In terms of treatment for depression in older people living in residential care, Ames (1990) was unable to positively influence the depression he encountered. However, there is some evidence from Rosen et al. (1997) that changes involving the milieu of the home (a recreational therapist working 1 h a day) can benefit depressed residents. Unfortunately, the benefit disappeared with the ending of the intervention.

Steuer (1982) listed the modifications which psychotherapists currently believe are necessary for the treatment of older people:

- The therapist needs to take an active role in directing any therapy, at the same time allowing the patient to actively seek solutions to their own problems.
- Current problems should be the focus of treatment.
- Education of patients about normal ageing and intervention by helping to plan daily activities and acting as a social advocate is necessary.
- The goals of treatment may be more limited than in younger patients, e.g. symptom reduction, acceptance of greater dependency, learning new coping skills and increasing self-esteem all may be useful to improve the patient's quality of life.

Assertion training, problem-orientated treatment and cognitive-behavioural therapies may therefore all have a place in management. Certainly, acute intervention in the face of physical illness and multiple losses has been strongly advocated for older people, as has the supportive value of therapeutic groups (Ong et al. 1987).

6.5 Multidisciplinary "Packages" of Care

Most work in secondary care old-age psychiatry occurs within the community and involves multiple interventions rather than simple prescription. Blanchard et al. (1995) examined the effect on depression identified by screening within the community of brief, individually tailored packages of care developed by a secondary care multidisciplinary team. The team included doctors, a social worker, psychiatric nurses and a psychologist, with occupational therapy and physiotherapy advice available. Initial assessments and treatment were carried out in the older people's own homes, the former by a research psychiatrist and the latter by a community nurse in liaison with the primary health care teams. At 3 months after intervention, they discovered a significant benefit in depression when compared with normal primary care management, and this benefit was particularly marked in older people with long-standing depression. The prescription of antidepressants as part of the treatment package (which was suggested in just under half of the depressed people) was met with resistance from both older people and their general practitioners. However, psychological interventions were accepted by everyone offered them. In a similar study to examine the effect of multidisciplinary management on depression in older people who were in receipt of home care in the community, Banerjee et al. (1996) discovered a marked treatment benefit when compared to a "normal treatment" control. Again, antidepressant medication did not appear to be a significant factor in the treatment effect. These two pieces of work counter the therapeutic nihilism frequently met with when working with depressed older community residents. They demonstrate a possible way forward to improve the prognosis of this group, with cooperation between secondary and primary care teams developing multidisciplinary care packages which are delivered in the home and coordinated by a "key-worker".

7 Public Health Issues

Western societies are oriented towards youth and the future and are increasingly rewarding productivity and accomplishment – the establishment of "meritocracies". This, along with the negative therapeutic attitudes as discussed above, engenders negative stereotypical attitudes towards older people. Among older people there is a tendency to attribute depressive symptoms to growing old or physical illnesses. Depressed older people either avoid seeking help or search for medical rather than psychological treatments; they carry with them society's false belief that discomfort and unhappiness are to be expected in later years. Consequently, older people tend not to be referred to mental health services, but if they are, it may only be once their problems have become chronic. When health care intervention occurs, it is invariably shared by several medical specialists, social workers and other health care professionals. It is sometimes unclear who is assuming responsibility for coordinating the efforts of all concerned. Without such coordination, the care delivery is fragmented and occasionally actions are counter-productive.

It is important to advance a mental health policy to counter this negative stance taken by our society. There should be primary preventative measures such as education about ageing during school years, preretirement counselling, education of medical students (particularly those who are to become primary care physicians) and education of the general public through television and newspapers. Secondary prevention measures should include the necessary screening questionnaires, training in various interviewing techniques and easy access to, or the development of, specialist multidisciplinary mental health teams with attached care managers, whose role would be to carefully coordinate management (WHO 1996). All mental health professionals need training in the recognition, assessment and treatment of depression in older people. Novel ways of trying to manage older people with depression or those at risk of depression in their own homes need to be investigated. One example could be the use of volunteer "befrienders" to decrease the isolation which is commonly associated with

depression, and another would be more socially oriented local "drop-in" centres, which could start to foster a sense of community among the old. Tertiary prevention will require the establishment of psychosocial rehabilitative programmes within residential and nursing homes to prevent the suffering that currently occurs from this treatable mental illness.

Psychiatric Treatment and Rehabilitation of the Elderly Mentally Ill

1 Therapeutic and Rehabilitation Strategies

Psychiatric disorders associated with old age encompass both pathologies which began in earlier periods of life and those arising after 65 years of age. One of their principal characteristics is that they frequently develop within complex contexts where physical and psychiatric co-morbidity is frequently encountered and where interpersonal, social, environmental and economic factors are much in evidence. While a clinical approach reveals signs and symptoms allowing us to arrive at a diagnosis, an in-depth analysis reveals the extent to which a particular patient's situation is unique, defined as it is by a multiplicity of parameters. A therapeutic approach must take this data into account.

An investigation into the components of an elderly person's psychopathological situation and the drawing up of a suitable treatment follow two phases – analysis and synthesis. The actual process is rather more complicated than that. In practice, through the relationship established with the patient, a doctor makes a number of observations which he or she then combines in such a way as to progressively create a coherent overall image of the patient's situation, allowing a therapeutic plan of action to be established. It is not enough therefore to simply submit a patient to a whole battery of scales, collecting information on symptoms, signs, functional disorders, degree of dependence, level of family responsibility etc. The juxtaposition of this sort of information merely serves to conceal the qualitative subtlety inherent in their interdependence as well as the fact that they emanate from an individual human being. In short, synthesis and analysis must be contemporaneous.

An analysis based on case history, an examination, subsequent observation and further examinations will result in a classification of psychiatric and somatic entities and a description of deficits and their consequences on everyday life in terms of disabilities, handicaps and functional disorders. An analysis will further elucidate the relational dimension, notably the patient's capabilities in areas of human contact. This implies both instruments of perception (sight, hearing) and cognition (e.g. attention, memory, language) as well as personality traits and the human network comprising family, friends and medical contacts. Finally, an analysis will supply information on the practicalities of the patient's existence – the location and layout of his or her home, the degree of isolation, economic resources and use of care and support organizations and of the social services.

In view of such complexity, one speaks of a therapeutic strategy rather than a treatment. This presupposes a structuring of the various procedures employed in achieving a common end result. The term "strategy" also implies a time element. This time element is intimately integrated into the provision of medical care, a term which takes on broader dimensions allying clinical and therapeutic observation, analysis and synthesis, and fact and intuition.

Therapeutic strategy in geriatric psychiatry provides a good illustration of medical complexity where it is not only the illness that is in question, but the patient him- or herself. The older the patient, the more numerous the parameters implicated in defining his or her pathological situation. Rare are the cases where the simple treatment of a disease such as depression or delirium will result in the return of good health. In the majority of cases, doctors finds themselves in a system where causality is not linear but circular. For instance, delirium caused by an infection will increase if the fever-induced dehydration is not corrected. Consequences are transformed into additional causes.

This complexity is also related to the diversity of types of treatment employed. Simultaneous use is frequently made of biological means, relational techniques and measures aimed at rehabilitation, the latter producing an associated psychological impact. Finally, a therapeutic strategy needs to be adapted to each individual patient depending on the multiplicity of criteria which constitute his or her psychiatric and somatic illnesses and the behavioural pattern resulting from the disorders or influenced by character and motivation.

Any such therapeutic strategy must, therefore, encompass a logical coordination of various types of treatment as a means to an end which is unique in each individual case. This strategy could be that of rehabilitation defined as a number of medical, psychiatric, psychological and social measures coordinated into a joint programme whose aim is the restitution or conservation of optimum autonomy. This definition includes the aspect of complexity, the necessity for flexibility between therapies and the need for a realistic outcome, the aim of which is not a return to normality (which would be largely utopian in this age category), but to a reasonably adapted degree of autonomy. Finally, this strategy must be sufficiently supple to allow adaptation to individual problems and to the degree of evolution existing at the time of rehabilitation.

Elderly and very elderly individuals possess certain characteristics which indicate a degree of adaptation of normal rehabilitative measures. The tendency towards psychomotor slowing dictates the use of slower rhythms of activity than those used with young adults. The goal is rarely that of return to some professional activity. Hence, a rehabilitation treatment aims at

better adaptation to normal day-to-day activities and better social integration, including an assertion of the individual role. The problem of patients' motivation in cooperating in what is being done for them is particularly crucial. An apparent absence of such motivation is, however, no reason for giving up. It can be simply a manifestation of a disorder such as depression. The strategy then needs to be adapted to include a progressive resurgence of motivation. In such cases, rehabilitation will tend to channel its activities towards creating adaptation within the framework of daily life. Consequently, rehabilitation measures would be modulated so as to correspond to the nature of the disorder, its intensity and the patient's potential ability to cooperate.

The techniques employed in any therapeutic strategy may be divided into four categories (Table 1). The first of these comprises types of biological treatment which aim at pathological processes and are based on knowledge in the domains of the neurosciences, particularly neuropathology, neurobiology and neuropharmacology. The second concerns what patients, their friends and family and their carergivers are living through. It requires structured psychotherapy, psychological support or counselling. The third category brings together a group of techniques which tend to reproduce situations aimed at re-establishing skills, e.g. training in daily tasks of living, occupational therapy or social skills training. The final category of techniques aims at adapting the environment to disabilities and handicaps. It is of particular help to patients in teaching them to cope with their habitat and its space, and household and leisure equipment, while at the same time increasing safety. This type of passive adjustment encourages a greater margin of autonomy.

2 Biological Treatments

2.1 Medication

In general, the prescription of medicines to the elderly should be limited to substances that are absolutely essential. The high frequency of polymorbidity results in patients being exposed to multiple prescriptions with the concomitant risks of drug interaction and poor compliance.

Pharmacokinetics change with age. There is a slowing down of absorption, transfer, metabolism, distribution and excretion of medicines. Such changes can have an important effect on the plasma levels of psychotropic substances such as tricyclic anti-depressants. The resorption of these substances can be slowed down by their own effect on intestinal peristalsis, with their transfer by albumin being reduced by 15%–20%. This results in an increase in the free fraction of the substances, with their half-life being increased – due to their accumulation in the fatty tissues of the organism – from 10% at 20 years of age to 50% at 60. To that can be added a possible reduction in enzyme breakdown by the liver and a slowing down in the rate of elimination due to a reduction in the glomerular filtration rate, which falls by 50% between 20 and 70 years of age.

Compliance is influenced by numerous factors, particularly in elderly patients suffering from mental disorders. These factors are of three main orders. The first of these concerns the patients themselves – their cognitive ability, particularly memory, the ability to understand the objective pursued by the treatment and the ability to organize taking medication. The necessary motivation to take care of themselves is also implied here. This can be severely compromised where patients' awareness of their illness is low or non-existent, as can happen in cases of dementia and psychotic disorders or where a severe depressive disorder results in notions of incurability. The second factor influencing compliance is the doctor, who needs to reinforce his or her prescription by clear explanations concerning the reason for the choice of medication, the times when the medicines should be taken, their mode of action, the risk of side-effects and what attitude to adopt should they appear. Ideally, an elderly

patient should not be required to take more than three medicines at one time. The third factor comprises the medicines themselves: their size, taste and any undesirable effects. The doctor must take care not to complicate an already complex treatment by multiplying the galenic forms of the prescribed medication.

2.1.1 General Medication

Co-morbidity results in important reciprocal influences between psychic and somatic disorders. Some physical illnesses can lead to mental disorders, particularly in the elderly. Delirium is an example of a disorder which can result from an infectious disease (e.g. bronchopneumonia), a metabolic disturbance (e.g. dehydration, hyper- or hypoglycaemia) or medication (tricyclic anti-depressants, antiparkinsonian drugs). Another example, hypothyroidism, can be the cause of a depressive disorder. Conversely, mental disorders can have somatic consequences, particularly of a general nature, due to alterations in alimentary behaviour – negligence in the variety of food ingested by a demented person or lack of appetite in a depressive. On the other hand, the unexpected arrival of a physical illness concomitant with a mental disorder may aggravate a state of dependence and accentuate the psychiatric symptoms in the form of a regression, for instance. The diagnosis and treatment of physical illnesses are, therefore, indispensable in the context of geriatric psychiatry.

2.1.2 Psychotropic Medication

The whole range of psychotropic medication – neuroleptics, anti-depressants and tranquilizers – are accessible to the elderly. However, some precautions need to be respected because of the risk of side-effects. Most neuroleptics can trigger extrapyramidal syndromes (EPS) or increase the intensity of pre-existing EPS. Tricyclic and tetracyclic anti-depressants (TCA) have atropinic effects and are contra-indicated in cases of closed-angle glaucoma, cardiac conduction disorders and prostatism. Benzodiazepine tranquilizers (BZD), because of their dual sedative and muscle-relaxant action, can lead to patients falling down. These substances, which are among the most commonly taken by the elderly, can also lead to memory impairments. This assertion must, however, be treated with reserve, since the anxiolytic effect inherent in these drugs can also lead to beneficial consequences on memory functions by removing the anxiety which inhibits them. Of the three groups of psychotropic medication mentioned so far, only BZD are likely to bring about dependence.

A corollary of the high side-effect potential of psychotropic drugs is the on-going research into the development of less toxic substances. Unfortunately, powerful but harmless medication is not yet available to us. However, considerable progress in this direction has been made over the last 10 years. Among neuroleptics, clozapine has established itself as an anti-psychotic without EPS but with a risk of agranulocytosis. To the range of anti-depressants drugs have been added that are totally lacking in atropinic effects. These include a selective monoamine oxidase inhibitor (MAOI-A) called moclobemide, serotonin reuptake inhibitors (SSRI), such as fluoxetine, fluvoxamine, citalopram and sertraline, and serotonin and noradrenaline reuptake inhibitors (SNRI) such as venlafaxine. However, SSRI and SNRI produce side-effects in the digestive system.

It must be said that clinical pharmacological investigations involving groups of elderly persons are few and far between. Those that exist usually concern subjects of less than 70 years of age and conform to strict exclusion criteria. However, the clinical reality is such that the majority of candidates for psychotropic medication suffer from polymorbidity and a high percentage of them are very elderly. Their introduction to psychotropic substances must therefore be largely empirical. However, a certain number of guiding principles should be followed. In general, the initial dose should be a third of the normal adult dose. This will be adapted progressively as a function of tolerance. Where intercurrent somatic diseases occur, the dosage must again be modulated, particularly where neuroleptics have been administered to the mentally ill to calm their agitation. Preference should be given to substances whose side-effects are compatible with the patient's physical state. The administration of neuroleptics and anti-depressants can be monitored by regular measurements of serum level.

Psychotic Disorder

Stabilization of chronic psychotic illnesses among the elderly is usually achieved using strong doses of neuroleptics – identical to those of a young adult – either orally or by depot injection. Tardive delusions, the themes of which are usually theft and intrusion by third parties, only necessitate medication where great behavioural changes occur and where anxiety is present. In such cases, suitably adapted doses of sedative neuroleptics (chlorprothixene, thioridazine, clozapine) would be used where anxiety predominates, and incisive neuroleptics (e.g. haloperidol, moperone, pipotiazine) where it is absent.

