tended to gamble less frequently. The higher-income group experienced more frequent criticism by others about their gambling and had argued more often with others about this behaviour. They had more frequently borrowed from banks and loan companies or chased in stocks and bonds. It is probable that different treatment interventions will be found to be appropriate for different types of people who gamble excessively in different settings with different levels of severity.

2.3 Treatment

Although in most spheres of treatment, therapists have claimed a reasonable amount of success, it is probably fair to say that gambling has been fairly resistant to therapy interventions and that the gamblers themselves may be reluctant and resistant. The thorough meta-analysis of gambling treatment outcomes carried out by Walker (1992) claimed that only about a third of gamblers (37%) are still abstinent after 2 years. A recent study of cognitive-behavioural approaches in the treatment of excessive gambling on slot machines (Echebura et al. 1996) suggests that cue exposure and response prevention should be considered, especially since this approach has proven effectiveness with other compulsions (Rachman and Hodgson 1980). This successful treatment for gambling involved gradual in vivo exposure which encouraged participants to experience the desire to gamble and learn to resist this desire. At the start of treatment, high-risk situations were deliberately avoided and access to money was controlled. These rules were then gradually relaxed as treatment progressed. Cue exposure and response prevention was superior to cognitive restructuring therapy and also to a combined cognitive-behavioural approach at the 1-year follow-up point. Cue exposure resulted in a 69% rate of successful abstinence, whereas other treatments resulted in only 38% success.

Psychodynamic "cures" are at present almost non-existent (at least in the published literature), and aversive behavioural techniques are rarely used except in conjunction with other forms of treatment. The influence of the spouse of the adult gambler in successful treatment appears to be crucial, and it would seem that the most potentially effective treatments are those which acknowledge the multivariant nature of and influences on pathological gambling (e.g. cognitive, social and physiological) and utilise more than one therapeutic approach. The only "new" (and some might say radical) approach to the treatment of pathological gamblers could be in the field of psychopharmacology, which perhaps might see the use of beta blockers to decrease arousal levels during gambling (Brown 1986)

or the administration of opiate antagonists to block euphoric beta endorphin effects (Blaszczynski et al. 1986). There are already some published case studies on the success of treating pathological gambling using pharmacological agents, for instance, including the use of lithium carbonate (Moskowitz 1980) and clomipramine (Hollander et al. 1992).

3 Compulsive Buying

3.1 Definition

In the small body of literature on the subject, the condition is also referred to as oniomania, buying mania, compulsive consumption, compulsive shopping and addictive or impulsive buying. The ubiquitous and increasing use of credit cards is paving the way for an epidemic of compulsive buying, and yet there are still only a few research studies on which to base assessment and treatment advice (McElroy et al. 1994; Christenson et al. 1994).

As with many other excessive behaviours, compulsive buying can lead to severe personal distress and family disruption (Christenson et al. 1994). The main characteristics of this disorder are an irresistible urge to buy and a feeling of immediate relief following a purchase. Attempting to resist the urge upon the realisation that buying has become a severe problem often follows the build-up of large debts and criticism from family and acquaintances as well as legal problems and feelings of guilt.

In the study by Christenson et al. (1994), most compulsive buyers described experiencing irresistible urges, uncontrollable needs or mounting tension that could only be relieved by buying. Over 90% of them frequently attempted to resist the urges to buy, but were unsuccessful 75% of the time. Typically 1–5 h elapsed between initially experiencing an urge to buy and an eventual purchase. Usually compulsive buyers do not decide in advance exactly what they intend to buy.

Based upon a detailed study of 20 compulsive buyers, McElroy et al. (1994) proposed the following preliminary operational criteria:

1. Maladaptive preoccupation with buying or shopping, or maladaptive buying or shopping impulses or behaviour, as indicated by at least one of the following:
   a) Frequent preoccupation with buying or impulses to buy that are experienced as irresistible, intrusive, and/or senseless.
   b) Frequent buying of more than can be afforded, frequent buying of items that are not needed or shopping for longer periods of time than intended.
2. The buying preoccupation, impulses or behaviour cause marked distress, are time-consuming, significantly interfere with social or occupational functioning or result in financial problems (e.g. indebtedness or bankruptcy).
3. The excessive buying or shopping behaviour does not occur exclusively during hypomania or mania.

Note that for the first criterion either excessive buying or a preoccupation with buying must be present, but not necessarily both. For the second criterion, as with obsessive-compulsive and substance misuse disorders, the preoccupation or the buying behaviour must lead to marked distress, financial difficulties or interference with adaptive social or occupational functioning.

3.2 Treatment

There are no studies of effective treatments for compulsive buying, even though there are at least two self-help books which focus on this disorder (Damon 1988; Wesson 1991). McElroy et al. (1994) asked 20 patients to evaluate their response to treatments they had received. Neither insight-oriented psychotherapy nor pharmacological interventions (thymoleptic medications) appeared to be effective in the long term. It is also interesting to note that none of the patients had received cognitive-behavioural therapy for their compulsive buying.

4 Compulsive Exercise

4.1 Definition and Prevalence

Unfortunately, the lack of adequate research means that it is impossible to estimate the prevalence of compulsive over-exercising in the general population. To date, what evidence there is on this problem has mostly taken the form of clinical case reports (e.g. de la Torre 1994; Griffiths 1997a) and, where data have been reported, it is difficult to draw any firm conclusions since excessive exercising has been defined in vastly different ways by different authors (see Davis and Fox 1993; Davis et al. 1993). While over-exercising has traditionally been defined by the frequency and/or

duration of exercising (de Coverley Veale 1987), recent research has suggested that in order to adequately delineate this problem, it may be necessary to consider exercise cognitions as well as exercise behaviour (Davis and Fox 1993; Long et al. 1993).

4.2 Association with Anorexia

The lack of evidence concerning excessive exercising is perhaps surprising given that this problem has now been acknowledged for some time (de Coverley Veale 1987). However, what research there is has tended to focus on the relationship between over-exercising and eating disorders. It is known, for example, that there are high rates of eating disorders among athletes (Johnson et al. 1990) and that excessive exercising is commonly associated with anorexia nervosa (Crisp et al. 1980) as well as with dieting and weight preoccupation in the general population (Davis and Fox 1993). With regard to the hypothesised relationship between eating disorders and excessive exercising, it has been argued by some authors that regular exercise may foster weight preoccupation, while other authors have suggested that over-exercising and weight preoccupation are symptoms of the same underlying psychological disturbance (Eisler and Le Grange 1990).

4.3 Mechanisms of Exercise Dependence

However, recent research does suggest that it may be possible to isolate a group for whom excessive exercise is a problem in its own right, rather than simply being a feature of anorexia (Davis and Fox 1993). This problem has variously been termed exercise dependence (de Coverley Veale 1987), exercise abuse (de la Torre 1994) or exercise addiction (Kagan and Squires 1985). It appears that, in line with our previously presented model of compulsive behaviour, compulsive exercising may be maintained by the experience of an aversive state (withdrawal) when regular exercise is stopped (Morris et al. 1990; de Coverley Veale 1987). It has further been hypothesised that this may be mediated by the endogenous opiates (Russell et al. 1987). Similarly, some evidence suggests that when excessive exercisers are prevented from exercising, they experience guilt, dysphoria and the compulsion to exercise harder next time in order to make up for the missed exercise session or sessions (Davis and Fox 1993; Long et al. 1993).

A recent review of the exercise addiction literature by Murphy (1994) outlined the three most significant psychophysiological explanations for exercise addiction – the thermogenic hypothesis, the catecholamine hypothesis and the endorphin hypothesis. The thermogenic hypothesis suggests that exercise increases body temperature (which reduces tonic muscle activity), thus reducing somatic anxiety (de Vries 1981; Morgan and O'Connor 1988). The catecholamine hypothesis suggests that exercise releases catecholamines, which are strongly implicated in the control of attention, mood, movement and endocrine, cardiovascular and stress responses (i.e. dopamine, adrenaline, noradrenaline) (Kety 1966). Further to this, high levels of catecholamines are thought to be associated with euphoria and positive mood state. The third hypothesis – the endorphin hypothesis – is the best known and most empirically researched. It is also the hypothesis that seems to be accepted by the general public. For instance, in a study carried out by Griffiths and Duff (1993) of lay beliefs about 17 potentially addictive behaviours, it was reported that exercise addiction was perceived to be more of a physiological addiction than a psychological one when compared with other behaviours such as gambling, television watching and sex. The endorphin hypothesis suggests that exercise produces endogenous morphines (i.e. endorphins), which leads to a reinforcing enhanced mood state. Despite the general acceptance of the endorphin hypothesis, there remains little conclusive evidence to indicate a precise mechanism of effect (Murphy 1994). Moreover, not only does the type of exercise (i.e. steady state or progressive and incremental) and the mode (e.g. running, step aerobics) need to be taken into account in the role of mood modulation, but (perhaps more importantly) the person's psychological constitution.

4.4 Treatment

There are no systematic outcome studies for excessive exercise reported in the literature. However, given the apparent similarity between this and other compulsive behaviours, we might expect that a broad cognitive-behavioural approach might be an effective treatment.

5 Kleptomania (Compulsive Stealing)

5.1 Definition

Kleptomania has been recognised as a psychological disorder since the early nineteenth century. DSM-IV

classifies kleptomania as an impulse control disorder that is characterised by the failure to resist impulses to steal along with the experience of tension prior to committing a theft, which is relieved once the theft has been committed. Thus, for repetitive theft to be classified as kleptomania, the motive of the theft must not be financial gain, but rather the avoidance of an aversive psychological state. In this regard, kleptomania has the characteristic features of a behavioural compulsion.

5.2 Prevalence

The main sources of data on the prevalence of kleptomania are studies of shoplifters who have been referred by the courts for psychiatric assessment. In their review of these studies, McElroy et al. (1991) note that these studies suggest that an average of 4% of apprehended shoplifters meet the criteria for kleptomania. However, these authors suggest that this figure may underestimate the true prevalence of kleptomania in the general population due to systematic sampling biases.

It appears that kleptomania may be more common in women than in men, just as shoplifting is more common among women (McElroy et al. 1991). While it has been argued that the higher prevalence of kleptomania among women may simply reflect cultural stereotypes that pathologise criminal behaviour in women, it is likely that this higher prevalence may be due, at least in part, to the more frequent access women have to situations in which they can steal.

5.3 Association with Other Psychological Problems

It has been noted by many authors (e.g. Gudjonsson 1987) that kleptomania is frequently associated with a range of other psychological problems including depression, eating disorders, anxiety symptoms and a range of obsessive-compulsive behaviours. Given that kleptomania has often been defined as shoplifting that is "out of character", it is not surprising that this behaviour, like other compulsive behaviours, often leads to severe personal distress and significant social and family problems.

5.4 Treatment

While no controlled outcome studies have been reported for the treatment of kleptomania, a number of single case studies of behavioural interventions have been reported (Gauthier and Pellerin 1982; Glover 1985; Kraft 1970). These have focused on the use of desensitisation, contingency management and response prevention in the treatment of kleptomania.

6 Sexual Compulsions

6.1 Definition

Problem behaviours involving sexual compulsions have variously been termed sexual addiction, hypersexuality, hyperphilia and, most commonly, compulsive sexual behaviour (Coleman 1991). While most authors acknowledge that the term compulsive sexual behaviour describes a set of different, but related, problem behaviours, there is currently no agreed classification of compulsive sexual behaviour. For example, while DSM-IV classifies these problems as psychosexual disorders not elsewhere classified, others have classified these behaviours as impulse control disorders (for a discussion of the problem of classification of compulsive sexual disorders, see Travin 1995).

Despite the problem of classification, one important distinction to make is that between the compulsive enactment of normative (non-paraphilic) and non-normative (paraphilic) sexual behaviour. While the classification of some sexual acts as paraphilic is dependent upon social and cultural norms that have changed over time, this distinction does nonetheless have clinical utility. Most notably, many paraphilic sexual compulsions may be best treated within a forensic setting.

Coleman (1992) has proposed a classification of non-paraphilic compulsive sexual behaviours that may prove helpful to the clinician:

- Compulsive cruising and multiple partners: This involves compulsively searching for new sexual partners to satisfy the individual's need for sexual intercourse.
- Compulsive fixation on an unobtainable partner: This is frequently associated with unrealistic sexual fantasies concerning the targeted partner.
- Compulsive auto-eroticism: This involves compulsive masturbation that results in occupational, social or interpersonal problems or self-injury.
- Compulsive multiple love relationships: This involves compulsively searching for the experience of new-found love, with each relationship ending following the initial romance.

- Compulsive sexuality within a relationship: This involves an insatiable and compulsive demand for sexual intercourse.

6.2 Mechanisms of Compulsive Sexual Behaviour

While Travin (1995) has noted that compulsive sexual behaviour has been variously hypothesised to be a spectrum affective disorder, an impulse control disorder or an "addiction", he suggests that it should not be defined as an obsessive-compulsive disorder as the behaviour is ego-syntonic. In other words, he argues that the individual is motivated to engage in the sexual behaviour rather than resist the behaviour, as is the case with obsessive-compulsive disorders. However, in line with our previously described model of behavioural compulsions, Coleman (1991) has noted that "compulsive sexual behaviour ... is driven by anxiety reduction mechanisms rather than by sexual desire. The obsessive thoughts and compulsive behaviours serve the function of temporarily reducing anxiety and stress, but they create a self-perpetuating cycle" (p. 37). In this way, non-paraphilic compulsive sexual behaviours may be best defined by reference to the mechanisms that motivate the behaviour.

6.3 Prevalence

While there are no studies on the prevalence of such problems, Coleman (1992) has estimated, on the basis of her clinical experience in this area, that compulsive sexual behaviours may occur in as many as 5% of the adult population over their life time.

6.4 Treatment

There are no reported treatment outcome studies of non-paraphilic compulsive sexual behaviours. There are, however, case reports of the use of lithium carbonate, selective serotonin reuptake inhibitors (SSRI) and anti-androgens in the treatment of these problems (for a review of these case reports, see Coleman 1992). In addition, it has been suggested that psychological therapy may be effective in treating compulsive sexual behaviours. In particular, given the clear similarities that have been noted between such behaviours and other behavioural compulsions (Coleman 1991), we might expect cognitive-behavioural approaches such as cue exposure and response prevention to be potentially profitable treatment procedures.

7 Technological Compulsions

As our use of technology grows and increasingly becomes a major part of our everyday leisure activities, there is also the potential for the development of technological compulsions or addictions. The term technological addictions has been used to cover computer addiction (e.g. hacking, Internet usage), video and computer games, fruit machines, pinball machines and virtual reality addiction (Griffiths 1995b). Our use of technology can lead to excessive use, unsuccessful efforts to cut down, giving up other social, occupational and recreational activities and persisting despite recurring physical, psychological, social or occupational problems. Since technological compulsions will undoubtedly increase in the future, there is a need for more systematic research of the field. Three of these compulsions will be examined in this chapter: fruit machine playing, computer game playing and Internet usage. Fruit machines are a type of gambling (slot) machine. Three reels contain differing numbers of symbols (usually representations of fruit, e.g. cherries, lemons) which spin on predetermined time cycles. "Pay-out" rates of machines vary between 70%–90%, and money is won when the payline (i.e. the middle row) shows a winning symbol combination, e.g. a row of three cherries.

7.1 Compulsive Fruit Machine Playing

Compulsions to play fruit machines involve excessive person-machine interaction and to some extent rely on the machine's structural characteristics, i.e. features which have been put into the machine to make them more tempting (e.g. light and sound effects, graphics, pseudo-skill buttons). It could be argued that it is these features which make compulsive fruit machine playing more of a technological compulsion than a gambling compulsion. It is also worth noting that compulsive fruit machine playing also tends to affect adolescents more than adults.

7.1.1 Prevalence

There have been about 20 studies examining adolescent fruit machine playing (Griffiths 1995a). Research

figures suggest that 10% of adolescents are regular fruit machine players (playing at least once a week) and that up to 6% of adolescents are probably compulsive players or have severe playing difficulties (Fisher 1993; Griffiths 1995a). All studies have reported that boys play on fruit machines more than girls and that as fruit machine playing becomes more regular, it is more likely to be a predominantly male activity. Very few female adolescent fruit machine addicts have been identified by researchers.

Like other compulsive behaviours, fruit machine compulsion causes the individual to engage in negative behaviours such as truanting in order to play the machines (Huff and Collinson 1987; Moran 1987; National Housing and Town Planning Council 1988; Leeds Polytechnic cited in Long 1989; Griffiths 1990), stealing to fund machine playing (Barham and Cormell 1987; Moran 1987; Spectrum Childrens Trust 1988; Griffiths 1990), getting into trouble with teachers and/or parents over machine playing (Moran 1987; Griffiths 1990), borrowing or using of lunch money to play the machines (National Housing and Town Planning Council 1988; J. Rands and M. Hooper, unpublished; Griffiths 1990), poor schoolwork (Moran 1987; Griffiths 1990) and in some cases aggressive behaviour (Moran 1987; Griffiths 1990).

There is also a small body of evidence (Griffiths 1995a) suggesting that there may be at least two types of compulsive fruit machine player. The first type appears to be addicted to the fruit machine itself (a "primary addiction") and plays to test his or her skill, to get social rewards and most of all for excitement, i.e. plays fruit machines because of their arousing properties. The second type appears to play machines as a form of escapism, where the machine is possibly an "electronic friend", i.e. plays them because of their tranquillising properties. This is what could be termed a "secondary addiction" in that the player uses the machines to escape the primary problem (e.g. broken home, physical disability, relationship break-up). If the primary problem is resolved, the excessive playing disappears. Such a distinction has obvious clinical usefulness.

7.1.2 Treatment

There has been little in the way of treatment approaches specifically geared towards adolescent fruit machine gamblers. However, interventions and treatments for compulsive fruit machine playing do not differ significantly from other forms of compulsion or addiction treatment. The real difference is that fruit machine addiction is often harder to spot.

7.2 Compulsive Computer Game Playing

7.2.1 Prevalence

Home computer game playing is now a popular activity among children and adolescents (Griffiths 1993), with approximately one third of children and adolescents playing computer games most days (Griffiths 1997b). However, for a minority of children and adolescents, home computer games can take up considerable time and result in compliance use. Studies by Griffiths and Hunt (1993, 1995) and Parsons (1995) reported that 7% and 9% of schoolchildren, respectively, claimed to spend at least 30 h a week playing video games. The question to ask is what longitudinal effect of an activity that takes up 30 h of leisure time a week has on the educational and social development of children and adolescents. At present we do not know the answer to this, but any child who engaged in any activity excessively every day over a number of years from a young age would have their social and/or educational development negatively affected in some way.

7.2.2 Characteristics

Like fruit machine playing, computer game playing compulsions tend to be prevalent in adolescents. More recently, research has identified behavioural signs of video game compulsions. These have included stealing money to play arcade games (Klein 1984; Keepers 1990), stealing money to buy new games cartridges (Griffiths and Hunt 1993), engaging in minor delinquent acts (Kestenbaum and Weinstein 1985), using lunch money to play (McLure and Mears 1984), truanting from school to play (Keepers 1990; Griffiths and Hunt 1993), not doing homework/getting bad marks at school (Griffiths and Hunt 1993; Phillips et al. 1995), sacrificing social activities to play (Egli and Meyers 1984; Griffiths and Hunt 1993), irritability and annoyance if unable to play (Griffiths and Hunt 1993; Rutkowska and Carlton 1994), playing longer than intended (Griffiths and Hunt 1993; Phillips et al. 1995) and an increase in self-reported levels of aggression (Griffiths and Hunt 1993).

It must be recognised that computer games for some schoolchildren can be potentially compulsive – the underlying process of which may be similar to pathological gambling. For a complete understanding of the issues involved in the development and maintenance of computer game playing and its treatment at excessive levels, considerably more input will be needed from both a clinical and educational perspective.

7.2.3 Treatment

To date there have been very few accounts of treating computer game compulsions. Kuczmierczyk et al. (1987) reported the successful treatment of an 18-year-old college student. Kuczmierczyk and his colleagues assumed that compulsive video game playing was conceptually similar to pathological gambling and used a cognitive-behavioural modification approach in their treatment. Using a combination of self-monitoring, biofeedback assisted relaxation training, in vivo exposure and response prevention, a 90% reduction of playing was observed which persisted at 6- and 12-month follow-ups. Keepers (1990) treated a 12-year-old boy who was brought for psychiatric help by his mother because he was playing video games excessively. He was placed in a residential treatment centre and given family therapy. At 6-month follow-up, no recurrence of the boy's difficulty was noted. Keepers also considered his patient's behaviour to be reminiscent of pathological gambling.

7.3 Compulsive Internet Use

7.3.1 Characteristics

A few surveys have tried to examine the concept of Internet compulsions and addiction (e.g. K. Young, unpublished; Brenner 1997). None of the surveys to date conclusively shows that compulsive Internet use exists. At best, these studies indicate that Internet addiction may be prevalent in a significant minority of individuals, but that more research using validated survey instruments and other techniques (e.g. in-depth qualitative interviews) is required.

Both Griffiths (1996, 1997c) and Young (1996) have described what they consider to be detailed case studies of Internet addicts. The people they describe appeared to suffering from a genuine compulsion that is comparable with other more accepted compulsions and addictions. Taking all the case study and survey evidence together, it can be argued that excessive usage in a majority of cases appears to be purely symptomatic, but that for what appears to be an exceedingly tiny minority, the Internet *may* be compulsive. The case study accounts of Griffiths (1997c) show that the Internet was used to counteract other deficiencies in the person's life (e.g. relationships, lack of friends, physical appearance, disability, coping) and that all of the people studies used the computer for social contact (mostly for Internet Relay Chat services).

Kimberly-Young is founding President of the On-Line Addiction Centre (http://netaddiction.com). She has put forward the following warning signs based upon her own work:

1. Losing track of time once on-line
2. Minimising to others the amount of time spent on-line
3. Anticipation of on-line usage
4. Others complaining about the amount of time spent on-line
5. Others complaining about a large phone bill related to time spent on-line
6. Daily home use of on-line services
7. High phone bills related to on-line service fees and connect time
8. Being logged on to the personal account while at work
9. Poor interpersonal relationships due to increased time spent on-line
10. Sneaking on-line when the significant other is not at home

7.3.2 Treatment

As yet there are no recognised treatments for compulsive Internet use, although at a theoretical level, cognitive-behavioural treatments might be the most effective.

8 Cognitive-Behavioural Treatment of Compulsive Behaviour

There is insufficient evidence to strongly support the effectiveness of any treatment approach in the area of compulsive behaviour (or behavioural addictions). Nevertheless, if it is possible to generalise from obsessive–compulsive behaviours and addictive behaviours, then the following treatment plan would be worth investigating:

1. Motivational interviewing
2. Identifying high-risk situations or cues
3. Developing specific coping responses for the most important cues
4. Developing a general coping strategy to be used in a variety of situations
5. Exposure to cues and rehearsal of coping skills
6. Developing social relationships

The treatment programme outlined above relies upon evidence drawn from research on the treatment of alcohol dependence, compulsive eating and obsessive–compulsive disorder. It also relies upon general cognitive-behavioural theory and evidence of effec-

tiveness. There is a need to test the effectiveness of this approach in the area of compulsive behaviours.

An Overview of Substance Use Disorders and Their Management

1 Introduction

The misuse of psychoactive substances is of public health and social concern throughout the world. The commonest substances used are alcohol and tobacco, followed by cannabis, sedative-hypnotic drugs, opioids, psychostimulants and hallucinogens, roughly in that order. Most drugs that are misused have the potential to induce dependence. Many have intrinsic tissue toxicity and give rise to a range of physical and neuropsychiatric complications. Illicit drug use may be complicated by adverse effects of adulterants, and the intravenous route may act as the means of transmission of viral, bacterial and other communicable diseases. Adding further to the burden are the lifestyles associated with drug use, which may involve prostitution, sexually transmitted disease, malnutrition and the legal and penal consequences of crime.

The purpose of this chapter is to provide an overview of the epidemiology of substance use, the behavioural and clinical syndromes associated with it, techniques of diagnosis, and management strategies. In the chapters that follow, detailed information will be given about the syndromes and management approaches applicable to specific substances. The overview presented here will cover the main types of psychoactive substances, with the exception of tobacco. The reason for omitting reference to tobacco is that assessment and management of smoking-related disorders, and the provision of smoking cessation therapies, is usually a function of internal medicine clinics rather than mental health or alcohol and drug services.

2 Epidemiology of Substance Use

2.1 Alcohol

Alcohol is ubiquitous in Western societies, and its consumption has increased steadily in many countries in Asia and Africa over the past 30 years. A single summary measure, the per capita intake, is used to define "high-consumption" countries such as France, Portugal and Hungary (which average 20–35 l per adult per year), "moderate-consumption" countries such as the United States, Canada, United Kingdom, Australia and Germany (7–15 l per year) and "low-consumption" countries such as the Nordic countries, Israel, Turkey, China and India (1–6 l per adult per year).

Per capita alcohol intake has declined in many developed countries over the past 10–15 years, notably in France and Italy, where decreases of around 25% have been recorded. On the other hand, intake has increased substantially in Japan, China and several South East Asian countries. The prevalence of alcohol-related problems is correlated with the overall level of consumption, but there are substantial variations related to the different patterns of use. Specifically, Mediterranean countries, where drinking is often a regular daily activity, have a high incidence of chronic physical complications such as cirrhosis of the liver. Nordic countries have an intermittent pattern of drinking; overall consumption is low, but there is a disproportionately high incidence of trauma and acute physical sequelae.

2.2 Sedative-Hypnotic Drugs

There are numerous proprietary and traditional drugs that have sedative, anti-anxiety and hypnotic properties. Barbiturates, introduced in the late 1950s, were responsible for widespread morbidity due to their high dependence potential and toxicity in overdose. They have largely been supplanted by the benzodiazepines. These drugs were considered to have relatively low dependence potential, but there is now compelling evidence that the risk even at usual therapeutic doses is considerable: 40% of individuals taking a long-acting benzodiazepine for 3 months or more develop an identifiable withdrawal syndrome when it is ceased (Petursson 1994).

2.3 Inhalants

Inhalants are commonly misused by groups that do not have access to the more usual psychoactive substances. They include pre-teenage children and people living in isolated communities. Inhalants include petrol (gasoline), paint thinners, glues and adhesives, nail varnish removers, cleaning fluids and lighter fuels. Users tend to be male adolescents, particularly those who come from impoverished or isolated backgrounds. This group tends to experience significant social and psychological problems (Smart 1986) and is prone to depression (Jacobs and Ghodse 1987). Inhalants are considered "gateway" drugs in Japan (Fukui 1994). About 34% of drug-dependent patients in a mental hospital in Japan had a problem of inhalant abuse, and approximately 20% had started using inhalants before the age of 20 years (Fukui 1994).

2.4 Cannabis

Cannabis is the most widely used illicit drug in developed countries. Its use increased during the 1960s, and although this has declined in some countries, the majority of young people would have some experience with it. Frequent use is less common, its dependence potential being relatively low, and in developed countries only about 3% of the 18- to 40-year-old population are regular daily users. Reflecting the sporadic nature of its use among the majority, physical sequelae are comparatively uncommon. More potent forms of cannabis, with higher concentrations of the most active cannabinoid, Δ-9-tetrahydrocannabinol (THC), are becoming available. Cannabis-related psychosis appears to be increasing in prevalence as a result.

2.5 Opiates

Results of population surveys in the USA and Europe indicate a lifetime prevalence of heroin use of 1%–2%. In several countries this has increased over the past decade. This percentage rises to 4%–6% among young adults in the 18- to 30-year age-group in certain cities in the USA and Southern Europe. Overall, 0.3%–0.6% of adults in North America and Europe are dependent on heroin, with the highest rates being found in the USA, Italy, Spain, Switzerland and the UK (European Monitoring Centre for Drugs and Drug Addictions 1999). In Europe, deaths from heroin use, principally from overdose, have doubled over the past 15 years. Thus, while heroin use is relatively rare in the general population, it is associated with disproportionate costs in terms of drug-related problems and deaths. It is estimated that 25% of opiate-dependent patients are likely to die within 10–20 years of active drug misuse. Causes of death include unintentional overdose, suicide, homicide, infectious diseases, and toxic reactions to the drug or adulterants.

2.6 Psychostimulants

Three groups of psychostimulants are commonly misused: (1) amphetamine and its derivatives, (2) cocaine and (3) prescribed stimulants. Amphetamines were marketed at the beginning of the twentieth century as anti-depressants and appetite suppressants. They have been used by troops in wartime, by long-distance drivers and students, but increasingly are used by economically deprived young people. Amphetamines have become one of the most popular types of illicit drug in many countries in Europe, Australia and Japan. In recent surveys in Australia, 15% of young males admitted to using amphetamines, 3% to cocaine and 10% to Ecstasy (Department of Community Services and Health 1999). Ecstasy (methylenedioxymethylamphetamine) is one of several amphetamine derivatives that have been popularised as a teenage drug. It has both hallucinogenic and stimulant properties.

Cocaine has been used by the indigenous peoples of South America for centuries. In Europe, it was widely used in the early twentieth century and was readily available in proprietary tonics and medicines until the mid-1920s. In the 1960s, there was a wave of intravenous cocaine use, and in the late 1970s the free-base form of cocaine became commonly available, especially in the USA. Its use spread from the elite to the economically deprived and ethnic minorities in inner city areas. The number of people in the USA who have ever used cocaine increased five-fold from 5 million in 1975 to 25 million in 1985, by which time 3 million were considered cocaine dependent (Kleber 1988).

Prescription stimulants are abused predominantly by young women, often in a quest to maintain a low body weight. They include methylphenidate and fenfluramine. Caffeine and related compounds are contained in many brands of compound analgesic.

2.7 Hallucinogens

Thousands of naturally occurring hallucinogens have been identified. They occur in various species of mushroom and nuts, most commonly. Synthetic drugs such as lysergic acid diethylamide (LSD) became widely used in the 1960s and were an important aspect of youth drug culture. Less widespread now, there remain pockets of LSD use in many developed countries.

2.8 Polydrug Abuse

Polydrug misuse has become increasingly common, particularly among lower socio-economic groups, and it is estimated that 5% of adults use two or more illicit drugs. Concurrent alcohol, tobacco and/or benzodiazepine use add to the adverse consequences to health. The more chaotic drug use is, the worse the prognosis.

3 Predisposing Factors

The reasons for substance use are complex and interconnected. The reinforcing properties of the drug, genetic factors, cognitive factors, faulty learning, personality characteristics, availability of the substance, peer pressure, cultural factors, media influence and religious beliefs are all important in influencing why an individual initiates substance use, and why others do not. Likewise, the pharmacological properties of the substance, personality and social characteristics of the user and the setting in which the substance is used are important in influencing continuing use. Why people decide to stop and then re-engage is also determined by a host of factors and cannot be reduced to a single reason or cause.

It is useful to conceptualise substance use as being determined by three interacting forces: (1) the pharmacological properties of the drug, (2) the characteristics of the individual and (3) the influence of the environment. This conceptualisation has analogies to the bio-psychosocial model of mental and behavioural problems.

3.1 Nature of the Drug

Substances with abuse potential have two predominant characteristics. They have pleasurable psychic effects, and they are (nearly all) rapidly acting. The abuse potential is related both to the drug's intrinsic properties and to the mode of administration. Drugs that are smoked or injected intravenously are more reinforcing than those taken by mouth (Strang et al. 1998). There is no common mechanism of action. Some substances such as alcohol and barbiturates are relatively non-specific in their actions, having general central nervous system depressant effects. Others such as opiates interact with specific receptors. One possible "final common pathway" for the pleasurable and reinforcing effects is the dopaminergic system in the mid-brain. Following repeated exposure, a state of neuroadaptation develops to many substances. This may reflect downregulation of specific receptors or changes in secondary messenger systems. Neuroadaptation leads to tolerance and, in the absence of the drug, a withdrawal syndrome.

3.2 Individual Factors

There are numerous factors which influence individual susceptibility to developing substance use disorders. There is increasing evidence that genetic factors are important, particularly in relation to alcohol use and dependence, where perhaps 50% of the variance in susceptibility is explained on genetic grounds. The mode of inheritance seems to be polygenic, but with dopamine D_2 receptor polymorphism exerting a dominant influence (Noble 1999). Alcohol dependence is genetically linked to certain personality characteristics such as impulsiveness and novelty seeking. However, there is no evidence of a predisposing "drug-dependent personality" as was once thought, nor of a "depressive spectrum disorder" predisposing to alcohol dependence. Childhood conduct disorder and attention deficit hyperactivity disorder appear to be risk factors for later substance use disorders. Physical and sexual abuse are increasingly recognised as predisposing to the more severe dependencies. Individuals with antisocial personality disorder or post-traumatic stress disorder are more likely than the general population to experience problems with substance abuse. In general, where use of a substance is uncommon in the general population, individual predisposing factors are more likely to be identified than when a substance is commonly used.

3.3 Environmental Factors

The prevalence of alcohol and drug use varies widely from country to country, an observation which is largely explained by sanctions and constraints placed on substance use, the role of the substance in society or in particular subcultures, economic opportunity and its physical availability. When a substance is illegal and/or costly, its use tends to be lower than when it is widely available and cheap, though this may be at the expense of greater social damage when it is used. The use of legal substances, such as alcohol and tobacco, is responsive to promotional campaigns. Correspondingly, when restrictions are placed on their use (e.g. by legislating on the minimal legal age, random breath testing), levels of use and associated problems decline.

4 Core Syndromes

4.1 Spectrum of Use and Misuse

Patterns of substance use range from an occasional experimental or recreational exposure to continuous heavy daily consumption. A spectrum is observed not only in levels of use, but also in the psychological and

behavioural accompaniments of substance use, and in the prevalence and nature of substance-related problems. Diagnostic systems reflect this spectrum, defining a range of substance use disorders. The historical development of diagnostic schemata has been summarised elsewhere (see e.g. Babor 1992; Schuckit 1996; Krabman and Saunders 1996). ICD-10 and DSM-IV, the two current international classification systems for psychiatric disorders, both contain a separate section for substance use disorders. They agree in the main with regard to the diagnosis of dependence, but their approach to non-dependent use, termed "abuse" in DSM-IV and "harmful use" in ICD-10, differs significantly.

4.2
Non-dependent Use

Although drug and alcohol services tend to cater for those with established dependence, it is necessary to acknowledge that, at a population level, the majority of morbidity and mortality results from non-dependent substance use. Non-dependent use infers a level or pattern of repeated substance use that does not meet the criteria for dependence yet leads to recurrent and significant substance-related problems or confers the risk of harm. It encompasses hazardous use, harmful use (an ICD-10 diagnosis), and abuse (DSM-IV). Identifying non-dependent problem users is important, as their substance use can often be influenced through interventions much less costly and more effective than the treatment of dependence (Saunders 1989; Bien et al. 1993; WHO Brief Intervention Study Group 1996).

4.3
Hazardous Use

Hazardous or "at-risk" alcohol and drug use is defined as a repetitive pattern of use that significantly increases the risk of harmful physical and psychological consequences. As such, it is significant in terms of preventive medicine and public health, although it is not included in ICD-10 of DSM-IV. It is employed by the World Health Organization (WHO) and by some national authorities in public education campaigns. For example, hazardous alcohol consumption is defined by the Australian National Health and Medical Research Council (Hawks and Pols 1992) in terms of regular daily intake (more than 40 g alcohol for men and 20 g for women) and/or the amount consumed in any one occasion (more than 60 g alcohol for men and 40 g for women). Hazardous use can be extended beyond measures of consumption to include such at-risk behaviours as sharing intravenous needles, binge use with intermittent severe intoxication and use in unsafe settings such as while driving or operating machinery.

The importance of this diagnosis is that it identifies a substantial group in the general population which is at increased risk of experiencing substance-related social and medical problems and of progressing to harmful use/abuse or dependence (Conigrave et al. 1995a). Brief interventions providing information and advice have been shown to be effective in this group in reducing hazardous consumption and adverse consequences (Bien et al. 1993; WHO Brief Intervention Study Group 1996).

4.4
Harmful Use

Harmful use is defined in ICD-10 as a pattern of substance use that is actually causing physical or psychological harm to the individual. No specific level or pattern of substance use is predicated, although it is widely assumed that it would also fulfil the criteria for hazardous use.

4.5
Substance Abuse

DSM-IV takes a different approach to the issue of non-dependent use, focusing on social and interpersonal problems as the core of the concept of substance abuse. Failure in role obligations, and recurrent legal, social or interpersonal problems are listed as diagnostic criteria. These problems are prevalent in a wide diversity of cultures (Helzer and Canino 1989), and continued use despite them does demonstrate a dysfunctional pattern of use. Abuse can thus be defined as a significant failure to conform to the prevailing social standards with regard to substance use, even though those standards may vary with culture, gender and generation.

4.6
Dependence

Dependence is the diagnostic concept at the heart of both ICD-10 and DSM-IV. It was characterised in 1976 by Edwards and Gross, who described a "dependence syndrome" in relation to alcohol use. This concept has since been applied to a wide variety of psychoactive substances (Edwards 1986) and has largely replaced earlier formulations of alcoholism (see e.g. Jellinek 1960) and drug addiction. The syndrome encompasses a series of cognitive, behavioural and physiological

changes, the central elements of which are an increasing priority given to substance use over other behaviours, a strong desire (or "craving") to take the substance, impaired control over its use, tolerance, withdrawal symptoms (in some cases) and continued use despite harmful consequences. No assumptions are made about causality. In both diagnostic systems, the presence of three (out of six or seven) criteria is required for the diagnosis of dependence. Dependence is partially correlated with, but conceptually distinct from, the level of use and severity of problems stemming from substance use.

A diagnosis of dependence can be applied to all classes of psychoactive substance. This is especially relevant as increasingly individuals are using more than one drug, either concurrently or consecutively. The same criteria apply to all substances, but some will be less relevant to some classes or, rarely, not applicable at all (e.g. withdrawal symptoms are not specified for hallucinogens).

Both ICD-10 and DSM-IV allow a diagnosis of dependence without a requirement for the presence of the physiological phenomena of tolerance, withdrawal and relief of withdrawal by substance use. This broader view is especially relevant to drugs such as cocaine, which do not have prominent physical withdrawal phenomena. Some evidence suggests that the more psychological aspects of dependence often develop prior to the onset of significant withdrawal symptoms (Chick and Duffy 1979), so such an approach may be more sensitive to detecting moderate or early dependence. However, the physical criteria cluster most strongly together in factor analytic studies, and most strongly predict outcome. Both the DSM-IV and ICD-10 include the diagnostic specifier "with or without physiological dependence" to allow a differentiation to be made on this issue. Among treatment populations, dependence with physiological criteria appears to be more severe, and to be associated with more problems and a greater likelihood of relapse, than dependence without

Clinical Features of Depenence

A preoccupation with the substance and its use is a central element of the dependence syndrome. A great deal of thought and energy is expended on obtaining and using the substance, but also conversely on efforts to control and limit its use. A proportion of users will never attempt to limit their use, but the majority will have repeated unsuccessful attempts to stop or cut down on their consumption. Many report a strong urge or sense of compulsion to use (often termed a "craving") in an uncontrolled way after an initial "priming dose". Craving may be heightened by situational cues such as the smell or sight of alcohol or the drug in question, or proximity to people or places associated with its consumption. This dimension can be assessed by asking questions about a perceived compulsion to use. It can also be measured by observing behaviour, i.e. frequent failure to control substance use or failure to keep to set limits.

As dependence develops, the individual's life becomes increasingly centred on the substance, over and above other interests and role obligations. This is termed the "salience" of substance use. A large amount of time and mental energy is spent obtaining and using the substance at the expense of activities that were once considered important. Dependent individuals will often be able to list a number of past hobbies or interests that they no longer pursue due to their focus on substance use. Evidence of the high priority given to substance use is often demonstrated by continued use despite harmful consequences. Although the dependent individual is aware that their substance use is causing serious medical, family, occupational, financial or legal problems, they continue to use, thus worsening these problems.

When tolerance develops, a greater dose of the substance is required to achieve an equivalent effect, and there is a diminished effect from a given dose. Tolerance is seen in particular with alcohol, opiates and stimulants, where dependent users may maintain near-normal function after a dose that would be fatal to the naive subject. A withdrawal state develops when the dependent individual ceases or reduces substance use, and a cluster of cognitive, behavioural and physiological symptoms are experienced that are usually the phenomenological opposite of the drug's effect in intoxication. The desire to reduce or avoid withdrawal symptoms is seen by some as a key contributor to ongoing dependent substance use. Frequently, the dependent individual will take the substance or another related substance to avoid or alleviate withdrawal symptoms. Some manage to avoid withdrawal symptoms altogether by maintaining continuous high blood levels of the substance. Tolerance and withdrawal are primarily manifestations of a neuroadaptive state; however, they are also modified by environmental factors and conditioning. Previously drug-dependent individuals can experience withdrawal phenomena on returning to an environment associated with drug use (Grant et al. 1990).

these features (Langenbucher et al. 1997; Schuckit et al. 1998).

In their initial description of the dependence syndrome, Edwards and Gross (1976) described the rapid reinstatement of a dependent pattern of use, once a previously dependent individual recommences substance use after a period of abstinence. This phenomenon has been observed in animals and in humans (Edwards 1990). Follow-up studies confirm that return to controlled use in a previously dependent individual is uncommon (Orford et al. 1976; Cohen et al. 1989). Thus, for patients who are dependent to the extent that they experience recurrent withdrawal symptoms, it is advisable to recommend a goal of abstinence.

Lay groups such as Alcoholics Anonymous (AA) and equivalent 12-step programmes for drug dependence teach that life-long abstinence is the only means of overcoming dependence and that any use will inexorably lead to a loss of control and a return to old patterns of consumption. Controversy exists over the extent to which the ubiquity of these teachings has contributed to the self-fulfilling prophecy of previously dependent users reverting to uncontrolled use after treatment. This assertion is supported by the finding that outcome is linked as strongly to beliefs about ability to control drinking as to severity of dependence prior to treatment (Heather et al. 1983).

4.7 Withdrawal State

The "withdrawal state" or withdrawal syndrome is a central element of dependence, but it is also a diagnosis in its own right in ICD-10 and DSM-IV, reflecting the fact that it is often the presenting diagnosis when people attend for treatment. The nature of the withdrawal syndrome varies according to the pharmacological class of the substance to which dependence has developed. Thus central nervous system depressants such as alcohol and sedative-hypnotics have a withdrawal syndrome characterised by tremor, agitation, hallucinations and seizures, while withdrawal from stimulant drugs involves lethargy and inertia. Withdrawal is often accompanied by psychological symptoms such as anxiety, depression and sleep disturbance.

The onset and duration of withdrawal symptoms is related to the duration of action of the substance. Withdrawal from substances with shorter duration of effect such as alcohol or opiates will usually commence within 48 h and have settled within a week. Withdrawal from substances with longer half-lives such as diazepam or methadone may not commence for several days to weeks and can continue for 6–8 weeks. Predictors of increased severity of withdrawal include sudden cessation of use, high levels of consumption prior to cessation, previous severe withdrawal symptoms, concurrent medical disorders and metabolic disturbances. Withdrawal may be complicated by seizures, delirium or depression.

5 Complications of Substance Misuse

Substance misuse may have both acute and chronic adverse effects on the user. These may be direct consequences of use, such as alcoholic liver disease or human immunodeficiency virus (HIV) infection acquired through sharing contaminated injecting equipment, or indirect effects such as the medical consequences of malnutrition due to loss of income, or depression and loneliness related to family separation. Many adverse effects of substance use occur in non-dependent users.

5.1 Alcohol

Misuse of alcohol can lead to a vast array of physical, psychological and social complications. The range of physical disorders is particularly broad, reflecting the fact that alcohol possesses much greater intrinsic tissue toxicity than most psychoactive substances. Table 1 lists some of the recognised complications of harmful alcohol use and dependence.

5.2 Sedative-Hypnotic Drugs

By contrast, use of sedative-hypnotics is associated with little physical pathology. Serious morbidity and death is usually related to intentional overdose, often in combination with alcohol or other central nervous system depressants. Chronic use may produce cognitive impairment, although this is substantially reversed following prolonged abstinence.

5.3 Inhalants

Chronic inhalant abuse carries an increased risk of cognitive impairment (Zur and Yule 1990).

Table 1. Alcohol-related problems

Nature of problem	Type	Problem
Physical	Intoxication	Stupor Ataxia Coma Respiratory depression Inhalation of vomit and asphyxiation
	Liver disease	Fatty liver Alcoholic hepatitis Cirrhosis
	Gastrointestinal diseases	Carcinoma of oropharynx Reflux oesophagitis Gastritis Acute pancreatitis Chronic pancreatitis
	Brain damage	Wernicke-Korsakoff syndrome "Frontal lobe" syndrome Cerebellar disease Subdural haematoma Hypertensive stroke
	Other neurological diseases	Optic neuropathy Peripheral neuropathy Autonomic neuropathy
	Cardiovascular diseases	Cardiomyopathy Alcohol-induced arrhythmias Hypertension
	Respiratory diseases	Aspiration pneunomia Lobar pneumonia Pulmonary tuberculosis
	Endocrine and metabolic disorders	Hypothalamic–pituitary dysfunction Testicular atrophy Hypoglycaemia Pseudo-Cushing's syndrome Gout
	Musculoskeletal disorders	Acute rhabdomyolysis Chronic myopathy Osteoporosis Avascular necrosis of hip Gout
	Trauma	Head injury Fractures of rib Fractures of long bones Multiple trauma (e.g. from road accidents)
	Fetus	Fetal alcohol syndrome Low birth weight Second-trimester abortion
Psychological	Withdrawal state	Anxiety and agitation Malaise and lethargy Tremor Confusion Disorientation Hallucinations Paranoia
	Psychiatric disorders	Anxiety states Phobic disorders Panic attacks Depression Amnesic episodes Acute alcoholic hallucinosis Chronic delusional psychosis ("alcoholic paranoia") Deterioration in moral and ethical standards Self-centredness Suicidal ideation Suicidal attempt
Social	Domestic and allied problems	Loss of friends Deterioration in marital and other significant relationships Psychological symptoms in spouse, e.g. stress anxiety, tension Domestic arguments Domestic violence Neglect of children Separation Divorce
Social	Occupational	Absenteeism Poor work performance Unexplained absences Demotion Dismissal Unemployment
	Financial problems	Loss of regular income Hardship due to money spent on alcohol Gambling debts Victim of fraud
	Legal problems	Drink-driving offences Property crime Assault Homicide Prostitution

Lead encephalopathy is a serious complication of the use of petrol that has lead added to improve combustion.