Depressive Disorder

The administration of anti-depressants is imperative in the presence of depressive disorders. First-intention medication is likely to consist of SSRI, SNRI, selective MAOI or mianserine. SSRI share both the same method of action and the same therapeutic impact so

that they are frequently difficult to distinguish from one another. This is not the case for tricyclics and tetracyclics, of which some (imipramine, nortryptiline) tend to have a stimulating effect, whereas others (amitryptiline, maprotiline) have a tranquilizing effect. Despite their atropinic effects, these drugs should not be prescribed. They may be employed as a second resort or as a first resort where they have already proved their effectiveness in previous attacks, assuming there to be no contra-indication. Mianserine is indicated for depression disorder with anxiety. Where severe depression is accompanied by delusions, an association of an anti-depressant and an incisive neuroleptic is indicated.

In cases of resistant depression (absence of therapeutic response after 3 months and at least two changes in medication), an association with lithium (0.5–0.7 mmol/l) can be tried and, if that has produced no result after 2 weeks, electroconvulsive therapy (ECT) should be envisaged. Thymoregulators (lithium, valproic acid, carbamazepine) are still indicated in cases of bipolar disorders. A maintenance dose of anti-depressant should be continued for at least 2 years following remission of recurring depression.

Depressive disorder can be associated with mild, moderate or even severe cases of dementia. The prescription of SSRI is particularly indicated in cases of dementia associated with Alzheimer's disease where a serotonin deficit exists. Moclobemide may also be indicated here, since this type of dementia is accompanied by an increase in MAO.

Hypomania, regardless of whether it is episodic or has a durable influence on dementia, reacts well to haloperidol.

Delirium

As far as possible, treatment of delirium should only be directed at the cause of the illness: infectious disease, metabolic disorder or stopping the involved medication. Treatment can also be helped enormously by placing patients in reassuring surroundings with particular emphasis on helping them to orientate themselves correctly with respect to time, place and situation. However, a high intensity of agitation may necessitate treatment using medication. In such a case, oral administration of low-toxicity clomethiazole may be recommended.

Anxiety Disorder

Anxiety disorder is often associated with depressive disorder. Panic disorder is less common and may be treated, as for young adults, with SSRI. Medication used to treat anxiety is above all the benzodiazepine group (BZDs), which may be used, where necessary, in association with an anti-depressant. Depending on the clinical situation, BZD can be prescribed with medium-to-long-term action (bromazepam, lorazepam, alprazolam, oxazepam) or very long term action (prozepam, ketazolam, clobazam). Molecules with medium-to-long term action are used when symptoms require it, whereas those with very long term action cover states of permanent anxiety. It is important to limit the period of administration as much as possible and reduce the dosage progressively. Alternatives to BZDs are the sedative neuroleptics (thioridazine, chlorprothixene, levomepromazine) administered in small doses. These have the advantage of possessing few side-effects at such doses and do not induce dependence. Another possibility is buspirone, the anxiolytic effect of which is not optimal until after 7–10 days.

Sleep Disorder

Insomnia in the elderly is very often either the symptom of a physical or psychiatric illness or the manifestation of a psychological problem. Any prescription of sleep-inducing medication should be preceded by an investigation into the causes of the problem, causes on which it should be possible to act, e.g. cardiac insufficiency treatment, pain-killing. On the other hand, it is important to bear in mind the physiological changes as regards sleep that take place with age, notably a lengthening of the latency period for sleep to come after 70 years of age and an increase in the number of wakenings during the night.

Where a sleep disorder is associated with a depressive disorder, the administration of a tricyclic anti-depressant (amitryptiline, trimipramine) just prior to the patient's bedtime may suffice. Where recourse to a hypnotic is judged necessary, preference should be given to substances with which the risk of weaning and insomnia rebound symptoms is small (chloral hydrate, zolpidem, zoplicone). Occasionally, it is impossible to avoid administering BZD. In such cases, a choice has to be made between BZD with short- to very short term action (midazolam, triazolam) where the problem is that of experiencing difficulties in getting to sleep, or with medium-term (lormetazepam) or very long term action (flunitrazepam) where the problem is one of disturbed sleep or premature wakening. It is also possible to associate zolpidem, zopiclone or chloral hydrate with a retard form of neuroleptic (30 mg thioridazine retard). The administration of hypnotics should be limited in time. However, it may be necessary to allow some patients who have grown accustomed to taking a sleeping pill at night to continue to do so indefinitely.

2.2 Electroconvulsive Therapy

ECT is a treatment which comes up against prejudices that are of a strictly emotional nature. Yet it remains a

highly effective and often last-ditch means of treating serious psychiatric situations in the elderly. Indications concern severe depressive disorders with agitation and/or delirious ideas of ruin, blame or incurability. The sudden appearance of such a clinical picture can indicate an ECT as a first-line treatment. This treatment is used more frequently for resistant depressions and where the severity of the depression is such that the patient's life may be in danger. Less frequent indications are manias resistant to neuroleptics with accompanying lithium intolerance and depression associated with Parkinson's disease.

There are few contra-indications other than space-occupying lesions, although cardiac conduction disorder and recent myocardial infarction require caution. It should not be forgotten that a spontaneous epileptic seizure rarely has any serious effect on general health. Where ECT sessions are conducted at a rhythm of two per week for 3 or 4 weeks, the only complication is likely to be narcosis. Reversible confusional states and amnesia limited to the circumstances of a particular treatment episode are occasionally observed. Where dementia is associated with depressive disorder, unilateral ECT may be used. This implies less risk of confusion and memory disorder (Wilkinson 1994).

2.3 Light Therapy

Light therapy is indicated in cases of seasonal depression, even beyond 65 years of age. Such depressions tend to occur towards wintertime when there is less sunshine. They are frequently accompanied by an over-consumption of sweet things.

3 Psychotherapeutic Treatments

The patient–doctor relationship has in itself psychotherapeutic potential. During the first contact with a doctor, the patient often talks of physical complaints which may well be an initial movement towards tackling the themes of psychical and existential suffering. The patient's interlocutor must thus adopt an attitude of listening and observation, hence manifesting availability. At the same time, this attitude demonstrates the doctor's recognition of the patient as an individual.

Like all other health care personnel, doctors must be aware of their potential role as a mirror in which patients who have lost their self-esteem may rebuild it again. Hence psychotherapeutic input is not the sole business of specialists. It is implicit in all exchanges between carers and patients. This dimension must be taught at the same time as the characteristics inherent in each of the three periods of life, including old age, within a developmental perspective of the individual from birth to death. Indeed, the issue is not only to recognize and accept the losses accompanying old age, but also to restore a coherent, integral vision of the self, without a break and without abandoning what has become integrated into a whole life throughout its life span.

In principle, all types of psychotherapy applicable to adults can be used with the elderly, whose population is in fact very heterogeneous. It must be realized that, due to their cognitive and affective resources, some elderly individuals are able to undergo classical formalized psychotherapies implying a profound restructuring within themselves. This is often true of patients who have experienced such approaches during their active life and would like to continue with or reactivate them. However, many elderly patients requiring psychotherapeutic help are impaired in their perception (sight, hearing), in their capacity to move around or in their cognitive faculties. Such limitations must in no way be used as arguments for renouncing psychological help and abandoning patients in disarray.

Several problems lie behind the more or less conscious reticence of the psychotherapist to treat elderly patients. One of them is historical in nature. Despite the fact that he continued his self-analysis up to his death at the age of 83, Freud maintained that beyond the age of 40 psychic rigidity prevented any reappraisal of an individual. This prejudice – which is no longer accepted – can nevertheless, within the framework of an orthodox position, serve as an alibi either to abandon any attempt at treatment or remain on a superficial level even where exploration at greater depth is eminently possible. Another obstacle is the difference in age and generation between the younger therapist and his or her patient. The ambiguity here lies in the fact that the patient's life experience is likely to be much broader than the therapist's and that the patient is in a phase of existence way outside the latter's experience. In addition, the transferential relationship is itself the object of a further ambiguity since the therapist may well be identified successively or even simultaneously with a paternal or maternal image and a filial one. Another problem is that of time. Is it worthwhile undertaking steps the hypothetical benefit of which is limited by the approach of death? A corollary to this question is, for the therapist, the inevitable confrontation with the certitude of the fatal issue of existence. One final point to add is that the elderly patient can be experienced as an object of conflictual identification to the extent that, for the therapist, he or she may personify parents with which

relationships are difficult. This ensemble of questions contributes to the situation where psychotherapeutic help to the elderly is an area in which too many psychiatrists and psychotherapeutic psychologists refuse to become involved – a curious paradox in the context of our ageing society.

The needs are indeed enormous, given that the elderly are particularly exposed to situations of loss during a period in their existence where their capacity for adaptation is reduced. Some contribution of a psychotherapeutic nature ought to be available to everyone. Such a proposition is only possible from a pragmatic viewpoint where basic notions have been communicated to all those concerned so that, through indirectly relating various therapeutic techniques, contributions of a psychotherapeutic nature can be transmitted. The trained psychotherapist would intervene in particular situations and act as referent for the medical staff.

3.1 The Psychotherapeutic Attitude

The basic attitude to adopt conforms with general principles. The first of these is to consider elderly individuals, whether or not they are ill, as unique individuals with their own history and their own experience consisting of successes, failures and suffering. The second is to be available, i.e. attentive to the patient's expressed or implicit needs, and to be open to dialogue. The third is to maintain a suitable distance so as to avoid any harmful identification with the patient and to allow the necessary free reflection in order to arrive at an appropriate course of action. The fourth is to establish and maintain contact, whatever the sensory, cognitive, emotional or behavioural obstacles. The fifth is to appear consistent in one's way of behaving and communicating. The aim of these few rules is to encourage patients to develop a positive attitude towards themselves and to minimize the likelihood of the onset of depressive self-depreciation.

3.2 Types of Psychotherapy

The complex nature of the problems encountered necessitates flexibility in the classical psychotherapeutic concepts which advocate neutrality. Once again, even if the strict application of this principle should not be excluded, with some elderly patients these concepts are more likely to be laid aside in favour of joint therapies consisting of a mixture of psychodynamic interpretation, advice, concrete medico-social interventions and the prescription of medication. This flexibility also needs to be extended to the setting. A consultation should be face-to-face. It can take place on the therapist's premises or at the home of the patient, particularly if he or she lives in an institution. Consultations last between 20 and 45 min. The frequency of sessions depends on the severity of the symptoms and can vary between once or twice a week to once a month or less. When regular meetings are no longer necessary, the therapist remains available as a potential stand-by. This provides reassurance and a structuring point of reference. Consultations at regular intervals, arranged on the patient's initiative, also act as reference points and possess undoubted preventative value. In this way, a psychotherapy normally does not come to an end, but remains an on-going available resource.

3.2.1 Individual Psychotherapy

There are three main trends in individual psychotherapy for the elderly. These are psychotherapy based on support, on psychoanalytical methods and of a cognitive–behavioural nature.

Support-Based Psychotherapy

Support-based psychotherapy is probably the most frequently employed method of individual psychotherapy. It is particularly indicated where insight capacity is poor or when the patient is handicapped from the cognitive and sensory points of view. The mere fact of being listened to, implying recognition, tends to reassure patients. It helps and guides them in their decision-making, in approving whatever they undertake and in helping to provide whatever assistance they require. It is in short an approach aimed at recovery and tries to encourage elderly individuals to have recourse to their own resources.

Analysis-Based Psychotherapy

Analysis-based psychotherapy brings out a patient's faculties for introspection. The value of this model lies not only in the treatment it gives rise to but, also in its role as a reference point in the understanding of a given situation. The emphasis is laid on unconscious defence mechanisms, particularly those dealing with loss of faculties and fears accompanying old age. This period of very great vulnerability results in anxiety which may well be linked with similar previous experiences, particularly during childhood or adolescence, both phases of life characterized by fragility. Whereas support-based psychotherapy focuses on the present time, analysis-based psychotherapy aims at establishing links between the present experience and significant facts of past life. This method of approach is particularly indicated in depressive disorders.

Cognitive-Behavioural Psychotherapy

The same is true of cognitive-behavioural psychotherapy, which focuses on what the depressed patient is experiencing in his or her thoughts. This obviously assumes a capacity for introspection on the part of the patient. These thoughts are invaded by cognitive distortions in the form of exaggerations, of disproportionate reactions, of false interpretations - all impregnated with pessimism and feelings of guilt, indignation and incompetence. This realistic, pragmatic method of approach comprises four components: learning to identify negative thoughts, establishing a link between these negative thoughts and depressive feelings, learning to identify and modify the types of deformed thoughts which govern the negative feelings and incorporating this procedure in the development of a point of view which is less deformed and more adapted to oneself and to one's place in the world of today and the future (Meador and Davis 1996).

3.2.2 Group Therapy

Individual psychological problems often feature a social dimension in the broadest sense possible. This may have a negative influence on the individual's integration into society or into his or her own group structures or it may result in a loss of equilibrium within the immediate entourage, namely family and medical staff. Group therapy therefore has several potential objectives, including the reinforcement of self-esteem through interaction with others, better self-knowledge through common introspective procedures, giving value to oneself, one's decisions, one's actions and abilities through confrontation with others, mutual psychological support, exchange of experiences, exercises in sociability, adjustment in the relationships within families and couples, particularly in crisis situations, and the psychological support of medical teams.

This multiplicity of objectives lies at the origin of the large number of techniques employed. Hence one can distinguish groups centred on current psychological problems, on memory recall, on facts of day-to-day life and on interpersonal relationships - both those with a psychoanalytical orientation and those using group analysis or cognitive-behavioural therapy. To these must be added self-help groups for patients having the same pathology (e.g. Parkinson's disease) or for families of chronically ill (dementia) patients. Family intervention, which usually uses systematic concepts, is employed in critical situations when, for instance, a psychiatric pathology suddenly affects an elderly patient. Its objective is to help the family group to mobilize and harmonize its resources not only to solve the current problem but also to reinforce the group so as to be able to deal with possible similar situations in the future in an autonomous way.

4
Re-adaptive Treatments

Whereas medicine-based treatments are targeted on symptoms and psychotherapeutic approaches are essentially subjective, re-adaptive treatments attack functional disorders resulting from the illness. However, while this always remains the main objective of such techniques, they may also have an impact in the same areas as the two other categories of treatment.

4.1
The Corporal Approach

The corporal approach provides a good illustration of the potential diversity of impacts mentioned above. With the onset of old age, relationships with the body may change in so far as the capacity to perform is lowered and motor and sensory handicaps appear. As old age progresses, a retrogression in bodily functions may appear with a lowering of motor activity. Some organic cerebral problems - notably parietal lesions - are accompanied by disorders in the perception of the corporal image. Finally, the subjective perception of the body is intimately intermingled with psychiatric states such as depression, psychosis, somatoform disorders and hypochondria. The number of techniques adapted to these various situations is legion. One common element which should be more or less exploited is the relationship which invariably develops in this type of approach.

4.1.1 Physiotherapy

Physiotherapy used in geriatric psychiatry often assumes the double role of the re-adaptation of motor functions and as a means for psychotherapy. Without being verbalized, several subjective parameters are implicated, e.g. the degree of intrusion by third parties that can be tolerated or how to manage distance. A psychotherapeutic treatment also frequently helps in reinforcing self-awareness through the body and reactivating motor potential, all of which implies an enhancement of a patient's self-image. This lever is particularly useful in depressive states where verbal expression is inhibited.

4.1.2 Psychomotor Therapy

Psychomotor therapy aims at "improved corporal awareness (feelings, emotions, speech and thought)" (Bovier and Ramseier 1995). Observation of the motor function constitutes the first phase. This provides an image of the patient's "body style" and leads to the elaboration of a course of treatment acting on the main bodily functions – space/time motoricity, sensory impressions, feelings, movement coordination and visceral functions. This type of therapy applied to elderly subjects aims at encouraging them to adapt to their ageing body by accepting its limits and reorganizing their own capabilities. In addition, it reveals the patient's unique physical semiology and its link with psychiatric disorders and allows a remedial approach to be developed.

4.1.3 Relaxation Techniques

Relaxation techniques (Schultz's autogenic training or the psychotherapeutic relaxation of de Ajuriaguerra) or similar (Alexander's eutonia) may also be used with elderly patients. Their common factor is the use of bodily knowledge to increase self-knowledge.

4.1.4 Gymnastics

Gymnastics helps both to maintain physical fitness and to discover and practice the possibilities inherent in physical movement. In addition, being part of a group is valuable from a socialization point of view. Taking part in ball games in a sitting position introduces stimulation through emulation and competitiveness. This is particularly useful with patients whose psychiatric illness isolates them from contact with others.

4.1.5 Occupational Therapy

Occupational therapy employs a technique of confrontation between the patient and the outside world with a view to encouraging his or her adaptation to day-to-day existence. It can be used equally well at home or in a clinic, hospital or long-term institution. Depending on the particular objective in view, three types of occupational therapy may be defined – functional, psychiatric and dementia specific. The first of these is destined more specifically for re-adaptation of the upper limbs following traumatic, neurological or rheumatological damage. It employs supervised activities aimed at practising certain movements, e.g. weaving. In addition, it concentrates on an adaptation to a normal living environment by encouraging day-to-day activities and modifying this environment so as to accommodate handicapped persons.

Psychiatric occupational therapy is mainly concerned with relationships and creativity. In the course of various activities, patients establish contact with the occupational therapist and with other patients. In addition, through their own creative efforts, they learn to control the external world once more and re-establish a sense of values through the objects they have created.

Dementia-specific occupational therapy adapts activities to patients' abilities. It attempts to mobilize not only the abilities they use spontaneously but also potential, underemployed ones and those not employed at all. A potential pitfall is overstimulation, which may result in catastrophic reactions. These techniques may be applied both in individual and group situations. An important aspect of the therapy is observation with a view to recognizing areas where remedial care is necessary. A simple example is to arrange clothes in the order they should be put on for a patient suffering from dressing apraxia. Subsequent treatment would depend on the gravity of memory and attention-span disorders. The principle is to encourage patients to act rather than acting for them.

In the field of occupational therapy too, it is often difficult to separate what is functional and what is psychiatric re-adaptation in geriatric psychiatry. In reality, occupational therapy can usually be said to be of an integrated type, with the driving force being relationships and where the objectives of physical mobilization and discovery or re-development of an awareness of personal capabilities have an implicit psychotherapeutic impact.

4.2 Sociotherapy

Sociotherapy forms part of the broader concept of animation, i.e. the attempt to encourage some form of activity. In concrete terms, this is manifested by what is undertaken, be it at home or in a group environment, to maintain the natural rhythms of life alternating between activity and rest, effort and relaxation, action and passivity, constraint and freedom, wakefulness and sleep. Thus, in the particular case of an institutional situation, life must be modulated so as to integrate a multitude of rhythms, including influences due to habits, to what is planned and what is unforeseen and to daily, weekly or more distant events based on monthly, seasonal or annual rhythms.

The implicit aim is to encourage an awareness of time by creating points of reference in the present, past and future and developing memory and anticipation.

Sociotherapy is a technique which employs group dynamics. It is organized in a particular place and structures time by employing various activities such as stimulating interest in what is going on in the world, games and activities in areas such as physical exercise (e.g. gymnastics, walking), creativity and housekeeping (cooking). A patient has the possibility of influencing decisions. While the general aim remains the animation of the patient, sociotherapy also encourages self-awareness and self-esteem by virtue of the roles he or she assumes, the mobilization of his or her abilities and experience and the confrontation with others both as individuals and as a group.

4.3 Art Therapies

Art therapies are methods of approaching rehabilitation that employ the therapeutic potential of artistic activities. They operate simultaneously on cognitive faculties, affectivity and bodily perception.

Music is capable of mobilizing perception as much as expression and communication. It implies, through rhythm, an awareness of time and, through melody, the emotional sensitivity that is unique to each individual. Finally it stimulates memory from the points of view of recall, of affective recollection of the past and of procedural retention.

Music therapy calls on all of these aspects and endeavours to exploit them to the full in a carefully planned, rigorous and methodical fashion (Verdeau-Pailles 1995). These methods are based on listening or on improvisation and creativity. The chosen approach depends on the pathology and personality of the patient. A depressed patient, for instance, is likely to be more open to an adagio than an allegro. Music therapy is especially indicated where patients' ability to give verbal expression to their experiences is poor, notably in cases of psychosomatic disorders. Hence its field of action is very wide indeed. It includes dementia, in which music has proved to be a surprisingly effective tool capable of stimulating seriously ill patients to remember melodies and words of songs. Their participation in improvisation groups, using instruments of percussion or simple stringed instruments such as a dulcimer, provides them with a non-verbal means of expression and reawakens in them an awareness of rhythm, and hence time. Finally, music is used in dance, which can remobilize dormant rhythmic abilities often intact in demented patients.

Art therapy is fundamentally creative. Mainly employing drawing, painting and modelling, it provides a glimpse of the non-verbal area of a patient's inner life. As such, it reveals conflict as well as positive development. The created work or work in progress may also lend itself as a useful means to initiate a dialogue with considerable therapeutic potential. Even if the production goes no further than a few simple lines, as in the case of severe dementia, it has value as a manifestation of attention and intention. Art therapy may be practised as an end in itself or as an integrated part of occupational therapy or sociotherapy.

4.4 Memory Re-adaptation

Memory is a complex function comprising a number of subsystems said to be of the sensory, primary (short-term, work-associated), secondary (long-term), procedural (implicit) and prospective types. Normal elderly individuals employ memory-training techniques aimed at improving performance through the use of strategies which help recall things to mind. Use can be made of external means (diaries) or internal procedures, which may be verbal or employ visual imagery. Memory training may be carried out in groups ("memory workshops"), where emulation is obtained through the use of exercises based on different sensory registers. The advantage of this technique is that it adds a certain sociotherapeutic value. Memory complaints form part of an ensemble in which affectivity plays an important part.

4.5 Auxiliary Means and Adapting the Environment

Sensory disabilities produce negative consequences on an individual's control of his or her surroundings which may affect emotional susceptibility. Correcting or improving visual and auditive disorders using spectacles, crystalline lens implants or hearing aids is of primary importance. The employment of auxiliary means to help in walking (canes, crutches, walkers), instruction in the use of a wheelchair or the wearing of braces are indispensable methods to improve mobility and combat the psychological effects of a reduction in autonomy.

The environment in which patients live must also be adapted to their disabilities. This implies the modification of any obstacles which may occupy their living space and principally concerns the occupational therapist. To these modifications based on individual requirements need to be added more general adaptations in the architectural and ergonomic arrangements

of the patient's environment. From the architectural point of view, hospitals and similar establishments must be designed taking the characteristic needs of elderly patients into account. Ideally, the surroundings should provide the best quality of life possible. Particular attention should be paid to access, volume of living space, lighting, safety and signposting to facilitate orientation. Ergonomic factors are the business of furniture and hospital equipment designers. Ergonomics is at the origin of the discipline called gerontechnology, which introduces technical progress into the gerontological domain and adapts it accordingly. Examples are teletheses ("electronic prostheses"), which allow some operations to be carried out at distance (e.g. door opening). Gerontechnology also looks into the adaptation of equipment used by elderly handicapped persons in their everyday life (e.g. household appliances, TV, radio) and tries to find technical solutions to problems of rehabilitation. In short, all these measures of adaptation aim at remedying the fact that normally constructed environments, means of communication and consumables are not designed to take the disabilities of handicapped persons into account. Such measures must be integrated into the basic principles of rehabilitation in geriatric psychiatry.

4.6 Rehabilitation Organization

Rehabilitation in geriatric psychiatry employs the skills of a wide number of professionals, notably doctors with a variety of specializations (e.g. psychiatrists, psychogeriatricians, geriatricians, neurologists, internists), psychologists, social workers, nursing staff, occupational therapists, sociotherapists, physiotherapists, psychomotoricians, speech therapists and so on. To this vast array of disciplines has to be added the complex nature of the network of care and support in which the patient exists. The obvious risk that may be run in such a situation is that of therapeutic anarchy if communication and information exchange is not well organized. The danger may be further increased if the same philosophy towards patient care is not shared by all concerned. Hence the organization of rehabilitation must be coherent, must create a framework for discussion and must transcend individual organizations, i.e. must encompass the whole network.

The path followed by a particular patient may pass through several stages such as out-patient services, day care or short- and long-term hospitalization. A consistent approach in both objectives and attitudes is essential throughout these various stages. In addition, the multi-disciplinary team must coordinate the interventions of its members as a function of a common, rehabilitative objective which may be, for instance, the patient's remaining at home. The achievement of this objective will depend on the achievement of the specific objectives fixed by each of the professions as a function of its technical competence. Hence the patient is the object of a multidisciplinary project, the methodology of which (Rufini and Gaillard 1996) could well be that presented in Fig. 1.

A philosophy of patient care with the objective of rehabilitation requires the multi-disciplinary team to establish an interpretation of the patient's situation

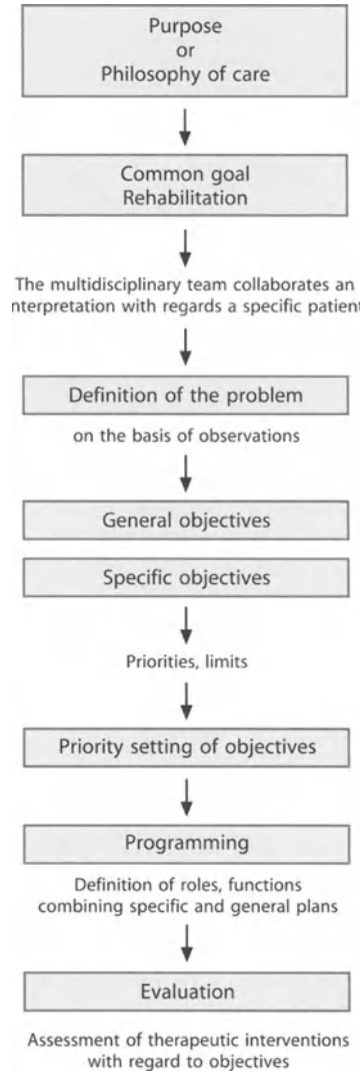

Fig 1. Possible methodology of multi-disciplinary treatment. (From Rufini and Gaillard 1996)

based on observation. It then proceeds to define the problems to be solved and the general and specific objectives to be pursued, taking priorities and limitations into account. This leads to a hierarchization of the objectives, to the drawing up of a programme and to the definition of roles. This whole process is subject to a series of evaluations which may modify the definition of problems to be solved.

This process implies on the one hand a shared involvement on the part of the different disciplines and on the other a clear definition for each of them. A mutual understanding of their individual competence allows the territory of each discipline to be well defined, hence avoiding the encroachment of one on the territory of another and ensuring overall treatment of the highest possible order.

Psychiatric Aspects of the End of Life

Translator: E. Taub

1 Introduction

End-of-life psychiatry remains an inadequately developed branch of research and clinical practice in the field. This is despite the frequency not only of psychological problems, but also of mental disorders requiring treatment in the last stages of life. Terminally ill and dying patients rarely receive psychiatric treatment, and the majority of psychiatrists have less experience with the problems of treatment in this field than many palliative care physicians.

Psychiatrists are most often consulted with questions of the pharmacological or psychotherapeutic treatment of dying patients. Usually, however, this occurs only in individual cases; an American study, for example, revealed that psychiatric consultation was requested for only 1.9% of cancer patients in internal medical or surgical wards (Levine et al. 1978). Still more surprisingly, psychiatric advice is rarely requested even in cases involving medical decisions about assisted suicide and euthanasia on demand; a poll among Dutch psychiatrists revealed that they had been consulted in only 3% of such cases (Groenewoud et al. 1997).

A number of trends imply, however, that end-of-life psychiatry will become increasingly important in the future. The development of thanatopsychology, of palliative medicine, and of the hospice movement reveals an increasing awareness of the significance of the last phase of life. More and more questions and problems are being posed that require the interdisciplinary cooperation of oncologists, palliative care physicians, psychiatrists, and psychotherapists. Further, the increasing prevalence of psychiatric illnesses of organic origin, especially dementia, makes it the psychiatrist's responsibility to be able to answer the relevant therapeutic and ethical questions competently, including in the advanced stages of illness.

Lastly, problems of euthanasia have recently become the focus of international debate and are of special relevance to psychiatry. In several countries, psychiatric expertise has been utilized in the drafting of recommendations for regulations on active euthanasia or assisted suicide or in the formulation of regulations that are currently already in effect (Fuchs and Lauter 1997; Fuchs 1997; see also Vol. 1, Part 2, Chap. 18). In view of these developments, a consideration of the psychiatric aspects of the end of life seems more urgent now than ever. The present chapter deals first with the way patients come to terms with impending death and terminal illness and then with the psychiatrist's responsibilities in this situation; finally, an overview is provided of human experiences in the immediate proximity of death.

2 Significance of Death in Psychiatry

Death is hardly as remote a concern to psychiatry as it may seem. Psychiatrists may, indeed, have little to do with the medical, biological side of death, but they are intimately concerned with its existential dimension. The horizon of death, however distant, lends every moment of life a certain qualification and orientation; life contains the possibility of dying within itself. Mental suffering results when human beings, in the midst of their lives, are suddenly and disturbingly confronted with the alternatives of hope or despair, success or failure, meaningfulness or futility of existence. When talking with patients, a psychiatrist who has been sensitized to this dimension will readily perceive that they are not merely interested in the treatment of their illnesses, but also in achieving a positive final outcome for their lives as the end draws near. In suicide, the central form in which death manifests itself in psychiatry, the patient seeking death confirms its role as a last judgment on the value and success of life.