5.4 Cannabis

The major health risks of acute cannabis use are impairment in psychomotor performance and psychosis. Long-term use may produce subtle cognitive impairment of memory, attention and organisation and integration of complex information. Evidence suggests that the longer the period that cannabis is used, the more pronounced the cognitive impairment is. While subtle, these impairments may affect everyday functioning, particularly in adolescents with marginal educational aptitude and among adults in occupations that require high levels of cognitive capacity. Repeated high-level cannabis use may be followed by the development of a psychosis (Hall 1998). Other recognised adverse effects include respiratory diseases associated with smoking such as chronic bronchitis. There is a concern that cannabis use may be a risk factor for lung and oesophageal cancers. Subfertility in cannabis users has been described.

5.5 Opiates and the Complications of Injecting Use

Heroin and the other opiates possess relatively little intrinsic tissue toxicity. Most morbidity and mortality results from unintentional overdose or from the injecting mode of drug use.

Sharing injecting equipment results in rapid transmission of disease, particularly HIV, hepatitis B (HBV) and hepatitis C (HCV). Drug use also leads to high-risk behaviour and the likelihood of contracting these diseases through sexual and other contacts. Insoluble additives to the drug (such as talc and starch) may cause granulomas in the lungs and thromboembolism. Bacterial, viral and fungal infections result from the injection site being a portal for entry of micro-organisms. Much effort in recent years has been directed to reducing communicable diseases among injecting drug users.

Bacterial infections may present as local infections, such as cellulitis, skin abscesses and thrombophlebitis, or systemic ones, such as septicaemia, bacterial endocarditis, thromboembolic disease and systemic abscesses in the brain, lung spleen and liver. Osteomyelitis and septic arthritis are also well-known complications. The emergence of multi-drug-resistant tuberculosis among HIV-infected drug users is of concern.

The prevalence of HIV infection among injecting drug users shows striking geographical differences not only between countries, but also within national boundaries and even within areas in the same city. In Europe and the USA, injecting drug users make up the second most important risk group for HIV/acquired immunodeficiency syndrome (AIDS) infection, with approximately one third of AIDS patients reporting injecting drug use as a risk factor. Among injecting drug users, HIV prevalence rates range between virtually zero and 48% among different states in the USA and from less than 4% in London to more than 60% in Edinburgh. The initially high (64%) HIV prevalence rate reported in Edinburgh between 1980 and 1985 has since fallen to 15% among more recent cohorts of injecting drug users. The introduction and expansion of drug use in developing countries is often followed by outbreaks of HIV infection. In Burma, Thailand and Manipur (India), the HIV epidemic has spread rapidly among injecting drug users, with prevalence rates of 30%–90% being described (Poshyachinda 1993).

The prevalence rates for HCV in the general population vary from 0.2% to 2.6%, the highest prevalence rates being in Asia, the Middle East, Southern Europe and South America. Injecting drug use (specifically sharing contaminated injecting equipment) is the single most important risk factor for HCV. High prevalence rates of anti-HCV seropositivity (68%–96%) have been reported among injecting drug users worldwide. Transmission is rapid, and 70%–80% of injecting drug users become anti-HCV positive within 1–2 years of use (Bell et al. 1990). Evidence of past or present HBV is seen in up to 80% of injecting drug users. In most there is complete recovery, but the infection remains active in approximately 5%. Regular alcohol consumption by patients with HCV leads to more rapid progression of the liver disease (Saunders and Devereaux, in press). HCV and alcohol appear to have important synergistic effects in alcohol-related liver damage and progression to cirrhosis and hepatocellular carcinoma.

5.6 Psychostimulants

Recurrent high-level use of amphetamine, cocaine and prescribed psychostimulants may lead to acute or chronic psychosis, even in the absence of pre-morbid vulnerability. Auditory and visual hallucinations, prominent paranoid ideation, thought disorder and hypomania are characteristic features. These drugs are also vasoconstrictors, and cocaine in particular is a recognised cause of acute myocardial infarction and

ventricular arrhythmias in young individuals in the absence of underlying cardiac disease. It can also cause vasculitis, infarcts, ischaemic limbs, thrombosis, thromboembolism and stroke. Other complications of cocaine use include bowel infarction and rhabdomyolysis, which may progress to acute renal failure if not promptly diagnosed and treated. Sniffing of cocaine free base may result in ulceration and perforation of the nasal septum.

6
Principles of Diagnosis

6.1
Substance Use Disorders Frequently Underdiagnosed

Substance use disorders are commonly underdiagnosed in both general medical and psychiatric populations. This is true of in-patient and out-patient settings. A missed diagnosis may lead to insufficient or inappropriate treatment, and thus to poorer outcomes. Likely contributory factors are the subtlety of presentation of drug problems, the complex interactions with other psychiatric disorders, failure of the patient to admit to the problem due to denial or lack of insight, and a low index of suspicion on the part of clinicians.

6.2
Subtlety of Presentation

One reason for a failure to recognise problems related to substance misuse is that these problems often present in a form that mimics other conditions. This is true in physical medicine, where excessive alcohol consumption is often the underlying cause for a number of common conditions such as hypertension, obesity, hyperlipidaemia or gout. An individual in acute intoxication or withdrawal may present with nausea and vomiting, diarrhoea, cardiac arrhythmia or seizures.

In psychiatric practice, drug intoxication and withdrawal can present as delirium, psychosis, sleep disturbances, anxiety, depression or agitation. Chronic substance misuse may lead to depression, dementia, phobias, persistent paranoia and psychosis. The only pointer to substance use may be an unexplained failure of social functioning, such as occupational problems in a skilled and previously successful businessman or failure to cope at home in an elderly person. Hidden substance misuse is a common cause of unexplained treatment failure, especially the pattern of repeated sudden deteriorations on discharge from in-patient care, followed by rapid improvement with re-admission.

6.3
Dual Diagnosis

Studies of in-patient and out-patient psychiatric treatment populations show a prevalence of a co-morbid substance misuse diagnosis of 30%–50% (Drake and Wallach 1989; Siegfried 1998). Substance abuse may precipitate or induce another psychiatric disorder or may be secondary to another disorder, or both may be the result of a common genetic, psychological or social pathway (Minkoff 1994). Cause and effect may be difficult to define and are often of little relevance to practical treatment issues. What is important is that substance misuse be considered as a possible cause of acute psychiatric symptomatology even in patients with a known chronic psychiatric illness, and that substance misuse is properly assessed and treated even when it appears to be "secondary" to another illness. Dual diagnosis is associated with poorer prognosis for both the substance misuse disorder and the other psychiatric disorder.

6.4
Validity of Self-Reported Substance Use

Another factor contributing to the under-diagnosis of substance misuse problems is that the individual may not perceive their substance misuse as a problem in situations where their level of use, although hazardous, is commensurate with that of their peers. The high prevalence of denial in substance misusers leads to a lack of awareness of the negative physical, social and psychological consequences of their use and contributes to under-reporting of such problems. Under reporting is also common in settings where excess consumption is socially unacceptable (e.g. alcohol consumption in Indian women) or illegal. This contrasts with clients who have self-referred for substance abuse treatment, among whom self-report is much more valid and reliable.

6.5
Practical Relevance

The end result of under-diagnosis of substance misuse disorders is inappropriate or inadequate assessment

and treatment. Symptoms caused by substance misuse can be attributed to other illnesses and over-treated. Ongoing untreated substance misuse can lead to non-compliance, disruption of therapeutic milieus and dangerous interactions between the substance and medications (Schwartz et al. 1993).

6.6 Techniques of Diagnosis

The likelihood and accuracy of diagnosis can be improved by appropriate training of clinical staff and a high index of suspicion based on knowledge of the incidence of substance use problems and the subtlety of their presentation. A full review of substance use should be included as a routine part of initial assessment or admission procedures. Brief screening questionnaires such as CAGE (Mayfield et al. 1974), the Munich Alcoholism Test (MALT; Feuerlein et al. 1979) or Alcohol Use Disorders Identification Test (AUDIT; Saunders et al. 1993) for alcohol use and the Severity of Dependence Scale (Gossop et al. 1995) and Drug Check (Kavanagh et al. 1999) for drug use help to identify likely substance misusers for more detailed review.

Knowledge of the local spectrum of substance use is important in terms of substances used, methods of administration and the social and physical environments in which use occurs. Accurate assessment is facilitated by knowledge of the local vocabulary for describing drug types and quantities. Where substance misuse is suspected, all avenues of inquiry should be used to assess the situation.

Information gained from these inquiries should be fed back to the patient in order to reinforce the negative effects of their substance use or to challenge denial of misuse in a situation where it is strongly suspected.

Assessment should include a specific substance use history:

1. Lifetime history:
   - Age at first use of substance
   - Age of first intoxication
   - Age of first substance-related problem
   - Periods of heaviest consumption in the past
2. Current history:
   - Levels and patterns of consumption
   - Date/time/quantity of last use
3. Aspects of dependence (current and previous)
4. Physical, psychiatric, social or legal problems
5. Family history of substance use or psychiatric disorder
6. Attitudes to substance use: reasons why the patient uses the substance and the negative effects (if any) the patient attribute to his or her substance abuse
7. Perception of a substance abuse problem: what does he or she see as the solution to this problem?
8. Previous help-seeking/treatment, attempts to cut down/cease substance use, out-patient or in-patient treatment, involvement with 12-step groups.

Appropriate interview techniques will improve the validity of self-report in patients who wish to hide or minimise their problem. The topic should be approached in a casual, non-judgemental manner. The "top-high" technique involves suggesting an extremely high intake, giving "permission" for the patient to admit to a high intake ("How many bottles of beer do you drink per day? Thirty?" "No! Fifteen at the most".). Where substance use is suspected, questioning techniques can place the onus of denial on to the patient ("How much marijuana have you smoked today?", not "Do you ever smoke marijuana?"). The clinician can then move from less threatening to more threatening subject areas, i.e. from legal to illegal substance use or from family history to past to current use. It is admissible to ask about the presence of a problem before it is related to substance use ("Do you get anxious and shaky sometimes?", then "Is that worse at a particular time of day?" and then "Is that worse the morning after you have been drinking?", not "Does drinking cause you to get anxious and shaky next morning?"). Questions on dependence are important in view of its prognostic and treatment implications.

General psychiatric, medical and social history provides useful information on the presence, severity and time course of any neuropsychiatric, physical or social complications of substance misuse. A working knowledge of these complications (discussed elsewhere in this chapter) is essential, as they may often be the only pointers to the presence of a substance misuse problem. Once again, the interview techniques discussed above can improve the validity of self-report.

Corroborative history can be obtained from relatives, friends, other treating professionals, such as the local doctor, and from old notes. Such information should be considered in the light of the overall clinical picture and not regarded as a "gold standard" by which to judge self-report. Understatement of substance use by collateral sources can occur due to co-dependence, fear of retribution or fear of negative social or legal consequences if use is revealed. Overstatement can result from false assumptions based on previous behaviour or hearsay or from a desire for retribution.

Physical and mental state examination may reveal evidence of recent drug use (smell of alcohol on breath,

signs of intravenous needle use), an intoxication or withdrawal syndrome, or of the acute or chronic complications of substance misuse. Substance misuse is a common cause of a general decline in global functioning, evidenced by a poor state of dress, general health, nutrition and hygiene. Neuropsychiatric testing may reveal patterns of abnormality consistent with the known effects of substance use, such as that of alcohol-related brain damage.

Laboratory tests may provide some evidence of substance misuse. In the acute situation, the presence and amount of most substances can be detected by urine or serum tests or (in the case of alcohol) breath tests. As most are cleared rapidly from the body, however, tests will be negative if no recent use has occurred. Exceptions are THC, which is stored in fat and may be detectable in urine and serum for several weeks after cessation of marijuana use, and long-acting benzodiazepines such as diazepam, which may be detectable for several days. Abnormal values for mean corpuscular volume (MCV) and γ-glutamyltransferase (GGT), both widely available tests, may indicate excessive alcohol consumption over the preceding weeks. Both have good specificity but poor sensitivity. More recently, carbohydrate-deficient transferrin (CDT) has been identified as a sensitive and highly specific marker of excessive alcohol consumption (Conigrave et al. 1995b).

If substance misuse is suspected, observation over time during treatment can provide additional information. Admission to hospital of a substance misuser may be followed by rapid resolution of symptoms, onset of a withdrawal syndrome, drug-seeking behaviour or signs of intoxication after ward leave. Observed tolerance to benzodiazepines or opiates may indicate alcohol/sedative or opiate abuse, respectively.

7 Management

Treating alcohol and drug problems is a major challenge for mental health professionals. In general, the prognosis and response to treatment is better when the problem is identified at an early stage. Correspondingly, the prognosis is worst and response to treatment least likely when dependence has become well established, the associated lifestyle entrenched, and physical and other complications severe.

When the disorder has reached the stage of dependence, it has a chronic, relapsing course. It is not likely to respond in the long term to a single session of treatment, no matter how intensive. Relapses following treatment are the rule rather than the exception. About two thirds of the patients attending treatment programmes for addictive disorders relapse within 3 months following treatment. Similarly, half of opiate users relapse within 6 months after completing in-patient treatment (Gossop et al. 1989), and 97% relapse in 1 year (Vaillant 1988).

Interventions may be classified into those that aim to assist patients in achieving abstinence and maintaining a relapse-free lifestyle, and those that respond to the statistical likelihood of relapse by aiming for stable maintenance on a substitute drug or continued use with a minimum of harmful effects (a "harm-reduction" philosophy). Although total abstinence from all psychoactive substances may be the ideal goal, it is achievable in only a minority of substance users (Seivewright and Greenwood 1996). Hence, it is crucial for mental health and other health professionals to embrace and promote an approach which recognises that there are diverse treatment goals, relevant to different individuals and treatment settings. Interim goals may differ from long-term ones. The multiplicity of non-abstinence goals is encapsulated in the harm-reduction approach (Des Jarlais 1995; O'Hare et al. 1992). In the following section, we will briefly review various interventions for alcohol, opiates and psychostimulants. We shall focus on those appropriate for ambulatory care and post-detoxification settings.

7.1 Alcohol

No one treatment approach is effective for all individuals with alcohol problems (Institute of Medicine 1990). A major reorientation of treatment has come about with the evidence that intensive in-patient treatments are, at best, only slightly more effective than briefer out-patient treatments (Annis 1986; Keso and Salaspuro 1990). Several important factors should be considered in advising on the form of treatment. They include the severity of alcohol dependence and the severity of alcohol-related problems, availability and quality of social support, strength of coping skills, patients' readiness to change, severity of cognitive impairment and personal choice of treatment goals. However, assignment to treatment is not a precise science (Project MATCH Study Group 1997), and the availability of different treatments and the skills, experience and enthusiasm of a therapist in a particular approach are also important factors.

Reviews of the effectiveness and cost-effectiveness of treatment of alcohol problems indicate that many widely used treatments have yet to demonstrate their effectiveness convincingly and/or are very expensive to

deliver (Finney and Monahan 1996; Holder et al. 1991; Saunders 1989). Those for which there is acceptable evidence of effectiveness include brief interventions, cognitive-behaviour therapy (CBT), cue exposure treatment, pharmacotherapies such as acamprosate and naltrexone, social skills training, behavioural marital therapy and stress management training. Other techniques are beneficial but are too expensive for widespread use. Some, such as AA and other 12-step approaches, are widely practised, but are not well founded on empirical evidence.

Brief Interventions

Brief Interventions for alcohol problems are usually between one and three sessions, which vary from 5 to 30 min. Hazardous and harmful drinkers who are not dependent on alcohol generally benefit from this approach (Babor 1994; Bien et al. 1993; WHO Brief Intervention Study Group 1996). Typically, following a standardised brief assessment, e.g. AUDIT (Saunders et al. 1993), patients are provided feedback regarding excessive alcohol use and related problems and, through reflective listening, guided to weigh the pros and cons of continued use versus change. Self-monitoring and simple cognitive and behavioural tips to reduce drinking are generally preferred and reportedly used by patients (Sitharthan et al. 1996).

Cognitive-Behaviour Therapy

CBT involves functional analysis of drinking behaviour, goal setting, self-monitoring and self-appraisal of progress. Patients are trained to identify high-risk situations and apply problem-solving coping skills to avoid the problem situation or drink less in such situations. In addition, patients are encouraged to gradually engage in different problem situations of graded difficulty to enhance their self-efficacy (Miller et al. 1992; Sitharthan and Kavanagh 1990). Most importantly, patients are trained to cope with setbacks by viewing "slips" as learning experiences to prevent further relapses from occurring (Marlatt and Gordon 1985). Although CBT is generally applied to moderating drinking, similar strategies can be applied to promote abstinence. CBT can be provided in individual or group format.

Cue Exposure Treatment

Recently, there has been an interest in applying cue exposure therapy for alcohol problems. The idea of this approach is that drinking cues (e.g. sight, smell, taste) are thought to acquire potency through conditioning, and extinction would require repeated exposure to alcohol cues with response prevention. In a trial aimed at moderation drinking, non-dependent problem drinkers were provided priming doses of alcohol (i.e. patients were provided two or three standard drinks) followed by exposure to alcohol cues and then prohibited from drinking further (Sitharthan et al. 1997). This approach to treatment appears promising.

Pharmacotherapies

Pharmacological treatments have received much attention since the early 1990s. The oldest drug used in the treatment of alcohol dependence is disulfiram (Antabuse), an inhibitor of aldehyde dehydrogenase. By itself, disulfiram has only a modest effect on abstinence rates among alcohol-dependent patients (Fuller et al. 1986). However, when used as an adjunct with behavioural interventions, it has produced favourable outcomes. In combination with behavioural counselling, contingency contracting and, where possible, supervised administration, treatment compliance, abstinence rates and overall outcomes are substantially improved (Azrin et al. 1982).

There has been a great upsurge in interest in pharmacological agents to reduce craving and avert relapses. Naltrexone, an opioid receptor antagonist, which is considered to block the reinforcing effects of alcohol, has been shown to reduce relapse rates in several randomised controlled trials when compared with a placebo preparation. Results are best when naltrexone is combined with CBT (O'Malley et al. 1992; Center for Substance Abuse Treatment 1998) and are most impressive in the first 3–6 months of therapy.

Acamprosate (calcium acetyl homotaurinate) has been shown in several controlled trials to increase abstinence rates among alcohol-dependent patients (Sass et al. 1996). Acamprosate appears to complement behavioural and psychosocial treatments (Whitworth et al. 1996). Both naltrexone and acamprosate are well tolerated in alcohol-dependent individuals. Fluoxetine and imipramine may be useful adjuncts to relapse prevention programmes, particularly for dependent drinkers with co-morbid depression (Kranzler et al. 1995; McGrath et al. 1996). Combinations of pharmacotherapies may result in improved outcomes compared with single agents (Besson et al. 1998; Swift 1999).

Social Skills Training

Social skills training involves teaching patients assertion skills, including drink refusal and general communication skills. Clients who are dependent on alcohol are usually provided social skills training in a group format. Through role playing and modelling, the therapist trains the patient to respond to different difficult high-risk situations. Attention is given to not just what the patient might say in a high-risk situation, but also how it might be said effectively. Social skills training can be part of a global relapse prevention treatment programme.

Behavioural Marital Therapy

Behavioural marital therapy provides an opportunity for couples to negotiate treatment goals, report on treatment progress and improve communication and problem-solving skills. Patients may also be prescribed pharmacotherapy, and the spouse/partner learns to reinforce non-drinking and other appropriate behaviours. In addition, the couples also invest time to engage in shared rewarding activities (O'Farrell 1993). Behavioural marital therapy can be conducted with individual couples or delivered in a group format.

Stress Management Training

Stress management training is suited for patients who need to learn to relax and reduce their stress. Patients can be trained in various relaxation and meditation techniques. However, improvement is dependent on compliance to practice these techniques on a regular basis. Hence, engagement in pleasant activities may be as beneficial as relaxation training for some patients to reduce stress. In addition, cognitive strategies aimed at challenging and correcting maladaptive thinking patterns (Beck et al. 1993; Ellis et al. 1988) can also be used as part of general stress management training.

Twelve-Step Approaches

Worldwide, AA and similar 12-step movements represent the most widespread, often most accessible and sometimes the only available form of care and support for people with alcohol and drug problems. This mutual support group of "recovering alcoholics" is organisationally, doctrinally and financially independent of any government or professional body, but is incorporated into many funded and professionally sanctioned treatment programmes.

AA teaches that alcoholism is a disease and that the only possible way of recovery is through lifetime abstinence from alcohol. This recovery is to be gained through admitting helplessness and seeking assistance from a "higher power" (which is not aligned with a particular deity), considering the effects of drinking on others and where possible making amends, and assisting other alcoholics to obtain and maintain sobriety.

AA fellowships hold regular meetings at which a number of speakers will recount their own histories, describing their drinking, its negative consequences and how they came to recovery. The content of these meetings reminds the members of their own past and the need to remain sober and may powerfully challenge new attendees who relate to certain aspects of the stories of others. AA provides social support formally in the allocation of a "sponsor" to new members and informally by providing opportunities for friendship and social interaction in an alcohol-free environment.

Considering that AA was established in 1935, there has been remarkably little scientific investigation into the conceptual basis of the 12-step approach or into the outcome of treatment in comparison with other modalities. Although many individuals attribute their long-term abstinence to involvement with AA (Chappell 1993), the only comprehensive randomised controlled trial of a 12-step approach in comparison with other alcohol dependence treatments is Project MATCH (1997). Outcome at 12 months was similar in those groups receiving a 12-step approach compared with two groups receiving cognitive–behavioural or motivational enhancement therapies. The 12-step approach was slightly superior when judged on abstinence duration criteria (Project MATCH Study Group 1997).

7.2 Opiates

There are three broad approaches to the treatment of opiate dependence: psychosocial interventions, substitution therapies and opioid antagonists.

Psychosocial Interventions

Psychosocial interventions for opiate dependence are generally modelled on treatments for alcohol dependence. Preventing or reducing drug use, reducing health care utilisations, crime and legal expenditure and improving health and psychosocial well-being are the principal treatment objectives. However, compared with the alcohol treatment literature, there are few treatment outcome studies. Cognitive behaviour therapy is reported to be effective for patients who are depressed or experiencing other psychiatric symptoms (Woody et al. 1995), but recruiting patients into such therapies is often difficult. Group relapse prevention plus participation in self-help groups has been found to be more effective in reducing opiate use, unemployment and criminal activities (McAuliffe 1990).

Agonist Maintenance

Substitution therapies are particularly valuable in the management of opiate dependence. To date, the most effective form of treatment is methadone maintenance (Ball and Ross 1991). Methadone is a long-acting opioid agonist that is well absorbed after oral dosage and binds to opioid receptors. Methadone maintenance was introduced in the 1960s in an effort to provide some "pharmacological stability" and as an attempt to blunt the effect of injected heroin. It has been employed in several ways since then and in combination with various forms of counselling and psychological therapy. It results in cessation of illicit

opiate use in only a minority of persons, at least in the early months. However, the frequency of injecting and the overall amount used are reduced by some 90%, with attendant benefits in reducing needle/syringe sharing, infective complications, preoccupation with drug use and property crime. With time, life becomes more settled, relationships are more stable and employment prospects improve.

The benefits of methadone maintenance are maintained for as long patients are on treatment. However, there is a high rate of relapse into illicit opiate use, needle sharing and HIV risk behaviour when maintenance is ceased. This applies particularly when patients are coerced or expected to progressively reduce their dose. Contemporary practice emphasises the need for a more participatory approach (Caplehorn et al. 1998), with patients taking the initiative to commence a dose-reduction regime. High-dose methadone maintenance (80–100 mg per day) is more effective in retaining patients in treatment and reducing extraneous heroin use than low-dose regimes (30–40 mg per day). In a recent large-scale study, patients maintained on dosage of less than 70 mg/day were more likely to use heroin during methadone maintenance treatment (Hartel et al. 1995). Split-dosing (half of the dose in the morning and half in the evening at a second visit to the clinic) (Kidorf and Stitzer 1996) and take-homes doses reduce illicit substance use among patients on methadone maintenance.

Buprenorphine is a shorter-acting partial opioid agonist. It is at least as effective as methadone for maintenance treatment of individuals with moderate to severe dependence. It appears to be easier to withdraw off than methadone and is safer in overdose because it results in little respiratory depression. Its wider safety margin make dosing every alternative day an option, which is more convenient for patients, more cost-effective and reduces the risk of diversion of take-home doses. Levo-alpha-acetylmethadol (LAAM) is a long-acting analogue of methadone. Patients may receive their dose every 48–72 h. It appears to be an effective maintenance agent when patients have been initially stabilised.

The use of heroin for chronic heroin dependence which is resistant to other treatments has recently been evaluated in Europe. Significant reductions in illicit drug use and criminal activity and substantial improvements in psychosocial outcomes were documented. Supervised administration of heroin appears to be viable. However, much of the benefit probably derived from the intense psychosocial support provided to patients in the programme.

Antagonists

Pharmacotherapies can also be oriented towards abstinence. Naltrexone is a long-acting antagonist which is administered orally and can block opioid receptors for up to 72 h. The positively reinforcing euphoric effects of heroin are blocked, and craving for drugs is reduced substantially. Patients need to undergo detoxification and be drug-free for 7 days before starting naltrexone. Alternatively, they can be offered rapid opiate detoxification in which naltrexone is administered under sedation or anaesthetic. This precipitates a withdrawal syndrome, which is controlled by clonidine and drugs to suppress gastric secretions, and offers a relatively comfortable and rapid means of induction onto naltrexone (Brewer 1997). Naltrexone is more effective than a placebo drug in reducing heroin use, but there is a high attrition rate from treatment, particularly compared with methadone. It is best administered under direct supervision. There is a high incidence of depression in the early stages of treatment, and there is some evidence of greater effectiveness if naltrexone is used in combination with a serotonin reuptake inhibitor.

Harm Reduction Strategies

Ongoing opiate use and at-risk sexual behaviour is common despite methadone maintenance treatment or psychosocial interventions. Reducing the harm associated with these practices is an important goal. Sterile injecting equipment can be made available, along with instructions on how to inject safely and information to prevent overdosing. Similarly, condoms should be made available for patients, and they should be provided with information about safe sexual practices and communicable diseases.

There has been a considerable debate as to whether controlled availability of heroin (or other opiates) is a legitimate policy for the health care system. Given the findings that, once maintained on heroin, they show substantial improvements in their health status, stability of residence and employment status, there is substantial support for this approach. Most countries have been reluctant to endorse such programmes, but there is a growing movement to allow prescription of injectable opiates under close supervision.

7.3 Psychostimulants

There are no specific cognitive, behavioural or other psychosocial interventions of sustained effectiveness for patients who abuse or are dependent on cocaine. Cognitive-behavioural relapse prevention was more effective than standard case management, particularly for severe cocaine users (Carroll et al. 1994). Providing gift vouchers that can be exchanged for retail items has been shown to increase compliance among cocaine-dependent patients in providing clean urine. Similar

voucher exchange methods produced favourable results among injecting polydrug users (Silverman et al. 1996). A community reinforcement approach plus incentives were found to produce better outcomes than 12-step counselling. Intensive day hospital treatment is as beneficial as intensive in-patient treatment for cocaine-dependent patients (Alterman et al. 1994). Cognitive–behavioural relapse prevention approaches which include identifying high-risk situations and planned coping in such situations, along with social support, and contingency contracting should be considered as part of the treatment plan for patients who abuse or are dependent on cocaine. Antidepressants (desipramine and the selective serotonin reuptake inhibitors) ameliorate the depression of psychostimulant withdrawal and appear to improve treatment compliance in the first few weeks. However, there are no pharmacological treatments of proven effectiveness in promoting long-term abstinence from cocaine (American Psychiatric Association 1995).

7.4 Simultaneous Versus Sequential Cessation

It is not uncommon for substance misuse patients to abuse more than one drug. Many opiate and cocaine users tend to abuse alcohol and other substances. As one psychoactive substance may serve as a cue or trigger to use another, it may be necessary for patients to try to abstain from all psychoactive substances. However, simultaneous cessation from all substances, including tobacco, will be considered a very difficult task by many patients. If sequential cessation is preferred by the patient, a clearly defined contract, specifying a timetable of cessation events, should be developed. The patient should be provided with professional support through individual or group counselling to achieve sequential cessation.

If simultaneous cessation is required (by legal mandate), contingency contracting, compulsory breath and urine toxicology testing, regular attendance at intensive individual counselling, participation in group therapy and other self-help groups and, where possible, family support and supervision should be considered as part of the overall treatment plan, along with appropriate pharmacological adjuncts.

7.5 Managing Psychiatric Co-morbidity

Several epidemiological studies have found a high prevalence of psychiatric disorders among substance misusers and of substance misuse among psychiatric patients (Alaja et al. 1998; Brown et al. 1995; Hall 1996). While there are suggestions regarding case management of dual-diagnosis patients, randomised controlled trials evaluating the effectiveness of different methods of psychological and pharmacological interventions for dual-diagnosis patients are few (Sitharthan et al. 1999).

Patients with mental illness usually have better access to treatment services than patients with a co-morbid substance use disorder (Minkoff and Drake 1991). It is not uncommon for psychiatric patients with alcohol problems to feel "unwelcome" in alcohol treatment agencies (Institute of Medicine 1990).

At a practical level, there are several problems that arise in the day-to-day management of such patients. One is inadequate liaison between addiction treatment agencies and specialist psychiatric settings. Secondly, many psychiatric patients may not relate well to the demands placed on them by specialist addiction settings. Thirdly, diagnosis of co-morbid affective and anxiety disorders or schizophrenia cannot be reliably established until the patient is alcohol or drug free for 4 weeks or more, a goal which is often difficult to achieve. Liaison between addiction treatment agencies and specialist psychiatric clinics can lead to more effective detection and intervention for alcohol and drug problems (Sitharthan et al. 1999).

Providing an environment that fosters an abstinent lifestyle should be part of the clinical management of patients. In addition to providing compassionate support and care, patients should be trained in appropriate coping skills to prevent re-engagement in substance use (Kavanagh et al. 1998). Encouraging them to attend a group such as Dual Recovery Anonymous may provide peer support for such patients. Voluntary participation in self-help groups may also reduce the overall costs of providing professional treatment (Humphreys and Moos 1996).

It is not uncommon for many psychiatric patients to engage in high-risk sexual practices. Hence, educating patients about HIV transmission and teaching them behavioural skills to reduce HIV risk reduction is crucial. Behavioural skills include teaching patients to identify high-risk situations leading to substance use and unsafe sexual practices, learning problem-solving skills to negotiate safe sexual practices and assertion skills to refuse participating in high-risk sexual behaviours (Kalichman et al. 1995).

Addiction treatment services generally aim to promote total abstinence from all substances. It may not be possible for dual-diagnosis patients to achieve this goal. Treatment agencies must be sensitive to the special needs of patients with a dual diagnosis and may need to work within a harm-minimisation/reduction policy. Increased compliance and reductions in overall health care utilisation should be considered

as legitimate treatment goals. As dual-diagnosis patients frequently report low levels of satisfaction with family relationships (Dixon et al. 1995), involving family members in planned intervention must be explored.

8 Conclusions

Substance misuse and dependence continue at a high level worldwide. Reductions in the prevalence of alcohol and sedative-hypnotic misuse in developed countries have been offset by substantial increases in developing countries and in growing illicit drug markets. There is increasing diagnostic precision in the main international diagnostic systems, which reflects much research into the spectrum of substance misuse, the phenomenology of dependence and the natural history of the dependence syndrome. There is also a wider array of interventions, including more potent brief treatments for hazardous alcohol use, pharmacotherapies for alcohol dependence and substitution therapy and antagonists for the management of opiate dependence.

The last decade has witnessed a growing demand for evidence-based interventions and clinical accountability. Gordis (1996), commenting on alcohol research and practice, asserted that clinical practice that functions on the basis that "Deep in my heart I know our program works" can no longer be funded. We believe the same sentiment should be extended to other forms of substance misuse and related co-morbid disorders. Economic constraints, sophistication in implementing and evaluating treatment outcome research and the development of innovative treatment programmes will compel us to think constantly as to how best to treat our patients.

Abuse of, and Dependence on, Medically Prescribed Drugs

Translator: E. Taub

1 Problems of Classification

The diagnosis of abuse of, and dependence on, substances that are partly or mainly prescribed by physicians is associated with major problems of classification, more so than in the case of alcohol and other "classical" addictive drugs, such as opioids or cocaine. The reason is partly that these substances are often given to treat mental or psychovegetative disorders; they thus possess a therapeutic effect that other psychotropic substances do not. A further reason is that the ICD-10 and DSM-IV criteria for psychotropic substance abuse and dependence are not easy to apply to medically prescribed substances.

"Harmful use" of a substance, in the terminology of ICD-10, involves actual harm to the individual consuming it, i.e. an injury to health rather than merely negative social effects. In DSM-IV, on the other hand, negative social effects are among the criteria for the diagnosis of substance abuse. Even protracted long-term consumption of certain hypnotics and anxiolytics may not lead, in all cases, to an immediately recognizable or readily diagnosable injury to health, even when injurious use is clearly present from the clinical perspective in view of the severe associated psychosocial problems.

The diagnosis of dependence on a medically prescribed substance may also be problematic. The desire or compulsion ("craving") to consume a psychotropic substance is typically not as strong in such cases as in alcohol or opiate abuse; furthermore, many of these substances do not demonstrably impair self-control. The development of tolerance is nearly always present with long-term consumption of addictive drugs, but need not be so in cases of medication dependence: thus clinicians have long been aware of the existence of so-called low-dose benzodiazepine dependence, in which there is neither tolerance nor an escalation of dose, and many frequently abused medications, such as anabolic steroids, do not give rise to tolerance at all in the narrow sense of the term.

It may also be difficult to distinguish the physical or mental manifestations of withdrawal from those of the underlying illness ("symptom re-emergence") when medications prescribed to treat mental health problems, such as hypnotics, are discontinued or when their dosage is reduced. To illustrate the problem, an epileptic patient treated with benzodiazepines might have seizures when they are discontinued, but such seizures would not be called "withdrawal seizures." In analogous fashion, the re-emergence of anxiety or of sleep disorders after the discontinuation of hypnotics or anxiolytics is not necessarily the result of a dependence syndrome. In recent publications, terms such as "rebound insomnia" and the like have been used to describe these phenomena.

In summary, the ICD-10 and DSM-IV criteria for abuse, harmful use, and dependence on psychotropic substances are somewhat problematic for many of the classes of medications listed below, and the diagnosis must also take other clinical aspects into account (e.g. behavioral abnormalities, "doctor shopping," etc.). Moreover, a clear distinction must be drawn between primary and secondary medication dependence (as in alcohol and drug abuse).

2 Epidemiology

The available estimates of the frequency of abuse of, and dependence on, medically prescribed drugs in the general population are highly variable. It is clear from official statistics that a number of substance classes, in particular hypnotics/anxiolytics, tranquilizers, and analgesics, are among the more commonly sold medications of all kinds. Glaeske (1996) estimated that approximately 6%–8% of all prescribed medications have an intrinsic potential for abuse.

There have been major changes in prescribing behavior in recent years. First of all, 38% of all medications sold require no prescription (so-called self-medication); analgesics account for the major share of these.

Community-based studies of medication use have revealed that approximately 6%–12% of the adult population is under treatment with psychoactive medications (Cooperstock and Parnell 1982; Weyerer and Zimber 1997). Population-based studies in a number of countries have demonstrated a relationship between the use of psychoactive medications and the age and sex of the consumer (Larson et al. 1991). Such medications, particularly tranquilizers and hypnotics, are used more frequently by women, and still more so with advancing age. Most psychoactive medications are not prescribed by psychiatrists. According to a representative study by Beardsley et al. (1988), two thirds of all psychoactive medications are prescribed by general practitioners and internists, and only about 17% by psychiatrists or other specialists.

The problem of dependence on medication is common knowledge not only among clinicians, but also in the general public. Thus the rate of prescription of benzodiazepines is steadily falling (though from a high baseline), and barbiturates now play no more than a secondary role. On the other hand, the prescription of codeine-containing drugs primarily

designated as antitussives has risen astronomically in the past few years, even though these are frequently used in the illegal drug scene as so-called escape drugs. Because of their relatively short half-life (4–6 h), medications containing codeine or dihydrocodone seem to be particularly unsuitable for substitution treatment, as compared with methadone.

Keup (1993) attempted to assess the addictive potential of medications in a relatively systematic fashion by means of the so-called early warning system. The latter has been operative in Germany since 1976 and involves the determination of all substances and preparations taken and abused by a representative, random sample of individuals with a history of substance abuse, including approximately 700–900 individuals annually.

Somewhat surprisingly, it has occasionally been stated in Germany in the last few years that antidepressants and neuroleptics are medications with addictive potential. This is probably because many individuals dependent on alcohol and illegal drugs value their general psychomotor damping effect, which reduces anxiety and tension. It is highly misleading, however, when medications such as amitriptyline and doxepine are mentioned in the same breath as tramadol, morphine, levomethadone, and clomethiazol in a table of abused medications listed by frequency of prescription, as in the last Addiction Yearbook (*Jahrbuch Sucht* 1998) published by the Hauptstelle gegen die Suchtgefahren (German Central Agency Against the Dangers of Addiction).

The so-called German Federal Study has been carried out at irregular intervals of 2–5 years since 1980 by order of the Federal Ministry of Health and has provided important data on the use of psychoactive substances among adults in Germany. It was last performed in 1997 on a sample of 8020 adults aged 18–59 (Kraus and Bauernfeind 1998). With regard to the prevalence of medication use, it was found that almost twice as many women (19.5%) as men (11.5%) had taken psychoactive substances, e.g. analgesics, laxatives, and appetite suppressants, in the 4 weeks before the study. The types of medication most commonly taken included analgesics (13.5% in women vs. 8.6% in men), hypnotics (3.2% vs. 2%), tranquilizers (4.4% vs. 2%), so-called stimulants (1% vs. 0.8%), laxatives (3.1% vs. 0.9%), and appetite suppressants (1.2% vs. 0.4%). It should be kept in mind that these figures do not reflect the use of psychoactive substances by persons over 60, which, according to all currently available data, is even higher.

Although certain psychoactive medications and analgesics are commonly prescribed, as stated above, it should be pointed out explicitly that the prescribing habits revealed by statistics in no way imply the development of an addiction in every case. Even so, the number of individuals dependent on medications in Germany has been estimated to be as high as 1.4 million (Hüllinghorst 1996). Women considerably outnumber men as consumers of practically all of the medications named in this chapter, with the exception of anabolic steroids. According to a review by Kraus (1996), 60% of those studied had taken one or more medications at least once a week in the month before the study (men 12.8%, women 19.3%). A further finding is that many of the substances named (psychoactive medications in particular) are increasingly consumed with advancing age and are very commonly prescribed to residents of old-age homes and nursing homes (for a review, see Weyerer and Zimber 1997).

An important, frequently overlooked aspect of dependence on medically prescribed substances is the associated mortality. Studies by Poser et al. (1990, 1992) revealed that the mortality of patients taking psychoactive substances was 2.1 times higher than that of a control group. This figure was lower than that found in other forms of addiction. Alcoholism led to a fivefold increase in the consumption of illegal drugs and to a 17-fold increase in mortality. Abuse was much less dangerous than dependence with respect to increased mortality (elevation by a factor of 1.1, as compared to 3.8). In cases of addiction that went on to take a favorable course, mortality was essentially normalized. The reported causes of death in patients dependent only on prescribed medication are of interest. Among such patients who died, one third died by suicide, and 8% as the result of accidents or intoxications. These findings may also indicate a high degree of psychiatric comorbidity among patients dependent on prescribed medication.

3 Individual Substance Classes

3.1 Anxiolytics and Hypnotics

Benzodiazepines

The benzodiazepines have largely replaced the "classical" hypnotics and anxiolytics, such as the barbiturates, because of their low toxicity and are among the more commonly used medications of all kinds. The therapeutic effect of these substances is due to specific binding to the γ-aminobutyric acid $(GABA)_A$ receptor, and the pharmacological potency of each benzodiazepine substance is a function of its affinity for this receptor. The effect results from GABA-induced neural inhibition in various regions of the central nervous system. All benzodiazepines have hypnotic, anxiolytic, anticonvulsant, and muscle-relaxing properties,

although there is wide variation in the clinical spectrum of the individual substances. The major indications for their use in psychiatry are anxious conditions and sleep disturbances. They are also used to treat withdrawal syndromes and withdrawal psychoses, as well as epileptic seizures.

It is important to note that benzodiazepines are also used for indications other than these classical ones, often without adequate medical justification. The study by Geiselmann et al. (1989) revealed a marked degree of "therapist non-compliance" with respect to the generally applicable recommendations for the use of benzodiazepines, which are clearly often given for nonindicated purposes. In addition, they are often administered in the long term and not merely in the short term, as generally recommended, and they are sometimes given even to patients with primary substance abuse. This study shows that erroneous or inadequately justified prescribing behavior on the part of the therapist may actually favor the development of substance abuse and dependence in many cases.

The most important side effects of benzodiazepine overdose include excessive sedation, disturbance of motor coordination (ataxia), somnolence and lethargy, delirium and disorientation, amnesia, and aggravation of dementia. Higher doses primarily impair cognitive and psychomotor function.

Although the short-term administration of benzodiazepines is regarded as relatively unproblematic, there have been numerous reports of long-term administration for months or years leading to the development of dependence. Some patients may develop a marked tolerance for the drug, which is, however, not as severe as with barbiturates. Tolerance is due to adaptation of receptors in the central nervous system, rather than to pharmacokinetic changes; benzodiazepines, unlike other hypnotics, do not induce the production of metabolic enzymes in the liver.

Benzodiazepine abuse and dependence are clearly very common. The findings of a number of studies suggest that benzodiazepines with particularly short half-lives or strong anxiolytic profiles have an especially high dependence potential (see Poser and Poser 1996; Soyka et al. 1988), yet essentially all of them have a considerable potential for addiction. As remarked above, benzodiazepine dependence differs from other types of addiction in that it may develop without a progressive increase in dosage, i.e. without any major degree of tolerance. Severe mental and physical withdrawal phenomena may follow the discontinuation of benzodiazepines even in the setting of low-dose benzodiazepine dependence (Soyka et al. 1988).

Linden et al. (1998) found that patients with low-dose benzodiazepine dependence, even those undergoing long-term treatment, had a type of medication craving, as well as many other, major mental and physical symptoms. The authors interpreted these findings as showing that low-dose benzodiazepine dependence is indeed dependence in the proper sense of the term.

Low-dose benzodiazepine dependence is said to be present when the daily dose does not exceed the equivalent of approximately 30 mg diazepam. Experience has shown that benzodiazepines should be withdrawn slowly and that patients taking higher doses of medication have a higher risk of developing withdrawal psychoses and seizures.

It is important to point out that most cases of benzodiazepine abuse and dependence are secondary, i.e. that they arise in the setting of other types of dependence (e.g. alcoholism) or multisubstance abuse. Patients who abuse and are dependent on other substances should thus be considered a high-risk group for benzodiazepine dependence, even when benzodiazepines are used preventively. The elderly are a further risk group: several studies have shown that patients in homes for the elderly and nursing homes are very frequently treated with psychotropic drugs, and with benzodiazepines in particular. As mentioned above, such treatment may lead to a certain degree of cognitive impairment and confusion; moreover, the elderly often have an impaired ability to metabolize benzodiazepines. Clinical and epidemiologic studies have shown that some types of psychoactive drugs, particularly tranquilizers, are prescribed very frequently to patients living in nursing homes and homes for the elderly (Weyerer and Zimber 1997b).

More than 20 different benzodiazepines are now on the market in Germany, including short-acting (triazolam), intermediate (alprazolam, lorazepam), and long-acting preparations (diazepam, chlordiazepoxide). The abuse potential of benzodiazepines is less than that of other hypnotics (including barbiturates); however, because they have largely displaced other hypnotics and tranquilizers in psychiatric practice, benzodiazepine dependence is now the most frequent indication for withdrawal treatment. A special role is played by the medication flunitrazepam (Rohypnol), which has achieved a regrettable degree of prominence in the drug scene and is often taken by many addicts because of its strong sedative effect and strong psychotropic activity. It is also sold on the black market in greater volume than other benzodiazepines.

The clinical manifestations of benzodiazepine intoxication are essentially no different from those seen with other sedatives, hypnotics, and anxiolytics. They possess a wide therapeutic window (i.e. there is a wide range between the minimal therapeutic dose and the minimal toxic dose), and thus lethal outcomes are to be feared only in cases of mixed intoxication.

Among its mental manifestations, benzodiazepine intoxication leads to the following: affective disinhibi-

tion; emotional lability; impairment of cognitive function, judgment and critical ability; impairment of psychomotor performance, including driving ability; and various other behavioral abnormalities, most importantly profound sedation or coma. Its most prominent general medical and neurological complications are slurred speech, incoordination, ataxia, unsteady gait, respiratory depression, and sometimes hypo- or areflexia. The differential diagnosis includes alcohol and other intoxications, hypoglycemia, epilepsy, cerebral hemorrhage or infarction, myocardial infarction, and other illnesses.

No specific measures are needed to treat less severe intoxications. The administration of the short-acting benzodiazepine antagonist flumazenil (Anexate, 1 ampoule IV) is indicated less for therapeutic than for diagnostic purposes (exclusion of benzodiazepine or multisubstance intoxication). Patients suffering exclusively from benzodiazepine intoxication awaken spontaneously in a very short time.

Benzodiazepine withdrawal phenomena are extremely variable. The individual manifestations of sedative and hypnotic withdrawal are very similar to those of alcohol withdrawal, though their course is somewhat different (usually prolonged). Perceptual abnormalities are very common, though not pathognomonic. Abuse of, or dependence on, these substances is often secondary, i.e. in association with the consumption of other psychotropic substances, particularly alcohol and opioids. Primary dependence is relatively rare and, as experience has revealed, develops most frequently in patients with an underlying psychiatric illness. The clinical picture of benzodiazepine withdrawal phenomena is correspondingly variable.

In general, two types of withdrawal syndrome can be distinguished on the basis of their course: a mild, brief withdrawal syndrome ("minor withdrawal") and a severe one accompanied by psychosis ("major withdrawal"). Perceptual abnormalities are highly characteristic, though not pathognomonic, of benzodiazepine withdrawal and may be deceptively similar to symptoms of neurological disease. Withdrawal psychoses are found mainly when higher doses of benzodiazepines have been consumed. When benzodiazepines have been administered in the long term, their sudden discontinuation or excessively abrupt reduction is contraindicated. A stepwise tapering of medication ending in discontinuation has proved useful in withdrawal treatment (e.g. halving of the dose every 5 days; Soyka et al. 1988).

As discussed above, the differentiation of substance-induced disorders from the manifestations of an underlying psychiatric illness is particularly difficult in the setting of hypnotic or anxiolytic withdrawal. Withdrawal psychoses in the form of delirium and schizophreniform psychosis are comparatively rare. Epileptic seizures, in contrast, are relatively frequent in benzodiazepine withdrawal. It is known that benzodiazepines can lead to amnestic syndromes and to an impairment of psychomotor performance, including driving ability. The personality changes that they produce are difficult to classify and often have manifestations of both anxiety and depression.

Barbiturates

Barbiturates, like benzodiazepines, exert their effects by way of the $GABA_A$ receptor. They have a markedly higher abuse potential than the benzodiazepines, and lethal intoxications are common. Most barbiturates have a very long half-life. Unlike the benzodiazepines, they have no specific antidote.

Tolerance and dependence often develop very rapidly. Metabolic tolerance occurs because of the induction of hepatic enzymes.

When they have been taken for a considerable length of time, barbiturates often have a paradoxical activating and mood-brightening effect. High doses often lead to a state of intoxication. Because barbiturates have a powerful hypnotic effect and suppress rapid eye movement (REM) sleep, their withdrawal often leads to REM rebound with increased dreaming, nightmares, and sleep disturbances. Delirium, hallucinations, disorientation, agitation, and epileptic seizures are common in barbiturate withdrawal.

Newer Non-benzodiazepine Hypnotics

The newer GABAergic non-benzodiazepine hypnotics, zolpidem and zopiclon, have found wide application in recent years. There have been a few case reports of abuse and dependence with both of these substances (Bottlender et al. 1997; Thome et al. 1997), but primary dependence is exceptional. For zolpidem, in particular, many very careful investigations of its possible potential for abuse and dependence have revealed these dangers to be considerably lower than with other hypnotics, including benzodiazepines; long-term use of zolpidem is relatively rare (Keup 1998). These substances have not found their way into the drug scene to date. Nonetheless, the possibility of intoxication, abuse, and withdrawal cannot be excluded in individual cases.

Clomethiazol

Clomethiazol requires special mention in this discussion. Dependence on clomethiazol often develops in the setting of primary alcohol dependence. It is a highly effective medication in the treatment of the alcohol withdrawal syndrome and of delirium (reviewed in Soyka 1995, 1997), but, when given in the outpatient setting, it often leads to a displacement of addiction and to secondary dependence. It should thus be given in the outpatient setting only in exceptional cases, when specially indicated, and only

in the short term. Clomethiazol withdrawal is often very difficult and protracted.

Other Hypnotics

The "classical" non-barbiturate hypnotics, like the barbiturates, have now been largely, though not completely, supplanted in clinical use by the benzodiazepines. A number of single and compound preparations of this type remain available in Germany, including methaqualone, meprobamate, chloral hydrate, piperidine derivatives, and bromourea derivatives. The latter substance class not only has a considerable dependence potential, but is also associated with a specific clinical pattern of chronic intoxication. Bromism is characterized by irritability, depressive mood disturbance, sedation, purpura, excessive tearing, intestinal complaints, anorexia, headache, and disturbances of speech and coordination, as well as acneiform cutaneous abnormalities. The diagnosis may be established by determination of the serum bromine concentration.

3.2 Caffeine

Caffeine is a mild psychostimulant unrelated to any other class of psychostimulants, e.g. the amphetamines. It is present not only in coffee, tea, cola, chocolate, and cocoa, but also in numerous combination drugs, particularly analgesics. It has various pharmacological effects. In addition to its stimulating effect, there is also a very mild euphoria and an acceleration of breathing. In higher doses (250–600 mg), caffeine produces nervousness, anxiety, restlessness, difficulty falling asleep, tremor, and hyperesthesia. The public has become increasingly aware in recent years that caffeine can be used for "doping," as it improves performance in endurance sports. The psychotropic effect of caffeine is largely due to an interaction with adenosine receptors in the central nervous system (for a review, see Poser and Poser 1996), but it also influences other neurotransmitters, such as dopamine, as well as second messenger systems.

Caffeine abuse is generally seen in connection with doping or with analgesic consumption. Caffeine is only rarely abused as a single substance (as sometimes occurs, for example, in penal institutions).

Caffeine intoxication, which requires doses of over 500 mg, is also very rare. Anxiety, insomnia, mood changes, tachycardia, and cardiac dysrhythmia, as well as elevated blood pressure and gastrointestinal complaints, are the most prominent manifestations. The consumption of high doses of caffeine can lead, in very rare cases, to acute psychosis (Poser and Poser 1996) or to epileptic seizures.

Caffeine-induced panic attacks are a special phenomenon. Patients with a predisposition to such attacks should avoid consuming caffeine. Usually, however, fairly high doses of caffeine are required to induce panic attacks in patients with anxiety disorders. This phenomenon is not observed in healthy individuals.

The so-called mixed analgesics are by far the most commonly abused caffeine-containing medications. Their chronic use may lead to headache as the most prominent symptom.

3.3 Mixed Analgesics

Mixed analgesics are medications in which a peripherally acting analgesic or antipyretic is combined with one or more centrally acting substances. The centrally acting substances most commonly found in such preparations were at one time barbiturates and tranquilizers, though opioids, alkaloids, and caffeine were also used. Combination drugs, e.g. caffeine with acetylsalicylic acid, paracetamol, or propyphenazone, are among the medications more commonly used in Germany at present. Some require a prescription, while others are available over the counter. Mixed analgesic abuse is one of the more common forms of medication abuse; it is seen most often among individuals suffering from headaches, but also among those with other underlying physical illnesses.

The clinical picture of mixed analgesic abuse is highly characteristic. Its neuropsychiatric manifestations include persistent headache, fatigability, frequent or intensified migraine attacks, personality changes, avid desire for medication, and, with heavy consumption of barbiturates or tranquilizers, seizures and withdrawal delirium. The cardiovascular manifestations include hypertension, arteriosclerosis, coronary heart disease, cerebral infarction, and an increased frequency of preeclampsia. The cutaneous changes are also relatively typical, including paleness and abnormal pigmentation. These patients often seem prematurely aged.

Renal damage, specifically analgesic nephropathy, is a potential concern in chronic analgesic consumption. Gastrointestinal disturbances also occur, particularly an increased frequency of pancreatitis, as well as hematologic disturbances (anemia) and an increased frequency of osteoporosis and infertility. Headache is a relatively typical finding with consumption of mixed analgesics that contain ergot alkaloids. A dull, bilateral headache occurs when the medication is taken, and severe migraine attacks occur when it is withdrawn. Caffeine withdrawal headaches were already mentioned above. In general, patients chronically consuming

mixed analgesics tend to suffer from dull, pressure-type headaches.

The withdrawal of mixed analgesics is often difficult and protracted and usually involves the administration of sedating tricyclic antidepressants of the doxepine class. Oral metoclopramide is recommended for the treatment of nausea and vomiting, while severe migraine attacks can be treated with newer antimigraine agents of the sumatriptan type (Imigran). Further treatment depends on the clinical course. Psychotherapy, instruction in relaxation techniques, self-help groups, or biofeedback may be indicated.

3.4 Psychostimulants and Appetite Suppressants

Cocaine and most psychostimulants with similar effects are illegal drugs and are thus not discussed in this chapter. Some psychostimulants, however, do have a narrow range of clinical application. Amphetamine may be prescribed and sold as the racemic substance, but not as dextro- or levo-amphetamine. The abuse of appetite suppressants is a major problem mainly among patients with eating disorders.

The effect of amphetamines is essentially due to their indirect stimulation of the release of newly synthesized catecholamines, primarily dopamine, from presynaptic terminals. This results in behavioral stimulation, elevated psychomotor activity and, with higher doses, stereotypic behavior patterns and aggression. These effects are found primarily in adults; in children, on the other hand, amphetamine derivatives are used to treat aggressive behavior and hyperactivity. Aside from this special area of clinical application, amphetamines also play a role in the current treatment of narcolepsy and of overweight. The latter indication is highly controversial; it may fall still further out of favor because of recent developments in pharmacology (see below).

It is generally recommended that appetite suppressants such as fenfluramine be used as monotherapy only for short periods of less than 3 months. The consumption of appetite suppressants has risen exponentially in the last decade, at least in the United States (Kahn et al. 1998). Some of the newer so-called appetite suppressants, not only fenfluramine but also the serotonin reuptake inhibitors fluoxetine and sertraline, enhance serotonergic rather than dopaminergic neurotransmission. In contrast, the mechanism of action of the "classical" appetite suppressant methamphetamine is similar to that of cocaine. The consumption of amphetamine in high doses has been repeatedly reported to lead to violent outbursts, paranoid psychosis, and other psychotic behavioral abnormalities. It probably has neurotoxic effects.

Moreover, express mention should be made of the cardiotoxicity of appetite suppressants, which has been reported with increasing frequency only in the last few years. Two recently published studies (Kahn et al. 1998; Jick et al. 1998) revealed an elevated risk for cardiac valvular insufficiency in association with the consumption of fenfluramine, phentermine, and dexfenfluramine.

3.5 Anabolic Steroids and Other Substances Used for Doping

Anabolic steroids and other substances used for doping constitute a very heterogeneous substance class comprising psychostimulants and caffeine (see above), other stimulants, opioids, and, most importantly, anabolic steroids and nonsteroidal anabolic substances. The "red list" includes a large number of substances that enhance performance in competitive situations and, like anabolic steroids, lead to increased strength and muscle mass. Most of these substances are sold illegally, but there are also medically justifiable indications for their use. Anabolic steroids are used to treat lack of appetite, generalized weakness, muscle atrophy, and bone decalcification, among other conditions. The consumption of anabolic steroids does not lead to euphoria or to other obvious psychotropic effects.

The question whether a physician may prescribe anabolic substances to a bodybuilder is to be answered as follows, from the legal perspective: a physician can and may prescribe such preparations, whether or not the patient is (coincidentally) engaged in bodybuilding, but a strict medical indication must be present for their use (Schlund 1998). If the physician prescribes such a substance in the knowledge that the "patient" is not ill and wants to take it only to improve athletic performance or to increase muscle mass, then he or she is behaving unethically from the legal viewpoint and is, furthermore, violating the fundamental canons of the medical profession. From the medical perspective, careful ethical consideration is necessary before anabolic substances can be administered in the absence of a compelling medical indication.

It is of great concern that not only high-performance athletes, but also amateur athletes and bodybuilders are now taking such substances. Recent studies of amateur athletes engaged in fitness training have revealed that the consumption of anabolic steroids is surprisingly common. Boos et al. (1998) surveyed participants in commercial athletic studios and found that 24% of the men and 8% of the women were taking anabolic medications. In 94% of such cases, the substances taken were highly hepatotoxic. The source of the medications consumed was also of interest: they

were mainly obtained on the black market, but approximately 14% were prescribed by physicians.

The social framework of doping-substance abuse is somewhat different in the United States, where this phenomenon has been recognized for some time, than in Germany. The abuse of anabolic steroids in the United States is by no means confined to high-performance athletes, as studies by American sports physicians have revealed. It is thought that not only the high social standing of the successful athlete, but also the potential receipt of athletic scholarships to finance college education are important sociological factors motivating the consumption of such substances (for a review, see Boos et al. 1998). Nevertheless, a study performed by Boos's group revealed that a lower educational level is strongly associated with a higher degree of consumption.

It is not entirely clear whether the abuse of these substances leads to dependence, as postulated by a number of American investigators (e.g. Kashkin 1992). Favoring this hypothesis is the fact that 72% of the athletes abusing medications who were questioned in the study by Boos et al. (1998) wanted to continue taking them. Moreover, there seems to be a relatively high correlation between the use of anabolic steroids and the consumption of cocaine, marijuana, and other intoxicating drugs, with the exception of alcohol.

Relatively little is currently known about the possibly adverse mental effects of long-term consumption of these substances. The mechanisms leading to dependence have also been little studied to date. The desired increase in muscle mass and altered body image are probably such powerful psychological reinforcers in themselves that they can perpetuate the self-administration of anabolic steroids (Julien 1997). The changed personal appearance and the associated increase in self-esteem are a sufficient explanation in many cases.

The physical harm resulting from the use of these substances is quite extensive. There is damage to the cardiovascular system (arteriosclerosis, heart failure), the endocrine system (hypothyroidism), the immune system, the musculoskeletal system, and, relatively frequently, the liver, including the development of hepatic tumors. The sudden death of high-performance athletes in connection with doping has repeatedly come to the attention of the public. In men, anabolic steroids lead to gynecomastia, testicular atrophy, acne, and baldness; in women, they lead to masculinization, with an increase in body hair, beard growth, and other changes. (Such abnormalities were readily apparent in many high-performance female athletes in East Germany during the period of Communist rule, and the fact that they were due to anabolic steroid use has now been officially acknowledged.) Long-term mental effects may include depression, fatigue, restlessness, reduced appetite, loss of libido, and sleep disturbances. It has been stated that mood fluctuations, aggression, suicidality, and psychoses can also be induced (Kashkin 1992; Haupt 1993).

The withdrawal of anabolic steroids may be associated with depression, fatigue, restlessness, sleeplessness, and reduction of appetite and libido, possibly also headache and, in some cases, suicidality. A clearly delineated psychiatric withdrawal syndrome has not yet been described; withdrawal-associated psychoses or bipolar disorders have not been found to occur, though depression has been reported (Julien 1997).

3.6 Other Substances

Many other medically prescribed substances are subject to abuse, and many of these have no psychotropic effects. The abusive consumption of glucocorticoids has been reported in very rare cases, while the abuse of anticholinergics is somewhat more common. The latter may lead to dry mouth, fatigue, mydriasis, tachycardia, constipation, cutaneous changes, and hyperthermia. Frequent psychiatric manifestations of anticholinergic abuse include delirium with confusion, sleeplessness, excitement, and hallucinations. There have also been sporadic observations of abuse of tri- and tetracyclic antidepressants and of clonidine.

The abusive consumption of antihistamines is somewhat more common, e.g. diphenhydramine, promethazine, and doxylamine, which are available in many combined preparations (antiemetics, antitussives, and antiallergic medications). Isolated abuse or dependence is hardly ever seen with these substances. Their abuse generally causes excessive sedation; delirium occurs rarely, in cases of overdose.

The abuse of laxatives and diuretics is much more common. The latter are predominantly prescribed by physicians. Female patients with eating disorders are particularly likely to be affected. Bodybuilders and prostitutes also take diuretics to alter the results of urinalyses or to achieve a desired "fighting weight" or appearance. The desire for a better appearance with regard to muscle mass and bodily proportion is an important factor in the abuse of these substances. Laxatives, in particular, are also commonly abused by elderly patients without any underlying psychopathology. The consequences of long-term laxative consumption may include chronic constipation or diarrhea, abdominal pain and cramps, and even, in severe cases, toxic megacolon. The abusive consumption of diuretics can lead to hypokalemia.

There have been only sporadic reports of the abuse of so-called aphrodisiacs, i.e. substances thought to increase sexual desire, heighten the sexual experience,

or improve potency. This is a very heterogeneous class of substances, most of which probably do not possess their purported effects. Amyl nitrite, a powerful vasodilator, is frequently used as an aphrodisiac. The recent introduction of sildenafil (Viagra) in the treatment of erectile dysfunction (see Chap. 13, this volume) and the associated public interest make it seem likely that cases of abuse will be observed more commonly in future. It has been reported that the simultaneous use of Viagra and Ecstasy is already common in the "techno" scene. The danger is obvious.

4 Potential Future Developments

In conclusion, we will venture to make a psychiatric prognosis and predict that a negative development will take place in the coming years. It is now clear that a number of new, so-called lifestyle medications will be introduced in the near future (see *Deutsches Ärzteblatt* 1998, no. 36, B1681). *Deutsches Ärzteblatt* (German physicians' weekly) counts Viagra, Xenical, and Propecia – used to combat erectile dysfunction, overweight, and baldness, respectively – among these medications. Almost nothing is known at present about their possible psychotropic effects and other side effects or about their spectrum of clinical application. From the psychiatric viewpoint, it may be assumed that the appearance of this very heterogeneous group of substances, administered for entirely novel indications, will call forth a desire for "improved well-being" among many people. Even if these substances turn out to have no psychotropic effects, they will likely be abused with increasing frequency in the future.

Just as doping substances, such as anabolic steroids, have recently come into widespread use among certain subgroups of the population, it can be assumed that these or similar lifestyle medications will achieve prominence in the public consciousness and in the treatment of various disorders of greater or lesser severity. In addition, because (as is now clear) only a small fraction of such medications will be paid for by medical insurance, they will increasingly be taken by self-medication or via private prescription. The Internet, too, is already an avenue for the distribution of many substances. Many medications with psychotropic effects, as well as Viagra, can now be ordered electronically with minimal difficulty and in the complete absence of medical supervision.

From the psychiatric viewpoint, it would be naïve for us to shut our eyes to these developments. In terms of prevention, we must work constantly to inform patients and the public of the risks of the new, so-called lifestyle medications, in order to prevent them from being abused.

CHAPTER 18

L.G. Schmidt

Alcoholism: Aetiology, Epidemiology and Diagnosis

Translator: S. Johnson

1 Aetiology

The term alcoholism is often used to encompass both alcohol misuse and alcohol dependence. It describes repeated impairment of an individual's health and social functioning due to frequent alcohol consumption. This disorder has a multifactorial aetiology. Thus a variety of factors influence whether a young person decides to become a regular drinker, and other circumstances determine whether the excessive drinking which may follow persists despite consequent health and social problems and becomes uncontrollable, so that it can generally no longer be given up.

1.1 Psychological Models

Psychological models are generally based on the experiences of people who have not developed alcoholism. They tend to report that alcohol in low concentrations can reduce the feelings of tension associated with stressful situations, such as after the mental effort involved in a difficult day at work or when coping with a new situation (tension reduction hypothesis). However, consumption of large quantities of alcohol results rather in the opposite effects, especially once blood alcohol levels begin falling. In this instance, people tend to experience an increase in muscle tension and greater feelings of unease and tension.

Excessive alcohol drinking is a behaviour which can be explained according to the established principles of learning theory. Thus the reduction in tension due to an ungratified wish and the positive subjective effects resulting from alcohol act as a reinforcer, so that the probability of further behaviour oriented towards consumption increases (operant conditioning). Classical conditioning processes also play a significant role, as previously neutral stimuli which become associated with alcohol drinking become triggers for craving for alcohol ("cue reactivity") and hence for the pattern of consumption with which they are associated. It has thus been demonstrated that even for subjects who are not dependent, expectations regarding effects associated with alcohol ("alcohol expectancies") closely correlate with actual alcohol consumption (Cooper et al. 1992).

Investigations in personality psychology have not led to identification of any cluster of characteristics which might constitute a specific "addictive personality" structure and thus be predisposing for the development of dependence (Nathan 1988). The generally accepted psychodynamic view is that alcohol weakens the demands experienced from a stern superego. Classical psychoanalytic theories assume that at least a proportion of those with alcohol problems have become fixated at the oral stage of psychic development, so that drinking alcohol makes frustrations more bearable. Alcohol is also postulated as a means by which people with narcissistic disturbances may experience feelings of power and importance which might not otherwise be accessible to them. Some empirical studies indicate that certain psychopathological factors, particularly antisocial personality disorder, are often associated with alcoholism. Raised rates of co-morbidity with anxiety disorders have been found in some epidemiological studies, but the prevalence of depressive illnesses among relatives of people with alcoholism remains in dispute (Maier 1995).

Some prospective studies have indicated that early experiences of loss have an important role in the development of psychiatric illnesses in adult life (Vaillant and Milofsky 1982). With alcoholism as with depression, loss through separation rather than through death has a particular association with later illness. This demonstrates the special importance of the quality of emotional relationships in the family. Growing up in a dysfunctional family characterised by a high level of psychological, physical or sexual violence is likely to constitute an important risk factor for the later development of alcoholism. Substance misuse by parents and norms in the peer group are influences which shape the drinking style of young people as they grow up, but which probably have less effect on the extent of associated problems related to alcohol (Berman and Noble 1993; Oyefeso 1994). Unemployment emerges as a particular risk factor for increased alcohol consumption among young people (Janlert and Hammarström 1992).

1.2 Sociocultural Models

The influence of ethnic and cultural factors in moulding the drinking customs of a society is well-known. In some cultures, stern religious prescriptions regulate alcohol use. On the whole, measures which reduce access to substances with addictive potential (age restrictions, taxes) seem to be more effective in limiting addiction problems than punitive measures (convictions and imprisonment). In the past, the so-called abstinence cultures (e.g. Islam, where there are religious sanctions against use of alcohol) have been distinguished from permissive cultures (e.g. the Mediterranean countries, where social drinking customs tend to promote a pathological pattern of continuous steady drinking and consequent inability to abstain) or ambivalent cultures (e.g. American puritanism; Scan-

dinavia, where because of a tight, socially controlled drinking style, excess typically takes the form of episodic binges with loss of control). Where alcohol use is not embedded in the rites and norms of a culture, the effects of alcohol can turn out to be very destructive, as indicated by the example of the American Indians or Australian Aborigines. When evaluating observations of this type, the potentially important role of genetic variations needs also to be remembered (e.g. in relation to availability of the enzymes which break down alcohol). Overall, socio-cultural theories have significant heuristic value, but are generally not verifiable or falsifiable through empirical data.

1.3 Biological Models

1.3.1 Predisposition to Excessive Drinking

The clustering of alcoholism in families has been recognised since the classical works of Aristotle and Plutarch and has also been established in many more recent studies. Family investigations demonstrate the power of genetic factors, indicating that the relative of an alcohol-dependent person is three or four times as likely to develop an alcohol problem as someone without such a family history. Further, twin studies regarding children of alcoholic parents show higher concordance rates for alcohol-related disorders for identical than for fraternal twins. Studies in which data from twins are used to construct models quantifying the relative influences of family and individual-specific environmental factors suggest that individual-specific environmental factors (e.g. critical life events in adult life) have about as strong an effect as genetic factors (Maier 1995).

Family environment seems above all to transmit a similar drinking style and in this way to influence the development of excessive consumption (as defined in the misuse concept) and alcohol-related problems. Its effect on whether alcohol dependence develops seems to be negligible in comparison. Finally, adoption studies have shown that the adopted-away children of alcoholic parents retain a higher risk of alcohol disorders, even if they have grown up with healthy adoptive parents. The risk is not increased much further if the adoptive parents themselves have alcoholism.

The genetic background of alcoholism is complex: it is accepted that multiple genetic factors interact with environmental factors. Thus, for example, a subtype of alcoholics with high genetic predisposition, above all men with antisocial personality characteristics and early illness onset (type II, "male-limited"), may be distinguished from a second subtype with more limited genetic loading and later onset (type I, "milieu-limited") (Cloninger 1987a). It is unlikely that a single major locus is responsible for all familial variants of alcoholism. Rather, genetic variance is likely to be explained much more through a multiplicity of susceptibility genes, whose products presumably influence the effect of alcohol in particular ways. Alcoholism research using animal models has indicated that the various components of the dependence syndrome, such as alcohol preference, sensitivity, neuroadaptation and withdrawal symptoms, may be separated from one another in terms of genetics and behavioural biology (Crabbe et al. 1994). Each behavioural characteristic is probably determined by the interaction of multiple genes (Lander and Schork 1994). Individually, these genes are probably neither necessary nor sufficient to produce the characteristic and have on their own only a limited role in shaping the characteristic ("quantitative trait loci").

Little is known about the influence of specific gene variations on illness risk. The only risk-modulating genes identified with any certainty act via alcohol dehydrogenase (ADH) and acetaldehyde dehydrogenase (ALDH) to control alcohol metabolism. Thus it has been known for some time that Asians who develop a flushing syndrome after alcohol consumption have a degree of protection from alcoholism because of an isoenzyme deficiency. The flushing syndrome primarily reflects a raised acetaldehyde level, resulting from a deficiency in mitochondrial (ALDH2). This occurs only in Asians and arises through a point mutation on chromosome 12. Thus Asians who are homozygous for this variant (ALDH2*2) have an 18 times lower risk of alcoholism than control subjects. However, this gene variation is too rare in European populations to play any significant protective role among them.

Because of the particular significance of the dopamine-driven mesolimbic–mesocortical reward and motivation system in addiction processes, researchers have recently concentrated on investigating the genes which regulate dopamine metabolism as candidate genes. Since 1990, the taqA-polymorphism ($DRD_2{}^*A_1$ allele), which lies very close to the dopamine D_2 receptor gene on chromosome 11, has been investigated in many association studies. Initial positive findings about its association with alcoholism (and other disorders such as drug dependence, Tourette's syndrome, autism) could not, however, be replicated in subsequent studies. This was attributable to confounding differences, above all ethnic differences, between patients and control groups in the original work. Thus population genetic studies have shown that the $DRD_2{}^*A_1$ allele varies ten-fold in frequency between different ethnic groups and is also combined in different ways with other polymorphic systems

(haplotypes) and genes (gene interactions). In any case, the first published haplotype investigations from the United States and Taiwan have shown no association with alcoholism (Kidd et al. 1996).

Despite these largely negative results, individual variations of a large number of neurotransmitter, neuromodulator, receptor and transporter systems may be significant for the development and maintenance of alcohol dependence. Thus my own investigations suggest that the A_9 allele of the dopamine transporter has a modifying influence on development of the withdrawal syndrome (Sander et al. 1997; Schmidt et al. 1998). The U.S. Collaborative Study on the Genetics of Alcoholism (COGA) project constitutes a hypothesis-free approach to discovering unknown gene regions which contribute to vulnerability to alcoholism and to alcoholism-correlated phenotypes such as personality type, blood and electroencephalographic (EEG) markers. In this project, the whole genomes of members of 105 "informative" families containing alcoholic probands were systematically screened with the aid of genome scanning in sections of 20 centimorgans (this corresponds to a region of 20 million base pairs, on which generally around 300 genes are coded) (Reich et al. 1998). This process gave indications of linkage with alcoholism for gene locuses on chromosomes 1 and 7, and for a locus on chromosome 4 which appears to exert a protective effect via the nearby ADH locus.

As well as a genetically linked predisposition, there are also indications that early acquired damage in the form of organic lesions or psychological experiences of trauma give rise to enduring characteristics ("traits"), which can in turn promote the development of alcohol dependence. For example, in subjects with a history of perinatal trauma who later develop alcoholism, a wide range of disturbances of functioning, emotions and behaviour have been found, often in the context of a hyperkinetic syndrome (Donovan 1986). In these cases, objective evidence can be found of disturbances of neuronal information processing, particularly in the forms of deficits in neuropsychological performance and neurophysiological abnormalities (flattening of the P300 amplitude in the evoked potentials, low α_a activity on EEG examination).

There is increasing evidence that early psychosocial stressors are associated with variations between individuals in the development of stress sensitivity and later alcohol responsiveness. High sensitivity to stress and marked damping of stress through ethanol seem to favour the development of alcohol dependence, a finding supported by high-risk paradigm research (Finn and Pihl 1987). In animal research, it has been shown that the hypothalamic–hypophyseal–adrenal system (HPA system) is an important biological substrate for individual differences in sensitivity to alcohol (and drugs) and influences individual readiness to self-administer addictive substances (Fahlke et al. 1994). This is also supported by findings that corticotrophin-releasing factor (CRF) is present in smaller concentrations in the hypothalamus, amygdala and prefrontal cortex in alcohol-preferring rats (developed through breeding) than in non-alcohol-preferring rats (Ehlers et al. 1992).

Corresponding findings from animal studies indicate abnormalities in the central serotonin system in subjects who have been subject to a social stress ("handling") immediately after birth or who have grown up with their peers rather than their mother (Higley et al. 1991). It may be that, in humans, reduced functional capacity in the central serotonin system represents a neurobiological correlate of reduced affect and impulse control. Increased susceptibility to anxiety or uncontrolled impulsivity associated with a serotonergic abnormality such as this (as opposed to testosterone-linked competitive aggressiveness) have also been considered as potential precursors to human alcoholism and elements in manifest alcohol dependence (Fils-Aime et al. 1996).

The tendency of alcohol (and other addictive drugs such as heroin, cocaine and nicotine) to modify the behaviour and motivation of organisms in a very characteristic way, so that they become oriented towards renewed self-administration ("positive reinforcement"), is explained in terms of effects on reward centres in the brain. These centres are usually activated by naturally arising stimuli such as nourishment or sexual activity, albeit not as intensively as by alcohol. A central neuronal cluster among the structures designated by Olds (1956) as pleasure centres is the mesolimbic–mesocortical dopamine system, which can be activated by alcohol and other addictive drugs (DiChiara and Imperato 1988). This projects from the ventral tegmental area (VTA) to the nucleus accumbens and beyond this to the prefrontal cortex and other limbic structures. In relation to this, Wise (1996) has developed the dopamine hypothesis of addiction, based on the psychomotor activating and motivational effects of dopamine after administration of addictive substances. According to the findings obtained by Herz (1995), processes dependent on dopamine (D_1) play a particular role in the perception of stimuli as rewarding or unpleasant. DiChiara and North (1992) distinguish processes involving psychomotor activation and orientation of the organism towards potentially rewarding, "incentive" (and conditioned) stimuli, which are all mediated by dopaminergic neurones, from the predominantly opioid mechanisms involved in the act of consumption. Thus both systems act as interfaces for conversion of motivations into behaviour. In addition, an important function in the anticipation and prediction of so-called incentive stimuli is ascribed

to certain dopaminergic neurones (Schultz 1997). Finally, this mesolimbic–mesocortical reward system is also modulated by γ-aminobutyric acid (GABA)-ergic, glutamatergic and serotonergic input.

The dopamine- and opioid-dependent interactions of alcohol with the GABAergic system in other regions of the brain (and voltage-gated calcium channels) is also of substantial clinical significance, as feelings of relaxation and calm and possibly also anxiolytic effects depend on these. Self-administration experiments with alcohol indicate that there are individual variations in the responsiveness of this system at systemic, cellular and molecular levels (DeWitt et al. 1989), which exist independently of the functioning of the stress axis (Piazza et al. 1996). For example, Wafford et al. (1991) have reported that potentiation of GABA effects of alcohol (in low doses) is dependent on the γg_{2L} subunit of the pentameter $GABA_A$-benzodiazepine (BZD)-receptor complex and that such potentiation no longer takes place with point mutations or deletions at this site. The findings by Volkow et al. (1993, 1995) indicate that people with alcohol dependence have reduced GABAergic activity in particular regions of the brain (e.g. orbitofrontal cortex, striatum, thalamus) and that this is manifest especially under stress and may correspond with excessive dopamine release in response to new stimuli. Compensation for this GABAergic deficit through alcohol use could thus lead to alcoholism.

Another target system for alcohol is the glutamatergic system, most important for its excitatory effects in the central nervous system (CNS), where it is the main system acting in opposition to the GABAergic system. This system is also characterised by great heterogeneity, e.g. in the structure and functioning of *N*-methyl-D-aspartate (NMDA)-linked ionic channels and the receptor subtypes and splicing variants associated with these, a heterogeneity which is reflected in varying degrees of alcohol sensitivity (Tsai et al. 1995).

Finally, clinical investigations show in a very general way that reduced sensitivity of neurobiological systems to alcohol is an important element in the development of alcohol dependence (Schuckit 1994). Thus sons from families with histories of alcoholism, when compared with those with no such family history, experience specific intoxicating doses of alcohol as less intensive in their effects, they respond less ataxically to motor tests ("body sway") and are less responsive to neuroendocrine tests (e.g. in terms of reduced adrenocorticotropic hormone, prolactin and cortisol release). Genetically and probably also environmentally related disturbances of neuronal information processing, recognisable through a reduced P3 amplitude in event-related potentials, further increase the risk of alcoholism (Begleiter et al. 1984). These findings are interpreted as meaning that, in a society in which alcohol drinking is widespread, appropriately predisposed individuals will experience few aversive effects from it (e.g. headaches, giddiness, nausea). Such effects are therefore less likely to prevent them from continuing to drink, and they will therefore experience higher ethanol concentrations, which are associated with greater risk of dependence and adverse consequences.

1.3.2 Development of Alcohol Dependence

The indicator of the onset of dependence is the transition from controlled to uncontrolled alcohol consumption. A requirement for this is repeated or chronic exposure of the brain of an organism to alcohol, with such a transition taking place above all when alcohol intake is determined by free choice (Wolfgramm 1995). The most important development in addiction research in recent years has been the recognition that the cerebral processes arising from positive reinforcement are progressively altered by alcohol- and drug-related sensitisation processes, providing the best explanation for the escalation of craving (Robinson and Berridge 1993).

Sensitisation to addictive substances involves a state of increased responsiveness of the dopaminergic mesolimbic reward system to the effects of addictive substances. This state is recognisable through an increased tendency to psychomotor activation (raised motility), which can be induced in particular through administration of psychostimulants such as cocaine or amphetamine (Wise 1996) and may also be triggered to a degree by alcohol (Weiss et al. 1993). It is further manifested in an increased sensitivity of this system to the motivational effects of addictive substances. A key aspect of increasing sensitisation is that euphoria-inducing effects do not increase, but the "incentive salience" of alcohol, drugs or associated stimuli is experienced and influences behaviour more and more forcefully. The dopaminergic reward system is thus the central neuronal circuit for anticipation and assessment of alcohol and drug-related cues. It awards these stimuli, especially those which have activated it, greater and greater attractiveness as consumption increases, and is thus also involved in the development of "craving". These attractive (incentive) effects of alcohol and drugs are distinguished from effects related to consumption, which are predominantly mediated by opioid pathways.

1.3.3 Persistence of Dependence and Vulnerability to Relapse

Dependence, tolerance and tendency to relapse (vulnerability to re-exposure) can be seen as neuroadaptive

sequelae to chronic alcohol exposure, arising at intersystemic, cellular and molecular levels (Koob and Bloom 1988). If we trace the dependence-inducing (i.e. anaesthetic–narcotic) effect of alcohol back to its physicochemical effects on the nerve cell membrane (fluidisation), many selective effects on particular neuronal systems, receptor subtypes, ion channels and intracytoplasmic and intranuclear processes have been identified and form the basis of addiction-specific changes in neurones (Nestler and Aghajanian 1997).

Thus, after acute consumption of addictive substances, the immediate early genes are first switched on and code for transcription factors (fos, jun), through which short-term and temporary effects on other target genes are exercised. With the transition to chronic consumption, the G-protein pattern in the nerve cell membrane changes, resulting in modification of the processes of signal transduction. Finally, formation of the so-called late (onset) Fos-related antigens (F ras) results in activation of the late (onset) genes. These alter the gene expression of the neurones in a long-term, possibly permanent, way. Thus a modulation occurs in the genomic programme, involving alteration in the work plan of the neurone cells and long-term changes in cell proliferation, task differentiation and specific functions.

These possibly irreversible changes in brain metabolism, which are associated with alteration of gene expression by addictive substances, may represent the molecular correlate of the phenomenon called addictive memory. A particular role may be played in its development by glutamatergic neurones, which develop certain connectivities through the mechanism of long-term potentiation and the close proximity of glutamatergic and opiodergic synapses in the hippocampus. When the different neuronal units are considered at an intersystem level, increasing dependence is accompanied by an increasing imbalance in facilitatory and inhibitory processes. As these changes at molecular, cellular and intersystemic levels probably do not all begin at precisely the same time, the "point of no return" or transition from controlled to dependent consumption is probably not a distinct event, but a continuous process (Coper et al. 1990).

Well-being is motivated by the experience of pleasant or euphoric states ("positive reinforcement"). Consumption of addictive substances has traditionally been regarded as maintained by a motivation to avoid or limit withdrawal symptoms ("negative reinforcement"), which tends to lead to renewed intake of the addictive substance. Typical of this are the morning withdrawal symptoms of people with alcohol dependence, which result from falling alcohol concentrations and are alleviated by consumption of alcohol on an empty stomach. Other neurobiological systems (e.g. the locus coeruleus) have also been ascribed behaviour-motivating functions in connection with this process; however, the significance of physical dependence-maintaining systems for perpetuation of addictive behaviour is not now believed to be very great.

In the context of addictive illness, the term relapse refers to renewed consumption of the addictive substance with early loss of control over this behaviour and accelerated reinstatement of the full dependence syndrome (Edwards and Gross 1976). This process requires a reward system which is already sensitised through conditioning. It begins when re-exposure to cue constellations previously closely associated with consumption of addictive substances sets off neurobiological processes which are themselves very similar to the effects of alcohol and drugs.

Thus the "craving" which induces relapse may result from a process in which substance-associated cue constellations (such as an alcohol-dependent person's visit to their regular local bar) trigger automatic processes resulting in dopamine release in a sensitised reward system. Internal processes (e.g. particular mood states) in an alcohol-dependent person may also induce such a process, as may the first mouthful of alcohol ("priming"), which is recognised as often leading to a stronger craving for drink and renewed addictive behaviour.

This means that an addict is characterised by a particular vulnerability to re-exposure, which fundamentally differentiates him or her from a healthy person and which cannot be reversed (Coper et al. 1990). Euphoric experiences are not "forgotten" either by an individual or by the relevant neurobiological structures in his or her brain, but retain a lasting influence. Knowledge is still limited about the particular molecular effects of excessive drinking on the brain maturation of young people and about the details of the psychological processes associated with this.

2 Epidemiology

2.1 Prevalence

In 1993, Germany had the highest per capita alcohol consumption of all nations, at 12.3 l of pure alcohol per annum. Surveys indicate that around 90% of the population have at some time tried alcohol, and around 60%–70% currently drink. Figures from the Deutsche Hauptstelle gegen die Suchtgefahren (the central German organisation concerned with substance misuse) suggest that around 5% of men and 2% of women are dependent on alcohol. However, this is probably an underestimate, as the method of case

definition does not correspond to modern diagnostic criteria. On the basis of such operationalised diagnostic criteria, 13% of the general population in Germany and in the United State report a lifetime history of alcohol use which is a hazard to their health (around 21% of men and 5% of women) (Bronisch and Wittchen 1992; Robins et al. 1984).

The 6-month prevalence of alcohol related disorders is around 5.1% (3.1% for conspicuous to severe forms; Fichter et al. 1996). According to studies by the World Health Organization (WHO), 6% of patients in German general practices are alcohol dependent (1-month prevalence), while a further 4% meet criteria for the diagnosis of harmful use or misuse. According to more recent general population investigations, 9.7% of young people between 14 and 24 years have a misuse and 6.2% a dependence diagnosis according to DSM-IV (Holly et al. 1997). Thus alcohol misuse and dependence are among the commonest forms of psychological disorder in the Western world (apart from nicotine dependence).

A wide range of consequences result from this. For example, foetal alcohol syndrome is the commonest cause of mental handicap, and alcoholism the most frequent cause of malnutrition states among adults. A total of 25% of all accidents at work are related to alcohol, and alcohol plays a part in around 20% of fatal road traffic accidents. While moderate alcohol consumption may have a protective effect against coronary heart disease, heavy misuse, especially when combined, as it often is, with tobacco consumption, greatly increases the risk of carcinomas of the oral cavity, pharynx, larynx and oesophagus. A total of 15% of people with alcohol disorders meet criteria for cirrhosis of the liver; and suicide, alcoholic myopathy and hypertension also contribute to an overall shortening of life expectancy of around 10–15 years.

Another form of impairment is alcoholic dementia, estimated as contributing 10% to the total number of cases of dementing illnesses. Thus, in Germany, around 30,000–40,000 people a year die of the consequences of excessive alcohol consumption, with smoking also contributing to this increased mortality. In American healthcare services, around 15% of the budget is taken up by alcohol-related disorders. The total direct and indirect economic costs (through loss of working hours, consequences of accidents, early retirement, treatment costs for related illnesses, rehabilitation measures) are likely to amount to more than DM 80 billion a year in Germany. This may be compared with state income of around DM 8 billion from taxes on alcohol (and DM 13 billion from tobacco).

The manifestations of alcohol-related disorders are extremely variable. While Jellinek (1960) still assumed alcoholism (at least the γ-form) to be a relentlessly progressive type of illness, the longitudinal studies conducted by Vaillant (1996) and the group working with Edwards (Taylor et al. 1986) indicate that individuals have greatly fluctuating symptom courses with varying degrees of severity. It has also been observed that the earlier alcohol-related problems arise ("early-onset alcoholism"), the more frequent co-morbid psychiatric disorders, especially antisocial personality disorders, are. The latter are characterised by behavioural abnormalities in family life, school and peer group and are frequently also associated with drug misuse.

In a second group of alcohol-dependent subjects ("late onset alcoholism"), medical problems are particularly prominent, while social difficulties are rather less conspicuous. Overall, however, the progression of alcoholism does have a typical course (Schuckit et al. 1993; Nelson et al. 1996); excessive drinking (end of the second decade of life) is followed by disturbances in a wide variety of areas of life, after which loss of control, development of tolerance, withdrawal manifestations and finally severe professional, social and health difficulties develop (middle to end of the thirties). Mortality is influenced by volume of drinking, health problems (above all liver diseases) and also unemployment; a good prognosis on the other hand is related to generally stressful circumstances, family environment and individual resources for actively combating the illness (Finney and Moos 1992).

2.2 Co-morbidity

Figures for co-morbidity of depression and alcoholism vary between 3% and 98% depending on survey method, diagnostic system used, method of defining illness, time criteria (e.g. primary, secondary) and time course (e.g. incidence, lifetime prevalence). They are also dependent on the context of the survey (e.g. specialist clinic, primary care, general population) and important sociodemographic variables (such as age, gender, marital status, social background, employment or presence of cognitive impairment).

Meta-analyses suggest that around 40% of people with alcohol disorders admitted to a psychiatric clinic have recognisable depressive syndromes. With regard to the sequence of lifetime history, in around 40% of these patients an alcohol problem has appeared first, followed later by depressed mood, i.e. primary alcoholism and secondary (major) depression, and in about the same number the presence of a primary depression prior to alcoholism can be established (time sequence cannot be established in 20%). Careful analysis of the sequence and severity of disorders, however, suggests that only around 5% of alcoholics have experienced an affective illness of the severity of

a major depression before the onset of excessive drinking and alcohol-related problems (Schuckit 1994).

People with alcohol disorders have a higher risk than the general population of developing another psychiatric disorder. The strongest association (in relation to lifetime diagnoses of alcohol dependence and misuse) is found for antisocial personality disorder (indicated by an odds ratio of 21.0); following this are drug misuse (7.2), mania (6.2), schizophrenia (4.0), panic disorder (2.4), dysthymia (1.8) and major depression (1.7) (Helzer and Pryzbek 1988). The current interpretation of the association found between alcohol and anxiety disorders in some studies is that generalised anxiety often precedes alcoholism, whereas panic disorder is usually observed as a sequel to it (Kushner et al. 1990).

3 Diagnosis

3.1 Diagnostic Criteria

Misuse, designated in ICD-10 as harmful use, is characterised according to clinical diagnostic guidelines by a pattern of consumption which results in damage to health. This can be a physical disorder, such as hepatitis after injecting substances, or a psychological disorder e.g. a depressive episode after massive alcohol consumption (WHO 1992). Harmful using behaviour is often criticised by others and often also has a variety of negative social consequences. Disapproval from others or from a whole society of the pattern of use or of a particular substance is not an indicator of harmful use, nor are negative social consequences such as imprisonment, job loss and marital problems (WHO 1992).

The DSM-IV criteria, in contrast, do include the social dimensions, defining alcohol misuse (abuse) as a maladaptive pattern of substance use which leads to clinically significant impairments or suffering, with at least one of the following criteria being met in the course of a 12-month time period (APA 1994):

1. Repeated substance use, which leads to failure to meet important obligations at work, school or home
2. Repeated substance use in situations in which there may be physical danger because of the consumption
3. Recurring problems with the law in connection with the substance use
4. Continuing substance use despite constant or repeated social or interpersonal problems, which are caused or reinforced by the effects of the psychotropic substance

According to ICD-10, a dependence syndrome involves a cluster of physiological, behavioural and cognitive phenomena in which the use of the substance takes on a much higher priority for a given individual than other behaviours that once had greater value. A central descriptive characteristic of the dependence syndrome is the desire (often strong, sometimes overpowering) to take psychotropic substances or medications (whether prescribed by a doctor or not), alcohol and tobacco (WHO 1992).

Accordingly, the diagnosis of dependence should be made only when at some stage in the last year, three or more of the following criteria have been met at the same time:[1]

1. A strong desire or sense of compulsion to take a psychotropic substance.
2. Difficulties in controlling substance-taking behaviour in terms of its onset, termination, or levels of use.
3. A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by substance-specific withdrawal symptoms or use of the same or a closely related substance for the purpose of alleviating or avoiding withdrawal symptoms.
4. Evidence of tolerance, such that increased doses of the psychotropic substance are required in order to achieve effects originally produced by lower doses (clear examples of this are found in alcohol-dependent individuals who may take daily doses sufficient to incapacitate or kill non-tolerant users).
5. Progressive neglect of alternative pleasures or interests because of substance use; increased amount of time necessary to obtain or take the substance or to recover from its effects.
6. Persisting with alcohol use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressed mood following heavy substance use (or drug-related deterioration in cognitive functioning); efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm.

Narrowing of the personal repertoire of patterns of substance use has also been described as a characteristic feature (e.g. a tendency to drink alcoholic drinks in the same way on weekdays and weekends, regardless of social constraints that determine appropriate drinking behaviour) (WHO 1992). The seven DSM-IV

[1]The first edition of ICD-10 had six criteria, whereas in the second the two concerning withdrawal were merged and the criterion concerning stereotyped repertoire of alcohol consumption removed.

criteria for dependence are very comparable to the six ICD-10 criteria, with the additional criterion no. 5 in DSM-IV ("great deal of time spent on obtaining the substance, taking it, or recovering from its effects") subsumed under criterion no. 5 in ICD-10. A more specific coding is made in ICD-10 to describe course (abstinent, current substance use, constant or episodic substance misuse), while in DSM-IV there is also subtyping in relation to the presence or absence of physiological dependency.