The theme of the finiteness of existence is also a visible or latent determinant of the central neurotic conflicts. It was no coincidence that psychoanalysis began with Breuer and Freud's *Studies on Hysteria* in 1895 (Breuer and Freud 1955), a study of patients (among them Anna O.) whose symptoms had developed immediately after an experience of death or loss. Freud himself certainly did not view the fear of death as the original source of anxiety and instead attempted to derive it from "castration anxiety." It was mainly Otto Rank and Melanie Klein who countered this theory with the concept of a fundamental fear of disintegration, loss of self, and annihilation, already present in earliest childhood (Rank 1931; Klein 1948). Thereafter, however, the psychoanalytic tradition largely ignored the problem of the awareness of death.

It was only recently that J.E. Meyer (1979) showed the great extent to which the fear of death contributes to the generation of many neurotic illnesses. The course of such "thanatophobic neuroses" as cardiac phobia, panic disorder, hypochondria, or obsessive-compulsive disorder is characterized by the gradual concealment of the originally manifest, elementary fear of death behind more tangible anxieties or psychosomatic complaints. Roth (1959) found that half of all patients with anxiety and depersonalization disorder had experiences of death or severe illness in the period immediately preceding onset. Skoog (1965) made the same finding in most patients with severe obsessive-compulsive disorder; Straus (1960) and von Gebsattel (1954) viewed the obsessive-compulsive patient's fear

of decay, illness, rottenness, and dirt as a latent fear of death, which the patient seeks to banish through rituals and obsessive thoughts. Individuals exposed to an extremely stressful situation and thereafter suffering from post-traumatic stress disorder often carry an awareness of the nearness of death with them throughout their lives ("death imprint"; Lifton 1979). Finally, many Holocaust victims nearing the end of their lives suffer a collapse of previously adequate coping and defense mechanisms, associated with a worsening of the mental suffering that is the lasting result of their earlier persecution (Lauter et al. 1999).

The importance of the awareness of death for psychopathology is particularly emphasized in existential psychotherapy, as Yalom recently wrote (1989, p. 179): "The attempt to escape the fear of death lies at the core of the neurotic conflict." Yalom views two forms of defense against the fear of death as central to the development of neurosis (Yalom 1989, pp. 143ff.): the belief in the "final rescuer," a person or mythical figure whose power and presence can save the individual from death, as long as this individual can successfully fuse with him or her; and the narcissistic belief in one's own specialness and invulnerability, which finds expression in the quest for independence and autonomy. The collapse of these forms of defense during life crises or in the immediate proximity of death expresses itself in many different psychopathological symptoms, but also gives the patient the chance to take a stand against the loneliness of death with appropriate therapeutic help and, in so doing, to gain in maturity (Yalom 1989, pp. 243ff.).

3
When Death Is Near: Stages of Dealing with Terminal Illness

The diagnosis of a disease that is expected to be fatal transforms the patient's general awareness of mortality to a sense of the immediate proximity of his or her own death. This is a radical change in the temporal perspective on life. The past, which, until now, could always be "left behind," suddenly assumes the nature of immutable fact: the course of life can no longer be fundamentally changed; it is now time to make up the accounts. The future, on the other hand, splits into two segments: the short time left to live, in which pressure is felt to make the most of life, and the anticipated later time "without me," and with it the questions, "What will remain of my life? What trace will I leave behind? In what way or ways will I live on?"

People today have much less effective defenses against this existential anxiety and distress than they once had. The prevailing doubt with regard to traditional notions of the afterlife has shrunk the period of time on which we can project our lives – even though the average life expectancy has increased. Life now seems to be the "last chance" (Gronemeyer 1993), and what we achieve or fail to achieve within its confines now assumes the character of the final and irrevocable.

The enormous abundance of thanatopsychological, popular scientific, and autobiographical literature on this subject in the last two decades bears witness to the intensive efforts that have been made to achieve mastery over the last phase of life, or at least to remove its terror. Not least, the works of E. Kübler-Ross (1974), reports of personal experiences such as those of Peter Noll (1984), Maxie Wander (1980), and Simone de Beauvoir (1965), and S.B. Nuland's demythologizing depiction of the biological and clinical process of dying (Nuland 1994) have contributed to the current, more realistic approach to the subject. The "phase model" proposed by Kübler-Ross has now given way to a more differentiated view of dying as a process that differs strongly among individuals depending on their personalities, their life histories, and the individuals around them. The following section includes a discussion of a number of typical attitudes and stages that combine, in highly varying ways, to shape the end-of-life process of each individual.

3.1
Initial Reactions

The diagnosis of a fatal illness is usually experienced as a "judgment" or death sentence; the immediate reaction is characterized, as a rule, by profound emotional distress that may rise to the level of a feeling of being annihilated and by massive anxiety and worry. This first reaction is often followed by defense processes, including an intensive effort to find a way out by trivializing or denying the illness. A few weeks usually pass before the reestablishment of an unstable equilibrium. The patient may avoid talking or thinking about the illness, while remaining aware of it; he or she may partly deny the illness by ignoring its fatal prognosis, or largely or totally repress it from consciousness – indeed, repression of symptoms by the patient may already have contributed to a delay in making the diagnosis. Switching back and forth between avoidance, partial or total denial, and acceptance may occur at any phase of disease and thereby create a problem for those around the patient.

In the past, the diagnosis and prognosis of fatal illnesses were often kept secret or conveyed only to the patient's family. Today, however, frank, caring, and

repeated conversations with the patient have become usual, so that there should be no unnecessary worry and anxiety caused by contradictory medical information or the "knowing silence" of others. Keeping the diagnosis a secret deprives patients of the chance to make the best use of the time remaining, to say goodbye to family members and to life itself in whatever way they choose, to settle unresolved conflicts, and, whenever possible, to acquire greater depth and maturity in the process. It would be just as wrong, however, to deliver an unfavorable diagnosis in a perfunctory and abrupt manner. In all phases of an incurable illness, there remains a certain amount of hope that must never be completely taken away from the patient, no matter how ill-founded it may seem. It must also be remembered that men over 69 have an elevated risk for suicide immediately after the delivery of the diagnosis (Fox et al. 1982).

3.2
Rebellion – Anxiety – Depression

Emotional reactions in the further course of the process include feelings of being wronged and offended by the injustice of an "undeserved" death sentence, disappointment over one's fate, and anger and rebellion against God or the world. Resentment, bitterness, and envy of the healthy, who will be allowed to live on, may become manifest as ill humor, irritability, or even latent enmity toward others. It is important for family members, and just as important for therapists, to meet such apparently unjustified emotional expressions with understanding and acceptance, whenever possible. They may thereby prevent the patient from adopting a destructive, spiteful attitude that will ultimately make the dying process very much more difficult.

Anxiety accompanies nearly all phases of dying, but it may take very different forms, all of which must be properly recognized and identified as a precondition to successful treatment:

- Fear of disease manifestations: Most severely ill patients fear pain, suffering, shortness of breath, and deformity caused by operative procedures. Fear is thus directed at the threatened loss of bodily integrity associated with the further progression of disease; when amplified by a lack of information and avoidance of medical explanation, this fear may often take on catastrophic proportions.
- Fear of isolation: The anonymity and solitude of dying in a hospital ward lead to the (often justified) fear of social exclusion and loneliness; this may be compounded by the fear, born of distrust, of being lied to or deprived of legal capacity by their family or physicians. Such fears are usually an expression of long-standing disturbances of interpersonal relationships and of trust.
- Fear of loss of autonomy: Severe illness means reliance on others, dependence, and often helplessness. The loss of control and autonomy is perceived by the patient as a threat and a humiliation; the idea that one's own dignity may also be confirmed by the recognition and caring assistance of others is often difficult to accept. Emotions of embarrassment and shame may then rise to the feeling of being no more than a burden to others, so that a "quick end" may be secretly desired. An amplified form of the fear of losing one's autonomy is the fear of ceasing to exist mentally, of fading away into unconsciousness or dementia. This fear has become very common as life expectancies have risen and dementing illnesses have become more prevalent.
- Fear of death: In its vital or "blind" form, the fear of death is probably present in all highly developed living beings. In human beings, however, it acquires anticipatory components: fear of the loss of, and final separation from, loved ones; fear of not having any further experiences, of no longer participating in what goes on in the world; and, finally, the elementary fear of simply passing into nothingness, of extinction, of "ceasing to be" – which has now largely replaced the earlier, religiously motivated fear of divine retribution in Hell.

In addition to these fears, there is also the retrospective anxiety aroused by the "irreparable," compounded by feelings of guilt, regret, and despair with respect to lost opportunities, unfulfilled wishes, and missed areas of personal experience. Thus Hinton (1975) asked 60 patients with advanced cancer about their feelings of satisfaction and fulfillment in life. It was found that the less satisfied they were with their lives, the greater their fear of death was.

Depression, like anxiety, may occur at any phase of the end of life. Psychic causes of depression include the stresses already mentioned: isolation and loneliness, feelings of guilt and worthlessness, the feeling that one's life has not been worthwhile, disappointed hopes of recovery or cure, persistent pain and other forms of bodily suffering perceived as uncontrollable often result in depression. Moreover, cancer patients often experience the tumor not only as a threatening and destructive enemy, but also as an evil and malevolent object within themselves; they may transfer these feelings onto themselves and perceive their illness as a punishment for their own imagined offenses or failures. Depressive episodes are most often provoked by recurrences of disease or by mutilating operative procedures (e.g. mastectomy, colostomy, amputation); such situations may prove

to be beyond the capacity of whatever coping mechanisms have been in place until that time.

3.3 Coping and Acceptance

As soon as the diagnosis is communicated, various coping strategies go into effect with which patients – insofar as they do not deny the existence of the disease – attempt to adapt to the new situation. At first, they may do all they can to postpone the moment of death and to influence the course of their illness with new information and with scientific medical, or paramedical, treatment processes. More effective in the long run, however, are internal processes of reinterpretation and reevaluation that allow patients to see the situation from a different perspective. These include emphasizing the present, using the awareness that one has a "last chance" to intensify personal relationships and strengthen one's sense of life, searching for opportunities that life still affords, resetting priorities, and making corresponding changes in life style. Patients must often come to terms with their own life histories, i.e. take stock of their lives and thereby find a meaning for life and death ("life review"; Butler 1963). Many patients draw deep satisfaction from the settling of "unfinished business," last conversations with relatives and friends, and the fulfillment of long-held wishes. Saying goodbye and grieving in anticipation of the loss of all that was dear and valued are also ways of coping with the last phase of life.

Nonetheless, the phase of acceptance, which Kübler-Ross (1974) described as being practically normative, is rarely completely achieved and should not be presented to patients as a challenge or a requirement. More often, death is viewed with resignation as the inevitable end. A Dutch study of 191 terminally ill patients revealed that only about one third were able to accept death, while one fourth abandoned life resignedly and a further fourth remained militant against death, or in denial, until the end. Women were found to be significantly more able to accept death than men (Bruning and Hesselink 1986, cited in Munnichs 1989).

3.4 Terminal Phase

The last phase of the disease is often heralded by the collapse of defense mechanisms, by generalized organic functional disturbances, by the failure of therapy, and by the transition to palliative measures; it is often signaled to patients by transfer to a private room, to a hospice, or to their own homes. The steady weakening of resistance and of the will to live leads to a state of emotional exhaustion, resignation, and quiet sorrow. Patients whose perception and articulation are impaired often have no further opportunity to come to terms with death by cognitive or communicative means. Their last words are often limited to brief exchanges or to trivial matters of daily routine. Nonetheless, contact through touch and voice is still possible, particularly when a relationship of trust already exists between the patient and the caregivers. In the agonal phase, consciousness is intermittently clouded, and reality gradually pales. In the Dutch study mentioned above, 45% of patients died while drowsy, sleeping, or comatose, 27% with quiet acceptance, but 21% while agitated, fearful, or anxious (Bruning and Hesselink 1986, cited in Munnichs 1989).

4 Objectives and Problems of Psychiatric Treatment

Studies reveal a high prevalence of mental disorders in the severely ill. In a multicenter study of 215 cancer patients, Derogatis et al. (1983) found psychiatric diagnoses according to the DSM-III in 47% of patients: 32% of the patients had anxious or depressive reactions, 6% had severe depressive disorders, 4% had organic brain syndromes, 3% had personality disorders, and 2% had severe anxiety syndromes. Several other studies have shown that the incidence of severe depressive disturbances among cancer patients is on the order of 25% and increases, in later stages of disease, to as high as 75% (Plumb and Holland 1977; Bukberg et al. 1984; Massie and Holland 1990). The prevalence of delirium syndromes among cancer patients in the terminal phase varies from 40% to 85% (Massie et al. 1983). Still more frequent are psychiatric complications in the course of acquired immunodeficiency syndrome (AIDS) (Tross and Hirsch 1988).

4.1 Anxiety

A number of causes of anxiety syndromes in the severely ill have already been mentioned. Anxieties of mental origin may manifest themselves as diffuse inner restlessness, irritability, aggression, or somatic complaints, but even a seemingly "composed" and well-adapted attitude may actually be the product of an intensive effort to conceal latent despair under the appearance of normality. Anxieties of mental origin rarely produce erethic restlessness, agitation, and

panic; such manifestations are more characteristic of anxiety syndromes of organic origin, particularly incipient delirium, arterial hypoxia, dyspnea due to pulmonary metastases or embolism, or an incipient reaction to the withdrawal of benzodiazepines or opiates. The differential diagnosis of such syndromes may require a thorough medical and neurological evaluation.

Pharmacological therapy is indicated for organically induced anxiety, but may also be used as an adjunct to psychotherapeutic intervention. Short-acting benzodiazepines such as lorazepam, alprazolam, and diazepam are recommended for use in the severely ill because of the slowing of metabolism and the consequent risk of a cumulative dosage effect. They should be given multiple times a day in order to ensure an uninterrupted therapeutic effect. Clonazepam is a longer-acting agent that has been found useful for the treatment of patients who additionally have seizures or neuropathic pain (Breitbart and Passik 1993). If benzodiazepines are ineffective, or if their use raises the concern of respiratory depression, neuroleptics of low potency may be used. For panic disorders, tricyclic antidepressants such as imipramine or the newer serotonin antagonists are effective.

Psychotherapy for the treatment of anxiety and depression in severely ill patients is of a supportive nature and is directed toward enhancement of self-esteem and short-term crisis intervention. The therapist faces a major challenge with regard to his or her own life experiences and anxieties. Therapy can encourage the patient to verbalize anxiety and other threatening affects, give vent to grief over imminent separations, and overcome the barriers to others that are posed by shame or distrust. The therapist's own experience with the dying, and even literary descriptions such as Tolstoy's *The Death of Ivan Ilyich*, may help the therapist guide the patient through the processes of reinterpretation mentioned above.

One important approach, "life review therapy," makes use of the patient's own life history; the patient's achievements and skills are emphasized, and attempts are made to correct the patient's negative views of his or her life (Fuchs 1992a). If certain subjects are too heavily charged with anxiety to be verbally accessible, nonverbal processes such as painting and art therapy may be valuable means of expression (Dreifuss and Meerwein 1984). Finally, direct methods of reducing anxiety include relaxation techniques, directed imagery, and hypnosis.

All of these psychotherapeutic interventions not only can improve the mental state of the patient in the last phase of life, but also, on occasion, prolong life. Thus Spiegel et al. (1989) showed that patients with breast cancer who participated in supportive group therapy lived significantly longer than those who did not.

4.2 Depression

Depressive disorders often arise in the last phase of life, but are not easy to diagnose. Severe depression often manifests itself as an apathetic exhaustion syndrome that is difficult to distinguish from the manifestations of the physical illness, as are the typical vegetative symptoms (loss of appetite or weight, sleep disturbance). On the other hand, phases of sadness, dejection, and anxiety are normal accompanying phenomena of dying, as discussed above.

The diagnosis of depression masked by a bodily illness is supported primarily by psychic symptoms such as continuous hopelessness, negativism, excessive guilt feelings with ideas of punishment, feelings of worthlessness, and, above all, suicidal ideation; these symptoms are nearly always associated with treatable depression (see below). Finally, the differential diagnosis must include side effects of chemotherapeutic agents (e.g. vincristine, steroids, interferon) and other medications, endocrine disturbances, and paraneoplastic syndromes (see also Chaps. 17, 18, Vol. 2, Part 2).

Even though depression cannot always be distinguished from the manifestations of physical illness or from the undesired side effects of somatic treatments, all cases of moderate or severe depression should be treated with medication; the notion that depression is a normal reaction to cancer is not a valid argument against such treatment, as the effectiveness of antidepressants in cancer patients is well documented (Popkin et al. 1985; Massie and Holland 1990). Lower doses (25–125 mg) have generally been found to be sufficiently effective in such patients; higher doses may lead to toxic effects because of the lowered metabolic rate. Tricyclic agents and serotonin antagonists (beware of nausea and agitation!) are also used; trazodone and trimipramine have proved their worth as agents with both analgesic and sedating effects.

4.3 Painful Conditions

Persistent and insufficiently controlled painful conditions are a major source of suffering for severely ill patients. The frequency of such conditions in cancer patients is approximately 30% and rises to 60%–90% in the terminal phase. Cancer patients with persistent pain have twice as many psychiatric complications as other patients, primarily depressive syndromes (Derogatis 1983). Sedating antidepressives and anxiolytics are often indicated in such situations and may help prevent a premature elevation of opiate dosage (Kocher 1984).

Psychotherapeutic interventions, relaxation techniques, imagery, and hypnosis may influence the emotional component of pain perception and thereby help guard against an excessive fixation on medications.

4.4 Organic Brain Syndromes

A total of 15%–29% of hospitalized cancer patients have mental disturbances of organic origin (Levine et al. 1978); more frequent types include delirium, dementia, affective disorders of organic origin, hallucinoses, and personality changes. Metabolic disturbances such as hypercalcemia or hypothyroidism, toxic effects of medications (steroids, opiates, chemotherapeutic agents), radiation toxicity, or brain metastases in the final phase of melanoma or other cancers are often associated with organic brain syndromes, which present as cognitive impairment, acute anxiety, or hallucinatory and paranoid states.

The AIDS–dementia complex, which occurs in two thirds of all AIDS patients at some point in their course, consists of a combination of memory disturbance, cognitive slowing, motor disturbance, and depression or psychosis. Psychopathological changes in the agonal phase include reduced drive, vigilance, and attention, confusion, anxious restlessness of a vegetative character, and many types of exogenous reaction (Bonhoeffer's symptom).

Neuroleptics are the most suitable agents for the psychiatric treatment of these organic brain syndromes. In marked agitation, parenteral haloperidol (0.5–2 mg) may be given every hour until the symptoms have become less severe, and may then be given orally. In addition, the patient's potential for orientation should be maximized by means of a well-structured, individually arranged environment, continuity of nursing staff, frequent contacts with relatives, and gentle correction of misinterpretations.

4.5 Suicidality and Death Wish

The desire of terminally ill patients to end their lives prematurely is one of the most serious problems confronting the psychiatrist and is currently a matter of public concern in the ongoing debate over euthanasia. Generally speaking, elderly and very elderly persons seldom have death wishes or suicidal ideation, which, when they do occur, are almost without exception signs of a diagnosable psychiatric illness; despite multiple stresses and losses, the great majority of such patients feel no desire to die as the end of life approaches (Linden and Barnow 1998).

There are, however, hardly any studies of representative sample populations regarding the prevalence and reasons for death wishes in the severely ill. Brown et al. (1986) interviewed 44 patients with terminal cancer in a palliative care ward; all ten patients who expressed a wish to die prematurely were suffering from clinical depression. Chochinov et al. (1995) studied 200 patients with advanced malignancies in a palliative care ward; just under half (45%) reported having brief and transient death wishes, and 17 patients (8.5%) had more serious and lasting death wishes. The latter patients also complained significantly more frequently of pain and lack of family support; ten of them suffered from clinical depression. Finally, Emanuel et al. (1996) questioned 155 cancer patients and found that more than one quarter (27%) had already thought seriously of asking their physicians for euthanasia or assistance with suicide; 12% had actually discussed this subject with their physicians. The latter 12% of patients had a significantly higher frequency of depression than the other patients.

Figures on suicide yield an indication of the prevalence of death wishes: cancer patients in advanced stages of disease have a significantly higher suicide rate than the age-matched general population (Farberow et al. 1971; Luohivuori and Hakama 1979). Risk factors include preexisting personality disorders, alcohol abuse, social isolation, depression, and inadequately treated pain (Breitbart 1990). Significantly elevated suicide rates have also been found among AIDS patients (Marzuk et al. 1988; Coté et al. 1992).

Among the 2.7% of annual deaths in the Netherlands that are the result of active euthanasia on request or of medically assisted suicide, three quarters occurred in the setting of advanced cancer. A sample of such patients less often gave pain as the reason for their desire to die than feelings of meaninglessness, dependence, and lack of dignity (van der Maas et al. 1996; Fuchs 1997).

The available studies imply that, among the many motives underlying the death wishes of severely ill and dying patients, the more important ones are depression and anxiety, lack of family support and security, feelings of the indignity and meaninglessness of their own suffering, and inadequately treated pain. The desire to die is often an expression of the need for attention and esteem, a cry for help to others, or a protest against unbearable suffering. Finally, a problem of communication with the physician, the nursing team, or family may motivate the desire for "salvation by injection," through which the patient wrongly thinks he or she will relieve others of an unwanted burden.

The marked fluctuation of death wishes (Chochinov et al. 1995), their many-layered motivation, and their dependence on successful or unsuccessful communi-

cation with others all imply that supposedly simple solutions, such as the championing of "self-determination" and rapid termination of life through active euthanasia, can hardly do justice to the complexity of the situation of dying patients. Not all, but certainly many patients who want to die have a psychiatric disturbance that must be recognized and treated.

Moreover, the experience from palliative care wards and hospices for dying patients reveals that adequate medical care, competent treatment of pain, and good emotional support can strongly influence the patient's attitude toward living and dying. It is doubtless important to discuss the patient's desire to die openly and non-judgmentally; the patient may gain significant relief through such an interaction alone. It may also be reasonable to inform family members gently of the patient's dire situation. The physician can retain credibility and help the patient through times of desperation only after coming to terms with his or her own personal attitudes toward premature termination of life.

4.6 Withholding Life-Prolonging Medical Treatment

Psychiatric problems of the end of life also include the question of whether life-prolonging medical treatments should be withheld when a fatal illness has already severely impaired the patient's life functions, and death can no longer be prevented ("passive euthanasia"). Patients' unwavering desires to terminate, or not to initiate, medical treatment measures must surely be respected; the physician, however, has the duty to ascertain whether such a decision has come about because of the influence of others, external pressure, or depression.

The consultation of a psychiatrist is mandatory when there is doubt as to the patient's decision-making competence and the withholding of treatment would be associated with serious risks or disadvantages. Particularly with patients in advanced stages of dementia, the question arises as to whether life-prolonging measures ought to be continued even if the health and well-being of the patient are impaired by a second illness or if the patient's survival depends on the artificial provision of nutrition and hydration (Karger and Haupt 1997). Such decisions may be made easier if the patient, while still able to make such decisions for him- or herself, has already clearly expressed the desire to forego life-saving treatment in the case of a severe and incurable illness and if this can be credibly attested by family members. Even then, the question remains as to what extent the patient's previously expressed wishes still correspond to present, possibly quite different wishes and needs, and whether they can be applied to the current situation even though it could not have been foreseen in every detail.

If the patient's attitudes and preferences are unknown, the physician, family members, or legal guardian must try to ascertain the patient's interests as well as they can. The ethical principles underlying such determinations are controversial (Beleites 1998). The decision taken in the individual case depends, among other things, on whether the proposed medical intervention – ranging from the administration of antibiotics or infusions to the insertion of a gastrostomy, to dialysis and surgical procedures – offers a sufficient prospect of palliating of the patient's suffering, or whether it essentially serves only to prolong the patient's life and may actually produce further, iatrogenic suffering. Clearly, when such decisions are made, attention should be paid to the body language with which a demented patient may convey his or her distress.

On the other hand, it must not be assumed a priori that the quality of life of a patient in an advanced stage of dementia is necessarily negative, particularly because so little is known about the experiential world of the demented. Indeed, the current emphasis on cutting expenditures for medical and nursing care only increases professional caregivers' responsibility to afford demented patients special protection. It may be ethically justifiable to withhold artificial nutrition or medical interventions in some cases, but this should never become routine practice, as such measures have a very important symbolic value: they bear witness to the respect in which the patient is still held as long as his or her personal identity, though overshadowed by illness, remains perceptible; and they raise a necessary barrier against the human tendency to neglect weak, powerless individuals and exclude them from society.

4.7 Environment of the Dying Person

A further important aspect of psychiatric assistance at the end of life consists of the support of family members and professional caregivers. The family of the dying person is exposed to severe stress by his or her illness. The emotional and nursing support of the patient, the associated restrictions of life style and financial burden, uncertainty over the course of the illness, and anticipatory grief over the impending final separation often lead to a continuous conflict between hope and despair and, finally, to exhaustion of the ability to help. Further stress is created by family members' uncertainty over how openly they should discuss the grave situation with the patient and deliberately say goodbye – over whether the family members themselves might be overcome with grief in

such a situation or potentially undermine the patient's remaining will to live.

Such conflicts, and the need to fend off feelings of hopelessness and depression, often lead family members to withdraw inward and away from the dying person; the patient may note this and desire more strongly to die. According to a study by Krant and Johnson (1977/1978) on near relatives of 75 terminally ill patients, only one fifth of the relatives had spoken with the patients about the possibility of death. A study of couples (Hinton 1981) revealed that two thirds of the partners had spoken only incompletely, or not at all, with the patients about their impending death. Many physicians, too, react to the patient's worsening condition and their own therapeutic powerlessness with an unconscious retreat from the patient.

A study by Schulz and Aderman (1976) revealed that the determination of a poor prognosis significantly changes the behavior of staff and family members (shorter visits, less verbal communication, fewer contacts). Nursing care is made more difficult by certain coping styles, character idiosyncrasies, or personality disorders of severely ill patients, which often lead to an increased need for control in response to the fear of dependence, distrust, or a withdrawal inward.

The psychiatrist can recognize interpersonal conflicts of these types and, by maintaining contact with the individuals caring for the patient, providing accurate medical information, and advising on the best ways to cope with the situation, can contribute to the maintenance and reinforcement of the emotional support system that the patient needs from his or her social environment. The psychiatrist thus plays an important mediating role by promoting dialogue among all those involved in the dying process. Furthermore, the psychiatrist can encourage family members to discuss stressful topics and uncertainties with the patient and motivate them to anticipatory grief. Repression of impending death can make it difficult or impossible to cope with the loss when it finally occurs. Such pathological grief reactions are most commonly found among family members whose bond to the dying patient is ambivalent or not emancipated. It is particularly important to bear this possibility in mind in view of the elevated morbidity and mortality of widowed partners (particularly men) in the first year after death; timely psychotherapeutic help should be made available.

4.8 Hospices

The hospice movement arose in England in the late 1960s as an attempt to counteract the increasing anonymity of death in our society. Its purpose is to create a secure space in which the dying can be accompanied on their last journey with appropriate medical, psychological, and pastoral care, just as the medieval hospices gave shelter to pilgrims and travelers. In 1967, Dame Cicely Saunders founded St. Christopher's Hospice in London; the first hospice in Germany opened in 1985. Since then, approximately 30 inpatient hospices and as many palliative care wards have been established in Germany, along with approximately 270 ambulatory care services and more than 180 volunteer initiatives with some 10,000 volunteers (Saunders 1993; Student 1993; for hospice movements in other countries, see also Aranda 1999; Haber1999).

In hospices, patients with incurable, fatal illness are treated under a different set of objectives requiring a different approach from medical personnel. The relief of physical and mental suffering is the primary concern; to this end, new medical, physiotherapeutic, and psychotherapeutic techniques for the treatment of pain are tested and further developed. The principle of timely and often prophylactic analgesic treatment, in coordination with acupuncture, hypnosis, and other techniques, enables the successful treatment of painful conditions in most cases, without making patients confused or sedated.

The fundamental concept of the hospice movement is that of using brief inpatient stays to optimize medical treatment, especially the treatment of pain, so that patients can be cared for in their home environment again as soon as possible, in coordination with specially trained nurses, lay assistants, and family members. A hospice is thus not a "death house," but an institution that is open to the community and oriented toward outpatient care. Assessment studies have shown that the subjective and objective life quality of hospice patients is positive (Greer et al. 1986; Morris et al. 1986). The potential for good medical care at the end of life that the hospice movement affords is certainly underutilized.

5 Near-Death Experiences

This discussion of psychiatric aspects of the end of life will be brought to a close with a look at so-called "near-death experiences," which are not only of psychiatric interest, but also of great personal concern to many people who are dying.

As early as the end of the nineteenth century, there were reports by people who had been through externally life-threatening situations, such as falls while mountain-climbing, saying that they had experienced states of inner alienation and absence of feeling that

would today generally be referred to as depersonalization and dissociation. Noyes and Kletti (1976a,b) collected more than 200 such reports of accident victims in life-threatening situations and derived the following essential components of the near-death experience:

1. Slowing of the subjective passage of time down to a complete standstill
2. In contrast, a considerable speeding up of the train of thought
3. Sudden inner calm and freedom from pain and fear, associated with a feeling of not being involved and of unreality
4. Alienation from one's own body
5. A rapidly running inner panorama of life memories

The actual end-of-life experiences associated with out-of-body states were first made known to a broader public through their description by Moody (1975) and, later, mainly through the research findings of Ring (1980). According to several studies now available, comparable extraordinary perceptions and experiences are reported by 30%–40% of people who were resuscitated after cardiac arrest, lay in a coma, had a life-threatening accident, or seriously attempted suicide (Ring 1980; Ring and Franklin 1981; Greyson and Stevenson 1980; Sabom 1983; review in Roberts and Owen 1988). In these studies, there was no association of specific experiences with demographic and social characteristics of the subjects, such as age, sex, ethnic origin, education, occupation, religion, or beliefs, or with possible previous knowledge concerning near-death experiences. It is possible that we are dealing here with a common, basic pattern of human experience in the immediate proximity of death that is independent of individual orientation and socialization (Fuchs 1997).