3.2 Empirical Research on Diagnosis

Two lines of development may be traced in the history of diagnostic practices in alcohol-related disorders (Schmidt 1995). While Huss, Jellinek and latterly a large American specialist association have adhered to a categorical or unitary concept of alcoholism, the WHO, influenced by Edwards (Edwards and Gross 1976) have developed a biaxial (or dichotomous) classification. This biaxial classification differentiates patients with alcohol dependence from those who are not dependent but incur alcohol-related disabilities through habitually drinking excessive quantities of alcohol. The definition of misuse or harmful use in ICD-10 is rather vague (based on an intuitive global judgement without time or frequency criteria), and correspondingly the reliability of this diagnosis has also proved to be low. For example, prevalence rates for harmful use (as defined by ICD-10) are around twice as high as for misuse (at least when still applying DSM-III-R).

Longitudinal investigations have, however, also shown that for 70% of patients with a misuse diagnosis, the diagnosis remained unaltered after 4 years. A series of investigations have shown that an overall distinction can be made between two groups of excessive drinkers: those who are not dependent and can return to asymptomatic drinking, and a dependent group for whom this is no longer the case. An research question still to be fully resolved is for which patients and in what circumstances excessive drinking does eventually lead to dependence.

Studies investigating the reliability and validity of the dependence syndrome indicate that both diagnostic systems result in similar prevalence rates and that there is evidence of the same syndrome in a great variety of the countries. Investigations into construct validity (at least when based on the dependence syndrome as defined by Edwards) have shown that the symptoms load onto a common factor and correspond to clinical degree of severity.

Evidence for the unidimensional nature of the dependence syndrome is its extensive independence from measures of damaging consequences, while its universality is demonstrated by evidence of its existence for a range of different substances. The syndrome becomes more homogeneous as severity increases. Thus the high inter-correlations found in investigations in clinical groups have not been replicable among young people or in population surveys. In relation to this, it should be noted that ICD-10 and DSM-IV are "polythetic" systems, in which no single diagnostic criterion is necessary or sufficient and the diagnosis of dependence can be made when the minimum quantity of three criteria (not empirically validated) is reached.

In contrast, Edward's concept of the dependence syndrome is nomothetic, i.e. the set of criteria he proposes (narrowing of the drinking repertoire, excessive salience of drinking, increased tolerance, repeated withdrawal symptoms, drinking to relieve or avoid withdrawal symptoms, subjective awareness of a compulsion to drink, rapid reinstatement of withdrawal symptoms after abstinence) are regarded as sufficient and necessary for a diagnosis to be made, and all the phenomena described in these criteria are expected to be present to a lesser or greater extent where dependence is diagnosed. According to this concept, dependence is a unitary syndrome, whose development is facilitated or inhibited by a variety of factors, above all psychopathological ones.

3.3 Instruments

A large variety of standardised instruments are available to detect and describe alcohol-related disorders (Table 1). The screening instruments most frequently used in English-speaking countries to detect clear-cut cases of alcoholism in clinical research or epidemiology are the Michigan Alcoholism Screening Test (MAST), the MacAndrew Scale and also the CAGE questions. The MALT and the *Kurzfragebogen für Alkoholgefährdete* (KFA) are the principal instruments used in German-speaking countries. The Alcohol Use Disorders Identification Test (AUDIT), which consists of ten questions, is suitable for early recognition.

Detailed questionnaires such as the *Trierer Alkoholismus Inventar* (TAI) or the *Fragebogen zur Klassifikation des Trinkverhaltens* (FTA) are available as instruments for clinical case diagnosis. The goal of the Addiction Severity Index (ASI) and the Severity of Alcohol Dependence Questionnaire (SADQ) is to measure the severity of dependence. The *Lübecker Alkoholabhängigkeitsskala* (LAS) represents a new development in quantification of the development of alcohol dependence and the secondary characteristics of the dependence syndrome. The *Baseler Drogen- und Alkoholfragenbogen* (BDA) has been developed as a

Table 1. Screening instruments for alcoholism

Instrument	Full title	Author(s)	Items	Comments
CAGE	Detecting Alcoholism – the CAGE questionnaire	Ewing (1984)	4	Brief, for routine use
MAST	Michigan Alcoholism Screening Test	Selzer (1971)	25	For primary care
MAC	MacAndrew Alcoholism Scale	MacAndrew (1965)	49	Part of the MMPI
KFA	Kurzfragebogen für Alkoholgefährdete	Feuerlein et al (1976)	22/23	Four domains of drinking behaviour
MALT	Münchner Alkoholismus Test	Feuerlein et al (1977)	24 self- and 7 observer-rated items	Self- and observer-rating
AUDIT	Alcohol Use Disorders Identification Test	Saunders et al (1993)	10 core and 8 clinical questions	Early detection

method of delineating multiple dependence. For research purposes, ICD-10 recommends the use of "craving scales" to document desire for alcohol (e.g. *Lübecker Craving-Risiko-Rückfall-Fragebogen*, LCRR; Obsessive Compulsive Drinking Scale, OCDS) (Table 2).

Structured questionnaires have also been developed in which generally comprehensible questions have been formulated on the basis of the operationalised criteria found in modern diagnostic systems. These are indispensable not only in clinical diagnosis, but also in precise epidemiological research. For example, the Composite International Diagnostic Interview (CIDI) is a fully standardised interview, which allows diagnosis based on ICD-10 and DSM-III-R criteria (WHO 1990). The core version of the CIDI covers a comprehensive range of psychiatric disorders. However, if more detailed information is needed about time

course, the various consequences, the quantity and frequency of alcohol consumption (as an indicator of degree of severity) and the pattern of use of different substances in a particular population, the substance abuse module of the CIDI (CIDI-SAM) should be used as a separate instrument (see Table 3).

Biochemical laboratory tests are often also regarded as a helpful aid to diagnosis. Blood alcohol concentration may be measured as an indicator of acute intoxication, which clinically may be associated with disturbances of conscious level, cognitive functions, perception, affect, behaviour or other psychophysiological functions and reactions. Thus the first signs of motor and cognitive impairment appear with a blood alcohol level of 0.2%–0.3%; between 0.8% and 2% there are disturbances of coordination, judgement and affect; over 2% there are disturbances of memory (so-called alcoholic blackouts); and levels over 3% begin to be life-threatening. Other laboratory parameters such as γ-glutamyltransferase (GGT) and mean corpuscular volume (MCV) are often regarded as markers of chronic tissue damage due to alcohol, but their sensitivity and specificity are unsatisfactory. Carbohydrate-deficient transferrin (CDT) is superior in this respect and is suitable for detecting chronic excessive alcohol consumption and even relapse (Schmidt et al. 1997).

Quantitative measures are very useful in the treatment of the withdrawal syndrome, and various scales have been developed for this purpose (Table 3). The Beck Depression Inventory (BDI) is generally recommended as a measure of associated depressive syndrome, Spielberger's *State-Trait Angstinventar* (STAI) for anxiety and, as a measure of personality, Cloninger's Tridimensional Personality Questionnaire (TPQ) or the Neuroticism-Extraversion-Openness Five-Factor Inventory (NEO-FFI) by Costa and McCrae (1989). As well as these, a great variety of inventories of associated complaints and problems are in use. Because of the high prevalence of co-existing nicotine dependence among people with alcohol disorders (between 80% and 90%), measurement of smoking habits is increasingly required. The modern ICD-10 and DSM-IV diagnostic systems are suitable for multiaxial assessment of patients.

Finally, tendencies to lying, dissimulation or falsification (a fundamental characteristic of people's reports regarding alcohol) may limit the validity of diagnostic results. However, people with alcohol disorders have no greater overall tendency to lie in self-reports than is encountered in the non-alcoholic population. Dissimulation occurs above all in diagnostic interviews for forensic purposes, so that 50% of forensic patients are thought to conceal their alcohol problems.

Alcohol-dependent patients also dissemble regarding their problems much more frequently in the phase of initial clinical contact than directly after withdrawal or at the beginning of residential treatment. Typically, the distortion consists of alcoholic patients willingly recognising their problems, but seeing them more as cause than as consequence of drinking.

In view of the immense health and socio-political significance of alcoholism, techniques for early diagnosis and brief intervention have been recently developed. These have proved effective particularly as a means of reducing psychological and physical damage among patients with less severe and chronic alcohol problems (Schmidt 1997).

CHAPTER

19

K.F. Mann

Alcoholism: Clinical Syndromes and Treatment

Translator: S. Johnson

1 Introduction

The previous chapter describes definitions and diagnostic criteria for alcohol misuse and dependence, as well as recent advances in understanding their aetiology. In this chapter, new findings regarding clinical syndromes and treatment are outlined; as in the last chapter, these represent a significant advance on previous textbook knowledge.

Alcohol dependence is now primarily understood as a disease of the brain which in certain social contexts gives rise to particular behaviour patterns. As proposed by Heimann (1992), this disorder may be regarded as a neurobiological model system which allows study of the effects of a defined toxin on various brain structures and functions, including the regenerative and restorative changes observed under conditions of abstinence. Work based on such a formulation opens a "window onto the brain", as understanding of the effects of alcohol can be used to deepen our knowledge about the structure and functioning of the brain. This therefore represents an extension of the heuristic value of the dementia model (Mann and Widmann 1995).

There have also been exciting changes in the treatment of alcohol misuse and dependence. The international trend is towards day hospital or primarily out-patient treatment. In-patient types of treatment are still offered to dependent individuals who have a poor prognosis or are severely damaged. The old division between medically oriented detoxification and psychotherapeutically oriented rehabilitation is becoming more and more blurred, and targeted psychotherapeutic interventions have come to be seen as indispensable during withdrawal (a process previously generally described as detoxification). Pharmacological interventions are now increasingly used to augment psychological relapse prevention work.

The structure of this chapter needs to accommodate these far-reaching changes in treatment practices. Treatment options are described in sequence according to the severity of misuse or dependence for which they are appropriate. Thus this survey begins with brief out-patient interventions and extends across a range of treatments to in-patient psychological treatment.

2 Clinical Syndromes

2.1 Acute Alcohol Intoxication

The following symptoms are observed as blood alcohol levels rise in simple drunkenness, depending on the extent of habituation to alcohol and development of tolerance: elevated mood, a reduction of anxiety and tension and an increase in impulses and motor activity. With increasing doses, dysphoria, irritability, dysarthria and disturbances in attention, awareness, judgement and co-ordination set in, together with drowsiness, which may progress to reduced conscious level and coma (Julien 1997).

Pathological drunkenness is a syndrome whose existence remains in dispute. It no longer features in DSM-IV, as it is not considered an adequately valid diagnosis (APA 1994). In the German literature, too, discussion of its diagnostic specificity has been predominantly critical (Athen 1986). Further, the symptoms of simple drunkenness can hardly be regarded as non-pathological. Pathological drunkenness describes a state which is not just a quantitative progression from simple drunkenness, but something really qualitatively different. Triggered even by small quantities of alcohol, in the majority of cases there are disturbances in orientation and in consciousness, progressing to sleep and amnesia (twilight state). Further striking manifestations are personality-incongruent disturbances of behaviour, often with aggressiveness and anxious, irritable mood.

2.2 Alcohol-Induced Amnesias (Blackouts)

Anterograde amnesias and gaps in memory are common disturbances in alcohol-dependent subjects, but can also occur in healthy individuals after sufficiently severe states of drunkenness. As a rule, amnesia is complete (Goodwin et al. 1969). These episodes are thought to occur particularly in the presence of rapidly rising blood alcohol levels (Ryback 1970). The pathogenesis has not as yet been elucidated (Charness 1992).

2.3 Withdrawal Syndrome

The withdrawal syndrome has the following principal characteristics: alcohol-dependent people who inten-

tionally or unintentionally end or interrupt their drinking (e.g. when admitted to hospital) may develop withdrawal symptoms within hours or a few days. These show great inter-individual variation in type and intensity and are categorised according to the systems affected (Table 1).

As a rule, the withdrawal syndrome subsides after 3–7 days, and longer courses are rare. About a third of patients need pharmacological treatment. A wide range of medications have been proposed for this purpose, including chlormethiazole, benzodiazepines, clonidine and carbemazepine.

Scholz (1982) has described a so-called protracted alcohol withdrawal syndrome. This is described as lasting several months and consisting of fluctuating levels of disturbances such as dysphoria, anxiety, sleep disorders and episodes of sweating. This syndrome has recently been discussed again more frequently, as there are at least temporal associations with increased vulnerability to relapse. Most relapses occur in the first few months after withdrawal, and craving for alcohol appears to be particularly irresistible during this period. There may be a neurobiological basis for this phenomenon, in the form of altered expression of various intracellular proteins (e.g. fos, jun) of the *N*-methyl-D-aspartate (NMDA) receptors, which are up-regulated during chronic intoxication (Buck and Harris 1991). Activation of "late-onset genes" may result in long-term changes in the gene expression of the nerve cells (see Chap. 18, Vol. 3, Part 2).

In delirium tremens, disorientation is a major element added to the symptoms already described, which are generally present in a severe form. Patients are disoriented with respect to time, place and circumstances and sometimes also person. Conscious level is not necessarily reduced. Visual hallucinations (e.g. insects, small animals) are often observed. About half of all episodes of delirium begin with a cerebral convulsion. The pathophysiology remains uncertain. Speculation that disturbances in water balance with electrolyte imbalances might be causal has not been confirmed (Flink et al. 1954; for an overview, see Lishman 1990). Delirium tremens is always a life-threatening condition, which as a rule requires intensive treatment.

Alcoholic hallucinosis is rare. Compared with individuals with alcohol dependence and no hallucinosis, patients with alcoholic hallucinosis are characterised by earlier onset and larger volumes of alcohol consumed, and sometimes also by high levels of drug use (Tsuang et al. 1994). Difficulties sometimes arise in differentiating this from delirium tremens. While various of the symptoms take a similar form (e.g. feelings of anxiety, psychomotor arousal, vivid hallucinations – predominantly auditory in the case of alcoholic hallucinosis), autonomic manifestations and disturbance of orientation are entirely absent. A particular factor differentiating schizophrenia from alcoholic hallucinosis is that passivity phenomena are very rare in the latter (Soyka 1990). The age of illness onset is earlier in schizophrenia.

Alcoholic hallucinosis is principally treated with neuroleptics, which do not need to be prescribed on a long-term basis. The prognosis of acute alcoholic hallucinosis is good. In approximately 80% of patients, symptoms abate within weeks or a few months (Glass 1989). The course is described as chronic if symptoms persist for more than 6 months (Benedetti 1952). In these cases, prognosis is unfavourable, regardless of whether neuroleptics have been prescribed.

Table 1. Withdrawal symptoms

System affected	Symptoms
Gastrointestinal	Nausea; diarrhoea
Circulatory	Tachycardia; hypertension
Autonomic	Increased sweating; sleep disturbances; moist, cool extremities
CNS	Generalised seizures (grand mal); tremor; dysarthria; ataxia; inner agitation; increased impulsiveness; anxious, dysphoric, depressed mood; hallucinations (predominantly visual); tendency to take fright; short episodes of disturbed awareness with transient dissociation

2.4 Alcohol-Related Pathological Jealousy

Alcohol-related pathological jealousy is a rare disorder, observed almost exclusively in men (Kolle 1932). It not infrequently results in criminal behaviour. Patients have an unshakeable belief that their partners are unfaithful. Onset is insidious, and it can therefore be readily differentiated from delirium tremens and alcoholic hallucinosis. The aetiological significance of the disturbances of sexual functioning which frequently occur in alcoholics has not been clearly established (Laux and Reimer 1979). Treatment is difficult, and success is limited regardless of whether psychopharmacological treatment with neuroleptics or psychotherapeutic measures are used. Achieving abstinence is important, and following this the symptoms may very slowly recede (Vauhkonen 1968).

2.5 Structural and Functional Changes in the Nervous System

The findings described in this section do not solely occur in the presence of alcohol dependence. Evidence of them may also be found in the context of alcohol consumption fitting diagnostic criteria for harmful use or misuse.

Recent work has confirmed older findings (Courville 1955) of atrophic changes in the cerebrum in about a third to half of patients (Miyakawa et al. 1977). The subcortical white matter is particularly affected. There is probably also a reduction in the number and density of neurones in the cortex (Harper et al. 1987), although final resolution of persisting doubts about this (Jensen and Pakkenberg 1993) has not been possible (for a review, see Mann and Widmann 1995).

Imaging procedures allow the reduction in volume in the subcortical and cortical regions to be measured (Jernigan et al. 1991a). These changes are partly reversible with abstinence (Carlen et al. 1978; Schroth et al. 1985), although full recovery to a normal state does not occur (Muuronen et al. 1989). These changes are correlated to some extent with deficits in cognitive performance (Mann 1992). In severe cases, disorders of memory and fine motor performance also occur (Parsons et al. 1987). The neuropsychological deficits do not correspond closely to the patterns characteristic of damage to particular brain regions. The overall picture suggests much more a global deterioration in brain functioning (the mild generalised dysfunction hypothesis of Parsons et al. 1987), which varies from a mild to a severe form. Cognitive and visuo-motor disturbances are also partly reversible with abstinence (Brandt et al. 1983; Mann 1992).

The pathophysiological basis of the atrophic changes in the brain and their partial reversal has been intensively investigated for many years. According to the "rehydration hypothesis" (Carlen et al. 1978), the chronic effects of alcohol mediated by anti-diuretic hormone (ADH) lead to dehydration of the brain with a consequent reduction in volume. It is postulated that this can then be reversed by abstinence, with re-entry of water into the brain explaining the observed increases in volume. This hypothesis has largely been refuted through experimental neuropathological investigation (Harper et al. 1988) and imaging procedures (Mann et al. 1993a,b). The alternative hypothesis of partial regeneration of neuronal material with new growth of axons and dendrites and increased synapse formation long met with considerable scepticism. It seemed incompatible with the fact that, as neurones are post-mitotic cells, regeneration by cell division cannot occur. However, this view failed to take into account the finding that subtotal nerve cell damage can occur (Ferrer et al. 1986; Harper and Corbett 1990). For such partially damaged neurones, new growth in axons and dendrites and renewed synapse formation is quite conceivable. This process has been demonstrated in animal experiments (McMullen et al. 1984; Dlugos and Pentney 1997). These findings underline the way in which alcohol dependence can act as a model for the study of neuronal plasticity.

Wernicke's encephalopathy is commoner than previously believed (3%–12% of individuals with alcohol dependence; Dufour 1993) and appears to affect women more frequently (Glenn 1993). The basis is thiamine deficiency. A genetically determined reduced affinity of the enzyme transketolase for the co-factor thiamine pyrophosphate has been described (Blass and Gibson 1977). This could explain why, despite the high prevalence of alcoholism, this disorder is not seen more frequently. The principal symptoms of the syndrome are clouding of consciousness, ataxia and disorders of the eye muscles (ophthalmoplegias, paralysis of conjugate gaze, pupillary disturbances) and nystagmus. These conspicuous manifestations are often preceded by a prodrome involving gastrointestinal disturbances and fever. In neuropathological terms, the characteristic changes are primarily in the brain regions around the third and fourth ventricles, in the aqueduct, the dorsomedial nucleus of the thalamus and the mamilliary bodies. A pattern of gliovascular damage has been described (Peiffer 1985). Haemorrhagic lesions are characteristic (Colmant 1965; Victor et al. 1971). There may also be a subclinical form of Wernicke's encephalopathy (for a review, see Lishman 1987). This is supported especially by the discrepancy between the frequency of neuropathological evidence in autopsy studies and the relative rarity of a clinical diagnosis of the disorder being made (Harper 1983).

Treatment of Wernicke's encephalopathy requires immediate administration of vitamin B_1 (50 mg thiamine i.v. and 50 mg i.m.). The very rarely encountered hazard of anaphylactic reactions should not result in avoidance of parental administration, as many alcoholics do not absorb oral thiamine (Thomson and Cook 1997). Treatment with thiamine is continued following hospital admission. The ophthalmoplegic symptoms of the illness generally recede quite quickly with such treatment, while the confusion may persist for days or weeks. Nystagmus and ataxia can continue for longer and in some cases persist indefinitely.

Korsakow's syndrome often begins with Wernicke's encephalopathy, but sometimes also with a confusional state of other origin (Victor et al. 1971). The principal symptoms are disturbances of long- and short-term memory, together with confabulation, and of concentration and orientation. There are often additional symptoms in the form of polyneuropathy, chronic eye muscle and pupillary disturbances and nystagmus. The

course is generally chronic. The mortality rate is around 15%–20%. An increase in prevalence has been reported in recent years (e.g. Ramayya and Jauhar 1997), and women are more often affected than men (Victor et al. 1971; Torvik et al. 1982). Autopsy studies indicated that in this disorder the specific neuropathological changes are found much more frequently than the corresponding clinical diagnosis is made (Harper 1983). Neuropathological and computed tomography (CT) and magnetic resonance imaging (MRI) studies indicate that cortical atrophy occurs in addition to the pattern of damage characteristic of Wernicke's encephalopathy (Victor 1990; Jernigan et al. 1991b). Lishman (1990) reported the direct neurotoxic effect of alcohol and its breakdown products, which also particularly affects the cortex and may compound the central changes resulting from thiamine deficiency.

Influenced by Victor et al. (1971), the two symptom complexes described above have often been encapsulated in recent years as a single Wernicke-Korsakow's syndrome. However, this should not be misunderstood as indicating that the two syndromes cannot occur in isolation from each other. Victor later re-emphasised this (Victor 1990). Some authors distinguish between Wernicke-Korsakow's syndrome and an alcohol-induced persistent dementia (e.g. Martin et al. 1986). The latter term describes global impairments of intellectual performance and, to a lesser extent, of memory. However, making such a distinction between persistent memory disturbance and persistent dementia has not been uncontroversial (Lishman 1990).

Atrophic changes, especially affecting the superior vermis of the cerebellum, have long been recognised (Thomas 1905). Clinically, these result in tremor, dysarthria and ataxia. This finding is more frequent than previously believed and occurs in 30%–50% of patients (Torvik and Torp 1986; Mann 1992). Improvements in functioning with abstinence have been shown (Diener et al. 1984). The reductions in volume are at least partly reversible (Ron et al. 1982; Schroth et al. 1988; Mann 1992).

Between 10% and 40% of people with alcohol dependence develop symptoms of a polyneuropathy (Victor and Adams 1953). This encompasses motor, sensory and autonomic pathways. To begin with, reduced light touch and pain sensation occur in the foot region in a sock distribution. This is followed by reduction in reflexes, beginning with the ankle jerk reflex, and by muscle atrophy. Superficial and deep sensation are impaired, and burning pains are sometimes experienced in the feet and toes. The symptoms can extend to the upper extremities, and disorders of sweat production and sexual functioning can also develop. The onset may be signalled by T-reflex prolongation (Schott et al. 1995).

3 Treatment

The treatment of hazardous or dependent drinkers is individually planned according to the stage of illness. Damaging alcohol use among young people requires different measures than treatment of severely dependent individuals with many associated problems. Treatment options will be described according to severity of dependence and its consequences. The common interventions will therefore be described first and the more uncommon and more radical measures later. The focus will also shift from residential treatments more towards out-patient forms of care.

The aim of treatment is to reduce motivation for drinking in favour of motivation for abstinence. Insight into illness, readiness for change and a subjective understanding of the cause of the dependence play a role in motivation, as do specific defence mechanisms, extent of social support and fear of sanctions such as removal of driving license, loss of partner or employment. Previously, motivation tended to be seen as an enduring aspect of personality (a trait). Such a trait model is not, however, very helpful in considering how to influence readiness for treatment or for change. More recently, a dynamic concept of motivation as an alterable state has become prominent. Thus establishing and maintaining motivation become tasks rather than conditions for treatment.

Prochaska and DiClemente (1986) distinguish stages in readiness for change. Their model is essentially applicable to all forms of dependence and can be used in all the therapeutic contexts described below. A requirement is that patients are capable of the cognitive tasks of problem recognition, decision-making and organisation of behaviour. The stages of readiness for change are divided into pre-contemplation, contemplation, preparation, action and maintenance. Any stage may persist for a long period of time (sometimes many years), and during each, a slide back to the pre-contemplation stage is possible as well as progress on to the next stage. Thus the model provides an account of an ambivalent motivational state between readiness for treatment and relapse.

3.1 Early Interventions

When harmful use or misuse of alcohol is first diagnosed, a minimal intervention is indicated. This may consist of discussion with a doctor, in which the warning symptoms already present are identified and a reduction in the level of drinking is recommended. If alcohol dependence is present, early intervention may

be successful, in the form of a discussion in which the problem is explained and confronted. The diagnostic criteria and laboratory investigations (see Chap. 18, Vol. 3, Part 2) are discussed point by point. The goal is motivation for abstinence. The following factors have been described as helpful in establishing and maintaining motivation (the *frames* presented by Bien et al. 1993):

- Give *feedback* on the personal risks associated with drinking
- Emphasise personal *responsibility* for change
- Give clear *advice* about aims
- Highlight alternative behaviours ("*menu* of behaviour change")
- Use a non-confrontational style of discussion ("*empathy*")
- Reinforce the *self-efficacy* of the patient

At this stage of the motivational process, involvement of relatives is very important, as many dependent individuals show a characteristic defensiveness and tendency to minimise problems. If all these measures fail, the next step is in-patient withdrawal or, in some exceptional cases, an out-patient detoxification programme.

3.2 Withdrawal

The first stage of withdrawal is physical detoxification, including appropriate treatment for the manifestations of withdrawal (see below). However, without work on motivation, simple physical withdrawal is associated with high rates of relapse and is a prelude to continuing treatment in only a few cases (Wieser and Kunad 1965). On the other hand, the vulnerability of patients and relatives at this stage provide particularly good conditions for building up and stabilising motivation for change. Thus the integrated withdrawal programmes which have recently been described (e.g. Mann et al. 1995) involve use of psychological interventions simultaneously with physical detoxification (e.g. "motivational interviewing" as described by Miller 1983).

Treatment goal is again dependent on severity of dependence:

- Participation in self-help groups
- Self-help groups together with primary care treatment, supplemented by anti-craving substances
- Out-patient psychological treatment (rehabilitation)
- In-patient psychological treatment (rehabilitation)

Only around 30%–50% of patients with withdrawal syndromes require pharmacological treatment. Chlormethiazole has proved to be of value for this purpose in in-patient settings. Clonidine, carbemazepine (not in a slow-release form) and benzodiazepines, sometimes combined with neuroleptics, can also be prescribed.

Clinical investigations support the effectiveness of integrated detoxification and psychological intervention (Veltrup et al. 1995; Stetter and Mann 1997). Following this, up to 50% of patients are capable 6 months later of taking up continuing treatment. The objection that a concept of motivation as externally imposed and confrontational cannot lead to success does not seem convincing, as few of the patients receiving this type of programme drop out during the first 2 weeks of entering in-patient treatment (Küfner and Feuerlein 1989; Mann et al. 1995). The decision about what therapeutic steps should follow withdrawal again depends on the severity of dependence and related problems. In the majority of cases, out-patient care, perhaps combined with adjuvant pharmacotherapy (see below), and participation in self-help groups seem to be indicated.

3.3 Primary Care Treatment and Self-Help

In-patient treatment aimed at relapse prevention has substantial success (see below), but in Germany is taken up each year by only around 1% of all people with alcohol dependence. Every year, around 2.5% of people with alcohol dependence undergo physical detoxification once or several times; 25% are treated for a variety of reasons in a general hospital setting. The great majority of people with alcohol dependence (70%) are seen by general practitioners at least once a year (Wienberg 1992).

Thus only few patients manage to find their way after withdrawal to in-patient, specialist addiction treatment. People with alcohol disorders are, however, especially vulnerable to relapse in the few weeks following withdrawal. This is the stage at which there is a particular requirement for the development of new treatments. These need to be community-based, immediately available and applicable by a doctor who is not an addiction specialist, in collaboration with addiction therapists. This requires substantially improved higher training and continuing education in addiction medicine.

The out-patient treatment of more mildly dependent and less damaged patients by general practitioners should, whenever feasible, be supplemented by self-help groups (e.g. Alcoholics Anonymous). In each form of continuing out-patient care for alcohol-dependent individuals, use of an adjuvant pharmacological treatment should be considered at least in the 6 months following withdrawal (see below).

3.4 Relapse Prevention (Rehabilitation)

3.4.1 Out-patient Psychological Treatment

Out-patient psychological treatment should begin immediately after withdrawal. The central therapeutic goal is reinforcement of the wish for abstinence. A broad spectrum of psychotherapeutic methods have proved useful to this end. In principle, the same fundamental factors influence effectiveness as in general psychological treatment, e.g. clarifying the nature of the problem, establishing motivation, activating resources and providing active help in overcoming the problem (Grawe 1995). Meyer (1990) distinguishes the following: mobilisation of hope, application of a theory as to how healing may be achieved, provision of a helping relationship, clarification or redefinition of problems and the search for constructive options for solving problems.

Despite all the common ground with psychological treatment for other disorders, a number of particular aspects of the treatment of people with addictions modify psychological treatment procedures:

- Abstinence is the central goal of the treatment and in fact a requirement for traditional psychological treatment for patients with dependence.
- The behaviour targeted in psychological treatment is an "approach behaviour" (the consumption of an addictive substance). In contrast, the psychological treatment of other disorders often mainly involves changing an avoidance behaviour (e.g. in anxiety). While in the latter case a graded hierarchy of success can be followed, in people with dependence a comprehensive alteration in behaviour needs to be achieved as quickly as possible and then needs to be stabilised.
- Self help movements implemented the first steps towards change decades ago. This success has continued to influence psychological treatment of people with dependence to the present day.

Relapse prevention programmes based on the work of Marlatt and Gordon (1985) have attracted particular interest in the last few years. According to these authors, relapse is not to be seen as an event which suddenly occurs, but as a developmental process. It involves a sequence of events affecting cognition and behaviour, which finally culminate in relapse. It follows that appropriate measures can reduce the likelihood of relapse if they can be targeted properly and applied at the right time. Despite the theoretical brilliance of the model, for relapse prevention, as for most models, a few positive evaluations have to be set against the majority of studies, in which no evidence has been found for a specific effect of relapse prevention (Veltrup 1995).

A recent meta-analysis summarises all the studies of psychological treatment for people with alcohol dependence which meet a methodological standard. It is based on around 30 experimental and 20 non-experimental studies and compares effectiveness with control conditions (Süß 1995). Investigation of differences in effectiveness suggests no statistically significant advantages for behavioural treatments compared with standard methods, which in this context also included family and couple therapy. Behavioural treatment was superior to minimal interventions and to disulphiram treatment.

Therapist variables probably play an important role in treatment outcome. Thus controlled studies have indicated that the degree of therapist empathy is correlated with the outcome of treatment (Institute of Medicine 1990). Confrontational and directive techniques led to a higher relapse rate during a 12-month observation period than supportive and accepting ones. The extent of initial motivation played no role in later treatment outcome.

Overall, the following conclusions have been made (Institute of Medicine 1990):

1. An appropriate and specific treatment of alcohol-dependent people can lead to clearly positive results. Comparisons made with waiting-list groups or other forms of treatment in controlled trials indicate that a wide range of specific forms of psychological treatment are associated with good outcomes.
2. No single form of treatment is clearly superior to other types and appropriate for all alcohol-dependent individuals. "Rather than trying to prove the superiority of a single method through examination of specific interventions in heterogeneous samples, outcome studies should investigate the characterstics of sub-groups for whom particular forms of treatment are especially successful" (Institute of Medicine 1990, p. 537ff.).
3. The importance of therapist variables in determining outcome has so far clearly been underestimated. Therapist skills and attitudes have an important influence on outcome, regardless of the nature of their training and theoretical orientation.
4. Self-help groups, especially Alcoholics Anonymous, are very widespread. There have, however, been hardly any studies evaluating their results. Nonetheless, it appears likely that, in general, self-help groups represent a positive and stabilising factor in the struggle of many alcohol-dependent people with their illness.
5. The treatment of other life problems associated with drinking can have a positive influence on the

outcome of treatment. This includes social skills training, couples and family therapy and sometimes anti-depressant pharmacological treatment, stress management and involvement in a community-based system of care.

6. Global treatment outcomes for non-selected patients appear to show no difference between in-patient and out-patient forms of treatment. The same applies to more long-term treatments compared with brief ones. However, an important limitation of this is that a longer, in-patient treatment is superior to a shorter out-patient one for greater severity of dependence, more marked psychiatric co-morbidity and more serious alcohol-related damage.

The results of the largest study of psychological treatment for people with alcohol dependence emphasise some of these points. In the Matching Alcoholism Treatments to Client Heterogenity (MATCH) Project, around 1800 patients receiving out-patient treatment were investigated. They were randomised to receive three different types of treatment: (1) a treatment based on the 12-step programme of Alcoholics Anonymous, (2) a cognitive behavioural intervention aimed at improving "coping skills" and (3) a programme aimed at increasing motivation.

The overall outcome of the study was positive. It indicated a highly significant increase in drink-free days. When drinking occurred, the volume consumed was less than before treatment. The authors were surprised to find that all three treatment modalities had similarly good outcomes. Of numerous matching hypotheses (e.g. cognitive behaviour therapy is superior to the other two in the presence of cognitive deficits), only one was confirmed: for low degrees of psychiatric severity (measured using the Addiction Severity Index, ASI), the 12-step programme was better than both other forms of treatment. Patients who initially received in-patient treatment did significantly better than those who received mainly out-patient treatment, despite more severe initial symptoms (Project MATCH Research Group 1997).

3.4.2 In-patient Psychological Treatment

The first in-patient facility in the world for the treatment of alcohol-dependent individuals was opened in 1851 in a village near Düsseldorf. It was led by the village pastor. The initial aim was to bring about improvements by providing patients with good role models and imparting ethical values, but looking back on his experience 30 years later, Pastor Hirsch was able to identify two other conditions which were decisive for success: selection of patients and a clear requirement for abstinence, reinforced by controls and sanctions.

For decades, in-patient "cures" lasting 6 months or more dominated German practice. Küfner and Feuerlein (1989) investigated the effectiveness of standard treatment in these specialist clinics and came to some noteworthy conclusions. Successful treatment facilities are characterised by the following features: selection of patients with better prognosis, use of a therapeutic community model, active involvement of spouses and people who can exert a positive influence on patients and active aftercare following therapy.

In recent years, there has been a gradual reduction in treatment times in in-patient facilities. This trend was fostered by positive outcomes from model facilities (Mann and Batra 1993) and fitted with international experiences. Thus length and modality of treatment is determined on an individual basis. Depending on the stage of illness and the personal and social resources of a patient, out-patient, partial hospitalisation, brief in-patient (2–4 months) or intermediate-length in-patient treatment (4–6 months) is recommended. Treatment lasting 6 months will continue to have a place, especially for patients with a poor prognosis and limited social support.

The outcomes of inpatient and outpatient treatment are difficult to compare, as there is only a limited number of relevant studies. An older review (Miller and Hester 1986) reached the conclusion there was no real difference in treatment outcome. Recently, this conclusion has been emphatically rejected (see above). It has been argued that the samples on which this statement was based were not comparable in severity of illness. If this is taken into account, in-patient treatment has continued to show superiority for the severely dependent (Pettinati and Belden 1996). The results of the MATCH Project (see above) also support a slight superiority for in-patient treatment and are an argument against abandoning this proven treatment modality.

3.4.3 Adjuvant Pharmacotherapy

The final development to be discussed is the introduction of anti-craving substances. This development was scarcely considered possible until a few years ago and significantly enriches the treatment options available, at least in out-patient management of alcohol dependence. These drugs can be used not only during out-patient rehabilitation treatment following a withdrawal programme (see above), but also by experienced general practitioners in the context of early interventions. Substances with effects on the cholinergic, glutamatergic, dopaminergic, serotoninergic and opioidergic systems have been clinically tested. The most

promising so far have been the glutamate modulator acamprosate and the opiate antagonist naltrexone.

Animal experiments provided the first indications that acamprosate (calcium acetyl homotaurinate) could reduce craving for alcohol and could do so without altering overall fluid intake (Boismare et al. 1984). Relapse behaviour was suppressed in rats (Spanagel et al. 1996). As the substance does not interfere with the pharmacokinetics and pharmacodynamics of alcohol (Le Magnen et al. 1987) and does not substitute for the alcohol stimulus in a discrimination task, it has been concluded that its anti-craving qualities are responsible for this effect (Spanagel and Zieglgänsberger 1997). Acamprosate reduces withdrawal symptoms (Gewiss et al. 1991). The excitatory effects on neurones of L-glutamate are suppressed by acamprosate (Madamba et al. 1996; Zeise et al. 1993). A reduction in mesolimbic dopaminergic activity during withdrawal (Diana et al. 1993) and an increase in the extracellular concentration of L-glutamate in the nucleus accumbens have also been described with acamprosate (Dahchour et al. 1996). The neuronal over-excitability observed during withdrawal is accompanied by increased expression of c-fos, an immediate-early gene. Here, too, may lie one of the effective elements in the action of acamprosate, as the substance suppresses increased c-fos expression in many neuronal structures, including the nucleus accumbens (Littleton 1995; Putzke et al. 1996). Binding probably occurs to the polyamine binding site of an NMDA-R1/R2 receptor combination (Spanagel and Zieglgänsberger 1997).

Clinical successes have been demonstrated in several placebo-controlled double-blind studies. Studies from Austria (Whitworth et al. 1996) and Italy (Poldrugo 1997) have shown increased abstinence rates for patients treated with acamprosate. In France, two different doses of acamprosate were tested, as well as placebo. The higher dose (2 g/day) was more effective than the lower one (1.3 g/day). Statistically, only the higher dose was superior to placebo (Paille et al. 1995). In a multicentre study in Germany (Saß et al. 1996), medication was administered for a period of 12 months, and patients were observed for a further 12 months after it was discontinued. The time to the first relapse and the number of days of abstinence were significantly different between the two groups. After 12 months, 42.8% of the patients in the acamprosate group were abstinent, compared with 12.7% of patients in the placebo group. The positive effects in the acamprosate group were also maintained after medication was discontinued. In a summary evaluation of 11 independent placebo-controlled studies in Europe, the effectiveness of acamprosate was demonstrated in an overall sample approaching 4000 patients. Apart from one English study, the remaining ten studies all showed positive outcomes (for reviews, see Mann 1996; Soyka 1997).

In animal experiments, multiple interactions have been demonstrated between alcohol and the endogenous opioid systems (overview by Herz, 1997). These have also received confirmation in human experiments. In probands with a high risk of alcohol dependence, the administration of alcohol led to a dose-related rise in plasma level of β-endorphin (Gianoulakis et al. 1996). Conversely, in animal experiments, small doses of opiates increase alcohol consumption (Hubbell et al. 1988). This leads to the assumption that the blockade of endogenous opioid receptors reduces alcohol intake. This was already demonstrated in the 1980s in a variety of animal experiments (e.g. Altschuler et al. 1980). Thus a direct effect might be expected from opiate antagonists such as naloxone on the rewarding effects of alcohol. Not only the μ- but also the δ- and κ-receptors appear to have a role in this (Ulm et al. 1995). Their action in humans might be connected with effects on extero- and interoceptive stimuli. These stimuli mediate conditioned alcohol-related responses, which provoke physical and psychological states such as reinforcement or conditioned withdrawal.

The effectiveness of the opiate antagonist naltrexone has been demonstrated in three studies in the United States. Volpicelli et al. (1992) investigated 70 men with alcohol disorders over a 12-week period. Patients in the experimental group showed less craving for alcohol than those in the control condition. Where relapse occurred, volumes consumed were significantly lower and episodes of excessive drinking rarer. O'Malley et al. (1992) investigated the combination of naltrexone, placebo and two psychological treatments. They compared a general supportive psychotherapy with a behaviourally oriented "coping skills" training. In a sample of 97 alcoholics, the authors were able to demonstrate that, over the course of 12 weeks, naltrexone was associated with significantly better outcomes than placebo. In addition, there was an interaction between medication and psychological treatment processes. The greatest degree of success in attainment of abstinence resulted from the combination of naltrexone and general supportive psychotherapy. Anton (1997) also found naltrexone to be superior to placebo in 136 alcohol-dependent subjects.

In Europe, the effectiveness of naltrexone has been examined in two multicentre studies in England and Germany. The results of intention-to-treat analysis were negative in both studies (Chick 1996; Gastpar and Mann 1998). On the other hand, a Swedish study (Balldin et al. 1997) did confirm the American results cited above.

On the basis of findings from animal experiments, a variety of investigations involving administration of

dopamine agonists or antagonists in humans have been carried out in the last few years. However, initial positive effects from the agonist bromocriptine could not be replicated (Borg 1983; Dongier et al. 1991). Positive effects found in open trials of the dopamine antagonist tiapridex were initially confirmed in a randomised double-blind study of 32 alcohol-dependent subjects, using a dose of 100 mg/day (Shaw et al. 1994). However, a large multicentre study showed no difference between experimental and control conditions (M. Gastpar, unpublished). Because of its high affinity for the D_1 receptor, the dopamine agonist lisuride was investigated in a placebo-controlled double-blind trial. Contrary to expectations, the relapse rate was significantly higher in the experimental than the control condition (Schmidt et al. 1997). Overall, outcomes from dopaminergic substances are not convincing. In addition, where treatment employs neuroleptic substances, the risk of extrapyramidal side-effects, especially tardive dyskinesias, must be considered.

Positive effects found for serotonin reuptake inhibitors in animal studies were not confirmed or were demonstrated only transiently in clinical studies. In a placebo-controlled double-blind trial of fluoxetine in 20 patients, significantly reduced volume of consumption and craving were observed only during the first week of treatment (Gorelick and Paredes 1992). In a 4-week placebo-controlled trial with fluoxetine, no specific reduction was demonstrated in volume of alcohol consumed, but only a general reduction in fluid intake (Naranjo et al. 1990). Kranzler et al. (1995) also found no effects. Administration of the 5-HT_2 antagonist ritanserine was not superior to placebo (Böning et al. 1997). Testing of serotonin agonists such as buspirone has proved similarly disappointing. These may, however, still be helpful in anxious alcohol-dependent patients, for whom a reduction in anxiety rather than a change in drinking patterns has been described (Kranzler et al. 1994).

A meta-analysis of studies with a treatment duration of at least 3 months has shown that some of the anti-craving substances tested so far give good results. The effectiveness is as great as that of classical antidepressants in long-term relapse prevention in unipolar depression (Engel and Schöchlin 1995). Thus combined treatment by psychological and pharmacological means has now also become possible for alcohol-dependent individuals. There may be a case for requiring that anti-craving substances should be used only in the context of psychological treatment. Otherwise, there is a danger of neglecting or even obstructing the confrontation with their illnesses and life situations which individuals in treatment need to have. Anti-craving drugs are essentially adjuvant or supportive elements in treatment.

Tobacco Misuse

Translator: S. Johnson

1 History of Tobacco Consumption

Several thousand years B.C., the tobacco plant (*Nicotiana tabacum* L.) was already in use in South and Central America for both medical and religious purposes. Only with the return of the Spanish conquistadors in the sixteenth century, however, did tobacco arrive in Europe and begin its controversial triumphal progress across the continent as a new recreational substance. Smoking was initially confined to the upper echelons of society. The tobacco pipe, which was used to "drink" of tobacco smoke in the seventeenth and eighteenth centuries, required elaborate and careful manipulation and skill. Tobacco consumption therefore demanded a great deal of time and effort. Smoking was not simplified until the cigar was introduced in the nineteenth century, followed by the mass production of cigarettes in the second half of the nineteenth century. From this time onwards, tobacco products became widely available, quick and unproblematic to consume, and readily affordable even for the lower classes.

Tobacco had considerable economic importance as early as the eighteenth century. Income from tobacco tax financed the English merchant navy and the American War of Independence, for example.

A positive, mentally stimulating effect was ascribed to tobacco. Even so, in the first decades after the plant's introduction, critical voices, including both statesmen and doctors, were already warning against "dry drunkenness" (von Birken 1658) and the health risks associated with tobacco use. They recognised both the danger of addiction and the potential health risks and also complained that smoke was polluting the environment. However, they had no more success in impeding the spread of tobacco use than the societies founded around the beginning of the twentieth century in North America and Central Europe in the fight against smoking.

2 Epidemiology of Smoking

After the Second World War, there was a remarkable increase in smoking in Central Europe. In the space of a few decades, between the 1950s and the 1970s, the quantity of cigarettes purchased in Germany increased by a factor of 4. Information about the latest trends in prevalence of smoking in Germany is available from the surveys carried out by the Federal Statistical Office in Wiesbaden in 1978, 1989, 1992 and 1995 (Statistisches Bundesamt 1993, 1996) (Fig. 1). The prevalences quoted relate to the adult population aged over 15 and include all consumers of tobacco, both heavy smokers and occasional users.

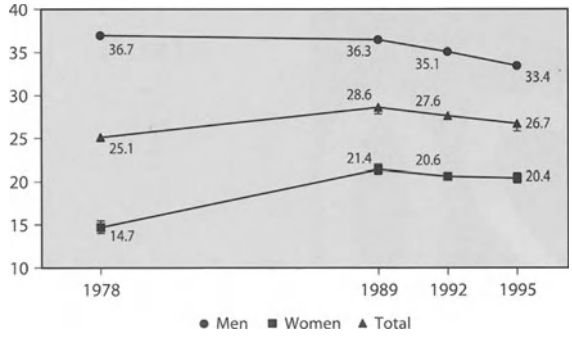

Fig. 1. Proportion of smokers in the German population, 1978–1995. (Source: Statistisches Bundesamt 1993, 1996)

The surveys document a slight decrease since 1989 in the proportion of the population smoking. The most recent data, collected in 1995, indicate that around 33.4% of all men and 20.4% of all women in Germany are smokers. Comparison with figures from the preceding surveys show a small decrease among men of 3%, while among women the reduction over the preceding 3 years was a mere 0.7%.