The experience typically begins with a feeling of peace, well-being, and freedom from pain, which may rise to the level of ecstatic joy. Almost without any intervening transition, this is followed by the sensation of hovering outside one's body and of perceiving what is happening all around without any emotional participation. Remarkably, the subjective passage of time becomes profoundly slowed, often so much so that a "feeling of eternity" is experienced. This out-of-body experience then gives way, in most individuals, to a tunnel or darkness experience, finally followed by an encounter with a person-like apparition of light or by a fast-forward-type sequence of remembered autobiographical images ("life panorama"). Very often, affected individuals retrospectively ascribe a special religious or spiritual meaning to this experience. There may be a fundamental resetting of life priorities and lasting changes of personality.

The possible explanations of these phenomena may be divided into neurophysiological, psychodynamic, and transpersonal approaches.

Some of the essential components of the near-death experience also occur in toxically or functionally altered brain states such as temporal lobe epilepsy and states produced by the administration of narcotics, such as ketamine, or hallucinogens, such as mescaline, LSD, and phencyclidine. This fact is the basis for the hypothesis of a disturbance and activation of the temporal limbic system caused by terminal hypoxia or hypercapnia, in association with the endogenous production of endorphins (Rodin 1980; Carr 1982).

Psychodynamic explanatory approaches are based on the model of a dissociation of consciousness into a participating and an observing self, along with a regressive defense against the threat of death by means of hallucinatory wish fulfillment (Ehrenwald 1974; Noyes and Kletti 1976b).

In transpersonal interpretations, near-death experiences are viewed as a kind of "altered state of consciousness" belonging to an archetypal psychic matrix that is shared across cultures and has manifested itself in all historical periods in religious, visionary, and mystical experiences (Grosso 1983).

Even if none of these theories provides an entirely satisfactory and conclusive explanation of near-death experiences at present, the significance of these experiences is undiminished. They represent a profound transformation of human spatial, temporal, and emotional experiences and can have long-lasting effects on the human personality. They provide an impressive demonstration of the central, and ultimately therapeutic, importance of death for human life.

Psychiatric Illnesses in Women

The sections by M. Lanczik were translated by E. Taub.

1
Psychiatry of Menstruation

1.1
Introduction (M. Lanczik)

The reciprocal relationship between gynaecological and psychopathological processes is particularly evident in the setting of menstruation. Alterations or disorders of rhythm in either the psychological or the biological sphere may affect events in the other sphere. This occurs, for example, when a woman suffering from melancholia loses her normal rhythm, so to speak, not only with respect to "temporally rhythmic living conditions" – a term used by Pauleikhoff (1986) in allusion to Tellenbach (1983) – but also in her menstrual cycle, or when psychic inhibition leads to inhibition of menstruation and, in extreme cases, to amenorrhoea. On the other hand, the normally functioning menstrual cycle can give rise to psychopathological phenomena occurring in the same rhythmic pattern, such as the relatively common pre-menstrual dysphoric syndrome and, in extreme cases, the rare menstruation psychoses.

The fact that mental illnesses may bear a temporal relationship to certain phases of the menstrual cycle was one of the earliest discoveries of biological psychiatric thinking. Hippocrates explained mood alterations related to menstruation as the consequence of an obstruction to the flow of menstrual blood. Menstruation-related mental illness became a subject of scientific investigation in the early eighteenth century, with the submission of a dissertation by Georg Ernst Stahl in the year 1702. In the nineteenth century, psychiatrists assumed that 10% of all organic psychosyndromes in women were causally related to menstrual disorders (Splett 1998). Robert C. Frank, in 1931, was the first to postulate a direct aetiological relationship between psychopathology and ovarian hormones. Collins et al. (1985) simultaneously measured all of the relevant cyclically secreted hormones and plasma catecholamines and were able to show that depressive and anxious mood disturbances occur primarily in the luteal phase. Mental well-being, on the other hand, is observed significantly more frequently in the follicular phase of the menstrual cycle.

1.2
Pre-menstrual Dysphoric Syndrome (M. Lanczik)

The most frequently reported psychopathological disorder bearing a temporal relationship to changes in sex hormone concentrations is the so-called pre-menstrual dysphoric syndrome. Research on this mood disorder was long hindered by the inadequacy of its definition. It was first included in a system of psychiatric classification, the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), in 1987. In the revision of DSM-III, it was named late luteal dysphoric syndrome. In DSM-IV, it was given the clinically accurate designation of pre-menstrual dysphoric syndrome (Spitzer et al. 1989).

1.2.1 Clinical Features

Hamilton et al. (1984) list approximately 150 different mental and physical manifestations that may occur in the pre-menstrual period. There is, however, a fairly characteristic, clinically relevant pattern of manifestations, including sadness (56%), anxiety (36%) and lability of affect (26%) (Freeman et al. 1985). The latter condition expresses itself clinically as suddenly occurring phases of tearfulness and increased irritability (48%), which may frequently lead to interpersonal conflict with the patient's life partner and also interfere with her professional activities. Depressive mood alterations are frequently reported, expressing themselves as self-reproach or other self-demeaning thoughts, and as a feeling of hopelessness that may, in the long term, result in withdrawal from social relationships. Interest in normal activities, such as work and hobbies, is diminished (Moos 1968a,b). Moreover, patients complain of a subjective feeling of difficulty concentrating, easy fatigability and a feeling of tension.

Suicidal behaviour may occur as a very serious complication of this disorder. The incidence of parasuicidal behaviour has been found to be elevated in women suffering from pre-menstrual dysphoric syndrome who are subjected to a non-specific stress (Chaturvedi et al. 1995).

Pre-menstrual changes in appetite express themselves less commonly as loss of appetite (as in endogenous depression) than as a craving for certain types of foods; there is a significant association between the intensity of such cravings and the severity of the mood disorder (Dye et al. 1995). Increased appetite is, however, also observed in connection with the menstrual cycle in women who do not suffer from pre-menstrual mood changes.

Sleep disorders occurring frequently in the pre-menstrual period include both insomnias and hypersomnias.

Finally, there are often a number of somatic symptoms, such as breast pain and headache (23%), swelling and abdominal complaints (Freeman et al. 1985). The latter, however, almost never attain the

intensity of the somatic symptoms accompanying dysmenorrhoea. Some women suffer both from a pre-menstrual syndrome of psychopathological significance and from a gynaecologically relevant dysmenorrhoea; in this context, the simplifying term "peri-menstrual syndrome" is often used (Bancroft et al. 1993).

1.2.2 Diagnostic Evaluation and Classification

The decisive factor for the provision of a diagnosis and for differential therapeutic planning is not the fairly typical clinical picture, but rather the course of the disorder, i.e. the regular appearance of its manifestations – in varying degrees of severity – in the late luteal phase of the menstrual cycle and their remission after the onset of menstruation. Manifestations never occur in the week after the menses. Thus these women are free of mental disturbances during only 1 week of the menstrual cycle.

For most women with pre-menstrual dysphoric disturbances, the psychopathological changes are not severe enough to affect their social lives or their professional performance. The diagnosis of pre-menstrual dysphoric syndrome is, therefore, only given when the manifestations of the disorder significantly limit social or professional performance ability and when they have occurred in the majority of menstrual periods in the year preceding diagnosis. Nevertheless, there are as yet no uniform guidelines for determining the degree of severity of pre-menstrual syndrome or for the validation of inter- and intra-individual studies of the course and treatment of the disorder (Hurt et al. 1992). In DSM-IV, a distinction is newly drawn between pre-menstrual syndrome and pre-menstrual dysphoric syndrome: the former is said to be distinguished from the latter by its lesser severity and lower frequency of exacerbations. In our opinion, this dichotomy is not justified from the psychopathological, the course-typological or (especially) the aetiological point of view and should therefore be discarded.

It is noteworthy that the psychopathological manifestations are the same as those of the so-called post-partum blues; we have accordingly coined the designation "post-partum dysphoric syndrome" for the latter disorder (Lanczik et al. 1992; Heidrich et al. 1994; Lanczik and Brockington 1999).

There is some evidence that pre-menstrual dysphoric syndrome is a heterogeneous disorder. It is not yet clear, for example, whether subtypes of pre-menstrual dysphoric syndrome tending towards depression, dysphoria or anxiety are psychopathologically distinct.

1.2.3 Differential Diagnosis

Pre-menstrual dysphoric syndrome differs from dysmenorrhoea in that the latter is clinically characterised essentially by pain and physical discomfort rather than by a pattern of psychopathological manifestations. Moreover, dysmenorrhoea occurs not pre-, but peri-menstrually.

Pre-menstrual dysphoric syndrome is distinguished from other affective disorders such as dysthymia or endogenous depression primarily by its course. Dysthymia and endogenous depression do, in fact, occur at increased frequency in the late luteal phase, but, unlike pre-menstrual dysphoric syndrome, they do not remit with the onset of the menses (Brockington et al. 1988; Endicott 1993). It should be remembered that the affective manifestations of pre-menstrual syndrome may have the intensity, though not the duration, of a phase of endogenous depression.

In rare cases, it may be difficult to distinguish an affective disorder of "rapidly cycling" type from a combination of pre-menstrual dysphoric syndrome with an oligo-ovulatory cycle. This example suffices to make clear that these patients require attentive gynaecological and psychiatric care.

Disorders of adaptation, like affective illnesses, also tend to be worse pre-menstrually.

1.2.4 Course and Prognosis

The earliest manifestation of pre-menstrual dysphoric syndrome may appear at any time after menarche. Its course in interrupted only by pregnancy, during which these women feel exceptionally well mentally; they tend, however, to develop depression shortly before the first post-partum menstruation (O'Hara 1987).

When pre-menstrual dysphoric syndrome remains untreated, its intensity increases over time, although the severity of manifestations often varies from cycle to cycle. The period of greatest vulnerability for the development of pre-menstrual dysphoric syndrome is between the ages of 25 and 35. Women usually present for treatment between the ages of 30 and 40. The manifestations usually become less severe after age 45 and generally disappear after menopause or hysterectomy (Casson et al. 1990; Freeman et al. 1995). Bäckström et al. (1981), however, reported cases in which manifestations persisted after oophorectomy.

1.2.5 Epidemiology

Precise data on the prevalence of pre-menstrual dysphoric syndrome are not yet available in adequate

quantity. This is partly the result of the use of different definitions of this affective disorder in the various studies published to date. Nonetheless, it has been clearly shown to occur very frequently in comparison to all other mental illnesses.

A total of 40%–73% of all women are said to suffer from pre-menstrual mood alterations, which are, in most cases, not severe enough to affect these women to a major degree in their everyday lives. Such mood alterations are regarded by many women as a quasi-normal pre-menstrual phenomenon. However, 28% of all women report that their work is adversely affected by pre-menstrual mood alterations, 5%–8% consult a physician for this problem and 2.1% are unable to work in the pre-menstrual period (N. Wood et al. 1982; Andersch et al. 1986; Rohde et al. 1992).

1.2.6 Aetiology

Biological Factors

The possible causes of pre-menstrual dysphoric syndrome that have been considered to date are quite diverse. Bancroft and Rennie (1995) found that pre-menstrual mood alterations were positively correlated with the quantity of menstrual bleeding and the occurrence of pre- and peri-menstrual pain, although the cause-and-effect relationship between these pathological phenomena remains unclear, and it has not been determined whether they might all be produced by a common causal factor.

It has been known for some time that oestrogens raise the overall concentration of cerebral neurotransmitters (Distler and Graf 1986) by inhibiting the enzyme monoamine oxidase (MAO) (Luine and Rhodes 1983), and they should, therefore, have an antidepressant effect (Klaiber 1979). Oestrogens also have serotonergic effects (Sherwin 1990). They increase the number of cerebral serotonin receptors as well as serotonin receptor sensitivity (Kow and Pfaff 1985).

The central nervous system also possesses specific receptors for progesterone (Steiner 1987); unlike the oestrogens, progesterone increases MAO activity (Luine et al. 1975). Nonetheless, through its activity as a serotonin re-uptake inhibitor and an independent slowing effect on serotonin metabolism, it simultaneously increases serotonin activity and may, therefore, also have an antidepressant effect.

The results of these studies are theoretically compatible with the conclusion that the higher hormone concentrations in the follicular phase of the menstrual cycle have an antidepressant effect (Biegon et al. 1983; Luine and Rhodes 1983; Kow and Pfaff 1985). In the late luteal phase, the concentrations of these hormones are lower, and this protective factor is lacking.

In general, however, the temporal coincidence with the pre-menstrual drop in hormone concentrations does not explain why some women suffer from an affective syndrome and others do not. No direct relationship has yet been demonstrated between the syndrome and changes in the concentrations of the steroid sex hormones (Rubinow et al. 1988; Schmidt et al. 1991). Different groups of researchers have obtained inconsistent results. Pre-menstrually dysphoric women have been found to have both lower progesterone levels and higher oestrogen levels in the luteal phase than psychopathologically unaffected women. Bäckström et al. (1983) and Rubinow et al. (1988), however, found that these patients had the same peripheral blood levels of gonadal hormones as normal control subjects (reviewed in Dinane and O'Keane 1991). These observations also accord with the findings of Schmidt et al. (1991) that steroid hormone concentrations are not abnormal in pre-menstrual dysphoric syndrome and that an interruption of the late luteal phase by progesterone supplementation does not improve the psychopathological manifestations. Only Eriksson et al. (1992) found that affected women had higher progesterone levels in the late luteal phase than mentally healthy control subjects. In any case, it seems that pre-menstrual dysphoric syndrome cannot be explained as solely the result of elevated levels of one steroid hormone or depressed levels of another. There are even reports that manifestations may persist in the rhythm of the menses after hysterectomy with simultaneous oophorectomy (Bäckström et al. 1981), although, in the overwhelming majority of cases, the manifestations subside with menopause or after the pharmacological or surgical prevention of ovulation (Muse et al. 1984; Bancroft et al. 1987a; Casson et al. 1990).

Some patients with pre-menstrual dysphoric syndrome have corpus luteum insufficiency, which is characterised pathophysiologically by a disturbance of follicular maturation and by inadequate secretion of the corpus luteum products progesterone and oestradiol. This disorder, which is thus associated with labile ovarian function, also occurs at increased frequency post partum and pre-menopausally, i.e. in phases in which mental illnesses are also more prevalent.

There is increasing evidence that chronobiological factors also play a role in the aetiology and pathogenesis of pre-menstrual dysphoric syndrome. Patients are reported to have a low melatonin level and a premature termination of melatonin secretion (Parry et al. 1990).

It remains unclear to what extent thyroid endocrine function is involved in the aetiology of pre-menstrual dysphoric syndrome or of post-partal mental illnesses (Okano 1999). It is currently known only that women

with pre-menstrual dysphoric syndrome have a greater variability of thyroid hormone levels (Roy-Byrne et al. 1987; Schmidt et al. 1993; Girdler et al. 1995), as do women with post-partal mental illnesses (Pop et al. 1991).

Biography, Psychodynamics and Personality

There is no relevant evidence to date suggesting that pre-menstrual dysphoric syndrome can be induced by pschodynamic factors of any kind. Early psychoanalytic explanatory models postulated a suppressed conflict in the perception of the female role, which expressed itself in the manifestations described above on the onset of the menses. Against this idea is the fact that the psychopathologically relevant manifestations actually subside when menstruation begins. Furthermore, this disorder is also observed in hysterectomised women with intact ovarian function. Rohde et al. (1992) found no significant difference between fertile and infertile women regarding the incidence of this disorder. Furthermore, the large majority of studies documented no correlation between any specific personality type or personality disorder and pre-menstrual dysphoric syndrome, although 10% of affected women fulfil the DSM-IV criteria for a personality disorder of some kind (Gise et al. 1990).

It remains controversial whether the finding that women with pre-menstrual dysphoric syndrome generally have a high score for neuroticism, as reported by Keye and Trunnell (1986), Hallman et al. (1987) and Chuong et al. (1988), is relevant to the aetiology of the disorder. Schwarzer and van der Ploeg (1987) maintain that such a finding is not a constitutive element of the disorder and that it lacks causal significance because women have the same pattern of manifestations, and to a comparable degree of severity, regardless of whether their neuroticism scores are normal or elevated.

The sociobiographical traits listed by Appelt (1988) as possible determinants of the experience of menstruation, including age, social stratum, education, occupation and experiences of giving birth, were not confirmed as such in the more recent studies by Bergant et al. (in press). The significance of the experience and expression of anger in the causation of various somatic illnesses, which has received attention in recent years, leads directly to the question of the extent to which these might be operative in the pre-menstrual period, a time of increased psycho-endocrinological vulnerability. Despite frequently expressed opinions to the contrary, however, Bergant et al. (in press) were able to show that there is no significant difference in the ways that women with and without pre-menstrual symptoms deal with anger. The same study provided evidence that objectively and subjectively elevated risk factors, such as double stresses in professional and private life, multiple somatisation tendencies, negative experience of menarche and attitude toward menstruation and a tendency towards depressive mood changes are among the predisposing variables for this disorder.

In summary, the research findings discussed above concerning the pathogenesis of pre-menstrual dysphoric syndrome indicate that it most likely has endocrine-biological causes, though the chain of causation may also include psychological components, and supportive psychotherapeutic care of the patient may be necessary.

Genetics

It has been found that 70% of all daughters of patients with pre-menstrual dysphoric syndrome also have this condition, as opposed to 37% of daughters in a control group. When a twin suffers from pre-menstrual dysphoric syndrome, her co-twin is more likely to be affected than a non-twin sister: the concordance rate is 93% for monozygotic twins, 44% for dizygotic twins and 31% for non-twin sisters. The difference between dizygotic twins and non-twin sisters is, however, not statistically significant (Dalton et al. 1987). These data should not be overinterpreted, as the severity of the syndrome was not assessed as part of the study, but they clearly indicate that genetic factors play a role in aetiology and pathogenesis (Condon 1993).

1.2.7 Co-morbidity of Pre-menstrual Dysphoric Syndrome with Other Mental Illnesses

There is still controversy over the extent of co-morbidity of pre-menstrual dysphoric syndrome with other affective illnesses, e.g. with endogenous depression (de Jong et al. 1985; Warner et al. 1991). Bancroft and Rennie (1995), in a prospective study, did not confirm the presence of a relationship, which had been suggested by earlier retrospective analysis, between the occurrence of pre-menstrual mood disturbances and a history of previous manifestations of endogenous depression. On the other hand, the findings by Graze et al. (1990) and Pearlstein et al. (1990) do support the hypothesis of co-morbidity with endogenous depression. The lifetime prevalence of post-partum depression has been reported to be twice as high in women who suffer from pre-menstrual dysphoric syndrome (Pearlstein et al. 1988; O'Hara 1987). Hallman (1986) goes so far as to consider pre-menstrual dysphoric syndrome a variety of endogenous depression with an atypical course.

All clinicians are aware that endogenous depression is exacerbated pre-menstrually (Malikian et al. 1989) and that hospital referrals and suicide attempts cluster in the pre-menstrual period (Dalton 1959). It is

still unknown, however, whether there is a direct (genetic or other) aetiological or pathogenetic relationship between pre-menstrual dysphoric syndrome and manic-depressive illness. Evidence in favour of such a relationship is provided by the studies carried out by Harrison et al. (1985) and Freeman et al. (1990). Harrison et al. (1985) found an elevated prevalence of endogenous depression in first-degree relatives of women with pre-menstrual dysphoric syndrome, and Freeman et al. (1990) found a positive psychiatric family history in 45% and a family history of alcoholism in 40%. Women with pre-menstrual dysphoric syndrome have a significantly elevated prevalence of other affective illnesses – 56% according to Freeman et al. (1990), 60% according to Halbreich and Endicott (1985) and 30% according to de Jong et al. (1985), who further documented a 45% prevalence of psychiatric disorders of all types in these patients.

1.2.8 Treatment

Almost fifty more or less rational methods of treatment for pre-menstrual dysphoric syndrome have been proposed. They vary from psychotherapeutic to pharmacological, hormonal and even surgical interventions. Only a few controlled therapeutic trials have been performed. Thus little can be said to date about the potential efficacy of treatments other than psychopharmacologic and hormonal.

Psychopharmacotherapy

Antidepressants. Among the tricyclic antidepressants, therapeutic studies are available for clomipramine, which acts mainly through a serotonergic effect, and nortryptiline, a relatively specific inhibitor of noradrenaline re-uptake. Clomipramine was described as effective in doses as low as 25–75 mg per day by the research group of Eriksson et al. (1990) and Sundblad et al. (1992, 1993). The dosage of nortryptiline is given as between 50 and 125 mg per day, but therapeutic successes have been reported at doses as low as 10 mg per day (Harrison et al. 1989). The dosage of these tricyclic antidepressants may be titrated upwards or downwards depending on the severity of disease manifestations; it is clear that lower doses are generally required than for endogenous depression. Desipramine is also effective in pre-menstrual dysphoric syndrome, but it is not as effective as the selective serotonin re-uptake inhibitors. A study by Freeman et al. (1996a) revealed that the constellation of adverse effects of desipramine, which is typical of the tricyclic antidepressants, is less well tolerated by this group of patients than by those with endogenous depression. Other 5-HT_2 agonists have been found to be less effective in pre-menstrual dysphoric syndrome, with the exception of nefazodone (Freeman et al. 1994), which also inhibits serotonin re-uptake and is reported to have a good therapeutic effect, including an anxiolytic effect (Eriksson et al. 1995; Freeman et al. 1996a).

Selective inhibitors of serotonin re-uptake are reported to be effective in 60%–70% of patients with pre-menstrual dysphoric syndrome (Steiner et al. 1995) and are the treatment of first choice (Barnhart et al. 1995). Their effectiveness has been very well demonstrated scientifically; 20 mg daily of fluoxetine has been found to be effective (Rickels et al. 1990; Stone et al. 1991; Menkes et al. 1992; S.H. Wood et al. 1992; Su et al. 1997). A comparable effect can be achieved with sertraline at a dose of 50–150 mg per day (Freeman et al. 1996a; Yonkers et al. 1996, 1997) or paroxetine at 10–40 mg per day (Eriksson et al. 1995; Sundblad et al. 1997). Fluvoxamine, at a dose of 100 mg per day, leads to a significant improvement of pre-menstrual dysphoric syndrome manifestations (Freeman et al. 1996b).

A possible advantage of sertraline over fluoxetine in the treatment of pre-menstrual dysphoric syndrome is its shorter half-life, which facilitates the temporal restriction of treatment to the late luteal phase of the menstrual cycle; unlike tricyclic antidepressants, selective serotonin re-uptake inhibitors have been shown to be therapeutically effective when taken only during the late luteal phase. According to a recent study by Steiner et al. (1997), 75% of patients respond to intermittent treatment with fluoxetine. Undesired effects, which may be caused by active metabolites and may not appear until after menstruation, can thus be kept to a minimum (Halbreich and Smoller 1997; Lenzinger et al. 1997). Intermittent treatment with selective serotonin re-uptake inhibitors, i.e. treatment during the luteal phase only, is superior to continuous treatment throughout the menstrual cycle (Sundblad et al. 1993), particularly with regards to accompanying somatic manifestations (breast swelling, abdominal complaints).

With respect to physical symptoms, noradrenaline and serotonin re-uptake inhibitors appear to work equally well (Sundblad et al. 1992; S.H. Wood et al. 1992; Sundblad et al. 1993). Tricyclic antidepressants also continue to have a place in the pharmacological treatment of pre-menstrual dysphoric syndrome.

With respect to side-effects, it should be noted that patients with endogenous depression suffer more from their condition than patients with pre-menstrual dysphoric syndrome and are thus more likely to tolerate side-effects of medication. For this reason, too, selective serotonin re-uptake inhibitors are the agent of first choice for pre-menstrual dysphoric syndrome. Nevertheless, they are not entirely free of side-effects:

many patients complain of sleep disturbances that first appear when the medication is taken. Disturbances of sexual function that may occur in connection with pre-menstrual dysphoric syndrome, such as loss of libido and anorgasmia, may be positively influenced by the use of selective serotonin re-uptake inhibitors, but may also be brought on or exacerbated by it.

The psychostimulant and serotonin agonist fenfluramine has been reported to alleviate food cravings and to have an antidepressant effect at a dose of 15 mg twice a day. Nevertheless, it seems to be less effective than other selective serotonin re-uptake inhibitors against other manifestations of the disorder, such as lability of affect with increased irritability, tearfulness etc. (Brzeznski et al. 1990). It is not on the market in all countries and has been removed from the market in some.

The listing of antidepressants in this section is not meant to imply that others not mentioned here are ineffective, but there are as yet no studies on the use of other agents in the treatment of pre-menstrual dysphoric syndrome.

There are, surprisingly, no controlled studies on the treatment of pre-menstrual dysphoric syndrome with monoamine oxidase inhibitors. At present, only case reports on the two irreversible MAO inhibitors phenelzine and tranylcypromine are available. Nothing is known concerning the possible effectiveness of the reversible MAO inhibitor moclobemid in pre-menstrual dysphoric syndrome.

Anxiolytics and Psychostimulants. Benzodiazepines have been prescribed for many years as a treatment for pre-menstrual dysphoric syndrome. An inadequate number of therapeutic trials were available until the introduction of the atypical benzodiazepine alprazolam (Harrison et al. 1987), which has both anxiolytic and antidepressant effects. Most, but not all studies (Schmidt et al. 1993) indicate that 4 mg per day is effective when taken starting 6–14 days before menstruation. The dose should be reduced stepwise, by 25%, each day after the onset of the menses, in order to prevent a rebound effect with increased anxiety. Interestingly, alprazolam was found to be less effective in patients who had anxiety disorders and depressive mood changes in the follicular phase, as well as in those who became ill only in the late luteal phase (Berger and Presser 1994). Freeman et al. (1995) found a larger therapeutic effect than with progesterone treatment when alprazolam was given at a dose of only 0.25 mg four times daily. The fact that alprazolam has no clinically active metabolites simplifies the management and temporal restriction of treatment. The currently available studies of intermittent alprazolam use by patients with pre-menstrual dysphoric syndrome suggest that the danger of physical dependence is small (Smith et al. 1987; Harrison et al. 1990).

The partial 5-HT_{1A} receptor antagonist buspirone, which is said to have a good anxiolytic effect, particularly in long-term use, was shown by the studies of Rickels et al. (1989) to be especially effective against the dysphoric components of the syndrome, in the narrow sense of the term. Intermittent treatment is recommended for 12 days before the menses at a dose of 25 mg daily (Rickels et al. 1989). This medication, too, has a short half-life, which facilitates the management of treatment.

The advantage of treatment with alprazolam and buspirone over treatment with most of the antidepressants is that they are very well suited to intermittent use (Freeman et al. 1995), although the selective serotonin re-uptake inhibitors are otherwise more effective (Pearlstein et al. 1997).

Lithium. Lithium prophylaxis against pre-menstrual dysphoric syndrome is ineffective in most cases (Singer et al. 1974). This may be because the blood lithium level varies over the course of the menstrual cycle despite constant dosing and is, in fact, lowest in the pre-menstrual period. Perhaps the subgroup of patients who respond consists of those suffering not from pre-menstrual dysphoric syndrome in the narrowly defined sense, but from a pre-menstrual relapse or exacerbation of endogenous depression or cyclothymia (Sletten and Gershon 1966; Singer et al. 1974; Steiner et al. 1980; de Leon-Jones et al. 1982). It has not yet been scientifically studied whether, as we suspect, the lithium responders are precisely those patients with a positive family history of bipolar affective disorders (Lanczik 1995).

Hormonal Treatment

Case reports and controlled scientific studies of hormonal treatment for pre-menstrual dysphoric syndrome have yielded partly conflicting results. There are many reports of therapeutic success with progesterone. The suppression of ovulation by the continuous administration of gestagen–oestrogen combinations is still considered the most promising method of hormonal treatment for the alleviation, if not total suppression, of disease manifestations (Andersch and Hahn 1981; Graham and Sherwin 1987; Walker and Bancroft 1990). This may be achieved by the use of contraceptives, which suppress ovulation while preserving menstruation, or by the percutaneous application of oestradiol at an anovulatory dose of 0.2 mg daily (Watson and Studd 1990). According to Corney and Stanton (1991), oral contraception improves both the physical symptoms and mental concentration in 31% of patients and causes a deterioration of well-being in 20%. Graham and Sherwin (1992) confirmed this finding and pointed out that

oral contraception is more effective against the somatic than against the psychic manifestations. Maddocks et al. (1986) found no therapeutic effect with progesterone supplementation alone and even, in some cases, an anti-therapeutic effect. Oestrogen supplementation alone, however, was found to improve mental well-being (Herzberg and Coppen 1970; Winston 1973).

Anovulatory cycles may also be obtained by down-regulating pituitary secretion of the gonadotropins with gonadotropin-releasing hormone (GnRH) analogues, which, when given continuously, result in complete hypogonadism. Oestrogen and progesterone must be given in addition. The presence of undesired vegetative side-effects may lead to the usefulness of this method in obtaining the desired mental effect to be questioned. This method is, in our opinion, only of theoretical interest at present; it serves to highlight the importance of the hypothalamic–anterior pituitary–ovarian functional loop for the pathogenesis of pre-menstrual dysphoric syndrome (Muse et al. 1984; Mortola et al. 1991; Hammarbäck and Bäckström 1988).