The validity of these figures requires critical scrutiny: the actual prevalence of smokers should be assumed to be higher than these government surveys suggest. Public campaigns have resulted in smoking increasingly becoming an undesirable social behaviour, and some smokers therefore tend to give responses about their smoking habits which gloss over reality.

Rates cited in a European comparative study (BASP 1994) are higher: the average prevalence rate for men in the European Union is 42% and for women 28%. While this survey puts the proportion of German men who are smokers slightly above the European average (former West Germany 42%, former East Germany 47%), women in Germany are somewhat less likely to smoke than in the European Union as a whole (former West Germany 27%, former East Germany 23%). The highest proportions of smokers among men are reported in Spain (46%), France (47%) and the Netherlands (48%). The peak figures for women come from Denmark (48%), the Netherlands (37%), France and Great Britain (both 30%) and Luxembourg (29%).

While the epidemiological data from the Federal Statistical Office quoted above suggest a slight decline in smoking, a contrasting picture emerges from statistics regarding purchase of tobacco products and income from taxes on tobacco (Fig. 2). In 1996, taxes were collected on 136.2 billion cigarettes, 0.9% more

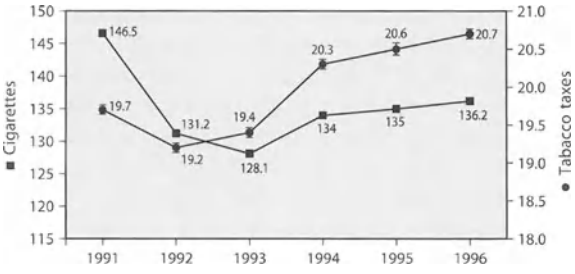

Fig. 2. Approximate levels of cigarette use (in billions of cigarettes) and income from tobacco taxes (in billions of German marks), 1991–1996. (Source: Statistisches Bundesamt 1995, 1996)

than in the preceding year. The tax income from all tobacco products in 1996 was 36.1 billion German marks, 1.4% more than in the preceding year. The constantly increasing consumption of tobacco products suggests either that smoking is continuing to become more widespread or that tobacco is being consumed more intensively by smokers. Estimates from the cigarette industry and the customs authority suggest that an additional 3.5–7 billion untaxed cigarettes are consumed per year (quoted in Junge 1995). Within Europe, cigarette smuggling is less a problem in those countries where taxes on tobacco are high than in Eastern and Southern European countries, where there is extensive street dealing in smuggled international cigarette brands (Joossens and Raw 1995).

The past few decades have seen extensive efforts to educate the public about smoking. Restrictions on tobacco advertising, repeated tax increases and campaigns, as yet not fully successful, for laws to protect non-smokers through smoking bans on public transport and in workplaces have been initiated. These initiatives have not had any enduring impact on patterns of smoking. Smoking cessation programmes offered through health insurance companies, local public health departments, doctors, psychologists and pharmacists have also failed to result in the reductions in the prevalence of smoking that were hoped for.

3
Definitions of Tobacco Dependence and Misuse

3.1
Types of Smoker

It is no longer disputed that regular tobacco consumption can lead to dependence. However, not all tobacco users are necessarily dependent smokers. A variety of motivations are associated with the use of tobacco, generally in the form of cigarettes, sometimes cigars and pipe tobacco, and rarely snuff. A frequently used typology differentiates between the opportunistic or hedonistic smoker, the conflict or stress smoker and the dependent or habitual smoker. The opportunistic smoker reaches for a cigarette in company or on particular occasions, but does not generally engage in any smoking rituals, consumes only a limited number of cigarettes and, if he or she does consume larger quantities of tobacco, often develops signs of tobacco intoxication. The hedonistic smoker has learnt to reward him- or herself in certain situations by smoking a cigarette, cigar or cigarillo, but does not consume larger quantities of tobacco. The conflict smoker, meanwhile, resorts to cigarettes in psychologically stressful or distressing situations, and he or she may therefore at times smoke large quantities of cigarettes, but is also capable of relatively long periods of abstinence. These patterns of use may be seen as instances of tobacco misuse. In contrast, characteristics of psychological and/or physical dependence are generally manifest in habitual smokers. The habitual smoker usually smokes a similar quantity of cigarettes each day, often around 20–40 or even more, inhales deeply and develops a powerful craving for cigarettes if they cease to be available. This type of smoker rarely displays manifestations of intoxication and begins to report withdrawal symptoms as soon as a significant period (usually a few hours) has passed without a cigarette.

3.2
Smokers' Motives

In surveys, more than 50% of heavy smokers say that they would like to reduce or even completely stop their consumption of cigarettes, yet only a few succeed in maintaining abstinence.

A wide variety of motivations lead people to smoke. The most frequently cited reasons are habit and pleasure. In moments of inner tension, smoking is experienced as calming, distracts from boredom and is felt to be a well-earned reward after coping with a situation which has been experienced or anticipated as aversive. Many social reinforcers (e.g. fitting in, sociability, image) encourage smoking in company.

A significant motivation for the dependent smoker to smoke is suppression of withdrawal symptoms. Withdrawal symptoms are triggered by a falling blood nicotine level and include nervousness, agitation, irritability, aggression, sleep disturbances, feelings of tiredness and exhaustion, disturbances of concentration and depressive and anxiety symptoms. Associated somatic symptoms include headaches, dizziness, faintness and gastrointestinal symptoms and are related to vagal cholinergic overactivity. The weight gain

observed in most cases is attributable to an increase in appetite, the attempt to find alternative oral gratification and altered metabolism. While the somatic and psychological symptoms are generally present only for a few days (usually between 1 day and 2 weeks), craving for cigarettes and weight gain generally persist over a period of several months.

In the early stages of abstinence, there may be a deterioration or relapse in pre-existing illnesses (e.g. depressive illnesses or ulcerative colitis), which is a further threat to abstinence.

3.3 Definition of Dependence

More than half of all heavy smokers can be described as dissonant smokers, in that they would like to give up smoking, but continue to smoke or repeatedly relapse.

According to the classification criteria for disorders related to psychotropic substances in the psychiatric section of the International Classification of Diseases (ICD-10, Chap. 5), the following features indicate the presence of tobacco dependence: a persistent strong wish or compulsion to smoke, diminished control over the initiation of tobacco consumption and over how much is consumed, the emergence of withdrawal symptoms or tolerance to the physiological effects of the substance. Other features include narrowed behavioural repertoire in patterns of use of the substance, persisting use despite awareness of obvious damaging consequences in physical, psychological or social domains and a persisting *fruitless* wish or multiple unsuccessful attempts to limit tobacco consumption.

By way of simplification, the following features can be used in practice as indicators of the presence of tobacco dependence: smoking early in the morning, consumption of more than ten cigarettes per day and evidence of multiple fruitless attempts at abstinence in the past.

Recently, the distinction between tobacco misuse and dependence has come to be seen as dimensional rather than dichotomous. Severity of dependence is indicated not only by the number of cigarettes consumed each day, but also by the pattern of consumption. Where dependence is severe, the smoker inhales deeply, lights the first cigarette soon after getting up and often smokes more heavily in the morning than in the afternoon or evening. Observing local or temporary bans on smoking is a struggle, and tobacco consumption continues during periods of illness.

Various psychometric scales allow measurement of severity of dependence. The most widely used at present is the Fagerström Test for Nicotine Dependence (FTND; Heatherton et al. 1991). Several studies have shown severity of dependence to be a significant predictor of the probability of long-term abstinence following completion of a smoking cessation treatment. Investigations in a variety of European countries also suggest a reciprocal connection between severity of tobacco dependence and prevalence of smokers. Thus the fall in the proportion of smokers in the population seems in some countries to be attributable primarily to a reduction in the number of light smokers. As it is principally heavy smokers who develop the adverse health consequences of smoking, a falling proportion of smokers in the population can unfortunately not be interpreted as a direct indicator of an improvement in the population's health.

3.4 Causes and Conditions in the Development of Dependence

Psychological and physiological factors are considered to be equally important in the development and persistence of tobacco dependence.

The psychotropic effects of nicotine are believed to be responsible for the development of physical dependence. Results from animal experiments, which show activation of the mesolimbic dopaminergic system and, in particular, release of dopamine in the nucleus accumbens, the main area involved in the self-reward system of the brain, suggest that nicotine has an addictive potential approaching that of amphetamines, alcohol or cocaine (DiChiara and Imperato 1988).

An increase in central $(\alpha_2\beta_4)$-acetylcholine receptors due to nicotine is regarded as being responsible for the emergence of withdrawal symptoms. In animal experiments, regular administration of nicotine stimulates an increase in neuronal nicotinergic acetylcholine receptors (Balfour and Fagerström 1996; Hsu et al. 1996; Wonnacott 1990).

The directly and contingently arising psychotropic effects of nicotine on the self-reward system of the brain promote intense craving for stimulation through nicotine. The formation of an association between pleasant psychotropic effects and smoking behaviour underlies classical and operant learning mechanisms. Meanwhile, maintenance of dependence occurs when the organism strives to avoid experiencing aversive withdrawal symptoms as blood nicotine level falls by renewed consumption of nicotine. Even the first manifestations of withdrawal, of which the smoker may hardly be aware, are discriminative stimuli for the maintenance of smoking (Tölle and Buchkremer 1989).

Smoking is a learned behaviour as well as a biological process, and the processes of imitative and operant learning have a role. Both positive and negative reinforcement mechanisms ensure that the addictive behaviour persists.

As smoking develops in youth and young adulthood, it is increasingly associated with certain situations: smok-

ing becomes important to relieve stress at work, leads to a reduction in tension during conversation, encourages concentration and promotes relaxation. Cues such as ashtrays, cigarette boxes lying around, the break at work, morning coffee or an evening rendezvous in a bar lead to unconscious craving for a cigarette. The smoking habit encompasses both responses to key cues and individual patterns of behaviour.

4 Development of Smoking Behaviour

Smoking generally begins in youth and early adult life. Role models are responsible – parents, teachers and peer group members, but also youth idols and cleverly used images in advertising. Many attributes make smoking attractive to young people: it represents entry into adult life, serves as a display of courage or as a "cool", socially desirable behaviour and increases the social status of the smoker. This explains the fact that the prevalence of smoking among the young has remained high and stable. Societal influences also underlie the continuing slight increases in prevalence of smoking among women. Rates of smoking among young women are clearly rising with increasing emancipation in Western European countries.

5 Adverse Effects of Tobacco on Health

While nicotine seems to have only limited aetiological significance in severe physical illness (in an adapted smoker, nicotine itself does not cause any severe health disorders: recent studies suggest that nicotine has no influence in changing the lipid distribution in the blood, and administration of pure nicotine does not increase the tendency towards developing thrombosis), the adverse effects of smoking on health can be ascribed to others of the many substances contained in tobacco. It is estimated that tobacco contains more than 3800 substances, several of which are carcinogenic and/or teratogenic.

Great methodological problems arise in calculating the frequency of tobacco-associated illnesses and deaths. However, comprehensive epidemiological surveys do allow relatively reliable estimation of tobacco-associated mortality from ischaemic heart disease (25% of deaths from this cause among men and 20% among women are thought to be caused by smoking), lung cancer (90% of deaths among men, 50% among women) and bronchitis and emphysema (75% of deaths among men, 60% among women). According to this conservative estimate, which does not take into account any other causes of death, around 80,000 smokers died of these illnesses in 1994 in Germany alone. Estimates for Europe suggest around 500,000 tobacco-associated deaths per year.

Smoking leads to an increased tendency towards developing thrombosis, altered lipoprotein fractions (high- and low-density lipoproteins, HDL/LDL) and damage to vessel endothelium, probably due to free radicals. This clearly elevated risk of cardiovascular disease should certainly not be attributed simply to the effects of nicotine: cardiac infarction is promoted by other components in tobacco smoke, such as carbon monoxide, which reduces oxygen saturation.

Smoking is not only a major aetiological factor in the development of lung cancer, but also one of the risk factors for other cancers, including laryngeal, oral cavity, pancreatic, and bladder cancer and even leukaemia (Table 1). More than 40 carcinogenic substances in tobacco (e.g. *N*-nitrosamine, vinyl chloride formaldehyde, benzol, polycyclic aromatic hydrocarbons, free radicals, polonium-210, lead, cadmium) promote the development of malignancies.

Not only the smoker, but also his or her environment is contaminated by the substances contained in tobacco smoke. Passive smoking is a term which has become increasingly prominent in recent years in discussions about the effects of smoking on health and in campaigns for legal regulations to protect non-smokers. It describes the exposure of non-smokers to tobacco smoke in the workplace, at home and during leisure activities. The connection between passive smoking and increased risks of lung cancer (EPA 1992) and heart disease (Glantz and Parmley 1995) is accepted as established. A particularly important association is the tendency of children from households where there is heavy smoking to develop respiratory illnesses. The newborn children of mothers who smoke tend to have reduced body size and low birth weight (Behavioral Risk Factor Surveillance System 1989; Conter et al. 1995). They are also at statistically greater risk of developing respiratory illnesses. Passive smoking has been shown to be a significant factor in sudden infant death syndrome (Cnattingius et al. 1988; DiFranza and Lew 1995).

6 Parkinson's Disease, Alzheimer's Disease and Tobacco Misuse

Smokers are actually at reduced risk of developing Parkinson's or Alzheimer's disease (Graves and

Table 1. Tobacco smoking and cancer mortality (Newcomb and Carbone 1992)

Carcinoma	Sex	Relative risk [a]	Proportion of mortality attributable to smoking (%)
Lung	Men	22.4	90
	Women	11.9	79
Larynx	Men	10.5	81

[a]Risk for non-smokers, 1.0.

Mortimer 1994). The effects of nicotine include release of dopamine in the extrapyramidal motor system (Balfour and Fagerström 1996). The reduced relative risk of Alzheimer's disease has been explained in terms of the increase in cortical and subcortical nicotinergic acetylcholinergic receptors (Benwell et al. 1988). In addition, a neuroprotective effect mediated by stimulation of production of nerve growth factor (NGF) has been described (Freedman et al. 1993).

7 Tobacco Misuse Among Psychiatric Patients

Psychiatric patients are a high-risk population for heavy smoking. Among alcohol- and drug-dependent patients, in particular, but also those with schizophrenia or personality disorder, the prevalence of smoking has been shown in a variety of studies in both inpatient and outpatient settings to be far above general population rates (Hughes et al. 1986).

Depending on the study, the prevalence of comorbid tobacco dependence among people with schizophrenic illnesses is between 50% and 90%. Various hypotheses have been advanced to account for the high prevalence of smoking among patients who take neuroleptics. Smoking may be fostered by situational factors such as boredom or lack of diversion during an inpatient stay, by the influence on generally young schizophrenic patients of fellow patients who smoke or by anhedonia and apathy. Schizophrenic patients with severe negative symptoms seem to be particularly at risk, as they use the stimulation associated with tobacco consumption to increase motivation.

An advantage of tobacco consumption to patients taking neuroleptics is that it reduces the biological half-life of highly potent neuroleptics, and the experience of extrapyramidal side-effects therefore becomes less unpleasant (Erdmann 1995). The explanation lies in the greater concentration and increased release of dopamine in the mesolimbic system. Recent genetic studies on the genesis of schizophrenia have shown a connection between the expression of a cerebral α_7-acetylcholine receptor coded for on chromosome 15 (Freedman et al. 1997) and tobacco misuse: the measurable neuropsychological defect associated with this genetic characteristic can be influenced by administering nicotine.

An increased prevalence of tobacco dependence has also been recognised among people who suffer from depression. Conversely, smokers are more likely than non-smokers to have a history of depressive illness. In addition, smokers who have experienced at least one depressive episode are less likely to attain abstinence.

Some authors go so far as to see causal connections between a tendency to depression and smoking. They explain this in terms of tobacco-associated suppression and inhibition of monoamine oxidase A and B among smokers (Berlin et al. 1995).

8
Strategies for Reducing the Prevalence of Smoking

The damaging effects of smoking and resulting costs to the healthcare system make measures to reduce smoking essential. Two goals are relevant: people who do not smoke must be prevented from becoming smokers, and current smokers must be helped to quit.

Primary prevention includes measures such as restrictions or bans on tobacco advertising, legal regulation of trade in and consumption of tobacco products, limits on smoking in public buildings or on the public transport system, protection for non-smokers in the workplace and increases in tobacco taxes. Education about the dangers of smoking needs to be directed at young people who have not yet become smokers and at people who are already heavy smokers.

Smoking continues to be linked with too many positive attributes: in advertising, it is associated with freedom, adventure, attractive appearance, sociability and good taste. Only comprehensive information about the mechanisms which make advertising effective and the conditions in which dependence develops can help to combat this image.

9
Smoking Cessation

Finally, the numbers of tobacco-associated deaths expected to occur over the next few years will only be reduced if regular smokers stop smoking.

Smoking cessation treatment has a long history. However, only since the 1960s have interventions that draw on scientifically based concepts been developed and investigated empirically.

The smoking cessation interventions which have so far proved most successful are based on the methods of behaviour therapy and may be offered in individual or group form. Pharmacological interventions are also available with some degree of effectiveness in supporting withdrawal, particularly when combined with psychological interventions (APA 1996).

9.1
Nicotine Replacement

Since 1984, nicotine has been available as a medication, to be used above all as an adjunct to behaviour therapy aimed at smoking cessation. Nicotine replacement takes the form of a patch, chewing gum or a nasal spray and is intended as a temporary, bridging strategy to reduce the withdrawal symptoms which endanger abstinence. Other potential forms of replacement (nicotine inhalers or tablets) are not available in Germany. Nicotine replacement preparations are primarily intended to alleviate withdrawal symptoms at the beginning of smoking cessation treatment. The greatest success has been achieved with nasal sprays and skin patches (Silagy et al. 1994). The principle on which these preparations work is that chewing nicotine gum or continuous administration of nicotine via a patch reduces the manifestations of withdrawal and the intense craving to have a cigarette. This facilitates the initial process of withdrawal and increases the likelihood that psychological treatment will be successful.

Nicotine chewing gum and nasal spray, which rapidly satisfy craving, are unduly similar to the previous addictive behaviour. Thus from the perspective of behavioural psychology, it is preferable to use a nicotine patch in order to break the association between replacement of the addictive substance and the previous pattern of behaviour.

9.2
Behaviour Therapy

In behaviour therapy for smoking cessation, the often still fragile motivation of the smoker for abstinence first needs to be reinforced. This is followed by a self-monitoring phase which involves identification of the old behaviour patterns associated with smoking. This allows these patterns to be erased and replaced with new ones.

After a short period of preparation, the smoker should, if possible, endeavour to give up smoking completely, rather than to gradually reduce the number of cigarettes smoked. This prevents the smoker from achieving a temporary reduction to five to ten cigarettes and deciding that this is an acceptable and attractive target, thus endangering the original goal of total abstinence. As nicotine replacement preparations are not intended to be used concurrently with cigarettes, giving up completely makes the use of these preparations less problematic than with gradual reduction.

Relapse prevention strategies include using role playing to recognise and cope with situations where there is a high risk of relapse, and regular booster sessions aimed at reinforcing motivation for abstinence.

Current combination treatments combine these various behavioural interventions with nicotine replacement, generally in the form of a nicotine patch (Buchkremer and Rath 1989).

Variants of the behaviour therapy for smoking cessation used in groups allow smokers to try to

achieve smoking cessation on their own with the help of written material.

A major target in current research on smoking cessation is the development of risk group-specific smoking cessation programmes. These are tailored to the specific needs and characteristics of particular subgroups of smokers, such as highly dependent smokers or those who are in serious danger due to associated medical illnesses.

9.3 Other Smoking Cessation Interventions

A plethora of alternative smoking cessation interventions (laying on of hands, natural healing products) are offered and utilised by many patients, but cannot be considered valid smoking cessation treatments, as scientific evidence is insufficient. Dubious treatments frequently offer smokers the prospect of remarkable treatment results without it being at all clear what therapeutic principle is being applied.

Interventions such as acupuncture, treatments based on suggestion such as hypnosis and aversion therapies are also worth mentioning. Acupuncture and hypnosis have the disadvantage that they equip the smoker with few strategies for self-help when their abstinence is under threat. The "rapid smoking" procedures used in aversion therapy may involve significant dangers to health.

Other pharmacological treatments used for smoking cessation include antagonism of the effects of nicotine (mecamylamine) and use of silver nitrate to spoil the taste of cigarettes. Very promising initial results have been reported for use of the antidepressant bupropion (300 mg/day, not available in Germany), which appears to be superior to nicotine patches. Results from investigations of the effectiveness of other antidepressants, beta blockers or neuroleptics in assisting cessation have been contradictory or not very impressive.

9.4 Outcome of Smoking Cessation Treatment

The great difficulty of achieving smoking cessation is highlighted by the fact that figures for prevalence of smoking in Germany have remained consistently high, despite extensive initiatives in the areas of education and smoking cessation. This reflects not only the small proportion of smokers to whom smoking cessation treatment is made available, but also the success rates of the treatments, which have thus far been low (Batra 1996). Whereas merely making a resolution to give up smoking leads to long-term success rates of less than 3%, prospects of success are increased to 5%–15% if a nicotine patch is used without the provision of any other treatment. The most successful smoking cessation method currently appears to be behaviour therapy combined with nicotine replacement via a patch. This achieves 1-year abstinence rates of around 25%–40%. Risk group-specific smoking cessation treatments which are geared to the needs of particular patient groups (e.g. coronary patients, pregnant women) achieve 1-year abstinence rates of up to 50% in some cases.

Greater success in reducing smoking can only be expected if extensive measures can be implemented in primary care and if smoking cessation treatments are made available to a wider section of the population.

Drug Abuse: Overview and New Research Directions

1 Introduction

With the burgeoning growth of knowledge, no single chapter can adequately address all aspects of drug abuse. Therefore, this chapter provides a general overview with a special focus on current "state-of-the-art" methods of evaluation and treatment. Emphasis is placed on areas which are currently being researched as well as those that need further scientific exploration.

2 Epidemiology

2.1 Surveys to Assess Substance Use Patterns in the General Population

A variety of surveys are routinely carried out in the United States and are useful for discerning trends in the pattern of drug and alcohol use. Although each has flaws, taken together they can be important for detecting patterns of change in the populations. They are generally less useful for providing estimates of heavy or addicted use.

The High School Survey is a yearly questionnaire given to approximately 50,000 eighth-, tenth-, and twelfth-graders in school with a representative sample chosen for follow-up. Based on statistics collected in 1995, there have been several trends of concern. Following a decline of over 50% between 1979 and 1991, marijuana use has increased since the early 1990s, with a 2.5-fold increase since 1991; the use of LSD has also increased. The rise in adolescent use has been accompanied by a decrease in perceived risk and peer disapproval of marijuana and LSD use. Until these turn around, it is likely that use will continue to rise. The 1995 rate, however, still remains substantially below the 1979 peak.

The National Household Survey on Drug Abuse, in which over 20,000 individuals are interviewed yearly, provides important data on both adult and adolescent use. The 1995 report showed that the number of adult illicit drug users has remained steady since 1992.

In an average month, approximately 5% of Americans used illicit drugs, 4% used marijuana, 1.4 million used cocaine, 5% had five or more drinks per occasion on 5 or more days in the month, and 24% – including 4 million adolescents aged 12–17 – smoked cigarettes.

Since 1985, "casual" (non-addicted) cocaine use has sharply declined among those at high school and in the population at large, but heavy use has not declined, as shown by a gradual rise in emergency room surveys (the Drug Abuse Warning Network data, DAWN). This may reflect both the large numbers already in the pipeline and the shortage of adequate treatment services. Heroin abuse is the most difficult to track. A variety of indicators suggest a gradual rise in such use accompanying the increased availability of cheaper and purer drug on the streets. Between 1990 and 1995, the number of emergency room episodes related to heroin doubled. Traditionally, the purity of heroin in a "bag" has averaged less than 10%; in 1996, the national average was 35%, with purity over 50% not uncommon in New York and other areas (Office of National Drug Control Policy 1997).

2.2 Surveys to Assess Psychiatric and Substance Use Disorders in the General Population

The Epidemiologic Catchment Area Program (ECA) was carried out in the early 1980s to determine the prevalence rates of various DSM-III disorders, including substance abuse and dependence, within five communities in the United States. It used structured interviews to ascertain whether or not individuals had lifetime or current psychiatric conditions. Using the ECA data, Robins et al. (1984) found that 11%–16% of individuals gave a lifetime history of alcohol abuse or dependence. Approximately 5% met criteria for lifetime drug abuse or dependence. Not surprisingly, alcoholics were more likely to abuse drugs and have additional psychiatric comorbidity. Compared to men, alcoholic women were more likely to suffer from another psychiatric disorder, suggesting that problem drinking may be more deviant for women (Helzer and Pryzbeck 1988). Young adults who experienced a major depression or anxiety disorder had twice the likelihood of developing a substance use disorder (Christie et al. 1988), suggesting that certain psychiatric conditions impart an increased vulnerability for substance abuse.

The National Comorbidity Study (NCS) is a more recently completed large-scale survey to assess the prevalence of psychiatric disorders, especially the extent of psychiatric comorbidity, in the general population. Lifetime alcohol and drug dependence rates were fairly similar for both the ECA Study and the NCS. Kessler and colleagues (1996) found that between 41% and 66% of respondents with a lifetime substance use disorder also had a lifetime history of another psychiatric disorder, while 51% of individuals with a lifetime psychiatric disorder also had at least one lifetime substance use disorder. The one situation where substance use disorders were more

likely to precede the psychiatric disorder involved co-occurring affective disorders and alcohol use disorders in men.

Elevated rates of psychiatric disorders – both axis I (e.g. depression, attention-deficit hyperactivity disorder, ADHD) and axis II (e.g. antisocial personality) – have also been documented among substance abusers seeking treatment, and up to 50% of those entering psychiatric treatment have a current or lifetime history of substance use problems. Regardless of the specific psychiatric disorder, individuals seeking help for a psychiatric disorder are more likely than the general population to have a comorbid substance use disorder. Those who abuse substances are more likely to be rehospitalized, be noncompliant with treatment, have a greater utilization of health resources, and have less satisfying familial relationships (Drake and Wallach 1989).

3 Theories of Causality

There have been several models to "explain" chemical addiction, including the moral, learning, disease, self-medication, and social model (Brower et al. 1989). Each employs a different etiology to explain addiction behavior and has different treatment strategies and goals.

3.1 Biologic Model

During the past 20 years, there have been many adoption studies to support the suggestion that alcohol dependence may be biologically transmitted. Goodwin et al. (1973) found that adopted men of biologic alcoholic fathers who were raised by nonalcoholic fathers were four times more likely to develop alcoholism than adopted sons of nonalcoholic biologic fathers. Schuckit and Smith (1996) found that individuals who experienced a low level of reaction to alcohol (i.e. less body sway, less hormonal effects) were more likely to develop an alcohol-related problem than those with a high level of reaction, suggesting that individuals who experience less bodily cues related to alcohol ingestion may be at greater risk for alcoholism.

Another intriguing area of research is the potential link between novelty-seeking and drug use behavior. Both novelty-seeking and taking abusable substances activate the mesolimbic dopaminergic system, the brain's reward pathway. This suggests that there may be a similar biologic predisposition for novelty-seeking and drug abuse (Bardo et al. 1993).

Since the majority of individuals with positive family histories do not develop alcoholism, other factors are likely to impede the development of alcohol dependence.

There are less available data regarding familial transmission of drug use disorders because of the changing availability and purity of various illicit substances. One study by Rounsaville et al. (1991) compared the prevalence of psychiatric disorders, including substance use disorders, in first-degree relatives of a large sample of opiate addicts compared to a sample of normal controls. Compared to relatives of normal subjects, opiate addicts' relatives had substantially higher rates of alcoholism, drug abuse, depression, and antisocial personality disorder. Because alcohol remains readily available, and therefore exposure to it remains relatively stable, contributory biologic factors are easier to assess.

3.2 Psychologic Model

There is ample evidence to suggest that certain individuals may be predisposed to drug abuse due to underlying psychopathology or psychological vulnerabilities. Individuals may self-medicate with specific addictive substances in order to deal with painful or disturbing affects. Drug abusers often have great difficulties in dealing with both positive and negative feelings about themselves and in relationship to others.

Several large epidemiologic surveys have found that individuals with both psychiatric and substance use disorders are more likely to develop a psychiatric illness first, suggesting that psychopathology may lead to substance abuse (Kessler et al. 1996; Christie et al. 1988). However, such an association does not necessarily prove causality; another coexisting factor may need to be present. For example, epidemiologic studies have found high rates of childhood and adult ADHD in substance-abusing populations. However, being impulsive, a common characteristic found among individuals with ADHD, may not be enough; instead, having an antisocial peer group or drug availability may be important intervening variables.

Risk factors for future alcoholism include childhood antisocial behavior, achievement-related difficulties, greater activity level, and interpersonal deficits. There are less data regarding whether early identity problems predict the occurrence of substance abuse in patients (usually female) who are eventually diagnosed with borderline personality disorder and may use chemicals to deal with painful feelings associated with real or perceived rejection.

3.3
Social Model

Steinberg (1991) outlines the individual, interpersonal, cultural, and societal factors which may lead to increased drug use in adolescents. Individual risk factors include school failure and academic difficulties, precocious sexual activity, truancy, or non-drug-related criminal or delinquent behavior. Interpersonal risk factors include distant or hostile relations with parents or guardians, familial disruption, and membership in a peer group that encourages or tolerates substance use. Institutional risks include school transitions into less personal, less protected environments, lack of access to meaningful roles in the community, and growing up in poverty. Adolescents who work more than 20 h per week may be at higher risk for drug use because they are paying less attention to schoolwork and have access to money to pay for drugs. Clearly, some of these factors might be associated with or due to underlying psychopathology. Therefore, both psychological and social factors might have an additive or synergistic effect on drug use.

Whereas most drug use begins in adolescence, for some individuals problematic use may not occur until mid-adulthood or later. Job dissatisfaction or loss, disruption in relationships, medical problems, or other significant losses may increase the risk for substance abuse, particularly among those who do not have adequate supportive relationships or who have never learned how to effectively cope with stress.

Cultural influences may also make drug use more or less likely. For example, Irish Americans may be more likely to develop drinking problems than Italian, Jewish, or Chinese Americans (Valliant and Milofsky 1982). It may be that for groups which allow limited drinking, but do not tolerate "loss of control" drinking, alcohol dependence may be less likely (Peele 1988). Similarly, women may have lower rates of alcohol and drug dependence not simply because of lower genetic/biologic vulnerability, but because women face disapproval for excessive drinking/drug use, particularly during pregnancy.

Societal factors can also have a substantial impact on the extent of use. With increased availability, drug use tends to increase. Thus it is not surprising that nicotine and alcohol are the most highly abused substances in the United States. Even if the government attempts to prohibit the use of certain substances by making them illegal, e.g. marijuana, or not allowing the sale of certain drugs to minors, e.g. alcohol and tobacco, if the society has permissive attitudes regarding the use of these substances, the magnitude of use will increase.

3.4
Biopsychosocial Model

A more inclusive model favored today is the biopsychosocial one, which encourages psychiatrists to examine the biological, psychological, and social factors that initiate, exacerbate, or ameliorate the symptoms associated with substance abuse. For any particular individual, certain factors might be more influential than others in promoting chemical dependency.

4
Course of Illness and Recovery

Perhaps the most well-known work regarding the course of illness has been Dr. George Valliant's work on alcoholism (1983–1996). In the late 1930s, researchers at Harvard began to study adult development. Although not all of the initial subjects were evaluated regarding their alcohol use, the extraordinary length of follow-up allowed important information regarding the natural progression of alcoholism to be evaluated. For most individuals, the progression from asymptomatic social drinking to alcohol abuse/dependence occurred over a period ranging from 3 to 15 years. Progressive alcoholics were more likely to be heavy cigarette smokers compared to nonprogressive alcoholics, with the death rate among alcoholics between the ages of 40 and 70 being approximately three times that of age-matched controls. Social stability was a good predictor of short-term outcome. However, long-term outcome was not necessarily correlated with factors cited as positive predictors in short-term studies (e.g. length of education, exposure to Alcoholics Anonymous (AA), physiologic dependence on alcohol; Valliant 1996.) Because Valliant's work focused on white males and did not assess individuals for other drug use, the results can only be generalized to a limited extent.

Cloninger et al. (1981) have proposed that there are two types of alcoholism, which may have different clinical courses. Using a Swedish adoption sample, Cloninger delineated type I and type II alcoholics. Type I occurs in both sexes, begins in the third decade, is likely to have significant environmental influences, and has limited destructiveness. Type II occurs more often in men, begins in adolescence, is less influenced by environmental factors, and is more malignant. More often, clinicians divide alcoholics into those with and without a family history of alcoholism, and those with a family history may have an earlier age of problematic use. Less information is available regarding the genetic

risks associated with alcoholism in women. Similar to men, women who have an alcoholic father may be at an increased risk for alcoholism (Lex et al. 1994). However, once a woman develops an alcohol problem, data suggests that women become "sicker quicker" (Hill 1984), perhaps related to biologic factors such as decreased amounts of alcohol dehydrogenase, a gastric enzyme that metabolizes alcohol before it enters the bloodstream, lower weight, and higher concentration of fat. Consequently, the same amount of alcohol will produce higher blood levels in women and ultimately greater organ damage.

With the epidemic rise in cocaine use in the 1980s, clinicians became interested in the natural history of its use. Similar to the patterns described for marijuana use, Siegel (1984) described cocaine users as having one of five patterns: experimental, social/recreational, circumstantial/situational, intensified, and compulsive. Using these categories, Siegel found that all users had episodes of decreased or no use. A limited supply and legal risks, along with other factors, may allow some individuals to use cocaine without progressing to a more debilitating pattern of use. However, when individuals switch to more potent routes of administration, i.e. from using cocaine intranasally to smoking crack cocaine, they usually become addicted and get into trouble faster. Not surprisingly, as cocaine use becomes more severe, antisocial behaviors increase and work and relationships with others decrease.

Recovery can occur spontaneously or through treatment. Vaillant (1983) estimated that approximately 1%–2% of alcoholics will become abstinent with each successive year. More recent work by Vaillant's suggests that those with alcohol abuse, compared to dependence, may be less likely to become abstinent. One explanation is that individuals who are alcohol dependent may be more likely to die earlier from their disease than alcohol abusers and thus have less opportunity to become abstinent. Another possibility is that abusers, compared to alcohol-dependent individuals, may suffer less negative consequences and therefore have less impetus to stop using alcohol. Recovery rates for clinical samples may be different from individuals who cease using drugs without treatment.

Various clinicians have proposed the use of developmental stages to describe the recovery process. DiClemente and Proschaska (1982) describe several stages of recovery, including commitment to change, initial change of addictive behavior, and maintenance of change. Gorski and Miller (1986) emphasizes that each stage has a major task or goal, has an approximate duration, and has predictable relapse causes. Minkoff (1989) emphasizes that recovery from psychiatric illness and from addiction have a parallel process and include progressive stages of acute stabilization, engagement, prolonged stabilization, and rehabilitation. Working with severely mentally ill patients with co-occurring substance abuse, it becomes clear that recovery is a long-term process, measured in years rather than weeks.

In the past, it was not uncommon to view any return to alcohol or drug use as a treatment failure. Marlatt and Gordon (1985) stress the importance of distinguishing between a "lapse" and a relapse: "A lapse provides useful information about both the cause of the event and how to correct for its occurrence in the future." Washton and Stone-Washton (1990) state that "the major difference between slips and relapses does not depend on the quantity of drugs used or how often the drug use occurs, but on the outcome. If the patient fails to immediately reestablish abstinence, continues active drug use, and rejects offers of help (i.e. drops out of treatment), it is a relapse." Several researchers have explored whether there are specific variables that can predict short-term relapse. Generally, length of prior abstinence periods and involvement by supportive significant others in the patient's treatment are correlated with improved treatment retention. Not surprisingly, patients who achieve abstinence during treatment are more likely to remain abstinent at follow-up than patients who use drugs during treatment (Kosten et al. 1992).

While income and marital status may not predict outcome conclusively, they are often reflections of a level of social support that is correlated with improved likelihood of a good outcome. It does not seem that the amount or frequency of alcohol or drug use predicts treatment outcome. Depressed or anxious mood are common reasons given for relapse, while situational factors are given less often (Pickens et al. 1985). Severity of psychiatric problems in alcohol- and drug-addicted patients is also associated with poor treatment outcome, supporting the need for adequate assessment and treatment of psychiatric illness in addiction settings in order to improve treatment outcome (McLellan et al. 1983).

5
Diagnostic Assessment

5.1
Defining Substance Use Disorders

There are various ways that clinicians and lay people describe individuals who use substances. Unfortunately, this often leads to miscommunications and the mistaken belief that "addiction" is a poorly defined concept, somehow different from other well-defined medical disorders. In fact, there are widely accepted

definitions which provide reliable criteria for making an accurate diagnosis. Appendix A shows the commonly accepted definitions of abuse and dependence (American Psychiatric Association 1994).

Making the diagnosis of abuse requires having *repeated* negative consequences as a result of regular use, while the diagnosis of substance dependence focuses on the personal impact of the use, the compulsivity of use, and the associated physiological changes. The diagnosis of abuse or dependence is not drug specific; although specific withdrawal symptoms or drug effects may vary, the same diagnostic criteria can be applied regardless of the drug. Second, a distinction is made between physiological and non-physiological dependence, emphasizing that there may (or may not) be physical aspects to being dependent on a psychoactive substance. Third, the amount or frequency of use is not critical when making the diagnosis. Given the highly variable patterns of substance use, i.e. daily versus weekend binge use, using frequency or amount of use as part of the criteria would be difficult. However, this contrasts with how clinicians often "decide" whether someone has a substance use problem.

The ICD-10 classification uses a similar approach to diagnosing substance use disorders as DSM-IV Dependence, but differs with regard to DSM-IV Abuse (American Psychiatric Association 1994; World Health Organization 1992). The term used in ICD-10 is "harmful use", which, as in DSM-IV Abuse, requires that the substance use has caused damage to the physical or mental health of the patient. However, an individual cannot be diagnosed as having "harmful use" if the pattern of substance use has only resulted in negative social consequences, i.e. marital arguments or arrest. This contrasts with the DSM-IV diagnosis of abuse, which allows repeated negative social consequences to serve as an adequate criterion of abuse. The diagnosis of dependence is more similar between DSM-IV and ICD-10. Both diagnostic systems focus on the compulsion to use, difficulties in controlling use, physical withdrawal and tolerance associated with chronic use, neglect of other interests, and harmful consequences of use. Neither diagnostic system requires the presence of physiologic withdrawal or tolerance to make the diagnosis of dependence. Unlike "harmful use" versus "abuse", DSM-IV and ICD-10 appear to be "speaking the same language" when diagnosing an individual with substance dependence.

5.2 Initial Interview

In order to obtain reliable and accurate information, rapport needs to be established. What often gets in the clinician's way is his or her attitude toward substance abuse. Clinicians may believe that substance abuse "is not a medical problem". Additionally, they may be moralistic, or even punitive, toward substance abusers. Part of this may be related to the fact that clinicians are frequently exposed to individuals with end-stage addictive disease during their professional training. Because these individuals may require repeated medical intervention as a result of their chronic drug use, clinicians may hold the mistaken belief that all individuals with substance use problems refuse treatment or invariably relapse despite any treatment provided.

These attitudes and misconceptions need to be addressed in order to effectively diagnose and treat this population. Substance abusers manifest various levels of denial and may be unaware of the negative impact that drug use has on their lives. Physicians who recognize this will be more likely to view substance-abusing patients not as "withholders" of information, but as individuals who need to receive information and understand how drug use has affected their lives and that of others.

Unfortunately, in general psychiatric evaluations, substance use histories are often obtained in a cursory manner. Simply asking patients whether or not they use alcohol or drugs may lead patients to answer no or grossly underreport their actual use. Instead, asking patients (in a nonjudgmental fashion) about their pattern of drug use over the course of their life, first starting in the past and eventually moving towards the present, may provide useful data both for assessment and for making an appropriate treatment referral. Specific questions might include the following:

- When did you initiate use of tobacco/alcohol/drugs?
- When did you begin using regularly? What factors led you to use?
- When did you use most heavily? How did/does your use impact on your life?
- How often do you drink/use drugs in a typical week? How much do you use on heavier use days?

Generally, it is better to weave questions regarding a patient's substance use pattern into the clinical interview with specific focus on the three areas of dependence mentioned previously, namely the salience and compulsivity of the drug use and whether the individual is physiologically dependent on the abused substance. In addition, it is particularly important that a comprehensive medical and social history is taken in order to assess the impact of the substance abuse on the patient's physical, occupational and social functioning. Although repeated injuries, pancreatitis, or gastritis might signal the clinician to consider substance abuse, even vague symptoms such as insomnia or weakness may be due to an alcohol or drug

problem. A significant loss, a change in peer group, or deterioration in functioning at school or work may have triggered or been triggered by substance use. Physical, emotional, or sexual traumas often precede substance abuse and need to be explored in a sensitive fashion. Recent estimates suggest that approximately half of all women substance abusers and 40% of male adolescents in substance abuse treatment have been abused. Legal difficulties such as disorderly conduct, driving while intoxicated, and selling/carrying drugs invariably signal problematic use.

5.3 Screening Tests

Several reliable screening tests are available to enhance a clinician's ability to detect possible substance abuse. Perhaps the most widely used screening tool is the CAGE (Ewing 1984). The CAGE is an acronym used to remember four questions:

C Have you ever felt you should *Cut* down on your drinking/drug use?
A Have other people *Annoyed* you by criticizing your drinking/drug use?
G Have you ever felt bad or *Guilty* about your drinking/drug use?
E Have you ever had a drink/used drugs first thing in the morning to steady your nerves (or other drug-specific withdrawal symptoms) or to get rid of a hangover (*Eye-opener*)?

For individuals endorsing two or more items, problematic alcohol or drug use is likely. The CAGE has been found to have both good sensitivity and specificity (91% and 77%, respectively). Other screening instruments available include the Michigan Alcoholism Screening Test (MAST), which consists of 25 questions about drinking behavior, consequences of use, and prior treatment (Selzer 1971); the brief MAST, which consists of ten items (Pokorny et al. 1972); and the Trauma Scale, which consists of five items regarding prior injuries. None of the screens are as simple to use and have as good a sensitivity and specificity as the CAGE.

An instrument commonly used in Europe is the Munich Alcoholism Test (Feuerlein et al. 1980). This consists of seven items to be assessed by a physician and 24 items which are assessed by the patient as being "true" or "not true". The physician's rating is based on information gleaned from physical examination, laboratory findings, the patient's history, and information collected from family and friends. The physician's assessment is weighted more heavily (i.e. each positive response by the physician receives 4 points) than the self-report items (i.e. each item is given 1 point). A total score greater than 10 is indicative of alcoholism.

5.4 Laboratory Tests

There are basically two types of laboratory tests, those to indicate that alcohol or drugs have been recently used or those which suggest that alcohol/drug use has produced some physiologic damage. Urine toxicological screens are the most common approach used for detection. There are a wide array of tests available to detect substance use, ranging from tests with lower specificity, e.g. thin-layer chromatography (TLC) or enzyme immunoassay (RIA), which are inexpensive and provide rapid results, to those which are highly specific, yet more expensive and more labor-intensive. These tests are usually employed to provide confirmation of positive results from other less expensive tests.

Detection of a particular drug depends on the frequency and amount of use, the patient's metabolism and ability to excrete the substance, the half-life of the drug, and the manner of urine collection (i.e. ensuring that the specimen has been taken from the patient and has not been tampered with). Generally, urine toxicology screens will detect cocaine via the metabolite benzoylecognine up to 12–24 h after use. Stimulants might be detected slightly longer, up to 48 h after use, and opiates up to 96 h after the last use. Cannabis often lasts 1–3 days for occasional users, but may persist up to 1 month for chronic heavy users after the last use. Depressants such as barbiturates may be detected 1 week or longer after the last use, but longer-acting benzodiazepines may produce metabolites which can be detected weeks to months in chronic heavy users. Whereas LSD is usually detected only up to 2 days, PCP may be detected for several days to weeks after the last use because it is fat soluble. One important factor influencing detection is the cutoff value used. Laboratories may vary such that samples with benzoylecognine concentrations less that 300 mg/ml may be reported negative by one laboratory but positive by another laboratory using lower cutoff values.

Urine testing has generally been the major method used to detect drug use. However, several disadvantages exist. Because urine collection is frequently done without direct observation, it can be easily adulterated or substituted, i.e. the patient may give the clinician or researcher someone else's urine. In addition, as described above, there is a short period of detection with most abusable substances. Therefore, other options which are currently being investigated include the use of hair, saliva, and sweat. Hair has the longest

length of possible detection, ranging from 20–90 days. However, laboratory studies have shown the potential for positive results based on passive exposure. Further, there are differences in the amount of cocaine and other drugs absorbed depending on hair type, with Black African permed hair having the greatest absorption rate.

An important caveat to the use of toxicological screens is that these tests are designed to assess patients for use of psychoactive substances and do not, in and of themselves, provide diagnoses of substance dependence or abuse. Unlike methods used for detection of substance use, there are other less direct laboratory tests which may indicate problematic use. These include tests which may show disturbances in hematologic or liver functioning (see Table 1). For example, heavy alcohol use with concomitant nutritional deficiencies may result in elevated mean corpuscular volume (MCV) values or cytopenias. Both inhalants and alcohol may produce elevations in SGOT and/or SGPT. Gamma glutamyltransferase (GGT) is the most commonly used laboratory marker of heavy drinking. Serum GGT is elevated in 75%–80% of heavy drinkers. The GGT level will generally return to normal after a 4- to 5-week period of abstinence (Miller and Gold 1991). Cocaine may produce elevations in creatinine phosphokinase as a result of muscle damage. Using several sources of information (the clinical interview, information provided by friends and family, the physical examination, screening instruments, and laboratory results), a fairly accurate picture of the patient's substance use problems is possible.

5.5 Differential Diagnosis

It is often extremely difficult to differentiate an underlying psychiatric condition from a substance-induced disorder. The presentation of psychiatric symptoms will depend on the substance used and whether the individual is intoxicated, overdosed,

Table 1. Physical and laboratory findings related to substance abuse

Substance	Possible physical findings	Relevant laboratory studies
Cocaine	Rhinitis, rash around the nasal area, perforation of the nasal septum, hypertension, tachycardia. *Crack:* hoarseness; parched lips, tongue and throat; singed eyebrows or eyelashes: IV stigmata	Immunoassay; chromatography; mass spectroscopy, urine toxicology screen (up to 12–48 h after use
Stimulants	Worn-down teeth (from tooth grinding), scratches, skin ulcers, dyskinesia	Urine toxicology screen (up to 24–48 h after use)
Inhalants (hydrocarbons)	Halitosis, rash around nose or mouth; mental status changes	CBC, liver function tests, kidney function tests
Cannabis	Conjunctival suffusion; distinct odor of burnt leaves on breath and clothes; dilated, poorly reactive pupils	Urine toxicology screen (occasional user, 1–3 days; chronic heavy users may have a positive screen for 1 month or more after cessation
Opioids	Track marks, skin lesions, constricted pupils, swollen nasal mucosa, thrombosis, lymphadenopathy	Urine toxicology screen (up to 2–4 days after use)
Depressants	Slurred speech without the odor of alcohol; "track" marks if IV user (especially barbiturates); pupillary constriction with glutethimide (Doriden)	Urine toxicology screen (detection time after last use: up to 1 week; barbiturates, chronic users. up to several weeks; long-acting benzodiazepines, chronic users: weeks to months
Hallucinogens	Myopathy; renal failures with PCP	Urine toxicology screen (detection time after last use: PCP, several days to several weeks; LSD, up to 12 h; LSD metabolites, 2 days); myoglobinuria elevated CPK creatinine/BUN with PCP

If a screening assay is positive for opioids, a confirmatory test specific for morpine or codeine is necessary. Illcit versus clinical use of these substances cannot be determined by test results alone. Further, it is impossible to distinguish whether heroin, codeine or morphine has been taken when low concentrations of morphine or codeine are found in the urine. Ingestion of a large quantity of poppy seeds will produce a positive immunoassay result up to 60 h after ingestion. To distinguish between poppy seed ingestion or heroin use, use the GC/MS to test for 6-*O*-acetylmorphine (a heroin metabolite). Methadone must be analyzed separately; fentanyl and its analogues are not detected by routine methods. Xanax (alprazolam) may not be detected in routine assays. If suspected, the laboratory test should be instructed to use GC/MS for specific testing for alprazolam.
From Project ADEPT (1989).
CBC, complete blood count; PCP, phencyclidine; CPK, creatinine phosphokinase; BUN, blood urea nitrogen; GC/MS, gas chromatography/mass spectroscopy.

withdrawing, or chronically using. Clinicians often have the greatest difficulties disentangling a "true" psychiatric disorder from a substance-induced disorder when a patient is withdrawing or chronically using a psychoactive substance. Complicating this picture is the increasing phenomenon of multiple substance use, in which combinations of drugs which might exacerbate psychiatric symptoms, i.e. chronic cocaine and alcohol use, may produce a severe depression. Alternatively, combined use may produce diagnostic dilemmas. For example, a young adult who combines marijuana and phencyclidine develops a prolonged psychosis lasting longer than 1 month such that the clinician is uncertain whether the psychosis is drug induced or a "first-break" psychotic disorder.

There are some guidelines suggested by DSM-IV to help guide the clinician in reaching a diagnosis (Appendix B). As these recommendations imply, the clinician needs to have a good understanding both of when the psychiatric symptoms began and when the substance use developed. Generally, the disorder which appears first is considered the primary one and the disorder which follows after is considered the secondary one. Clinicians also rely on periods of abstinence to distinguish whether psychiatric symptoms are persistent, and perhaps independent of drug use, or whether they diminish when the drug use ceases. A psychiatric condition which occurs during abstinent periods may also be referred to as the "primary" disorder. In order to facilitate whether periods of regular use, heavy use, and abstinence coincided with an increase/decrease or presence/absence of psychiatric symptoms, a time line can be helpful.

Unfortunately, clinical situations are rarely as clear as the DSM-IV guidelines would suggest. First, some psychiatric disorders may be episodic, whereas others are more likely to be continuous. With episodic illnesses, such as depression, obtaining reliable diagnoses can be particularly difficult. Evaluating an individual after a 1-month period of abstinence can usually help distinguish a *current* substance-induced depression from an underlying depressive disorder. However, it is often less clear when assessing individuals for prior depressive episodes.

Because depression may be episodic, the absence of depression during a prolonged period of abstinence, e.g. 1 month, does not necessarily mean that an individual's depression is secondary to the alcohol use. Thus "stable use periods" along with periods of abstinence may be useful when assessing the relationship between the patient's psychiatric symptoms and substance use. For example, if an individual reports a period of depression during a period of "stable psychoactive use", e.g. three beers a day, the clinician may "decide" that the patient had a major depressive episode, particularly if the patient had been drinking in this manner for a period of time prior to having a substantial change in his or her mood state. In assessing cocaine abusers for past and present psychiatric symptomatology, Rounsaville et al. (1991) counted psychiatric symptoms as not being substance induced if they took place during stable substance use periods. However, the research group made several noteworthy exceptions such as not making a diagnosis based on paranoiac, anxiety, or depression symptoms that occur during regular heavy use of stimulants (amphetamine and cocaine).

Other disorders which are less likely to totally remit, such as schizophrenia or social phobia, may be exacerbated (or even alleviated) by certain psychoactive substances and are less likely to remit after 1 month of abstinence. These and other long-standing disorders are therefore less likely to pose diagnostic dilemmas. Exceptions include situations in which the first presentation of symptoms, e.g. paranoia, is accompanied by the use of a drug which can produce psychosis, e.g. amphetamines. In this case, it is generally the persistence or absence of symptoms after the drug use has ceased which helps to differentiate an underlying psychiatric illness from a substance-induced psychosis.

5.6 General Considerations

Whenever a clinician is asked to evaluate the psychiatric status of a patient, drug use must be evaluated. Each class of drug can induce psychiatric symptomatology: depression, psychosis, anxiety, or delirium are all common. Whenever possible, several approaches should be used in tandem in order to reach the proper diagnosis. These include:

1. Always ask about alcohol and drug use. If possible, do not solely rely on the patient for the substance use history. Elicit information from family, significant others, and friends.
2. Obtain a urine/blood drug screen and carry out a breathalyzer test to probe for recent alcohol use. The urine test is more useful to determine whether any drugs have been used during the past 48 h, whereas blood is more useful on current status.
3. Examine the patient for physical signs of drug use (see Table 1); monitor vital signs and neurologic status.
4. Obtain appropriate laboratory studies (see Table 1); abnormal liver, renal, or hemopoietic tests may all indicate chronic use.
5. Observe the patient over time. Drug effects may diminish within a few hours, a few days, or a few weeks.

6 Treatment

6.1 General Remarks

Because drug dependence is due to a variety of factors, including biological, psychological, and social determinants, it makes sense that a combination of treatment approaches works best. Kleber (1989) emphasizes several important points:

1. Psychological problems or comorbid psychiatric illnesses may worsen treatment outcome. Some investigators have found that treatment outcome is worse among individuals who have high severity of psychological problems. Individuals with previous episodes of trauma or character pathology may require more intensive treatment with experienced clinicians.
2. The patient's motivation for treatment may affect treatment retention as well as other measures of treatment outcome.
3. Polydrug use is common. Treatment programs rarely find individuals who are abusing only one psychoactive substance.
4. Medications to treat substance dependence need to be given in the context of appropriate psychosocial intervention. Without such support, the patient is likely either to discontinue the medication or to take it while still using their drug of choice.

All of these points address the importance of "treatment-matching". McLellan and colleagues (1993) have repeatedly shown that, by providing adequate and appropriate services, patients can substantially improve in treatment. One particular treatment program or clinician may not have adequate resources to provide help for all of a patient's problem areas. However, by exploring a wide range of problem areas, either through structured instruments such as the Addiction Severity Index (ASI) (McLellan et al. 1980) or a psychiatric interview, the areas of greatest concern can be determined. These areas may be initially addressed within the treatment program, or concomitant treatment or referral to another program may be necessary. What is clear, however, is that a "one size fits all" kind of treatment program will fail with a substantial percentage of its patients.

6.2 Nonpharmacologic Treatment Strategies

6.2.1 Brief Interventions

Although treatment may be necessary for individuals with moderate or severe dependence, for some individuals who are heavily using, misusing, or are mildly dependent, a brief intervention, particularly from a family physician, may be all that is necessary. Repeatedly, large-scale studies have shown that a 5- to 10-min intervention in which information regarding the deleterious effects of alcohol and drugs are discussed and the patient's destructive drug-using behavior is confronted can dramatically reduce problematic use.

For those who continue to have problematic use, formal treatment may be required. Unfortunately, patients are often unmotivated to enter and comply with treatment. In order to understand why a certain patient is difficult to engage in treatment, the clinician needs to understand how a patient conceptualizes his or her addictive behavior and what motivated the patient to enter treatment. Although leverage from family, an employer, or the legal system may cause a patient to enter treatment, unless this leverage is consistently maintained, the patient is likely to discontinue treatment. Therefore, early on in treatment it is important to address any misconceptions that a patient might have about substance abuse and to work with the patient toward becoming more "internally" motivated for change.

One of the new techniques being used, referred to as "motivational enhancement therapy" (MET) is a treatment strategy designed to produce rapid internally motivated change. The MET approach is based on the stages of recovery model described by DiClemente and Prochaska (1982). Understanding these stages can help motivational enhancement therapists to empathize with their patients and move them toward the next stage in recovery. Miller and Rollnick (1991) describe five important aspects of MET: (1) express empathy, (2) develop discrepancy, (3) avoid argumentation, (4) roll with resistance, and (5) support self-efficacy. MET stresses active listening rather than telling the patient what to do. Persuasion is based on the assumption that change is up to the patient. Motivation to change may require the therapist to point out discrepancies of how the patient wants to function in his or her life and exploring how alcohol and/or drug use impacts on his or her current ability to function. A well-trained motivational enhancement therapist avoids confrontation with the patient; instead, the therapist helps the individual accurately see the consequences of his or her drug use. Resistance is not perceived as pathological, but rather is understood as a normal process based on the patient's ambivalence toward change. Further, optimism is imbued in the patient by emphasizing that change is possible and that the patient has the ability to accomplish this change.

More recently, clinicians working with substance-abusing patients with severe mental illness have developed a substance abuse treatment scale (McHugo and Drake 1995). This scale uses concrete, behaviorally

based descriptions for the stages of recovery rather than simply inferring psychological states. This allows clinicians to objectively determine an individual's current engagement in treatment. The level of engagement may reflect the individual's motivation for change.

6.2.2 Self-Help

Perhaps the most widely available form of help for alcohol and drug problems in the United States are the various self-help groups, e.g. Alcoholics Anonymous (AA), Narcotics Anonymous (NA), and Cocaine Anonymous (CA). The program consists of the 12 steps and 12 traditions. The steps provide a way for the alcoholic to learn to live effectively off alcohol. The 12 traditions describe the purpose of AA and the purview of the organization. AA meetings are autonomous and provide support for individuals striving to remain drug-free. Individuals are encouraged to form bonds with other members and to seek out a sponsor (another AA member with a sustained period of recovery) who can guide the individual through the program. Unlike the relationship established with a clinician, members develop a closeness based on their shared addiction. Outcome studies suggest that approximately 26%–40% of AA members report being abstinent for at least 1 year, and 20%–30% report being sober for at least 5 years (Nace 1992). It appears that those individuals who have greater participation in AA have a more favorable outcome. Increased involvement in AA is associated with better social adjustment, greater occupational satisfaction, and greater concern for others.

Although it is clear that self-help groups can be quite effective for some individuals, it is less obvious who these individuals are. Most clinicians will encourage patients to attend self-help groups and attend a variety of meetings in order to find a group in they which feel most comfortable. However, if a patient refuses these programs, it may be more pragmatic on the part of the clinician to explore other treatment options with the patient.

A recently developed alternative to traditional self-help programs, for example, is rational emotive therapy. Initially started by a clinical social worker, groups consist of eight to ten members led by lay coordinators and have a cognitive orientation. Because of legal issues related to the use of the term "Rational Recovery" (RR), a new organization, Self-Management and Recovery Training (SMART), was instituted. This treatment approach differs from AA in that (a) crosstalk is encouraged, and members provide feedback to one another with the past 2 weeks and next 2 weeks being stressed; (b) labeling of individuals as "addicts" or alcoholics is discouraged; (c) recovery is viewed as a process which has an end point; individuals may be "recovered" not exclusively in perpetual recovery; (d) it is recognized that individuals are ambivalent about being abstinent; therefore, supportive, nonconfrontational, motivating approaches are used; (e) a lapse or relapse does not mean that the patient has to "start over." Instead, it is an experience to learn from and lead to new, more effective coping strategies (Bishop et al. 1995).

RR may be a reasonable alternative to AA, particularly for those who have difficulties with the spiritual orientation of AA. The utility of this treatment approach deserves further study. This form of self-help is much less available than AA or other traditional self-help groups both in terms of cities where it is offered and number of meetings per week.

6.2.3 Cognitive and Behavioral Treatment

In the last few years, there has been much greater emphasis on cognitive and behavioral treatment approaches for addiction. Marlatt and Gordon (1985) stress the importance of the patient recognizing his or her high-risk situations or feelings that lead back to drug use as well as early warning signals and then utilizing various strategies to avoid relapse. Many ongoing clinical research studies have used manualized versions of this form of treatment to ensure the treatment is provided in a consistent manner and to allow it to be compared to other methods. In order for this method of treatment to be effective, the patient must be fairly cognitively intact and be willing to be an active participant in his or her treatment. For some patients who cannot view themselves as "powerless" over their addiction, both rational emotive and cognitive/behavioral approaches are often preferred.

The other behavioral approach which is being actively researched and applied in treatment settings is contingency management. This treatment seeks to increase prosocial, positive behaviors through the use of reinforcement. Higgins et al. (1994) have successfully used a system of vouchers for cocaine-negative urine which could be exchanged for a variety of goods and services among patients in a small metropolitan location. The reinforcement for "clean" urine was combined with therapy designed around the community reinforcement approach. This research was extended into an urban methadone program with good results (Silverman et al. 1996). Three key factors which may increase the likelihood of success are the following: (1) providing positive reinforcers rather than negative ones, (2) increasing the value of the reinforcer with each successive negative urine, and (3) administering reinforcement temporally close to the desired behavior. Although this technique was shown to be effective in reducing drug use, a large number of

patients did not respond to this method, particularly those with the heaviest drug use, and most relapsed after the positive contingencies were removed. It may be necessary, therefore, to maintain abstinence contingencies until other lifestyle changes are implemented, internal motivation for change is adequate, and other techniques, such as coping with relapse triggers, have been learned.

6.2.4 Network Therapy

Up until recently, it has been assumed that clinicians working in office-based practices have little success in treating addicted individuals. Galanter (1993) describes "network therapy", an approach consisting of cognitive/behavioral and psychodynamic techniques while incorporating individuals significant in the patient's life into the treatment process. Family members and peers meet with the patient and therapist at periodic intervals. Orchestrated by the therapist, the therapeutic network provides support and cohesiveness, confronts denial, and promotes the patient's compliance. Within the context of this approach, ambulatory detoxification, monitoring of compliance with medications such as disulfiram or naltrexone, or contingency contracting can be accomplished. Although research data demonstrating network therapy's efficacy is not yet available, clinicians have begun to employ this approach within their private practices.

6.3 Pharmacological Treatment

With the meteoric rise in cocaine use in the late 1970s through to the mid-1980s, there has been great interest in finding medications which might reduce drug craving and use. Not unexpectedly, clinicians turned to medications which were readily available and administered these medications to various groups of substance abusers, sometimes on a slim theoretical basis. Unfortunately, with the exception of alcoholism, this strategy has not yet proven effective. However, there is much reason for optimism. Novel medications for the treatment of opiate and cocaine addiction are currently being explored as well as other biologic approaches which may impact on the metabolism of certain abusable substances. Similar to the recent plethora of new medications that have become available to treat both depression and psychosis, it would not be surprising if new medications for the treatment of various drug dependencies soon become available.

There is an extensive literature on the pharmacologic treatment of opiate addiction. Generally, the first approach is to attempt to detoxify the opiate-dependent patient using various pharmacologic strategies. Some clinicians substitute longer-acting opiates, e.g. methadone, for shorter-acting ones, e.g. heroin, and slowly lower the dose over a period of 5–7 days. A second method is to use the alpha adrenergic agonist clonidine, which ameliorates opiate withdrawal symptoms by decreasing the activity of the locus coeruleus and thus the noradrenergic outflow that is responsible for much of the withdrawal signs and symptoms. Clonidine-assisted detoxification has the advantage of not using a narcotic, but does not shorten the duration of the heroin withdrawal.

Another approach which is gaining greater acceptance is to carry out rapid detoxification (2–3 days) using a combination of clonidine, naltrexone, and benzodiazepines. A withdrawal syndrome is precipitated by using low doses of naltrexone and simultaneously treating with clonidine to block some of the physiological symptoms, ondansetron to treat the nausea/vomiting, and benzodiazepines such as oxazepam to alleviate the anxiety and insomnia. The advantage of this approach is that detoxification can be done quickly, and by the end of the 48- to 72-h period, the patient is already maintained on naltrexone, an opiate antagonist, which can be continued in order to help the patient maintain his or her abstinence. The procedure can be done by experienced personnel on a day basis on day 1 and then on an outpatient basis. All three methods have been recently reviewed in detail (Kleber 1996).

Naltrexone mentioned above is a long-acting orally effective antagonist used to help patients refrain from using illicit opiates. It can be taken daily or as little as three times a week. Although naltrexone is quite effective, most patients are unwilling to take it. Often those who have the "most to lose", i.e. physicians whose licenses are contingent on taking the medication, are the individuals who comply with this treatment. Other good candidates include those individuals with strong family support and those under parole or probation supervision. A longer-acting injectable form of naltrexone is currently under development and may help improve patient compliance.

Most patients who have repeatedly failed detoxification prefer to be placed on an opiate agonist such as methadone rather than naltrexone. Many studies have shown that individuals maintained on methadone have substantial reductions in illicit drug use and other illegal activities, with improvement in both occupational and social functioning (Ball and Ross 1991). Methadone is well absorbed orally, does not produce euphoria by that route, and has a relatively long half-life, enabling it to be given once a day. This contrasts with heroin, which is not effective orally, is short-acting, and requires two to four doses a day. The practical implications of this are that patients can gain greater

stability in their lives via methadone maintenance and make use of other psychosocial interventions.

The major problems with methadone are difficulty in withdrawal and failure to decrease use of drugs such as cocaine and alcohol. Because of these disadvantages, new medications are becoming available in the United States, namely buprenorphine and levo-alpha-acetylmethadol (LAAM). Opiate-dependent patients report having less withdrawal symptoms when detoxified with buprenorphine compared to methadone. Buprenorphine is a partial mu agonist, producing less respiratory depression at high doses, and is less likely to be diverted than methadone, since opiate-dependent individuals taking additional buprenorphine may experience withdrawal rather than euphoria.

LAAM, a long-acting methadone derivative, was approved for maintenance by the Food and Drug Administration (FDA) in 1993. Because it may be given every 2–3 days, patients who are stable can come to the clinic less often. In addition, since take-home doses are unnecessary, diversion may be less.

Although methadone was originally proposed as a "life-long" treatment, there has been increased interest in tapering individuals off methadone after a 1- to 2-year period of maintenance treatment. Individuals who might be good candidates for this option are those who have attained occupational and interpersonal stability and have remained drug-free. Surprisingly, there are few data regarding which individuals will continue to do well after being tapered off methadone (or other opiate agonist agents) and which patients will be most likely to relapse. Given the risks associated with relapse, e.g. possible increased exposure to hepatitis and human immunodeficiency virus (HIV) infection and increase in illegal activities, the discontinuation of methadone must be approached cautiously.

The oral effectiveness and long duration of action along with lack of euphoria during chronic administration has made methadone the drug of choice for maintenance of heroin addicts. Prior to the advent of methadone maintenance in the mid-1960s, heroin was used for maintenance in countries such as England. While initially available from any physician, abuses by a few doctors increased heroin availability and led to heroin maintenance being restricted to specially licensed physicians and clinics. In the 1970s, the continued criminal activities of those maintained on heroin and the advantages of methadone maintenance led to a turning away from heroin maintenance. At present, there are an estimated 150,000 heroin addicts in England, of whom 17,000 are maintained on methadone and less than 400 on heroin, even though over 100 physicians are licensed to prescribe heroin.

In Switzerland, after the failure of the "Needle Park" experiment, where use and sale of heroin was permitted openly in the middle of Zurich and led to up to 20,000 individuals shooting up and hundreds of overdoses a day, the Swiss authorities opened up a heroin maintenance demonstration program. The program has been targeted to the most socially marginal addicts to try to bring them into the mainstream. Approximately 1000 patients are being maintained in this way, and data so far suggest mixed results with continued high rates of cocaine use and unemployment, but improvement in housing and physical health. Controlled experiments rather than demonstration programs would be needed to see whether heroin maintenance has any advantages over the known benefits of the longer-acting agonist methadone or the partial agonist buprenorphine, which is expected to become available in the sublingual form for maintenance in the United States in 1998.

Withdrawal from chronic cocaine or other stimulants may result in anhedonia, depression, and fatigue. Because of the associated dysphoria with prolonged cocaine use, researchers started using a variety of antidepresssants, most notably desipramine, to treat cocaine abuse. In early double-blind trials with cocaine-snorting addicts, desipramine reduced both cocaine craving and use. However, later double-blind trials with cocaine-abusing methadone patients or crack addicts have not shown clear-cut efficacy. Interestingly, desipramine-treated subjects did show greater reductions in cocaine use than the placebo group when individuals with antisocial personality disorder were excluded from the analysis. This suggests that individuals with certain additional psychopathology included in clinical trials may obfuscate any potential therapeutic benefits. Alternatively, certain medications may only prove beneficial for specific psychiatric subpopulations. For example, methylphenidate may be useful for cocaine abusers with adult ADHD (Khantzian et al. 1983, 1984; Levin et al. 1998a), but not among those without this disorder (Gawin et al. 1985).

Cocaine craving has been hypothesized to be the subjective response to dopamine depletion, leading to trials of a variety of medications to correct this supposed dopamine imbalance. These include bromocriptine, pergolide, amantadine, and neurotransmitter precursors. Other researchers have suggested alternative mechanisms for cocaine craving, i.e. the "kindling hypothesis", which has led to the use of carbamazepine. While early open-label trials suggested that carbamazepine may be effective, double-blind trials have not shown such success. Because serotonin receptors have been implicated as sites which contribute to the euphorogenic effects of cocaine, several studies have evaluated the impact of fluoxetine, a selective serotonin uptake inhibitor. Improvements have not been robust. The partial opiate agonist buprenorphine has shown mixed results in reducing cocaine use, and larger trials are necessary.

A third approach has been to develop agents to block the euphorigenic effects of cocaine in several ways: (a) block cocaine's binding to the dopamine transporter system, (b) to block dopamine binding, and (c) to increase cocaine's breakdown into inactive compounds. It is believed that the addictive properties of cocaine may be related to its ability to inhibit the dopamine transporter protein. Because cocaine binding is blocked by mazindol and bupropion, both medications have been tried, albeit with limited success. In the future, drugs may be designed which prevent cocaine binding but do not interfere with the transporter system.

Various D_2 antagonists have also been tried without any clear-cut efficacy. Animal data suggests that by blocking D_2 receptors there may actually be an increase in self-administration due to a partial masking of cocaine's effects. An open trial with flupenthixol reported a reduction in craving and use (Gawin et al. 1989), but controlled studies are needed. Other agents being considered include *N*-methyl-D-aspartate (NMDA) antagonists and gabaminergic agents.

One promising method to block cocaine's effects is to rapidly break down cocaine before it can produce euphoria. Unlike heroin, which is broken down to an active metabolite, i.e. morphine, cocaine can be deactivated by a simple cleavage reaction that produces two inactive products. Landry et al. (1993) have developed catalytic antibodies that bind to cocaine and degrade it and then repeat the sequence. The goal of ongoing research is to develop catalytic antibodies which would work fast enough to neutralize a large dose of cocaine prior to the cocaine reaching the brain. In the future, an individual may be given a passive immunization of a catalytic antibody which would remain in the body for several weeks. By blocking cocaine's effect, there might be a "window of opportunity" in which the patient would be able to become cocaine-free and perhaps be able to benefit from other behavioral or psychosocial interventions.

Unfortunately, even with the evaluation of over 30 medications in over 100 uncontrolled and controlled studies, no medication has shown clear-cut efficacy. This has led researchers to conclude that medications may need to be targeted for subpopulations of users and that medications or specific agents may need to be designed in the laboratory rather than taken from existing medications used for other clinical purposes.

In targeting subpopulations, preliminary data suggest that desipramine may be useful as an adjunctive treatment for schizophrenic cocaine abusers (Ziedonis et al. 1992) and depressed cocaine abusers (Carroll et al. 1994), methylphenidate may be useful for cocaine abusers with ADHD (Khantzian et al. 1983, 1984; Levin et al. 1998a), flupenthixol may be useful for schizophrenic cocaine abusers (Levin et al. 1998b), and mood stabilizers may be useful in reducing both manic symptoms and substance use (Brady et al. 1995). Bupropion, which was not found to be more effective than placebo in treating cocaine abuse, did show a moderate therapeutic benefit when a subsample of depressed cocaine abusers receiving it were compared with those receiving placebo (Margolin et al. 1995). Targeted treatment strategies may be important ways to improve the efficacy of certain medications.

7 Conclusion

In this chapter, the emphasis has been on the diagnosis and treatment of individuals with substance use disorders. New treatment strategies were presented, both pharmacologic and nonpharmacologic. With the development of new technologies, it is incumbent on clinicians treating substance abusers to gain greater facility with these new approaches. In contrast to the pessimism often voiced by clinicians who believe that substance abusers are "doomed to fail", the future of new, improved treatment strategies looks bright.

Appendix A

DSM-IV Criteria for Substance Abuse

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following, occurring within a 12-month period:
   1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g. repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
   2. Recurrent substance use in situations in which it is physically hazardous (e.g. driving an automobile or operating a machine when impaired by substance use)
   3. Recurrent substance-related legal problems (e.g. arrests for substance-related disorderly conduct)
   4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g. arguments with spouse about consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for substance dependence for this class of substances.

DSM-IV Criteria for Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
   a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   b) Marked diminished effect with continued use of the same amount of substance
2. Withdrawal, as manifested by either of the following:
   a) The characteristic withdrawal syndrome for the substance
   b) The same (or closely related) substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessfully efforts to cut down or control substance use.
5. A great deal of time is spend in activities necessary to obtain the substance (e.g. visit multiple doctors or driving long distances), use the substance (e.g. chain-smoking), or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of the substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g. current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Specify if:

- With physiological dependence: evidence of tolerance or withdrawal
- Without physiological dependence: no evidence of tolerance or withdrawal

Appendix B

DSM-IV Guidelines for Diagnosis

Label the psychiatric syndrome according to the most prominent symptom pattern.

Diagnose substance-induced disorder only if:

- It developed during or within 1 month of intoxication or withdrawal.
- Symptoms are consistent with exposure to the substances patient has been using.
- Disorder not better explained by a non-substance-induced disorder.

Diagnose primary, non-substance-induced disorder if:

- It developed before the substance use.
- It has been present during abstinence lasting at least 1 month.
- Symptoms not consistent with those produced by the abused substance.
- Symptoms better explained by a non-substance-induced disorder.

Imaging Studies in Substance Abuse

This work was supported by DOE DE-ACO2-CH00016, NIDA ROIDA06891, NIDA ROIDA09490, and NIDA ROIDA06278.

1 Introduction

Imaging technologies developed over the past 15–20 years such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) have bridged the gap between the basic neurosciences and clinical research. Their application to the investigation of substance abuse has allowed pharmacological mechanisms that pertain to the reinforcing and toxic properties of drugs abuse and the brain metabolic and neurochemical changes associated with addiction to be investigated directly in the human brain.

Most of the imaging work in substance abuse has been done using PET and SPECT. These are nuclear medicine instruments that detect and measure the spatial distribution and movement of radioisotopes in tissues of living subjects (Mullani and Volkow 1992; Rogers and Ackerman 1992). The tracers measured with PET are compounds labeled with positron-emitting radioisotopes, and those with SPECT are compounds labeled with single photon-emitting radioisotopes. Because there are positron emitters for the natural elements of life (^{11}C, ^{15}O, ^{24}N, and ^{18}F, which can be used to substitute for hydrogen), one can label compounds without affecting their pharmacological properties. SPECT radiotracers are usually labeled with ^{123}I or ^{99m}Tc. Although SPECT cannot be used to measure the pharmacokinetics of drugs, because of the need to use these isotopes many iodine-substituted radiotracers have been developed which have high biological selectivity and affinity for specific molecular targets (Kung 1993). The positron emitters used for imaging have shorter half-lives than the single photon emitters. Both of these types of isotopes can be used to label ligands for specific receptor, transporter and/or enzymatic systems to be used with PET or SPECT to quantify these parameters in the living human brains. In addition, PET using ^{15}O-labeled water, ^{15}O-labeled butanol, or ^{13}N-labeled ammonia and SPECT using ^{99m}Tc-hexamethyl propyleneamine oxime (HMPAO) can be used to assess cerebral blood flow (CBF), and PET using ^{18}F- or ^{11}C-labeled deoxyglucose can be used to assess glucose metabolism in brain. These parameters provide an index for regional brain function since, under normal conditions, glucose metabolism and CBF are tightly coupled to brain activity.

Recent advances in MRI have expanded its application from that of an anatomical imaging device to one that enables functional brain imaging (fMRI) to be carried out with a much higher spatial and temporal resolution than that achievable with either PET or SPECT (Andrew 1994). Functional imaging with MRI takes advantage of the differences in magnetic properties of oxygenated versus deoxygenated blood. During activation, there is an increase in CBF with a consequent increase in oxygenation of the activated region (decrease in the ratio of deoxyhemoglobin to oxyhemoglobin), which then gives rise to the activation signal. Because it is such a new technique, no studies have yet been published using fMRI in substance abuse. However, this will change as fMRI becomes a more widely available research tool.

Multiple studies have been performed with PET and SPECT to investigate the neurobiology of drugs of abuse from two perspectives, one involving an investigation of the pharmacological properties of the drugs of abuse themselves and the other investigating the consequences of these drugs on brain function and neurochemistry. These strategies, as they pertain to the various types of drugs of abuse, are summarized in Table 1. In this chapter, we discuss some of the main findings resulting from these studies.

2 Pharmacological Properties of Drugs of Abuse in the Human Brain

The investigation of the pharmacological properties of drugs of abuse entail studies of both their pharmacokinetics and their pharmacodynamics. Furthermore, because the studies are done in awake human subjects, one can investigate the temporal relation between the effects of drugs and their uptake and clearance from brain.

2.1 Pharmacokinetics

Pharmacokinetic properties of drugs of abuse are ideally studied with PET, because the availability of the positron emitter ^{11}C makes it possible to directly label drugs of abuse without changing their pharmacological properties. In this way, PET can be used to measure their absolute uptake, their regional distribution, and their kinetics in the human brain. The labeled drug and whole-body PET can also be used to determine the target organs for the drug and its labeled metabolites and thus provide information on potential organ toxicity as well as tissue half-lives. Table 1 shows the various addictive drugs which have been labeled with positron emitters and whose distribution has been evaluated with PET methodology.

Table 1. Various addictive drugs that have been labeled with positron emitters and whose distribution has been evaluated by positron emission tomography (PET)

Drug class	Specific drug	Parameter measured	Labeled drug or tracer	Reference
Psychostimulants	Cocaine	Pharmacokinetics	[^{11}C]Cocaine	Fowler et al. 1989; Volkow et al. 1995c
		Metabolism	[^{18}F]FDG	Volkow et al. 1993b; London et al. 1990b
		Blood flow	$H_2{}^{15}O$, ^{99m}Tc-HMPAO, [^{123}I]amphetamine	Volkow et al. 1988a; Levin et al. 1994; Weber et al. 1993

FDG, fluorodeoxyflucose; HMPAO, hexamethyl proplyeneamine oxime; DOPA, dihydroxy-phenylalanine; NMS, *N*-methylspiroperidol; IBZM, iodobenzamide; MP, methylphenidate.

An example of the power of this strategy is illustrated by its application to the investigation of the in vivo pharmacokinetics of cocaine in brain. Using ^{11}C as a label, PET has been used to investigate the pharmacokinetics and distribution of cocaine in the human brain (Fowler et al. 1989) and in the human body (Volkow et al. 1992a). These studies showed binding of cocaine in the human brain mainly to dopamine (DA) transporters in basal ganglia, as had previously been shown by animal studies. They also documented a high brain uptake of cocaine (8%–10% injected dose) and a very fast uptake (peaking 4–6 min after injection) and clearance (half-life, 20 min) from brain. Furthermore, for the first time it was possible to evaluate the relation between the kinetics of an abused drug and the temporal relation of the behavioral effects. In the case of cocaine, a parallelism was found between the kinetics of uptake and clearance of cocaine in the brain and cocaine-induced "high."

PET has also been used to compare the pharmacokinetics and brain distribution of cocaine with that of methylphenidate, another DA transporter inhibitor drug which is prescribed in the treatment of attention deficit disorder (Wilens and Biederman 1992; Barkley 1977) and of narcolepsy (Meyer et al. 1980). Comparison of the regional distribution and the pharmacokinetics of these two drugs in the living human brain using [^{11}C]cocaine and [^{11}C]methylphenidate (Volkow et al. 1995b) showed that, while the percentage uptake (7%–10% of the injected dose) and regional distribution of these two drugs in brain was almost identical, their pharmacokinetics were not (Fig. 1). They were both taken up rapidly (peak uptake, 4–8 min) by the human brain, but they differed markedly in their rate of clearance. Methylphenidate clearance from striatum (half-life, >90 min from peak uptake) was significantly slower than that of cocaine (half-life, 20 min from peak uptake) (Fig. 2). For both drugs, the fast uptake in striatum paralleled the experience of the "high." However, whereas for cocaine the rate of clearance paralleled the decline in the "high," for methylphenidate the "high" declined as fast as that for cocaine, while there was still significant binding of the drug in brain. Because it was the rate of uptake that was associated with the "high" for both drugs and not the presence of the drug in brain, it was postulated from this observation that the rate of clearance may affect the propensity of a drug to promote frequent, repeated administration. In the case of methylphenidate, its relatively slow clearance from brain may interfere with its frequent, repeated administration as occurs with cocaine.

2.2 Pharmacodynamics

Different labeled tracers can be used to assess drug pharmacodynamics, which include the biological processes involved in the drugs effects. For example, with appropriate radiotracers, the effects of a drug on metabolism and CBF, on neurotransmitter activity, and on enzyme activity have been probed. These parameters can be assessed directly in the human body both

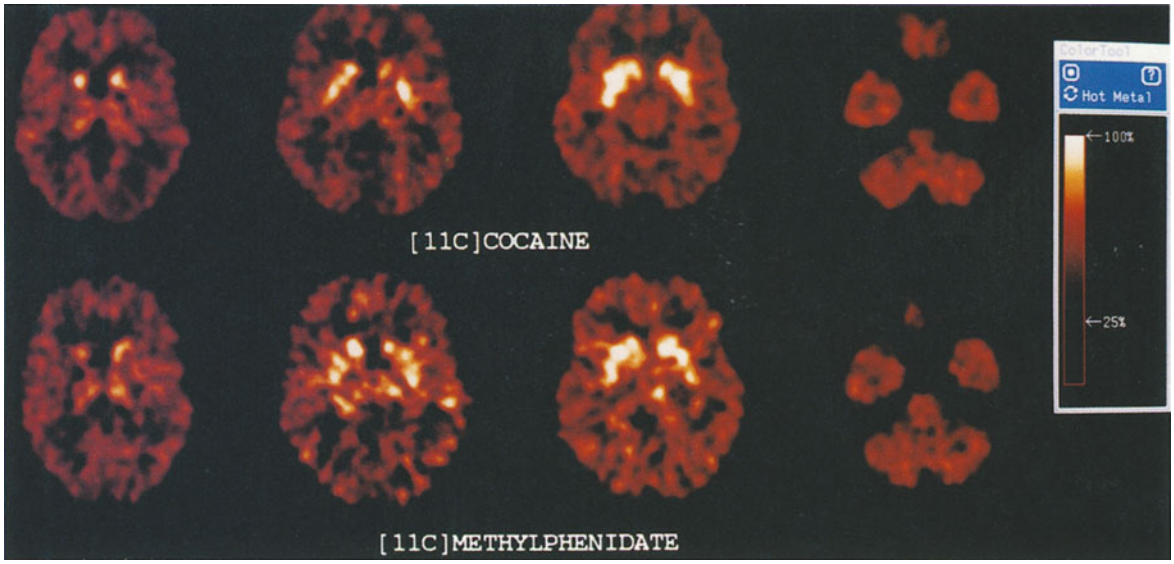

Fig. 1. Brain images obtained with [^{11}C]cocaine and with [^{11}C]methylphenidate. Notice the similar distribution of the two radiotracers in brain with the highest uptake in striatum

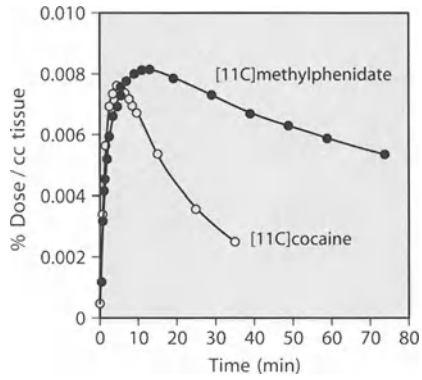

Fig. 2. Averaged time activity curves for [^{11}C]cocaine ($n = 20$) and for [^{11}C]methylphenidate ($n = 10$) in striatum. Notice that, while both drugs enter the brain almost at the same rate, cocaine clears much faster than methylphenidate does. Notice also that the peak uptake for the two drugs is almost identical

in normal controls and in addicted subjects to determine whether there are differences in the responses between addicted and nonaddicted subjects. The most widely utilized approach has been to assess the effects of acute drug administration on brain glucose metabolism and on CBF. This allows analysis of the brain regions that are most sensitive to the effects of the drug. Because the studies are done in awake human subjects, they allow an analysis to be performed of the relation between regional changes in metabolism or flow and the behavioral effects of the drug. This strategy has been used to investigate the effects on brain glucose metabolism and/or CBF for most of the drugs of abuse (Table 1). The effects of acute pharmacological drug administration on regional brain metabolism and CBF can also be used to determine the brain regions associated with drug effects. For example, heroin-induced changes in scores related to euphoria were associated with heroin-induced changes in metabolic activity in lateral occipital and primary visual cortex (London and Morgan 1993). While most drugs of abuse decrease regional brain glucose metabolism, their effects on CBF are increased by some drugs and decreased by others. This discrepancy between metabolism and CBF is probably an indication of the vasoactive properties of many of these pharmacological agents, a property that is relevant for understanding their toxicity as it relates to cerebrovascular pathology. In addition, the fact that changes in metabolism reflect an average of the changes which occur over the uptake period of fluorodeoxyglucose (FDG), which is usually 35–45 min, while the temporal resolution of blood flow measurements is higher, needs to be taken into account.

The effects of drugs of abuse on neurotransmitter activity have also been investigated with PET and SPECT. These studies have been targeted to assess the effects of psychostimulant drugs on DA activity (Volkow et al. 1994a; Laruelle et al. 1995). Changes in synaptic DA concentration in response to psychostimulant drugs have been measured using DA receptor ligands which are sensitive to the endogenous concentration of DA. For this purpose, subjects are scanned twice, at baseline and after administration of the psychostimulant drug known to increase DA concentration. The changes in binding of the ligand with the stimulant drug are an indication of the relative changes in synaptic concentration of DA (Fig. 3). Studies showed that the response between subjects was quite variable, that it decreased with age, and that the intensity of the behavioral effects was closely correlated with the magnitude of the changes in DA concentration.

Imaging technologies can also be used to investigate the relation between behavioral effects and degree of receptor or transporter occupancy. These studies use as receptor radioligand one which is the target of the drug actions, and the studies are performed at baseline and after the drug of interest is given. For example, SPECT was used to evaluate receptor occupancy by the benzodiazepine agonist lorazepam and showed that only a very small fraction of the receptors are occupied at pharmacological doses (Sybirska et al. 1993), findings which corroborate the existence of receptor reserve for benzodiazepine receptors in humans.

The effects of drugs of abuse on enzyme activity have also been assessed with PET for the concentration of monoamine oxidase B (MAO B) in brain. These studies used the PET radiotracer [^{11}C]L-deprenyl-D_2, which binds specifically to the enzyme MAO B. Using this ligand, the effects of cigarette smoke on MAO B have been investigated in human brain (Fowler et al. 1996). This study showed that cigarette smokers have a reduction in brain MAO B of about 40% relative to nonsmokers and former smokers. MAO B inhibition is associated with enhanced activity of DA, a neurotransmitter involved in reinforcing and motivating behaviors, in movement, and in decreased production of hydrogen peroxide, a source of reactive oxygen species (Reiter 1985). Inhibition of MAO by cigarette smoke could be one of the mechanisms accounting for the lower incidence of Parkinson disease in cigarette smokers.

2.3 Drug Toxicity

The toxicity from drugs can be assessed both for brain and for other organs. Because imaging technologies provide functional information, they are very sensitive tools to detect brain pathology secondary to drug use.

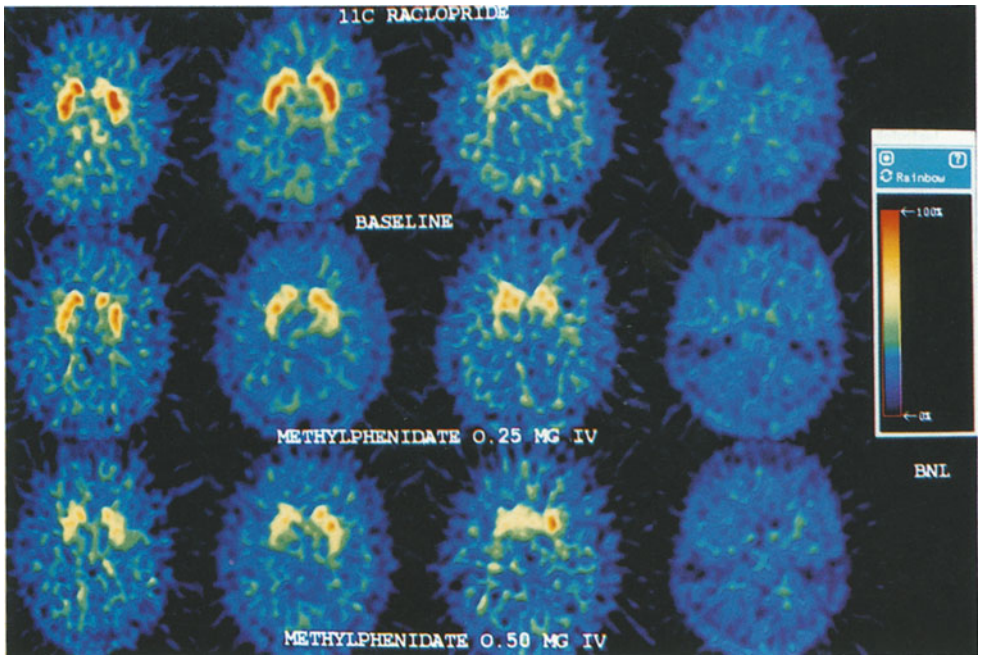

Fig. 3. Brain images obtained with [^{11}C]raclopride after placebo (baseline) and after methylphenidate (0.25 mg/kg i.v. and 0.5 mg/kg i.v.). Methylphenidate decreased the binding of [^{11}C]raclopride in the striatum, and the decrements were larger for the 0.5 mg/kg dose than for the 0.25 mg/kg dose. Binding of [^{11}C]raclopride to the D_2 receptors is sensitive to competition with endogenous dopamine (DA); thus methylphenidate-induced increases in dopamine concentration decrease its binding

Such sensitivity is illustrated by the PET studies which documented for the first time abnormalities in CBF in cocaine abusers (Fig. 4; Volkow et al. 1988a). These findings served to corroborate the clinical reports on the occurrence of cerebral strokes and hemorrhages associated with cocaine consumption. The defects in CBF appear to be secondary to the vasoactive properties of cocaine.

Imaging can also be used to evaluate mechanisms of enhanced toxicity when more than one drug is consumed at the same time, as is the case for the combined use of cocaine and alcohol (Grant and Harford 1990; Boag and Havard 1985). Although the factors mediating the increased risk associated with the combined use of cocaine and alcohol are not fully understood, it was postulated that cocaethylene, a metabolite of cocaine formed in the presence of alcohol, may contribute to the enhanced morbidity and mortality (Hearn et al. 1991a). Using PET, the pharmacokinetics of [^{11}C]cocaethylene was compared with [^{11}C]cocaine (Fowler et al. 1992a). The distribution of [^{11}C]cocaethylene in brain and heart was very similar to that of [^{11}C]cocaine, and the two drugs differed only in their rate of brain clearance, which was 20%–25% slower for [^{11}C]cocaethylene than for [^{11}C]cocaine. To evaluate the possibility that the enhanced toxicity resulted from changes in bioavailability when drugs are taken in combination, PET studies were also performed during alcohol intoxication to assess the effects of alcohol on the brain uptake and pharmacokinetics of [^{11}C]cocaine (Fowler et al. 1992b). Neither the distribution of cocaine nor its pharmacokinetics were affected when [^{11}C]cocaine was given while the subjects were intoxicated with alcohol, a finding that serves to rule out the possibility that the synergistic toxicity of alcohol and cocaine is due to changes in bioavailability. These studies showed that the enhanced toxicity is unlikely to be explained by unique pharmacokinetics properties of [^{11}C]cocaethylene or by changes in cocaine bioavailability. Rather, it is more likely that it reflects the direct toxic effects of the combined use of the two drugs.

Organ toxicity from drug use can be evaluated from several perspectives. In the heart, for example, functional imaging strategies can be used to assess whether there are changes in myocardial blood flow and metabolism in substance abusers. The labeled drug can be used to measure its distribution in the various organs, which is important when determining whether a given drug can have direct toxic effects on a given organ. In the case of cocaine, for example, PET studies done with [^{11}C]cocaine have shown significant accumulation in human heart (Volkow et al. 1992a). Also using [^{18}F]-labeled norepinephrine as a ligand to monitor the function of the peripheral norepinephrine transporter, cocaine was shown to inhibit the trans-

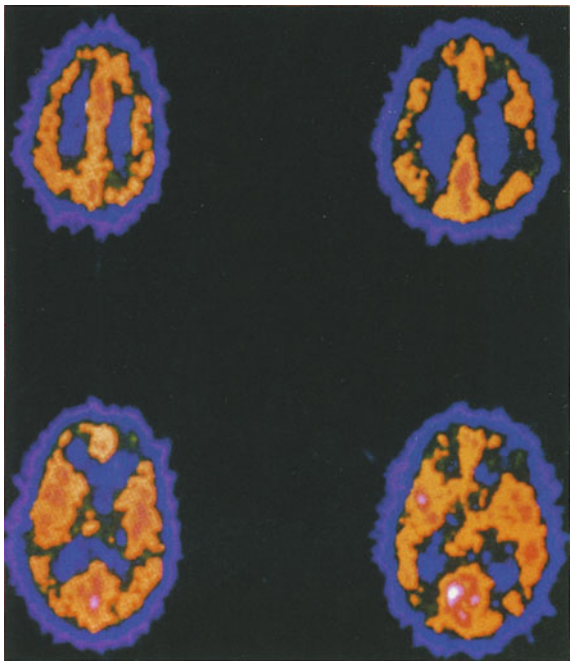

Fig. 4. Images obtained with [^{15}O]water to measure cerebral blood flow (CBF) in a cocaine abuser. CBF is scaled as red > yellow > green > blue. Notice the patchy distribution of the tracer in the cortex due to the decreased flow into both the frontal and parietal cortical areas

porter in heart (Fowler et al. 1994). This is of particular interest because of the documented cardiotoxic properties of cocaine. Cocaine is a local anesthetic, and its accumulation in heart could result in direct myocardial toxicity. At the same time, inhibition of the norepinephrine transporter by cocaine interferes with a protective mechanism of the heart to remove circulating catecholamines.

3
Imaging and Addictive Processes: Evaluation of the Addicted Subject

PET and SPECT have been used to assess neurochemical and functional changes in the brain of addicted subjects and their changes as a function of withdrawal and/or drug treatment. For example, imaging studies recently documented that the decrements in CBF in cocaine abusers improved with the administration of buprenorphine (Levin et al. 1995). Functional imaging strategies can also be used to assess the pattern of brain activation during drug-related states triggered by behavioral interventions such as those that induce drug craving. For example, it was recently reported that, in cocaine abusers in whom craving was elicited by exposure to a video showing cocaine paraphernalia, activation of limbic brain regions was induced (Childress et al. 1995). This area of research is likely to benefit tremendously from fMRI, by means of which multiple repeated studies can be performed in the same subjects without the limitation of radiation exposure in PET and SPECT. Imaging studies have been done in cocaine, marijuana, heroin, and alcohol abusers, tobacco smokers, and polysubstance abusers.

3.1
Cocaine Abusers

The effects of acute cocaine administration (30 mg i.v.) on regional brain glucose metabolism have been investigated with PET and FDG in cocaine abusers (London et al. 1990b). Cocaine decreased brain metabolism in all brain regions investigated, though to a less extent in cerebellum. The magnitude of cocaine-induced decreases in metabolism were correlated with the degree of ventricular enlargement. Subjects with enlarged ventricles were less sensitive to the effects of cocaine on brain metabolism than those that had less ventricular enlargement. This study postulates that one of the mechanisms of reinforcement of cocaine may involve the reduction of brain metabolism.

The effects of cocaine on the striatal DA system have been investigated with PET, since it has been postulated the decreased DA activity could underlie cocaine addiction (Dachis and Gold 1985). A multitracer approach to monitor DA D_2 receptors and metabolic activity in the same subjects was used to assess the relation between changes in DA parameters and regional brain metabolism during early and late detoxification. Regional brain glucose metabolism in recently detoxified cocaine abusers (<1 week) was significantly higher in orbitofrontal cortex and in striatum than in healthy nonabusing controls (Volkow et al. 1991a). The metabolic activity in these brain regions was found to be correlated with the days since last use of cocaine. The highest values were observed in subjects tested during the initial 72 h. Metabolic activity in orbitofrontal cortex and in striatum was also significantly correlated with the intensity of cocaine craving. Cocaine abusers who had the highest subjective ratings for craving were those with the highest metabolic values in orbitofrontal cortex and striatum. Studies done with ^{18}F-labeled *N*-methylspiroperiodol (NMS) on these same cocaine abusers revealed decreases in DA D_2 receptor availability (Volkow et al. 1990a). In contrast, studies done in cocaine abusers tested between 1 and 4 months of detoxification showed significant reductions in metabolic activity in prefrontal cortex, orbitofrontal cortex,

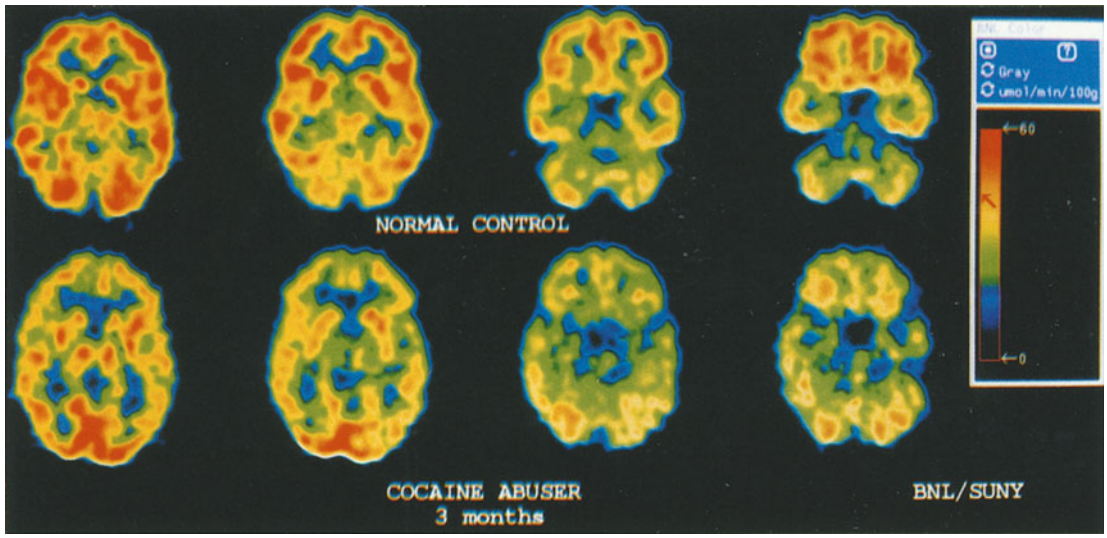

Fig. 5. Regional brain metabolic images in a normal control and in a cocaine abuser scanned 3 months after last use of cocaine. Notice the marked decrements in metabolic activity in the cocaine abuser. Decreases are most pronounced in frontal areas

temporal cortex, and cingulate gyrus (Fig. 5; Volkow et al. 1992c). Measures of DA D_2 receptor availability in these patients also showed a significant reduction, as had been observed during early detoxification. Measures for D_2 receptors correlated significantly with measures of metabolic activity in orbitofrontal cortex, cingulate gyrus, and prefrontal cortex (Volkow et al. 1993b). Decrements in regional brain metabolism and the reductions in DA D_2 receptor availability persisted in the follow-up studies performed 3 months after completing the inpatient detoxification program. The correlation between DA D_2 receptor availability and metabolic activity in orbitofrontal cortex and cingulate gyrus suggests an association between DA activity and the function of these brain regions. Lower values for D_2 receptor concentration were associated with lower metabolism in these brain regions.

This pattern of metabolic abnormalities is similar to that reported in patients with obsessive/compulsive disorders (OCD) (Baxter et al. 1987). Although these two clinical populations are distinct disorders, they share the pattern of compulsive repetitive behaviors. In OCD patients, this manifests as a behavioral ritual, and in cocaine abusers as a repetitive pattern of cocaine self-administration. Experiments in animals have shown that destruction of the orbitofrontal cortex leads to the emergence of repetitive behaviors that cannot be easily terminated (Kolb 1977), and a similar syndrome can be generated by the destruction of the mesocortical DA pathway (LeMoal and Simon 1991). Hence we postulate that DA disruption of the orbitofrontal cortex may be one of the mechanisms responsible for the compulsive administration of cocaine during a "binge" and for the loss of control experienced by the drug abusers when exposed to cocaine and/or cocaine-related cues. Thus DA involvement in addiction may be mediated by its interactions with frontal circuits involved in the control of repetitive and impulsive behaviors.

Findings from these studies have served to demonstrate that addicted individuals have neurochemical changes in their brains that may underlie their inability to control their impulses to take the drug and may explain relapse.

3.2 Alcoholics

PET studies in alcoholics have been done to measure CBF, brain glucose metabolism (baseline and with pharmacological challenges), benzodiazepine receptors, DA D_2 receptors, and DA transporters in brain. These studies have been done to determine whether the brains of alcoholics differ from those of nonalcoholic normal controls and to assess whether there are changes in the brains of subjects who have a genetic predisposition for alcoholism.

PET has been used to investigate brain metabolic changes in chronic alcoholics with and without neurological impairment (Sachs et al. 1987; Wik et al. 1988; Samson et al. 1986; Kessler et al. 1984; Volkow et al. 1992b). Alcoholics with Korsakoff's encephalopathy showed decreased metabolism in prefrontal, parietal, and temporal cortices, and alcoholics with neurological symptoms other than Korsakoff's encephalopathy showed decreased metabolism in frontal and parietal cortices. Studies in alcoholics with no evidence

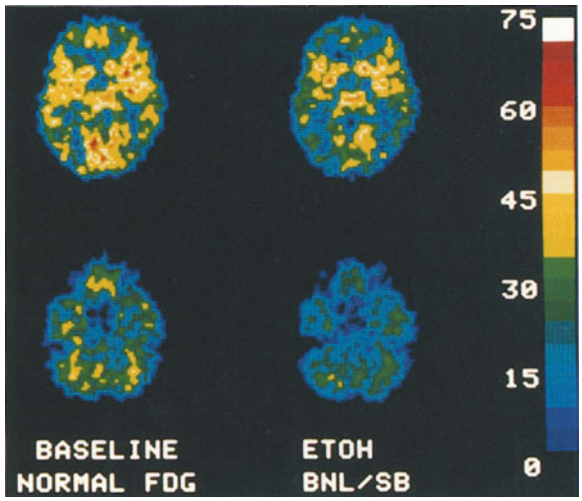

Fig. 6. Brain metabolic images of a normal control at the level of the striatum and the cerebellum at baseline (left-side images) and during alcohol intoxication (right-side images). Notice the decrements in metabolism during alcohol intoxication. FDG, fluorodeoxyglucose; ETOH, ethyl alcohol

of neurological impairment have also shown evidence of frontal abnormalities. Frontal dysfunction in alcoholics has also been consistently found in non-PET studies which measured regional CBF (for reviews, see Mathew and Wilson 1991; Lofti and Meyer 1989). The degree of brain metabolic recovery after detoxification was evaluated with PET in alcoholics who were evaluated at three different times after detoxification (Volkow et al. 1994b). This study showed that brain metabolism increased significantly during detoxification, predominantly during the first 16–30 days of detoxification. Regional increases in metabolism were larger in frontal regions. In alcoholics, metabolism in frontal, parietal, and left temporal cortices was negatively correlated with years of alcohol use and with age, whereas in the comparison group they were not. Decrements in metabolism were most accentuated in the older alcoholics with the longer histories of alcohol consumption.

The effects of ethanol on brain glucose metabolism (DeWit et al. 1990; Volkow et al. 1990b) and CBF (Volkow et al. 1988b) have been evaluated with PET. Such studies have shown that acute alcohol administration decreased brain glucose metabolism (Fig. 6). In contrast, acute alcohol administration increases CBF. When compared with normal controls, alcoholics showed a larger metabolic response to ethanol, despite showing a lower subjective response to the intoxicating properties of ethanol. In normals, the subjective response to the intoxicating effects of ethanol was significantly correlated with metabolic response (Volkow et al. 1988b). The paradoxical metabolic and behavioral responsiveness in alcoholics could reflect tolerance of the brain to ethanol-induced metabolic changes.

The acute (DeWit et al. 1991; Volkow et al. 1993a, 1995a) and chronic (Buchsbaum et al. 1987) effects of benzodiazepine drugs on brain glucose metabolism have also been evaluated with PET. Such studies have shown that, similar to ethanol, benzodiazepines decrease brain glucose metabolism and that the effects are more pronounced in the occipital cortex, the area of the brain with the highest density of benzodiazepine receptors (Braestrup et al. 1977). Studies comparing the response to benzodiazepines between normals and alcoholics have shown that, whereas normal and alcoholic subjects showed a similar response to lorazepam in occipital and cerebellar metabolism, the alcoholics showed a significantly lower response in thalamus, basal ganglia, and orbitofrontal cortex (Volkow et al. 1993a). These studies indicate that alcoholics have a blunted response to lorazepam. This is regionally specific and could reflect either chronic alcohol administration, withdrawal, and/or genetic differences.

In order to assess whether there is a genetic component in the differences in the sensitivity to benzodiazepines, the regional brain metabolic response to lorazepam was evaluated in subjects with a family history of alcoholism (FHP) and compared with that of subjects without a family history of alcoholism (FHN). At baseline, FHP subjects showed lower cerebellar metabolism than FHN subjects, and when challenged with lorazepam they also showed a blunted response in cerebellum and in cingulate gyrus. Lorazepam-induced changes in cerebellar metabolism were significantly correlated with motor impairment. These changes could account for the decreased sensitivity to the motor effects of alcohol and benzodiazepines in FHP subjects and indicate regional brain metabolic differences in children of alcoholics.

Imaging studies have also been done to measure receptors and transporters in alcoholics. Receptors studies have been done to assess changes in DA D_2 receptors as well as on benzodiazepine receptors in alcoholic subjects. Benzodiazepines were measured using [^{11}C]flumazenil and showed that, while there were no changes in receptor numbers between normals and alcoholics, the latter had a significantly larger variability for receptor concentration (B_{max}) measures than controls (Litton et al. 1993). DA D_2 receptors have also been evaluated in alcoholics with PET and [^{11}C]raclopride. This study showed that alcoholics had a 19.7% decrease in B_{max}/K_d and a 12% decrease in D_2 receptor numbers when compared with controls (Hietala et al. 1994). No significant correlations were found between days of detoxification (1–68 weeks) and D_2 receptor numbers. Because persistent reductions in

D_2 receptor availability have also been reported in cocaine abusers (Volkow et al. 1993b), D_2 decrements may represent a variable related to vulnerability for addictive disorders.

DA transporter availability has also been measured in alcoholics with SPECT and [^{123}I]2β-carbomethoxy-3β-(4-iodophenyltropane) (β-CIT). This study showed that, while violent alcoholics had increases (8%), nonviolent alcoholics had decreases in DA transporters (25%) when compared with nonalcoholics controls (Tiihonen et al. 1995). The interpretation for these two findings is not the same; the decreases in D_2 receptors in alcoholics result mainly from changes occurring in striatal GABAergic neurons, whereas assessment of DA transporters reflects DA cells.

3.3 Marijuana Abusers

Marijuana is the most widely used illicit drug of abuse in the United States (Goodman and Gilman 1990). Despite its widespread use, the mechanisms by which Δ-9-tetrahydrocannabinol (THC), the main psychoactive substance of marijuana, exerts its psychoactive effects are still not known (Martin 1986). Non-PET imaging has been used to assessed the effect of THC intoxication on CBF in chronic marijuana users (Mathew et al. 1989; Tunuing et al. 1986). Acute marijuana administration led to decreases in CBF in subjects who were not experienced marijuana smokers, whereas it increased CBF in subjects who were experienced smokers. Chronic marijuana users showed a temporary reduction in CBF that reverted to normal with abstinence. Interpretation of the effects of THC on CBF is confounded by the vasoactive properties of THC (Nahas 1986). Thus it is difficult to separate the effects of THC that are related to its action on nervous tissue from those that are related to its vasoactive effects. This problem is obviated when using deoxyglucose to measure brain glucose metabolism, since it is insensitive to fluctuations in CBF (Sokoloff et al. 1977).

The effects of THC on regional brain glucose metabolism have been evaluated in nonabusing controls (Volkow et al. 1991b) and in marijuana abusers (Volkow et al. 1996b). The whole-brain metabolic response to the effects of THC was variable among individuals; in some subjects it increased, in some it decreased, and in some it did not show change. Despite these variable responses in whole-brain metabolism, there was a very consistent pattern of metabolic activation by THC. In other words, under THC intoxication, most of the subjects showed activation of the cerebellum. The cerebellar activation by THC was significant both for the absolute and the relative measures. Apart from cerebellar activation, the only other region that showed a trend toward activation during THC intoxication was the prefrontal and the orbitofrontal cortex. In contrast to the activation of cerebellum, which was seen across most of the subjects investigated, activation of the orbitofrontal cortex occurred predominantly in the subjects who had a history of frequent marijuana use.

The regional localization of the effects of THC on brain glucose metabolism do not support a diffuse nonspecific mechanism of action for THC. These findings are more in agreement with the hypothesis that proposes interaction of THC with regionally localized receptor sites in the human brain (Howlett et al. 1990). The highly localized concentration of cannabinoid receptors in the cerebellum (Herkenham et al. 1990) supports involvement of the cannabinoid receptors in the metabolic response during THC intoxication. Activation by THC of the cerebellum, which is a system involved in motor coordination (Eccles 1973), proprioception (Brodal 1981), and learning (Derety et al. 1990), could explain some of the behavioral effects seen during THC intoxication. It could, for example, explain the disruption in motor coordination and proprioception during THC intoxication. Cannabinoid receptors are also localized in other discrete areas, namely, hippocampus, substantia nigra pars reticulata, and globus pallidus. The latter are too small to be measured with the spatial resolution of the PET instrument utilized.

Attempts to investigate THC in the living brain with PET by using the labeled drug with a positron emitter have been unsuccessful because of the highly lipophilic nature of THC. This was also a limitation for Δ-8-THC, an analogue of Δ-9-THC, which was labeled with ^{18}F (positron emitter with a half-life of 110 min). Its uptake and distribution were investigated in the baboon brain with PET, and widespread uptake in the brain with no particular pattern of localization was found (Marciniak et al. 1990). This pattern of distribution probably represented mainly nonspecific binding, since pretreatment with Δ-8-THC did not affect the uptake of [^{18}F]-Δ-8-THC in brain. A promising alternative may be the use of THC antagonists with high receptor affinities (Gatley et al. 1996).

4 Conclusion

Imaging technologies have started to document mechanisms of reinforcement of addictive substances and to delineate neurochemical changes in the brain of the addicted subject. Although these findings are still of a

preliminary nature, they provide an indication of the potential of imaging techniques in the area of substance abuse, including the following

1. The behavior of drugs of abuse in the human brain can be assessed. This is relevant both because drug pharmacokinetics and pharmacodynamics may vary across animal species. It also enables the assessment of drug behavior directly in the drug addict.
2. Because imaging studies are done in awake human subjects, the relation between behavior and regional brain effects can be determined with regard to both neurotransmitters and function as assessed by measures of glucose metabolism or CBF. Studies can also be done to assess the relation between pharmacokinetics of a given drug and the time course of its pharmacological effects.
3. Imaging technologies have the unique ability to view neurochemical and functional changes from many perspectives directly in the addicted individual.
4. The pharmacokinetics of the effects of drugs on regional brain activity can be assessed by taking advantage of the fast imaging capabilities of fMRI.
5. They can be applied in the development of new therapeutic interventions.

CHAPTER

23

A. Uchtenhagen

Substitution Treatment for Opiate Dependence

1 Definition and Objectives

Substitution treatment is a therapeutic option that includes the prescription of agonist substances as an adjunct to medical and psychosocial care. The indication and the duration of treatment are determined on the basis of an individual assessment.

Substitution treatment is at present available for opiate-dependent individuals only. As a rule, the opiate of abuse is diacetylmorphine (heroin). Earlier, prescribing alcohol to alcohol-dependent individuals proved to be ineffective and was abandoned. Medical prescription of stimulants as substitution treatment is sporadically practiced, not adequately evaluated, and controversial.

The objectives of prescribing opioid agonists as a substitution for heroin are the following:

- To replace the unhygienic, uncontrolled, and risky forms of illegal heroin administration (especially intravenous injections)
- To reduce all activities linked to the purchase of illegal heroin
- To facilitate a reorientation of heroin dependents toward a socially integrated, healthy, responsible lifestyle
- To improve the chances for permanent abstinence from opiates

The objectives of substitution treatment do not diverge essentially from those of abstinence-oriented treatment. However, there is a difference regarding the timing of intermediate objectives: while abstinence-oriented treatment regards abstinence as a prerequisite for better health and social status (and therefore prefers residential settings), substitution treatment attempts to improve health and social status in order to better achieve permanent abstinence (and consequently prefers outpatient settings). Substitution treatment also allows intermediate goals to be reached where the ultimate objective of abstinence cannot yet be reached or cannot be reached at all, where it serves as a palliative treatment or a risk-reducing measure.

2 Pharmacologic Basis

The substitution of diacetylmorphine by opioid agonists is based on their affinity to μ-receptors which are responsible for euphoric effects and which enhance dependence. This is the case for morphine, methadone, levo-alpha acetylmethadol (LAAM), and also for mono-acetylmorphine, a metabolite of diamorphine. Buprenorphine and, to a lesser degree, codeine also bind to μ-receptors. When these receptors are occupied by substitution agonists, no withdrawal symptoms may develop and additional heroin is not effective.

When opioids are administered continuously, multiple mechanisms induce tolerance; continually higher dosages are needed to achieve the same effect. At the same time, higher dosages can be tolerated which might be lethal in nontolerant individuals. There is cross-tolerance between the above-mentioned opioids. Prescribed opioids induce tolerance for the effects of heroin. Discontinuation of substitution is followed by a withdrawal state comparable to the state after cessation of heroin administration, and tolerance gradually diminishes. After complete withdrawal, the same lethal dosages apply as in nontolerant individuals.

Not all opioids have exactly the same effects. For substitution purposes, the following criteria apply: longer duration of action than heroin, less euphoria and oral administration. These characteristics make the synthetic compound methadone the preferred substitution opioid.

3 Indication

Substitution treatment was developed as an alternative if abstinence-oriented treatment was not available, not feasible or had repeatedly failed. When Dole and Nyswander introduced methadone substitution in 1965, they set up strict entry criteria: minimal age of 21 years, minimal duration of heroin dependence of 4 years, no serious psychopathology, no problems with alcohol or other substances of abuse, and multiple failures in other treatment approaches. As polydrug use and polydrug dependence became more frequent, it was unrealistic to exclude these patients from substitution treatment. The human immunodeficiency virus (HIV) epidemic, the rapid increase of acquired immunodeficiency syndrome (AIDS) cases among i.v. drug users and the transmission of HIV infections to their sexual partners signaled such a threat to public health that substitution treatment became an option to reduce such risks and the access to treatment was facilitated.

At present, the following general guidelines indicate substitution therapy:

- Confirmed opiate dependence (following the criteria of ICD-10 or DSM-IV)
- Informed consent to accept the conditions of substitution treatment
- No contraindication

Further conditions also have to be considered:

- Detailed history (biography, health and social history, history of addictive behavior, including consumption patterns, consequences of substance use, former treatment attempts etc.)
- Present living situation (housing, occupation, income, network, perspectives)
- Complementary medical and/or psychiatric examination regarding indicators for a comorbidity (not in order to exclude such patients, but in the interests of comprehensive treatment planning)
- Extensive information on all available treatment options and advise on the most appropriate option for the situation and the problem at hand
- Shared identification of treatment goals (detoxification, interim substitution, mid- or long-term substitution)
- Identification of the most appropriate substitution medication
- Discussion and identification of the treatment conditions and modalities, preferably using a written informed consent statement

Detoxification using substitution medication with a reduction scheme relieves withdrawal symptoms, but eventually prolongs the withdrawal syndrome (especially when using long-acting medications such as methadone).

Interim substitution and other forms of short-term substitution treatment may be helpful in specific situations, such as pregnancy, urgent hospitalization (which would not be accepted without substitution), and physical conditions necessitating an interruption of risky injections. The duration of interim substitution is determined by the nature of the specific situation.

Long-term substitution is to be considered if opiate dependence is already chronic and if abstinence-oriented treatment is not accepted (e.g. in order for the patient not to lose his or her job or if a somatic or psychiatric condition impedes participation in a residential program).

General conditions such as minimal age, duration of dependence, and number of previous treatments that have failed are no longer considered as exclusion criteria. However, substitution treatment must be considered carefully if dependence is a recent development, especially in minors.

The duration of long-term substitution should not be limited administratively. Routine time limits that do not respect the individual situation increase the risk for relapse after the termination of treatment (Ward et al. 1998).

Substitution treatment is not an emergency treatment, with the exception of some physical conditions such as morbus embolicus or myocardial infection. However, the assessment should not take too much time, in order not to undermine positive motivation for treatment. It has been shown that a 2-week time delay results in significant patient dropout, and this does not only involve those patients with a poor prognosis (Maddux 1995).

When the initial prognosis for the feasibility of substitution treatment is unclear, the indication may be limited to a trial period, delaying the definite indication for 3 months, for example. It is recommended that the indication be reevaluated periodically, at least every 2 years.

The indication for substitution treatment should be made by a physician who has adequate experience in the management of heroin dependents and who is familiar with both abstinence-oriented and substitution treatment. In some countries, the right to determine the indication is reserved for physicians with adequate experience or those who receive continued education on the problems and modalities of addiction treatment.

Absolute contraindications are not known (except failing opiate dependence). Relative contraindications are as follows: acute hepatic conditions, severe hepatic insufficiency (risk of overdose from retarded metabolism), respiratory deficiency (risk of oxygen deficit due to respiratory depression from opioids), individual oversensitivity to a specific opioid, age under 18 years. Partial detoxification is recommended prior to starting substitution treatment if the patient is dependent on alcohol or benzodiazepines (risk of a respiratory deficiency due to combined action). Psychotic and otherwise mentally impaired patients (e.g. patients with AIDS encephalitis) will need careful assessment with regard to their coping ability for substitution treatment, possibly in collaboration with relatives or other significant individuals. Pregnancy is not a contraindication for substitution treatment.

4 Implementation

Substitution treatment is not without risks. However, such risks can be minimized by taking appropriate measures (Table 1).

4.1 Program of Care

Ancillary care is of the utmost importance for the outcome of substitution treatment. It must be tailored to the individual needs of the patient. Comparative

Table 1. Risks in substitution treatment

Risks	Guidelines on how to avoid risks
Primary dependence	Opiate dependence established before starting treatment
Weakening of motivation for abstinence	Periodic assessment of motivation for abstinence
Simultaneous use of illegal heroin	Urine tests; adequate dosage of substitution drug
Simultaneous use of other dependence-producing substances	Urine tests; restrictive prescription of dependence-producing medication (benzodiazepines)
Passing the substitution drug to others; overdose	Visually monitored intake

analysis of methadone programs has demonstrated that a comprehensive care program allows for better retention rates and better outcome (Ball and Ross 1991; McLellan et al. 1993). A program answering the needs for medical treatment and for social and rehabilitative measures is just as important as the prescription of a substitution medication. Clearly formulated agreements between the doctor and the patient help to prevent and to manage problematic situations. Such an agreement should in some cases include other parties concerned (psychotherapist, social worker, pharmacist, parole officer, partner).

Psychosocial care includes advice in financial and legal matters, help in job placement or job seeking, in housing problems, and in all kinds of crisis situations. It includes advice for spouses or relatives and contact with other agencies. Psychosocial care must adapt to changing situations in the course of treatment. The same holds for the frequency of consultations: during the initial period and in situations of crisis, more frequent and more intensive consultation is needed. Consultation mainly focuses on improving living conditions and lifestyle, provides therapeutic support, and monitors the patient's physical and psychological health.

Psychotherapy may enhance the treatment process considerably. A specific indication is needed which takes into consideration the individual condition and the suitability of a given psychotherapeutic method, be it individual or systemic treatment. When carefully chosen, psychotherapy may improve the outcome of substitution treatment (Woody et al. 1995). Group therapy is an integrated element in many substitution treatment programs; the need for individual indications is less important than the need to assess possible contraindications (e.g. in psychotic or severely depressive patients).

Good psychosocial care requires professional competence in various fields. It is therefore often provided on an interdisciplinary basis, in a multiprofessional team, or in collaboration between physician and a specialized consultation agency. The medical responsibility lies with the prescribing physician. Coordination of the various care elements by case management is recommended.

Psychosocial care must also consider the patient's motivation for treatment and readiness for change. Forced consultations may lead to treatment being broken off completely, especially when the patient is healthy and well integrated and sees no reason for regular intensive care. Indeed, substitution treatment in well-integrated patients was found to reduce illegal drug consumption and its risks even without much ancillary care (Raschke 1994). On the other hand, many patients need motivational support in order to accept treatment and care. Motivation techniques have been developed and implemented primarily in the United States (Simpson et al. 1997).

Examples include reward systems (bonuses, reduction of monitoring, take-home privileges for methadone) for compliant behavior, such as regular participation in group meetings and individual consultation sessions (Chutuape et al. 1998). Another technique focuses on enhancing problem awareness by linking individual problems to addictive behavior (node-link mapping technique; Dees et al. 1997).

Some experiments with low-threshold methadone prescription in the Netherlands and in Switzerland have demonstrated the feasibility of a safe prescription practice without ancillary psychosocial care if controlled daily methadone intake is provided and measures against overdosing are taken. When offered to heroin addicts who are reluctant to engage in a care program, results seem to be doubtful, although transition to a well-structured methadone program is encouraged. In addition, a reduction of infection risks in a low-threshold regime has not been shown (Ward et al. 1998). The regime seems to be better justified in patients without major health or social deficits. There are no studies on the mid- and long-term outcome at present.

4.2 Management and Treatment of Comorbidity

Medical conditions that preceded drug dependence or have emerged as their consequence must be properly assessed in order to receive adequate treatment by the prescribing physician or the patient's family doctor or specialist. Two problem areas have to be kept in mind:

- Interactions between substitution medication and other medications
- Interference between the various therapeutic regimes if they are not clearly defined and coordinated, leading to irritation and inviting manipulative behavior

The main somatic conditions associated with heroin dependence are a range of infectious diseases, malnutrition, caries etc. When adequately treated during a substitution regime, they may improve rather quickly, due to the discontinuation of risky injections and an improvement in living conditions. The immune system improves, and the risk of an HIV or hepatitis infection diminishes (Ward et al. 1998).

Interactions between medications must be considered. Tuberculostatic drugs such as rifampicin and rifabutin, antiepileptic drugs such as phenytoin, and certain barbiturates and benzodiazepines, for example, enhance the breakdown of methadone by enzyme induction (P450 oxidase system). This may be compensated for by increasing the frequency of oral methadone intake, not by increasing the dosage. On the other hand, chinidine, clozapine, beta blockers, and anti-arrhythmic agents may impede breakdown through competitive inhibition, thereby increasing the risk of an overdose (for an overview, see Ward et al. 1998).

Psychiatric conditions associated with heroin dependence (dual diagnoses) include (in order of frequency of prevalence) depressive disorders, anxiety disorders, post-traumatic stress syndrome, personality disorders, and schizophrenic psychosis. They may be a consequence of dependence; if they precede dependence, heroin use may be understood as a form of self-medication. Stress may be an underlying factor contributing to both heroin use and the psychiatric disorder. The psychiatric symptoms can be improved in the course of substitution treatment, especially if the addictive behavior has contributed to its manifestation. Often, however, they need to be treated according to the specific diagnosis. The psychological status should be reassessed when the methadone dosage has become stable; if psychiatric symptoms persist, specific treatment has to be initiated (Ward et al. 1998). Patients with schizophrenic symptoms need antipsychotic medication and a well-structured regime without the confrontation often used in the treatment of substance dependence. There are no general rules for the management of opiate dependents with personality disorders, but a good therapeutic climate and well-trained therapists are essential.

Drug interactions, such as the competitive inhibition of methadone metabolism by tricyclic and tetracyclic antidepressants, serotinin reuptake inhibitors, and some neuroleptics, must be taken into account (Ward et al. 1998).

4.3 Polydrug Dependence

Simultaneous dependence on more than one drug is a major impediment to successful substitution treatment. It is an obstacle to implementing positive changes in lifestyle, and it increases risks of respiratory depression, on the basis of synergistic pharmacologic action. Death during methadone substitution treatment is mainly due to an additional intake of alcohol, barbiturates, or benzodiazepines. The risk of hepatitis or HIV infection is increased in patients who are also dependent on cocaine (especially if cocaine is injected, but also if crack is used in conjunction with unsafe sex practices). Continued contact with the illegal drug market with the temptation and risks this entails is another negative consequence of cocaine dependence.

Polydrug use is frequently reduced in methadone substitution treatment if dosage and psychosocial care are adequate. This effect may be enhanced through behavioral therapy measures (bonuses if urine samples are clean, reversal of privileges if they are not). Polydrug dependence may require for additional measures. Partial detoxification treatment or drug-specific combination treatments are recommended. Sanctions, however, especially exclusion from treatment after a given number of positive urine tests, increase the risks of relapse and mortality and are not recommended (Ward et al. 1998).

In order to reduce cocaine consumption, an antidepressant medication may be prescribed, especially in the presence of depressive symptoms. A positive outcome was reported for imipramine, while controlled studies with desipramine, amantadine, and bromocriptine had no effect on cocaine use (for an overview, see Mattick et al. 1998). Anticraving medication (acamprosate) has not yet been systematically tested for its efficacy against cocaine use.

Alcohol dependence in opiate addicts has attracted less attention from therapists and researchers than cocaine dependence has. However, alcohol dependence makes a methadone regime difficult, and it increases the mortality risk in treated and untreated heroin-dependent patients. It may persist even in cases of

successfully treated heroin dependence and increases the risk of subsequent relapse. All therapeutic measures developed for the treatment of alcohol dependence and for hazardous alcohol use can be applied during methadone substitution treatment. These include early outpatient intervention techniques, aversive therapies, participation in self-help groups, and other relapse prevention methods. As an aversive medication, disulfiram shortens the metabolism of methadone and can result in a higher frequency of intake.

Benzodiazepine dependence and dependence on other sedatives is a frequent and serious complication in heroin addicts. Most prevalent is the use of flunitrazepam. An adequate methadone dose can reduce its use.

4.4 Control Measures

An essential element, especially to be implemented during the initial phase and during crisis periods, and possibly during the entire treatment, is the visually monitored intake of methadone. The daily controlled intake must be combined with reliable identification of each individual client. Controlled intake may not be feasible where the service or the pharmacy is closed on weekends; in this case, one or two daily doses have to be taken home on Fridays.

At a later stage, when dosages and the living conditions of a patient have become stable, a take-home policy for a couple of days may be applied.

Take-home policies and the frequency of consultations do not follow uniform rules; they depend on the attitude and the experience of the prescribing physician, on official regulations, and on local traditions. The advantages of a take-home policy include the fact that patients who have become stable are more likely to remain in the program (Rhoades et al. 1998) and show better compliance (Stitzer et al. 1992). It also facilitates the vocational rehabilitation of patients.

Disadvantages include the additional risks for patients who are not sufficiently stable, as they may lose or sell their methadone and replace it by illegal injections, or they may use more than one daily dose at once. In particular, the mortality risk is increased in such cases, due to overdosing. In addition, prescribed methadone may be found on the illegal market and leads to substitution treatment being discredited. All these disadvantages and risks can be avoided if only those patients who are stable enough are allowed to take doses home (Senay et al. 1994).

Take-away doses of methadone should not be replaced if claimed to be lost. Administration through third parties is not recommended, with the exception of reliable relatives or other significant individuals well known to the prescribing physician, and only if the patient is physically unable to visit the methadone clinic regularly.

Urine tests are traditionally another essential element of a methadone program. In many instances, they are legally required, while in some countries they are merely recommended. Urine tests are carried out without prior warning. Visual monitoring, checking of the temperature, or testing for substances added to the oral methadone suspension are utilized in order to minimize urine substitution. The rationale for urine tests is the recognition of nonprescribed substances and evidence of the intake of prescribed methadone.

The high costs of urine tests and the unpopularity of this type of monitoring among staff and patients alike have encouraged research on the usefulness of such measures. It has been shown that frequent and regular tests are not necessary. Infrequent and irregular tests are not linked to an increase in illegal drug use or to less favorable outcomes (Ward et al. 1998).

Urine tests still have a role to play in everyday practice. Their frequency is highly variable. Tests should not be abandoned completely, even in patients with good compliance, because an objectively established drug-free status may considerably reinforce the patient's self-esteem and self-control. Frequent tests are performed in the initial treatment phase and in crisis situations.

Heroin and other opioids and sometimes also benzodiazepines, barbiturates, and cocaine are tested for.

If illegal or nonprescribed substances are detected, this must be discussed openly with the patient. Circumstances connected to the use of such substances, ensuing risks, motivation for better compliance, and measures to be expected if noncompliant behavior continues are the main topics of discussion. The results have to be documented in the case history. Without this process, urine tests have little value.

Urine tests are also used for documenting the evolution of the patient's behavior, for administrative or legal purposes, e.g. in order to obtain a driver's license. Informed consent that relevant information be passed on to the authorities concerned must be assured.

4.5 Duration and Termination of Treatment

The duration of substitution treatments must be determined for each individual patient. Rigid and schematic limitations of their duration are counterproductive and increase the risk of relapse (Caplehorn 1994).

Improvement in health status and reduction in illegal heroin use and in heroin-related delinquency

are observed within months. It takes more time to build up new social contacts and to become reintegrated into the labor market. It usually takes 1–2 years for living conditions to become stable and behavior changes to become permanent. In many instances, further improvements are still made after a few years. However, after 3–4 years, the chances of improvements being made tend to become lower, and there may be a risk of secondary deterioration and resignation.

Many patients are impatient and ask for an early termination of substitution treatment. They want to prove, to themselves and to others, that they are perfectly well prepared for a drug-free life. It is an essential therapeutic task to motivate these patients to accept prolonged treatment, comparable to that needed for prolonged antipsychotic medication for schizophrenia or aversive treatment with disulfiram for alcohol dependence. Less experienced doctors often consider short substitution treatment to be preferable, as they are unaware of the risk of relapse after short treatment and of negative effects on the patient's motivation to resume treatment again if it has failed once. On the other hand, some patients cannot find the courage to terminate substitution treatment after years of satisfactory consolidation and reintegration. These patients may need encouragement to gradually terminate treatment. There are also patients who are unable to mature or grow out of a dependence-prone state of mind and who may need substitution treatment for many years. The basis for such a condition has not been clarified yet.

The termination of treatment must be well planned with the patient and involves clearly defined steps. This includes timing and extent of dose reductions, modality of final detoxification, continued aftercare, management of later crisis situations, and options for restarting substitution treatment if needed.

Treatment should be discontinued if the patient does not comply with treatment plans, takes methadone on an irregular basis, behaves aggressively toward staff, or is selling prescribed substances or engages in drug trafficking. Continued consumption of nonprescribed drugs involving a risk of overdose is a reason for discontinuing treatment. In any case, such a far-reaching decision should be guided by weighing up the risks of keeping the patient in treatment against those of discontinuing it.

Whenever and however substitution treatment is terminated, care should be taken to keep the patient's options open for returning to treatment in the same program or in another service. Coming back to treatment should not be labeled as a failure for the patient or for the therapist. It has been shown that returning to treatment is often a real chance and may lead to better results.

5
Special Problems

5.1
Driving

The ability and permission to drive a motor vehicle is important for practical reasons and especially for vocational rehabilitation. Many patients have lost their driver's license because of their heroin dependence. In order to regain their license, they must present no unusual risks to road safety. Such unusual risks can be excluded on the basis of an assessment of their health status, of documented drug-free urine samples over a defined period of time, and of the patient's general behavior. Assessment is made independently, not by the prescribing physician, but the responsible agency usually consults him or her for observations and prognosis.

The individual assessment of the patient's driving ability does not use uniform criteria. As a rule, a minimal duration of 6–12 months on substitution medication at a stable dosage is required. Other requirements are adequate physical and psychological health, stable housing conditions, absence of delinquent and otherwise irresponsible behavior, and abstinence from illegal and nonprescribed substances (documented by urine tests).

Driving ability is not impaired by substitution medication if the dosage is stable and taken regularly and full opiate tolerance is reached. In the case of oral methadone, attention, coordination, and reactivity are only minimally impaired under steady-state conditions (Seidenberg and Honegger 1998). The use of short-acting substitution drugs is more problematic.

An overdose of methadone may lead to impaired driving if opiate tolerance is not fully developed. Underdosing on the other hand encourages collateral use of other substances that may have a negative impact on driving.

In case of relapse into illegal or nonprescribed substance use, the treating physician must determine whether the patient is still able to drive or whether he or she has to report the patient's inability to the authority concerned.

5.2
Vacations

A normal lifestyle includes the possibility of going on holiday. Social integration and engaging in social relations with friends and partners is difficult if someone is not allowed to travel to a holiday resort or to another country. The wish to go on holiday is often encountered during substitution treatment.

The treating physician must decide whether it is acceptable to hand out substitution drugs in the amounts needed for a vacation on the basis of the individual circumstances (stabilization of dosage and living circumstances, reliability of patient, duration of vacation).

In many places and countries, it is possible to arrange for controlled intake of substitution drugs, but the options have to be explored and there may be some administrative problems to be dealt with. The national laws and regulations concerned must be respected, and the availability of the drug must be checked. As a rule, in countries where methadone substitution treatment is an accepted therapeutic modality, such an arrangement can be made. A medical certificate confirming that the patient is undergoing substitution treatment can be useful. Taking drugs into another country is not recommended, as being detected at the border may cause serious problems.

5.3 Prison

In most countries where heroin dependence is a problem, there are major difficulties in the prison milieu both for dependent inmates and for the institutions and their staff. One difficulty concerns the withdrawal syndromes of newly admitted dependents. Another frequent difficulty is continued opiate use while imprisoned; this presents specific health problems, as needle and syringe sharing may lead to blood-borne infections with HIV and hepatitis. The occasional overdose deaths are also a problem.

In some countries, ongoing substitution treatment can be continued after imprisonment, and in others such treatment can even be started while the patient is in prison. The practice of using methadone in the detoxification of inmates is more widespread (Dolan et al. 1998). Substitution treatment is practiced as a special regime for some individuals or else in special units. In any case, such treatment should be voluntary. Ideally, inmates should be able to choose between substitution and drug-free treatment. Evaluation of such practices is limited at present.

While on remand, withdrawal symptoms may impair the prisoner's fitness for examination. This is not the case if the prisoner is under substitution treatment with adequate doses; the suicide risk is also reduced.

Ideally, substitution treatment in prison should be based on consultation with an external specialized agency which has already treated the patient or is going to take over after his or her release. Organizing proper aftercare is essential in preventing relapse.

5.4 Hospital

Ongoing substitution treatment should be continued if a patient is temporarily hospitalized, be it in a somatic or a psychiatric hospital, unless there are any medical contraindications. If this is not guaranteed, many patients in need of hospital treatment will not agree to being hospitalized or leave the hospital before treatment of their illness has a chance to improve their situation.

Substitution treatment should be initiated if hospitalization would otherwise not be feasible. Hospital physicians must be competent to carry out such a program, and clear rules on the regime must exist which are known to staff and to the patient concerned. Successful substitution treatment is enhanced if good contact is established with external agencies that have already treated the patient or will be involved in his or her aftercare.

5.5 Pregnancy

A patient's health status often improves considerably in the course of substitution treatments. Women patients will begin to menstruate within months. If not adequately instructed or willing to use contraceptive measures, they may become pregnant unintentionally, especially since they did not conceive while on illegal drugs even without contraceptive measures.

If a patient becomes pregnant, the following options must be considered:

- If the woman wants to terminate substitution treatment, the risks of withdrawal syndromes must be discussed, as spontaneous abortion may occur (Finnegan et al. 1991). In any case, the dosage has to be carefully reduced, preferably between weeks 14 and 32 in order to avoid abortion or premature delivery (Ward et al. 1998). Benzodiazepines should not be used to avoid withdrawal symptoms. There is also a major risk of relapse into illegal heroin use after detoxification (Finnegan et al. 1991), and retention in a follow-up drug-free treatment is much lower than in substitution (Svikis et al. 1997).
- If the woman decides to continue substitution treatment, the advantages and potential disadvantages must also be considered. In comparison with illegal heroin (Finnegan et al. 1991), methadone has less risks for the child in terms of birth weight and chromosome damage. A disadvantage is the withdrawal syndrome in the newborn child and the risk

for mid- and long-term effects on the child's development – risks that have not yet been sufficiently explored. Neuropsychological impairments and behavior disorders cannot be ruled out, although milieu factors such as the mother's lifestyle and living conditions seem to have more impact on development than pharmacologic factors (Lifschitz et al. 1985). It is important to note that doses of methadone should not be minimal but sufficient to prevent withdrawal symptoms and thereby collateral illegal or nonprescribed use of drugs. Daily doses should be split in two to be taken at an appropriate interval in order to facilitate stable blood levels and to avoid peak concentrations. After childbirth, methadone substitution is compatible with breastfeeding; problems arise only in cases of harmful use of alcohol or other drugs. Experience with substitution drugs other than methadone is still insufficient.

In conclusion, continuing methadone substitution during pregnancy has more advantages than disadvantages, but this should be determined in each individual case. However, methadone treatment should be considered only on the condition that there is no parallel use of illegal heroin. The main reasons for starting substitution during pregnancy are to avoid the risks of illegal heroin use and to increase the chances for prenatal care.

6 Substances Used in Opiate Substitution

In some Asian countries (Laos, Pakistan) where opium used to be an important substance for both medical and leisure purposes, opium was made available for dependent individuals. These systems were abolished under international pressure by the Single Convention of 1961.

At present, the following substances are prescribed as substitutes for heroin:

- Methadone (oral, intravenous)
- LAAM (oral)
- Morphine (oral, intramuscular, intravenous)
- Codeine, dihydrocodeine (oral)
- Buprenorphine (oral, intramuscular, intravenous)
- Diacetylmorphine (heroin) (oral, intravenous)

6.1 Methadone

Oral methadone is by far the most frequently used substance in opiate substitution treatment. It is usually available as a mixture of the pharmacologically active l-form and the inactive d-form. Preparations containing only the d-form were used in Germany, but are increasingly rare. Intravenous application is traditionally a therapeutic option in England, where it is still an accepted modality (Metrebian et al. 1998). This modality was also tested in a Swiss study and found little acceptance, due to frequent and severe side effects with comparatively high doses (Uchtenhagen et al. 1999).

When given orally, methadone has a bioavailability of 90%–100%. Initial doses are determined by opiate tolerance in a given patient. They should be handled cautiously in order to avoid overdose. If tolerance is not clearly evident, doses should not exceed 30 mg/day, and in cases of evident tolerance 60 mg/day in two doses should not be exceeded. Dosage is increased following the observation of withdrawal symptoms. It is advisable to see the patient once or twice a day in order to prevent unpredictable complications. It is only rarely necessary to hospitalize a patient to determine the adequate dosage.

Maintenance doses must be individually determined. The recommended medium range is between 60 and 100 mg per day. The maximum dosages formulated for nontolerant individuals do not apply. The general rule is to prescribe doses that are sufficient to avoid withdrawal symptoms. Randomized trials have demonstrated that low doses of around 30 mg per day are more frequently followed by treatment discontinuation, by collateral use of illegal substances, and by less favorable outcomes than dosages of around 80 mg per day (for an overview, see Ward et al. 1998). On the other hand, a high dosage that is inappropriate for a particular individual may also encourage the use of nonprescribed benzodiazepine or illegal cocaine. If daily intake is interrupted, the dose has to be reduced in order to avoid overdose; for each day that methadone was not taken, a dosage reduction of 20% is recommended (Seidenberg and Honegger 1998).

No strict correlations have been found between dosage, plasma level, and treatment outcome. It should be noted that plasma levels and pharmacologic action can be influenced by intervening illness and by interactions with other medications (see Sect. 4.2) and necessitate dosage adjustment. It should also be remembered that some individuals metabolize methadone more quickly than average and therefore need higher doses.

Before ending the treatment, a dosage reduction is recommended, usually involving a weekly reduction of the daily dose by 5–10 mg. The final reduction may use even smaller steps or else is made in a residential facility in order to avoid an early relapse. Many patients would prefer a quicker reduction, but in order to avoid relapse each individual case must be examined.

The most frequent clinical side effects of methadone

are constipation, sweating, sleep disorders, and a reduced libido. They can often be managed by dose adjustments and only rarely lead to premature termination of treatment. Side effects only detected in laboratory testing are clinically irrelevant (for an overview, see Seidenberg and Honegger 1998). A comprehensive presentation of the pharmacologic and toxicologic aspects is provided in Cooper et al. (1983).

Death during methadone treatment occurs in the initial phase if there is insufficient tolerance or if initial doses are too high. Death in the course of treatment is usually due to a combination of methadone and other substances (benzodiazepines, barbiturates, alcohol), while methadone alone is rarely found in autopsies of patients who have died of an overdose (Ward et al. 1998; Scott et al. 1999).

6.2 Levo-alpha Acetylmethadol

LAAM is preferred for the long-term substitution treatment of patients with stable doses because of its longer half-life (2.6 days, active metabolites up to 4 days). Intake frequency can be reduced to three times a week, with a dose of 100 mg each time. This has practical advantages, and patients are less restricted in their mobility.

On the other hand, the longer duration of pharmacologic action also means less flexibility in controlling dose effects. The risk of overdosing may be higher. In cases of increased liver function, the rate of metabolism and the level of active metabolites are also increased (Kreek 1996). LAAM should be considered in patients who are already well stabilized on oral methadone. The recommended doses are 1.2–1.3 times higher than the methadone doses (Kreek 1996). Switching from methadone to LAAM may lead to temporary withdrawal symptoms due to its retarded action. Once a stable dosage is reached, LAAM is regarded to be as safe for patients as oral methadone (Tennant et al. 1986).

As a consequence of the retarded action, there is no subjective perception of a rapid onset (flush). This may help to explain why in randomized trials higher dropout rates were found in the LAAM groups than in the methadone groups (Savage et al. 1976; Ling et al. 1980). However, these findings were not confirmed in later studies. An overview of the clinical results indicates a satisfactory therapeutic outcome (Tennant et al. 1986).

6.3 Morphine

Morphine has no important place in substitution treatment. The oral slow-release preparation MST Continus (morphini sulfas pentahydricus) is used as an alternative to oral methadone in patients who experience unpleasant side effects. The recommended dose is 600–900 mg per day (Seidenberg and Honegger 1998).

When intravenously applied, morphine provokes histamine-like local or generalized side effects. The Amsterdam pilot project prescribing intravenous morphine to a group of highly problematic heroin addicts was discontinued, in part on the basis of such side effects (van Brussel 1995). The Swiss project on medical prescription of narcotics also included intravenous morphine, which proved to be poorly accepted due to frequent and occasionally serious side effects (Uchtenhagen et al. 1999).

6.4 Codeine

Between 5% and 20% of codeine is metabolized into morphine. Around 10% of the general population do not have the isoenzyme needed for this process (cytochrome P450 2D6). In these individuals, codeine does not have the intended pharmacologic effect.

The action of codeine is easier to control than methadone, as codeine has a shorter half-life. It also has less potential for causing dependence. It can be reduced and discontinued with fewer problems. A disadvantage is its irritating effects on the stomach. Its usage is limited to patients who need low dosages of substitution drugs.

Clinical experience with codeine was obtained in Germany in particular when substitution with methadone was discouraged and restricted. Therapeutic results have been described as being equivalent to those in methadone substitution treatment (Verthein et al. 1996).

6.5 Buprenorphine

Buprenorphine is a synthetic drug derived from thebaine. It has mixed agonist–antagonist properties. With increased doses, the opioid-like effects are reduced, probably due to the increased antagonist effects. When applied sublingually, the maximum plasma levels are reached after 2–4 h. Half-life values for elimination are 3–5 h. Duration of action increases with dosage. Respiratory depression is minimal, and the mortality risk is comparatively low (Walsh et al. 1994). Bioavailability is much lower when applied orally as compared to sublingual application. Dose reduction and termination of treatment are followed by comparatively few withdrawal symptoms (Mattick et al. 1998).

These findings have led to an increased interest in buprenorphine as an alternative to oral methadone. It is the substitution drug of choice in France, where every physician is entitled to prescribe it. The most frequently used dose is 8 mg per day. The highest dose without an increased risk is reported to be 32 mg per day (Mattick et al. 1998). Prescribing a double dose every second day therefore seems feasible without disadvantages.

Therapeutic outcome is considered to be equivalent to oral methadone treatment, measured by retention rates and by a reduction of illegal substance use. Questions remain in patients who need higher doses of substitution drugs (Mattick et al. 1998). Randomized trials resulted in divergent findings. These may partially be explained by the use of rigid dose schemes and insufficient doses (for an overview, see Mattick et al. 1998).

Misuse of buprenorphine was reported in New Zealand, Australia, and Scotland. Attempts to prevent such misuse have been made by prescribing a combination of buprenorphine and naloxone (Robinson et al. 1993).

6.6 Diacetylmorphine (Heroin)

Diacetylmorphine is a highly effective analgesic with a short duration of 4–5 h and an elimination half-life of half an hour. Monoacetylmorphine and morphine are the active metabolites. If applied intravenously, the plasma half-life is 20–30 min and the duration of effect 3–4 h. It passes the blood–brain barrier easily.

Substitution of street heroin by pharmaceutical heroin has been practiced in England for decades. Special clinics were set up in the late 1960s in urban areas, especially in London. Heroin was handed out by pharmacies on the basis of prescriptions issued by the clinics. Since the early 1970s, this practice has been continuously reduced in favor of prescribing oral and, less frequently, injectable methadone (Strang and Gossop 1996).

In a national Swiss cohort study, injectable heroin is being prescribed to chronic patients in whom other treatments have failed. The individual doses are on average 471 mg per day, administered in two to four intravenous injections under visual control in the clinics. Injectable heroin is often combined with oral methadone in order to reduce the number of injections per day. This facilitates the vocational and social integration of patients, as their day is not interrupted. Side effects include histamine-like reactions as is the case with morphine. In some cases, cerebral seizures are observed following the injection in patients with or without previous episodes of epilepsy. Patients who are unable to inject because their veins are obliterated or inflamed have been treated in a pilot study with heroin-impregnated tobacco-free cigarettes. However, because of their low bioavailability of only 10%, these cigarettes were replaced by slow-release heroin tablets (Uchtenhagen et al. 1999).

In the Netherlands, a randomized trial of prescribing oral methadone with and without injectable or inhalable heroin has been started for a predefined period of time (van Brussel 1995). Results are expected in 2001.

6.7 Criteria for the Choice of Substitution Drugs

The present evidence does not allow well-founded indication criteria to be formulated. Oral methadone is still the standard, and other substances are mainly used if methadone cannot be used for some reason or if it has proved to be unsatisfactory. The only exception thus far is buprenorphine, which is preferred by some for substitution treatment of patients who need fairly low doses, of adolescents and young adults, and of noninjecting heroin dependents.

7 Outcome

Most outcome studies concern heroin substitution by oral methadone. Overviews of research results have been presented by the National Institute of Drug Abuse (NIDA) in the United States (Cooper et al. 1983), by the WHO (Senay and Uchtenhagen 1990), and in an Australian reference book (Ward et al. 1998).

Effects of long-term substitution treatment using oral methadone were examined in a large number of studies. The early randomized trials and later clinical studies (for an overview, see Ward et al. 1998) have documented the following positive results: reduction of illegal drug use, reduction of needle/syringe sharing, reduction in morbidity (especially in blood-borne infections) and mortality, improvements in health status, reduction of contacts with drug users, reduction of drug-related delinquency, reintegration into the labor market, and an overall normalization of lifestyle. These positive effects have been confirmed by the WHO (1998).

The "classical" evaluation studies using a control group design have documented significant reductions in daily heroin consumption and in arrest rates. Naturalistic studies without control groups often give inferior results; this is explained by the more selective procedures for participants and by a better treatment

and care quality in the randomized studies. In addition, in earlier years, the rules for running methadone programs were rigid and strictly applied.

Comparative cohort studies without a control group design on methadone substitution treatment, drug-free outpatient treatment, and residential treatment have been implemented on a large scale especially in the United States; these include the Drug Abuse Reporting Program (DARP; Simpson and Sells 1990), the Treatment Outcome Prospective Study (TOPS; Hubbard et al. 1989), and the Drug Abuse Treatment Outcome Study (DATOS; Simpson and Curry 1997). Similar national cohort studies have been performed in Switzerland (Uchtenhagen and Zimmer-Höfler 1985) and recently in England (National Treatment Outcome Research Study, NTORS; Gossop 1998). The main findings of these studies are that methadone substitution treatment attracts and serves many more patients than drug-free treatments, and fewer patients drop out of the program. There are no consistent findings on differences in therapeutic effects as measured by a reduction in heroin use and in drug-related delinquency. Residential drug-free long-term treatment (mostly in therapeutic communities) yield the best results in achieving a socially integrated drug-free lifestyle. The least favorable results were found in outpatient drug-free treatment.

Recent research focused on comparisons of various types of methadone programs with the aim of identifying predictors of outcome and improving the programs. Comparative analysis has identified insufficient methadone doses as a major reason for therapeutic failure and especially for continued heroin use. Retention and reduction in heroin use could be predicted on the basis of dosage policy. Other relevant factors are the availability of ancillary care services (Ball and Ross 1991; McLellan et al. 1993) and a flexible duration of treatment. Bureaucratic limitation of treatment duration proved to be counterproductive in terms of relapse rates (Caplehorn 1994). It is worth mentioning that improvements may still occur after years on substitution treatment. Factors which impair the prognosis are polydrug dependence, personality disorders, and non-drug-related early delinquency.

New research also concerns the prescription of pharmaceutical heroin as a substitution for street heroin. There has been little research into the British practice. The one randomized study that has been carried out found lower dropout rates in the group receiving injectable heroin, but no clear difference in therapeutic results as compared to oral methadone (Hartnoll et al. 1980). A recent study documents the feasibility of prescribing injectable heroin and methadone (Metrebian et al. 1998). An overview of the programs prescribing injectable heroin or morphine was presented by Mino (1990).

A national Swiss cohort study was started in 1994 comparing groups receiving injectable morphine, methadone, or heroin in the framework of a comprehensive assessment and care program. Entry criteria included multiple failed previous treatment attempts in drug-free programs or methadone substitution. Short randomized periods were used in order to identify differences in pharmacologic effects and side effects. The overall cohort was compared with a cohort of new entries into oral methadone programs using the same research protocol. A total of 1035 patients were enrolled in the cohort receiving injectable drugs, with an average age of 30.8 and an average duration of heroin use of 10.5 years.

The main results of the study were as follows (Uchtenhagen et al. 1999):

- In the randomized substudies, the heroin group was found to have better acceptability (recruitment rates), retention rates, and reduction in illegal drug use.
- Injectable heroin allows for stable dosages as well as oral medication.
- In the total cohort, there was a rapid improvement in health status and a reduction in illegal and nonprescribed substance use, in contacts with drug users, and in drug-related delinquency.
- There was no fatal overdose from prescribed substances.
- Illegal heroin and cocaine use was reduced to a significantly greater extent in comparison to the oral methadone cohort.
- Heroin prescription programs met with good acceptance from authorities and in the general population, as shown by repeated local and national referenda.

The research protocol, its implementation, and the results were examined by an international expert committee appointed by the WHO. The positive results for patients and the feasibility and safety of the programs were confirmed; however, the specific role of heroin prescription could not be identified due to the lack of consistent randomization. The committee made recommendations for further research in the field (Ali et al. 1998).

Based on the Swiss study, on a randomized trial which started in the Netherlands (van Ree 1998), and on the intention of the German Government to start another randomized trial, the international debate over the prescribing of pharmaceutical heroin has intensified. Among those engaging in such projects, the main objective is to supplement the treatment modalities already available by an additional one for those who have failed other treatments. Oral methadone is still perceived to be the drug of choice for substitution purposes. The scientific debate focuses on the place of

heroin prescription within the range of treatment options (Bammer et al. 1999).

8 International Perspective

An overview on policy and practice in methadone substitution treatment in an international perspective was first prepared by the WHO (Arif and Westermeyer 1990). A more recent overview on the legislation, regulations, and practice of methadone substitution in 12 Member States of the European Union was commissioned by the European Commission (Farrell et al. 1996). The latter contains detailed descriptions on the basis of information provided by key informants.

Europe has seen a major increase in methadone substitution treatment and in the respective treatment programs since 1988 as a consequence of the HIV epidemic and especially as a consequence of an increased prevalence of AIDS cases among i.v. drug users and their sexual partners. The total amount of prescribed methadone increased in the various countries by 100%–500%. The level of consumption and the speed of increase differ considerably, however. At present, Spain shows the highest increase rates. The estimated total number of patients receiving methadone has increased fourfold over the past few years.

The number of treatment slots in EU countries in proportion to the total population is highest in England, Holland, Italy, and Spain. Between 10 and 200 slots per 100,000 inhabitants (aged 16–60) are available. There are differences regarding regional distribution and waiting lists.

Another worldwide survey was made on behalf of Health Canada (Ruel 1996), including information from 24 countries. In relation to population figures, methadone substitution was found to be most frequently available in Switzerland and Hong Kong, followed by Australia, Belgium, and the Netherlands.

The international debate on substitution treatment has changed over time. Strict refusal to prescribe substitution drugs on the basis of ideological arguments has become quite rare, and awareness of the requirement for safe and effective implementation has increased. The WHO produced an expert report on the options for the use of substitution treatment in detoxification and maintenance, listing advantages and disadvantages (WHO 1989). According to this report, the most important advantages were the high potential to recruit dependents into treatment, the comparatively low dropout rates, and the low selectivity, while (avoidable) disadvantages were a diversion of prescribed drugs into the illegal market, endless duration of treatment, and the costs involved.

The specific risks of prescribing a narcotic substance as a substitute for heroin were already mentioned in the first treatment protocol (Dole and Nyswander 1965). The authors especially mentioned respiratory depression from overdose and deviation into the illegal market. The regulations in each case were respected in the first methadone programs and included the following: visually monitored intake of methadone, adequate medical and psychosocial care, and urine tests to check for nonprescribed substances. These regulations have been reduced or completely abandoned for economic reasons or in order to lower the threshold for patients. Especially after the arrival of the HIV epidemic, so-called low-threshold methadone substitution was introduced in some places. At present, substitution practices differ in so many respects that the report by the European Commission stated, as its most significant finding, a lack of binding treatment protocols, regulations, monitoring systems, and evaluation guidelines (Farrell et al. 1996). An overview of regulations in force by end of 1995 is provided in Table 2.

The most frequently applied rules are restrictions for handing out methadone on a take-out basis and checks for nonprescribed substance use by urine analysis. Less frequent rules include dose restrictions, special authorization needed for prescribing, and a central registration of patients receiving methadone. Only a minority of countries have detailed national treatment standards or recommendations for good substitution practice. Such provisions have been made in Switzerland, for example (Bundesamt für Gesundheit 1985), USA (Parrino 1991) and Germany (Bühringer et al. 1995).

9 Place of Substitution Treatment in a Therapeutic Network

The old debate on whether or not substitution treatment is acceptable has now been replaced by a debate on how substitution treatment can be implemented in a helpful way among other treatment approaches for heroin dependents.

Originally conceived as a treatment of second choice (in cases where drug-free treatment failed), substitution treatment is now one of the main pillars in the management of heroin dependence. More patients prefer substitution treatment compared to residential drug-free treatment, especially those who still have jobs and a satisfactory social network. Other groups

Table 2. Regulations for methadone substitution treatment (after Ruel 1996)

	Australia	Canada	Denmark	England	Finland	France	Germany	Hong Kong	Hungary	Israel	Italy	Mexico	Netherlands	New Zealand	Spain	Sweden	Switzerland	USA
Central registration of patients	x	x	x	x			x	x					x			x	x

Maximum dose per day		x	x	x		x	x			x		x	x	x	x		x	x
Restricted take-out policy	x	x	x	x	x		x	x		x	x	x	x	x	x	x	x	x
Special authorization required	x	x			x		x		x	x		x		x	x	x	x	x
Maximum patient load per prescribing physician	x	x					x			x	x	x		x				
Maximum patient load per clinic	x									x				x		x		
Authorization for specialized clinics only					x				x	x		x			x	x		x
Authorization only for physicians specializing in addiction treatment					x				x	x		x			x	x		

who favor substitution are those who feel discriminated or exposed in the context of residential programs (e.g. young females, dual-diagnosis patients, patients from ethnic minorities with language problems) and also patients who have tried drug-free treatment without positive results. Wherever heroin dependence is a problem for public health and order, substitution treatment is one of the most effective measures to improve the situation of patients and to reduce the public problems.

Substitution treatment does not necessarily lead to reduced applications for drug-free treatment. The more patients receive substitution treatment, the more will eventually need detoxification treatment, and the more will look for drug-free treatment if they are not satisfied with substitution treatment. On the other hand, many who were unsuccessful in drug-free treatment can be well cared for in substitution treatment. In addition to a meaningful coexistence of therapeutic approaches, there are also programs which offer a mix of approaches: therapeutic communities accepting methadone patients, and methadone programs using methods developed in therapeutic communities especially for day programs or semi-residential programs.

A well-functioning integration of approaches and services in a regional network is feasible if there is the political will to support this tendency in order to reach a maximum number of patients. This requires education to be offered to all staff concerned in order to improve knowledge of the potential of all therapeutic options and to improve coordination and collaboration.

10 Unsolved Problems

One of the most frequent problems arising in substitution treatment is the simultaneous use of nonprescribed substances. In the forefront are benzodiazepines, cocaine, and alcohol. Polydrug use increases the mortality risk considerably. It also undermines all efforts to reorient the lifestyle of patients. New ways of dealing with polydrug use need to be developed and tested.

The high relapse rates which are sometimes found after termination of substitution treatment also constitute a problem. Relapse is more frequent after a short duration of treatment or if the duration is determined on the basis of administrative rules rather than the individual needs of patients. The majority of patients need adequate psychosocial and rehabilitative measures in order to prevent relapse, but this is often in conflict with the need to keep down treatment costs.

Most treatment failures seem to be due to insufficient treatment quality. This includes inadequate diagnostic assessment when starting treatment, deficits in psychosocial care, and deficient dosage. Many programs need improved conditions and increased resources for coping with these demands, but at the same time they suffer from reduced budgets. A major improvement would be the implementation of binding treatment standards, as is the case in other medical fields.

Ambivalence in attitudes towards substitution treatment also has other roots, however. There is no motivation to substitute a drug of abuse if use and abuse are mainly considered to be irresponsible behavior that must be punished or at least not gratified. There is also little motivation if the subjective expectations of users for positive effects of their treatment are ignored. An evidence-based policy looking for pragmatic approaches and the proper evaluation of such approaches is needed in order to overcome the problems outlined here.

Co-morbidity of Psychiatric Disorders

1 Introduction

Co-morbidity has been broadly defined as the presence of more than one disorder in a person in a defined period of time (Wittchen 1996). The concept has gained increasing interest with the widespread use of DSM-III diagnostic criteria. "Two or three DSM-III-based diagnoses are the rule rather than the exception" (Van Praag 1996). Some researchers find the concept compelling, while others are critical of it. This chapter will describe the research which indicates the extent of co-morbidity and some of the explanations for the concept and will indicate the clinical importance of recognising forms of co-morbidity.

There are a number of general principles. Firstly, the chances of two disorders occurring concurrently varies according to the rates of each in the population under study; the higher the base rates of the two conditions, the greater the chance of them occurring together. Secondly, there are problems with independent diagnosis. The diagnoses of anxiety and depression may not be truly independent, whereas depression and alcohol dependence are separate diagnoses. Thirdly, different authors use different definitions. Some work has concerned "lifetime" diagnosis, where the chance of co-morbidity is greater than that occurring with current disorders.

Studies of co-morbidity have been performed in population-based, primary and secondary care settings. Most weight is now being given to population-based studies, because they demonstrate the true nature of co-morbidity, rather than that which might be attributed to artefacts of treatment-seeking or referral.

There are three main types of co-morbidity: co-morbidity of related disorders (e.g. depressive and anxiety disorders), co-morbid disorders that are less directly related (e.g. depressive and somatoform disorders or psychotic disorder and substance misuse) and co-morbid physical and psychiatric disorders.

There are practical and theoretical issues surrounding co-morbidity. On the one hand, the finding that two forms of disorder frequently co-exist may throw light on their aetiology; on the other hand, co-morbidity may be associated with greater disability and require special efforts to achieve successful treatment.

2 Extent of Co-morbid Psychiatric Disorders

2.1 Population-Based Studies

The National Co-morbidity Survey (NCS) of the United States (Kessler et al. 1994) documented psychiatric diagnoses in a population-based sample of 8098 individuals aged 15–55 years. This major study has documented co-morbidity in the general population more clearly than any other. The response rate to the Composite International Diagnostic Interview (CIDI) was 82.6%, and the results have been adjusted for non-responders and weighted so that the sample is representative of the U.S. population.

In terms of DSM-III-R disorders, 52% respondents had never had any such psychiatric disorder. During their lifetime, 21% had one, 13% had two and 14% had three or more disorders. The fact that 14% of the sample had a lifetime history of three or more disorders indicates that the major burden of psychiatric disorder is concentrated in a group of highly co-morbid people who constitute about one sixth of the population.

The most common lifetime diagnoses were major depressive episode (17.1%), social phobia (11.3%), simple phobia (11.3%) and alcohol dependence (14.1%). During the last 12 months (i.e. current/recent disorders), the commonest conditions were major depressive episode (10.3%), simple phobia (8.8%), social phobia (7.9%) and alcohol dependence (7.2%).

The features associated with co-morbid (three or more) disorders were: female gender, younger age-groups, low income, low educational level and living in a large city. These variables are associated with an increased prevalence of psychiatric disorder in general and may not be specific to co-morbidity.

The prevalence of psychiatric disorder and, therefore, co-morbidity was higher in this survey than in the previous Epidemiologic Catchment Area (ECA) study (Robins et al. 1991). It is not clear whether this difference may be mostly attributed to the type of interview and probe questions used to determine prevalence in the two studies, or whether there has been a real increase in the prevalence of disorder and extent of co-morbidity (Kessler et al. 1994).

2.2 Primary Care

In the World Health Organization (WHO) study of psychological problems in general healthcare, it was reported that 24% of patients attending primary care facilities around the world received an ICD-10 diagnosis and 9.5% received multiple diagnoses, i.e. co-morbidity (Sartorius et al. 1996). The most common diagnosis was current depressive episode (10.4%), followed by generalised anxiety (7.9%), dysthymia (2.1%), panic disorder (1.1%) and agoraphobia (1.5%). There was considerable overlap between the depressive and anxiety disorders: depressive disorder was

recorded alone in 7.5% of patients, anxiety disorder alone in 5.6% and co-morbid anxiety/depression in 4.6%.

This study documented the co-occurrence of depressive with other disorders: with alcohol dependence (odds ratio [OR], 2.1), anxiety disorders (OR, 9.3) and other psychological disorder (neurasthenia, somatisation disorder, hypochondriasis or dysthymia; OR, 10.6). The authors of this study noted the very frequent overlap of anxiety and depressive symptoms (as opposed to disorders), raising questions about the exact way that psychiatric diagnoses are made in relation to co-morbidity.

2.3
Affective Disorders Co-morbid with Anxiety and Substance Misuse

An international task force attempted to identify patterns of co-morbidity across several countries (Merikangas et al. 1996). Their attempt was partly successful, but also demonstrated problems of symptom-based research. Across five countries, the association between major depression and other psychiatric disorders was consistently greater for anxiety disorders (OR, 2.7–14.9) than for alcohol misuse/dependence (OR, 1.1–2.0). Depression was more often reported in association with panic disorder (OR, 2.7–30) than with phobic states (OR, 2.5–12.2). The authors admit that the very high co-occurrence of depressive and panic disorders reflects, in part, an artefact of the syndromal approach to diagnosis, in which the large overlap of symptoms between these disorders are allowed to contribute to two diagnoses.

2.4
"Dual Diagnosis"

Numerous studies from the United States have demonstrated an increased prevalence of substance misuse in patients with schizophrenia or bipolar affective disorders, so-called "dual diagnosis" (Regier et al. 1990). The clinical importance of this form of co-morbidity is that patients with psychotic disorder who also abuse drugs or alcohol have a worse outcome (Lehman et al. 1993). These patients are often heavy users of emergency services and in-patient care, and they may also have high rates of forensic histories and homelessness. There has been relatively little work on this particular form of co-morbidity in Europe, but approximately one quarter of patients admitted in Munich with schizophrenia also had a diagnosis of substance misuse or dependence (Soyka et al. 1993). In London, the 1-year prevalence rate for any substance misuse problem among patients with psychotic illnesses in contact with a mental health service was 36.3%. These patients had spent almost twice as many days in hospital as those without such a problem over the previous 2 years (Menezes et al. 1996).

It is unlikely that substance abuse is merely a response to schizophrenic symptoms, as no clear relationship has been found. Non-compliance with medication is associated with a poor outcome, more disturbed behaviour and longer hospital stays in people with schizophrenia who also abuse medication.

3
Co-morbidity of Psychiatric and Physical Disorders

3.1
Population-Based Studies

A number of population-based studies have assessed the prevalence of psychiatric disorders in respondents who have physical disorders. These have been summarised by Weyerer (1990), who documented an increased prevalence of psychiatric disorder in those with physical disorder (risk ratio of between 1.4 and 3.5). The main difficulty with such studies in the community is that they rely on the respondents' self-report of physical illness.

The most specific data were recorded in the ECA study (Wells et al. 1988b). The 6-month prevalence of any psychiatric disorder was 19.7% (most commonly phobic, depressive disorders, dysthymia and alcohol abuse), and the prevalence of a current chronic medical condition was 34% (most commonly arthritis and hypertension). Just over 7% of the population had co-morbid psychiatric and physical disorders. The prevalence of psychiatric disorders was greater in respondents with physical disorders than the remainder: a psychiatric disorder was present in 24.7% of those with and 17.5% of those without a chronic medical condition. Corresponding figures for anxiety disorders were 12% and 6%, and for depressive disorders 9.4% and 5.8%. These differences were significant even after controlling for demographic factors. The medical conditions with the greatest association with psychiatric disorders were arthritis, cancer, chronic lung disease, neurological disorder and heart disease. The exception was hypertension, which was the commonest chronic medical disease in the ECA sample, but was not

associated with an increased risk of psychiatric disorder.

3.2
Primary and Secondary Care

These associations between psychiatric and physical disorders have been repeatedly demonstrated in patients treated at general hospitals (Rodin et al. 1991; Creed and Guthrie 1996). The highest prevalence rates were in patients with cancer, arthritis, chronic respiratory disease and neurological disorders, notably stroke and Parkinson's disease. The principal difficulty in these studies is that of measuring psychiatric disorder independent of the physical illness. Many of the symptoms of depression overlap with those of physical disease (e.g. weight loss, fatigue, impaired sleep, pain; Creed 1997). It has been noted that the risk factors for psychiatric disorder in the physically ill are similar to those in the general population (female gender, living alone, single status, previous psychiatric history), together with aspects of the physical illness, notably its disabling effect and its treatment (Rodin et al. 1991).

The prevalence of psychiatric disorder in hospital samples depends on the location. Approximately 15% of medical in-patients have anxiety or depressive disorders; the same holds for out-patients with recognised physical disorders. The prevalence is higher (35%–60%) in out-patients with medically unexplained symptoms or syndromes (e.g. irritable bowel syndrome, chronic fatigue, headache). Approximately 18% of men and 4% women have alcohol problems, and dementia and delirium are common among older individuals in the general hospital setting.

3.3
Hypochondriasis in Patients Attending Secondary Care Settings

In a series of studies concerning medical out-patients, Barsky has demonstrated that 4%–6% have DSM-III-R hypochondriasis, compared to 13% with major depression, 8.5% with panic disorder and 5% with alcohol abuse/dependence. Co-morbidity of hypochondriasis and panic disorder is common, so these patients have three diagnoses – a physical disorder, hypochondriasis and panic disorder. Treatment of the panic disorder may lead to a reduction of hypochondriasis, emphasising the close relationship of the two diagnoses, but a majority of patients with hypochondriasis do not have panic disorder (Bass and Murphy 1996). One fifth also have an axis II (personality) disorder or somatisation disorder (Barsky et al. 1992).

4
Effect of Co-morbidity on Severity and Disability

4.1
Disability Associated with Co-morbid Conditions

Depressive disorders and chronic medical conditions have additive effects on patient functioning and well-being (Wells et al. 1989). In one study, respondents with a chronic medical condition who also had a psychiatric disorder were three times as likely to have spent 1 or more days in bed and twice as likely to have restricted activity because of illness than respondents with chronic illness who do not have psychiatric disorder (Wells et al. 1988a).

Patients with mixed anxiety and depressive disorders experience greater disability then those with "pure" anxiety or "pure" depression. Similarly, depressed patients with co-morbid panic disorder have poorer role and social functioning than those depressed patients without co-morbid panic disorder (Noyes 1990). The presence of anxiety co-morbid to depressive or medical disorders leads to a significant reduction of the functioning and well-being of patients, with an additional 3.8 bed days per month.

In the WHO Primary Care Study, there was a significant correlation between disability, whether rated by the doctor or the patient, and the extent of psychiatric disorder. A total of 31% of patients with a single ICD-10 psychiatric diagnosis rated themselves as moderately or severely occupationally disabled; in those with two or more psychiatric diagnoses, the figure was 50%. The study also found a less striking increase in disability in patients who had a physical disorder in addition to their psychological disorder. Further analysis indicated that both psychiatric and physical disorders were independently associated with disability. In relation to occupational disability, psychiatric disorder was somewhat more important. Both physical and psychiatric disorder contributed approximately equally to self-rated disability (Ormel and Costa e Silva 1995).

Patients with physical illness who also have a co-morbid psychiatric disorder have a worse outcome than similar patients without psychiatric disorder. For example, heart disease patients with concurrent depressive or anxiety disorders experience more chest pain and a worse quality of life than the remainder and are slower to return to work after a heart attack. Attention has been focused recently on patients with a recent heart attack, where concurrent depression is

an independent risk factor for early death, even after physical risk factors have been controlled for (Musselman et al. 1998).

4.2 Severity of Co-morbid Disorders

When depressive disorder is secondary to a prior anxiety disorder, it tends to be more persistent and more severe than depression without anxiety features. The increased severity is associated with greater self-perceived interference with life and activities, more suicide attempts and hospitalisation. In his longitudinal study, Angst (1996) noted that suicide attempts were particularly common in those who had either combined depressive disorders or a combination of major depressive disorder and anxiety disorder.

Data from the ECA study demonstrated that panic attacks and major depression occurred together 11 times more frequently than expected by chance. Patients with both disorders had worse symptoms than those who only had one disorder, but the pattern of symptoms was similar. This suggests that co-morbidity, in this setting, may represent a more severe form of depressive disorder.

4.3 Health Care Utilisation

In the NCS (Kessler et al. 1994), 22.5% of those with three or more disorders had attended a mental health treatment facility in the previous 12 months compared to 11.5% of those who had a single disorder. During the course of a lifetime, the figures were 41.0% and 26.2%, respectively. It is clear that those with co-morbid disorder consult more frequently than those with a single disorder, but these data indicate that only a minority of people with two or more disorders attend for treatment.

Similarly, in the general medical sector, the presence of depressive disorder in patients who also have organic disorder leads to increased health care utilisation (Barsky et al. 1986).

Paradoxically, although co-morbidity leads to additional demands and need for treatment, in certain settings it also reduces the chance that additional treatment is provided. Depression co-morbid with physical disorder is less likely to be recognised and treated than when depression occurs alone, as the attention of the doctor and patient is focused on the physical illness. When depressive disorder occurs with another psychological disorder, e.g. anxiety, the depressive disorder is more likely to be recognised because the depression is more severe. However, the concurrent anxiety is often missed leading to inadequate treatment. The same is true of depressive disorder in association with schizophrenia or substance abuse. There is also a considerable problem with recognition of substance abuse disorders among patients with schizophrenia (Citrome and Volavka 1999).

4.4 Response to Treatment

Depressed patients in primary care with a co-morbid anxiety disorder recover more slowly than the remainder and tend to terminate treatment prematurely more frequently than patients with major depression alone. A lifetime history of panic disorder in addition to current major depression led to a poor response to standard psychopharmacological and psychotherapeutic antidepressant treatments.

Panic disorders with co-morbid anxiety (including agoraphobia), depressive and personality disorders are less likely to improve with treatment than "pure" panic disorders (Page 1998). It has been recommended that co-morbidity in panic disorder be routinely sought, as the combination of disorders may respond particularly well to cognitive behaviour therapy. The high co-morbidity of neurotic disorders among panic disorder patients decreases after cognitive behaviour therapy, which is compatible with the concept that co-morbidity represents a more severe disorder.

5 Theories Surrounding the Aetiology of Co-morbid Anxiety and Depressive Disorders

There are different theoretical models of co-morbidity of anxiety and depressive disorders (Wittchen 1996; Kessler et al. 1998):

- One disorder (e.g. anxiety) may predispose a person to develop a second disorder (depression). For example, one hypothesis states that long-standing anxiety disorders predispose a person to develop later depressive disorders. The reverse may be true: depression could lead to anxiety.
- One or more common aetiological factors may be responsible for both anxiety and mood disorders. Such aetiological factors may be distant (e.g. genetic factors or lasting behavioural responses learned in childhood) or recent, such as life events or more situational behavioural responses.
- The "disorders" (anxiety and depression) may be different manifestations of the same disorder.

5.1 Primary or Secondary Depression

In the NCS, most cases of major depressive disorder were secondary, in the sense that they occurred in people with a prior history of another DSM-III-R disorder. Two thirds of the respondents in the NCS with a lifetime history of major depressive disorder had a previous history of another disorder (usually anxiety), i.e. this could be regarded as secondary depression. A further 12% of patients had "primary depression", i.e. the anxiety disorder only developed after the depressive disorder. The remaining subjects had "pure" depression, i.e. without any anxiety or other psychiatric disorder; this was more common among women than men (30% of depressive episodes in women and 19% in men).

The association between panic attack and depression is clear. The odds ratios between lifetime panic disorder and depression are statistically significant and substantial: for panic disorder with depression, the odds ratio is 6.2, and for panic disorder with depression, 6.8, i.e. a person with depressive disorder is six times more likely than others to experience a panic attack, and someone with panic disorder is 6.8 times more likely to develop depression. There are approximately equal numbers of those who experience depression first or panic first (Kessler et al. 1998).

When depression is secondary to anxiety or panic disorder, its onset occurs in very close association with the timing of anxiety disorder. However, when the primary disorder is agoraphobia, substance misuse or conduct disorder, the secondary depression occurs after a longer time lag (5–12 years), suggesting a much less close aetiological relationship.

5.2 Social Factors in the Aetiology of Anxiety and Depression

Brown et al. (1996) examined the role of social factors in co-morbidity of anxiety and depressive disorder. In a community sample of 400 women with children (a high-risk group for the development of depression), the 1-year prevalence was 16% for depression alone, 7% for anxiety alone and 16% for mixed anxiety and depression. The study indicated that both anxiety and depression were associated with the experience of childhood adversity (sexual or physical abuse or marked parental neglect) and with the experience of severe life events. The differences lay in the type of life event and current social situation. Whereas the onset of depression was associated with "loss" events (e.g. bereavement, marital or other family separation), the onset of anxiety was associated with a "danger" event (e.g. starting an affair or discovering a breast lump, which carries the risk of future threat). Women with co-morbid anxiety and depression had an excess of events that carried both elements of loss and danger (Brown et al. 1996).

The absence of adequate social support appears to be crucial to the development of depression, whereas in anxiety it appears to be unimportant. This suggests that anxiety disorders may be less responsive to current psychosocial factors.

In the second analysis, Brown et al. (1996) calculated the chances of anxiety and depressive disorders occurring together; this is likely: (a) as both are common in the population under study and (b) because the two disorders share a common antecedent factor – childhood adversity. However, even after taking these two factors into account, 47% of the co-morbidity of anxiety and depression remained unexplained; genetic or constitutional factors are suggested as the factors most likely to explain this remaining variance.

The last analysis in this study concerned the development of a new episode of depressive disorder during the year of the study. A depressive episode was three times more likely to develop in the context of an ongoing anxiety disorder than in a period free of anxiety. On the other hand, the reverse was not true: onsets of anxiety were not more common in the presence of ongoing depressive disorder.

Others have reported that the onset of anxiety disorders tends to precede or occur contemporaneously with depression, whereas the onset of alcohol misuse is equally likely to precede or follow the onset of depression (Merikangas et al. 1996).

Kessler and colleagues (1997) also found a link between childhood adversity and an increased chance of psychiatric disorder in adulthood. The clearest direct association lay between childhood adversity and mood disorders. Respondents who had co-morbid conditions reported a higher rate of childhood adversity than the remainder. The relationships between childhood adversity and addictive disorders were more likely to be attributable to an indirect link, i.e. through prior lifetime co-morbid disorders; in other words, the addictive disorders were more likely than other disorders to be secondary to another psychiatric disorder.

5.3 Genetic Factors in Major Depression and Generalised Anxiety Disorder

Using bivariate twin analyses, Kendler (1996) has tackled the question of whether genetic factors account for the common co-occurrence of major depressive

disorder and anxiety disorders. In a series of studies, he has demonstrated that the relationship between major depression and generalised anxiety disorder is greatly affected by the model of diagnostic scheme employed. If a non-hierarchical diagnostic classification was used, there was clear evidence of co-morbidity – if major depression was present, the odds ratio for generalised anxiety disorder was 8.9. If a diagnostic hierarchical model was used (so that generalised anxiety disorder that occurred only in the presence of major depression was not diagnosed), then the odds ratio fell to 3.9. Further analyses led to the conclusion that all the genes that influenced the liability to major depression also influenced the liability to generalised anxiety disorder. These results suggest that, although some environmental factors are both angiogenic and depressogenic, other environmental factors are relatively specific in their impact on the liability either to major depression or generalised anxiety disorder.

Further twin studies have suggested that common genetic factors are clustered into three groups. In one group, the genetic factors are shared by phobias, panic disorder and bulimia; a second set of genetic factors are shared by unipolar depression and generalised anxiety disorder; and a third genetic factor was specific to alcoholism (Kendler 1996). These results are not compatible with the idea that these six disorders are fundamentally distinct disease entities (Sullivan and Kendler 1998). They are also not consistent with the existence of a general neurotic syndrome, in which most or all of these disorders would result from the same genetic factors (Tyrer 1989).

6
Concepts of Co-morbidity: Dimensional Models for Mental Disorders

Some researchers reject the concept of co-morbidity between anxiety and depression, claiming that the same symptom contributes to both diagnoses (Goldberg 1996). Using latent trait analysis to visualise symptoms in dimensions rather than diagnostic categories, Goldberg and colleagues have found that two correlated dimensions accounted for all the common variance shared between symptoms. The more depressive symptoms were recorded, the more likely it was that a diagnosis of depressive disorder was made. The same was true of anxiety symptoms, but the majority of symptoms occupied shared space, i.e. they contributed to both diagnoses. The size of "co-morbidity" between anxiety and depression is not a measure of the frequency with which two independent morbid conditions co-exist; it merely indicates the extent to which symptoms contribute to both "disorders".

This model emphasises that anxiety and depression share a common cause, including the common genetic basis, the shared risk factor of parental neglect and abuse during childhood and the fact that pre-existing anxiety is a risk factor for depression. Certain social variables, such as dangerous events and inadequate social support, are seen to modify the symptom presentation rather than support the concept of independent disorders. Genetic factors are only seen as having a role in determining general vulnerability towards common mental disorders, but not at all in determining why one person develops anxiety and another depression (Goldberg and Huxley 1992).

An even broader view is taken in the concept of a general "neurotic syndrome", which has been suggested to describe a subset of patients whose symptoms are remarkably protean and who present at different times with varying symptom complexes of anxiety and depression. Consistent with this conceptualisation, psychiatric conditions approximating to these "neuroses" have a remarkable tendency to co-occur in epidemiological samples (Tyrer 1989). This model is similar to the view of a genetically determined general vulnerability, but is incompatible with the genetic findings of Kendler described above.

7
Co-occurrence of Physical and Psychiatric Disorder

The ways that physical and psychiatric disorders are associated show some similarities but some differences to the co-occurrence of psychiatric disorders. One difference lies in the category of psychiatric disorders which arise directly from physical disease (Creed and Guthrie 1996; Royal College of Physicians/Royal College of Psychiatrists 1995). There may be an obvious and direct link following cerebral involvement in disease (e.g. stroke, encephalitis, temporal lobe epilepsy), or there may be a less direct link. For example, there is an increased prevalence of depression in cancer, which may occur prior to the cancer becoming manifest.

The temporal relationship between the onset of the physical and psychiatric disorders has been intensely studied. This has led to the development of two distinct models. The first emphasises the importance of pre-existing life stress and depression, which is later followed by the onset of a physical disorder. This relationship is particularly close if the disorder lacks evidence of obvious organic disease, e.g. irritable bowel syndrome, chronic fatigue syndrome (Creed 1993).

A psychological disorder may develop following the onset of physical disease, and it has often been assumed that the pain, disability and potentially life-threatening quality of the illness leads to the later development of depression. This model is too simplistic, however, as other factors, including social support and prior history of psychiatric disorder, are involved (Creed 1990).

Part of the association between physical and psychiatric disorders can be understood in terms of an underlying, common aetiology. One example is the abuse of alcohol, which may lead to gastric or hepatic diseases associated with depression. Eating disorders may also lead to secondary mood disorders and physical illness.

Chronic fatigue syndrome and related disorders frequently co-occur with anxiety or depressive disorders. Whether this is true co-morbidity or whether they are different manifestations of the same disorder presents the same issues described above in relation to anxiety and depressive disorders. The close association between chronic fatigue and anxiety/depressive disorders may be similar to the anxiety and depression dimensions described by Goldberg (1996). Conventional explanations of the aetiology of these disorders characterised by pain or fatigue have assumed genetic, developmental, cognitive and social factors (Hickie et al. 1998). Recent research provides evidence for the role of health anxiety, treatment-seeking and neurobiological and physiological mechanisms in some of these patients.

The leading symptom in these disorders, apart from fatigue, is pain. Pain and depression are intimately related, and there are several ways in which pain and depression may be related (von Korff and Simon 1996). Neurotransmitters implicated in depressive illness also play a critical role in pain modulation. Chronic pain has been viewed as a form of somatisation in which negative emotions are expressed as bodily complaints. Somatosensory amplification occurs in depression, leading to an increased propensity to experience and report dysphoric symptoms, including pain. Depression may occur secondary to impaired social role performance and reduced activity levels as a form of learned helplessness.

8 Conclusion

Co-morbid disorders are frequent in population studies and clinical practice at primary and secondary care levels. Their importance lies in the fact that co-morbid disorders generally represent more severe forms of the constituent disorders compared to "pure" disorders. The co-morbidity is often overlooked because the doctor focuses on one diagnosis and may ignore the second disorder. Undetected co-morbid disorders tend to impair the prognosis of the first disorder.

The theoretical discussions will continue until such time as a combination of genetic, epidemiological and neurobiological studies indicates more clearly the relationship between disorders. It seems likely that there is very considerable overlap between anxiety, panic and depressive disorders and those concerning somatic expression of distress. The relationship between psychotic disorders and substance misuse and between physical and psychological disorders is more complex, as these may or may not be related disorders. There are a variety of reasons underlying the association. The practitioner should be guided by the statistical fact that if one disorder is present, then there is an increased, not reduced likelihood of a second disorder also being present. This must be detected and treated in addition to the primary disorder.