Two groups recommend hysterectomy with bilateral oophorectomy as a treatment of last resort in rare cases, such as in very severely affected patients with demonstrated non-response to GnRH analogues (Casson et al. 1990; Casper and Hearn 1990).

Psychotherapy

The response to supportive psychotherapeutic measures is said to be correlated with the response to placebo. Yet this disorder, whose origin is clearly pathophysiological rather than psychopathological, subjects many patients to interpersonal stresses, particularly in their relationships with partners and in their sexual lives, which may be accessible to treatment by supportive psychotherapy; a number of authors favour group therapy (Walton and Youngkin 1986). The motto for the treatment of pre-menstrual dysphoric syndrome should thus not be "medical treatment instead of psychotherapy", because, in many cases, medical therapy in combination with supportive psychotherapy is the best option.

Phototherapy

Phototherapy, which has been found to be an effective treatment for the subgroup of seasonally occurring cases of endogenous depression, has also been reported to alleviate the manifestations of pre-menstrual dysphoric syndrome (Parry et al. 1989, 1990, 1993).

Conclusion

In conclusion, treatment with psychoactive medications is the single best therapeutic approach in pre-menstrual dysphoric syndrome. Combinations with hormonal, psychotherapeutic and other adjuvant methods may yield better results than psychopharmacologic treatment alone.

1.3
Menstrual Psychosis (I.F. Brockington)

Menstrual psychosis disorder has the following features:

- Acute onset, against a background of normality
- Brief duration, with full recovery
- Psychotic features, i.e. confusion, delusions, hallucinations, stupor and mutism, or a manic syndrome – not merely pre-menstrual tension or depression
- A circa-mensual periodicity, in rhythm with the menstrual cycle

The first observations appeared in the eighteenth century, and as early as 1827 menstrual mood disorder was used as a defence in filicide (Hitzig 1827). In 1902, von Krafft-Ebing, in his monograph *Psychosis Menstrualis*, proposed a temporal classification. The present classification is a modification of this, organised by onset within the menstrual cycle and stage of reproductive life.

1.3.1 Classification by Timing Within the Menstrual Cycle

Pre-menstrual Psychosis. These psychoses start during the second half of the cycle and often end suddenly at menstrual onset.

Catamenial Psychosis. These begin with menstrual flow.

Para-menstrual Psychosis. These are psychoses with variable timing, always in harmony with the menstrual cycle. An excellent example, with 35 timed episodes, was published by Ewald (1922). There are instances of a systematic change from one epoch to another, e.g. from pre-menstrual to mid-cycle.

Mid-cycle Psychosis. These are comparatively uncommon (Wollenberg 1891).

Epochal Menstrual Psychosis. This is a term introduced by von Krafft-Ebing to denote bipolar psychoses lasting throughout the cycle, with switches linked to menstruation.

1.3.2 Classification by Stage of Reproductive Life

Pre-pubertal Cases. These girls develop circa-mensual episodes before the menarche (Friedmann 1894; Schönthal 1892).

Onset After Childbirth. This has been termed, in the literature on puerperal psychosis, "the menstrual relapse phenomenon". A menstrual psychosis can also begin in the puerperium, without a preceding puerperal episode.

Circa-mensual Psychosis During Amenorrhoea. There are examples of a menstrual psychosis continuing during months in which menstruation failed to appear, and others which occurred only during amenorrhoea.

Menopause. There are possible cases which began after the menopause or oophorectomy.

1.3.3 Features of the Illness

Menstrual psychosis is rare, but perhaps not excessively rare. It is not a specific disease entity. The most typical examples have manifested non-menstrual bipolar disorder at another stage of life. Clinically, it is similar to puerperal psychosis, with manic features, stupor, catatonia, schizo-affective depression and cycloid episodes. The close relationship between these two psychoses, linked to female reproduction, is also demonstrated by women who develop puerperal and menstrual mental illness at different times in their lives (at least 20 in the literature).

A major endocrinological investigation was conducted in Japan (Kitayama et al. 1984). This made the important observation that most closely studied patients had anovulatory cycles.

As for treatment, there are claims of success with progesterone or oral contraceptives, but they are not always effective. Arresting menstruation with danazol or gonadorelin agonists should be tried. In patients with anovulatory cycles, clomiphene, which promotes normal menstruation, has been used. This disorder offers an opportunity for unconventional treatments. They should be prescribed in the context of a long-term study of individual patients, with daily ratings or exact timing of events.

2
Psychiatry of Childlessness and the End of Child-Bearing (I.F. Brockington)

2.1
Infertility

Motivation for motherhood is among the strongest and most universal. Many women unable to bear children suffer greatly from this misfortune: infertility is the most upsetting experience of their lives, and the yearning for children dominates everything. Infertile couples often suffer from self-reproach over sexual indiscretions, abortions, contraception or venereal disease or simply from a tremendous sense of guilt over the fact of infertility itself. It is difficult to deal with the envy felt towards fertile couples.

Infertility differs from other stresses in its duration. The psychological reaction unfolds in stages over years, with initial denial and disbelief, followed by embarrassment, bitterness and recrimination. When treatment begins, there is a cycle of optimism and hope. Sexual functioning comes under strain during the investigation. The discovery of azoospermia is especially stressful. Eventually there is acceptance or resignation.

2.1.1 Artificial Insemination

Artificial insemination using the husband's semen has been available from the late eighteenth century, and insemination by donor (AID) since 1884. The psychological effects of the latter, on the husband and the marriage, seem minimal. Husbands rarely react with jealousy to the birth of the baby, any more than to an adopted child. The proof that the experience is entirely acceptable to most couples is that it is often repeated. One of the principles of treatment is privacy, ensuring that donor and couple never meet and remain ignorant of each other's identity.

2.1.2 In Vitro Fertilisation

In vitro fertilisation (IVF) was first performed in 1978. The success rate is low. Some women, however, report satisfaction at having tried everything possible; it is easier to cope with infertility, and they are able to focus their minds on adoption.

2.1.3 Surrogate Motherhood

Surrogate motherhood is another innovation, with psychological complications. It has two meanings:

- A woman contracts with a couple to be inseminated (artificially or naturally) with the husband's semen and to surrender the child to the genetic father and adoptive mother. The surrogate provides both oocyte and womb and is a substitute spouse.
- The wife is the genetic mother, donating a fertilised oocyte to the surrogate gestational mother. This method, involving IVF and embryo transfer, is the only method of enabling a wife with working

ovaries, but without a uterus, to have a child which is genetically her own. The first pregnancy by this method was reported in 1989.

Surrogate pregnancy has stirred up an intense ethical debate. Apart from religious objections, there is concern about the physical and psychological consequences for the gestational mother, who endures the discomforts and complications of pregnancy and may bond to the child during gestation. Even if she is a friend or a relative, she may be under psychological coercion. There are endless opportunities for custody disputes, and there may be complications for the laws of parental responsibility and property.

2.2 Pseudo-cyesis

When a woman believes herself to be pregnant and develops symptoms and signs of pregnancy, this is called pseudo-cyesis. Bivin and Klinger wrote their classic monograph in 1937.

The differential diagnosis includes the following:

- Delusions of pregnancy (Vié and Bobé 1932), in which there are no somatic signs of pregnancy. This is a common delusion, which can occur in a variety of psychoses. There is often a history of hallucinatory intercourse. Delusions of pregnancy also occur in men, with and without the somatic phenomena of pseudo-cyesis.
- Simulated pregnancy – for social, mercenary or legal purposes, e.g. to escape the capital penalty. A famous example is Olympe de Gouges, who wrote one of the first feminist tracts, *The Rights of Woman*, in 1791; in spite of her claim to be pregnant, she was guillotined.

The clinical features include the following:

- A firm belief in the pregnancy, usually lasting until a false labour at 9 months, after which the disorder usually resolves.
- Amenorrhoea
- Morning sickness and pica
- Enlargement of the breasts and nipples, even a discharge of colostrum
- Abdominal enlargement, caused by muscular contraction, tympanites, fat or pathological lesions, e.g. ascites or fibroids, but without effacement of the navel
- An illusion of foetal movements
- Enlargement of the uterus to the size of a 6-week pregnancy

Modern diagnostic tests, such as ultrasound, have greatly reduced its frequency.

The psychological basis is usually an intense desire for children, especially in older childless women. In some cases, however, a guilty fear of pregnancy has been the background; this has occasionally led to dangerous attempts at abortion in women who are not pregnant (von Neugebauer 1912; Percheval 1911).

Pseudo-cyesis is a demonstration of the influence of psyche over soma, mediated by hormonal secretion. It occurs in dogs, cattle and rodents, due to persistence of the corpus luteum. This explains the breast changes, moderate uterine enlargement and secretory endometrium. In humans, this has also been demonstrated by surgical examination (Courrier et al. 1927; Reeb 1933). Persistence of the corpus luteum, however, is not the only explanation. Hormonal measurements have been made in at least 30 patients and have shown chronic anovulatory states, hyper-prolactinaemia and hyper-androgenism as alternatives.

These women require psychotherapy. Simply revealing the diagnosis is unsatisfactory because the patient may go to another doctor with the same symptoms or develop a recurrence. The underlying conflicts must be explored, helping the patient to face the fact that she is not pregnant. Some require antidepressant medication.

2.3 Sterilisation

Women can be prevented from bearing children by various operations on the uterus and fallopian tubes. None of these methods is completely effective, with failure rates of about 0.5%, with an increased risk of ectopic pregnancy. Sterilisation can be reversed by repairing the fallopian tubes, and, with modern microsurgery, this is often successful. As sterilisation becomes more common, it is carried out in younger women. As the divorce rate climbs, its reversibility is becoming an increasingly important issue.

The indications are contraceptive, medical, eugenic and psychiatric. Contraception is by far the commonest, and sterilisation is the most effective and widespread contraceptive method. The medical grounds include diabetes, rhesus incompatibility, hypertension and renal and heart disease. Eugenic sterilisation for hereditary medical or psychiatric disorders is rare. Sterilisation of women with severe learning disability has been legal in certain countries at certain times. This remains a controversial issue, which is becoming more important. With the closure of institutions and the greater tolerance of sexual activity outside marriage, there is an increased risk of pregnancy in women with severe learning difficulties, with the spectre of inherited disorders and problems in moth-

ering. Yet these women greatly desire children, not having the same resources to compensate for lack of them.

Some early studies reported a high frequency of depression, but modern prospective studies have failed to confirm this. Cooper et al. (1982) in Oxford interviewed 201 women 4 weeks before non-puerperal tubal sterilisation, done for contraceptive reasons; 190 were re-interviewed 6 months later and 193 again 18 months after the operation. The number with psychiatric illness fell from 21 before the operation to nine 6 months later and then rose again to 18 at 18 months. Not surprisingly, the presence of psychiatric disorder before the operation was a predictor of its continued presence. The World Health Organisation has conducted a collaborative project to assess the effects of sterilisation in different cultures. In the report from the Nottingham field centre (Bledin et al. 1984), there was little evidence of psychiatric disorder either before or after sterilisation: nine out of 138 sterilised women were "cases" before the operation, and there were only three new cases 6 weeks afterwards and four more at the 6-month assessment, less than in the control group.

Regret is more common in the following groups of women:

- Those with fewer children (Ekblad).
- Younger women.
- Those in whom sterilisation was the condition for a termination. This barbaric and punitive practice used to be the rule in some countries. It is doubtful whether sterilisation should ever be carried out simultaneously with termination, because there is little time for discussion, and a woman may take a rash decision in the extremity of her anxiety about an unwanted pregnancy.
- Those sterilised at parturition. It is often difficult to make a balanced judgement when a new child is about to be born.
- Those under external pressure.
- Those with learning difficulties.
- Those sterilised for medical reasons. Particularly poignant are the feelings of women who have undergone tubal ligation because of an inherited disorder, which has since become diagnosable by amniocentesis.
- Those with psychiatric illness. Psychiatric illness often impairs judgement and, after recovery, decisions may be regretted.
- Those who seek sterilisation in a context of marital disharmony. In almost all cases undertaken to save the marriage, this was unsuccessful.
- Those with religious scruples.

Several have commented on a special group of women with an intense fear of pregnancy (tocophobia). Most of these women were greatly relieved by sterilisation (Binder 1937; Hoppeler 1955).

2.4 Hysterectomy

Hysterectomy is one of the commonest operations, performed in about 10% of women. Among the usual indications are menorrhagia due to fibroids and various types of abdominal, pelvic or back pain. It would not be surprising if the loss of the womb had psychological effects on feminine identity. In younger women, the loss of fertility can be a source of discontent. Hysterectomy is sometimes performed expressly to achieve sterilisation, having the advantages of greater certainty and the elimination of a non-functioning organ which could later become diseased.

Twenty years ago, there was a widespread belief that hysterectomy caused depression. Since then this idea has been thoroughly and systematically refuted. Several prospective investigations have shown that mental health improves after hysterectomy (Gath et al. 1995; Martin et al. 1980). The ranks of women with "post-hysterectomy" depression are swollen by those who seek a surgical remedy for psychosomatic complaints.

Apart from depression, hysterectomy may have an effect on libido, but on the whole this is also a myth. Authoritative prospective studies in St. Louis and Oxford showed an increase in the frequency of intercourse and of enjoyment.

3 Psychiatry of Pregnancy (I.F. Brockington)

3.1 Pregnancy Adjustment

The psychopathology of pregnancy needs to be understood in terms of the adjustment which all women have to make when they conceive. Pregnancy is not only a biological event, but also an adaptive process (Cohen 1988). A pregnant woman must not only carry the baby through safely, but square up to the sacrifices that motherhood demands. She must ensure the acceptance of the child by the family, develop an attachment to the baby within and prepare for the birth. She must adjust to the alteration in her physical appearance and develop a somewhat different relationship with the child's father.

Many pregnancies are unplanned and not initially welcomed. Many react to conception with grief and

anger. A recent random sample of English mothers showed that 44% of pregnancies were unintentional, including 17% which ended by legal abortion. The range was from 80%–84% intended pregnancies in married women aged 25–29 with one child born less than 4 years previously to 26% in the unmarried (Cartwright 1988).

The planning of pregnancy and its acceptance are two different things. The fact of planning does not guarantee acceptance; 6%–12% of those who planned their pregnancies switch to rejection. Usually, the change is in the other direction, and there is often an immediate acceptance of an unplanned pregnancy. Even if the initial response is negative, it is usually replaced by gradual acceptance. In a small proportion, however, rejection continues to the end. Although there is a shift to acceptance, this may be superficial, involving an ambivalence which continues after the child is born.

Pregnancy has a profound effect on the relationship with the child's father. At every stage, this relationship is of the highest importance. A pregnant woman needs increased attention and care and is sensitive to perceived rejection. For many women, the baby is viewed as a gift to the husband. Pregnancy alters other relationships. The need for attention and care extends to family members and friends. Many women become closer to their families of origin and their in-laws. The change in shape is sometimes distressing, but others take pride and pleasure in their pregnant appearance.

Pregnancy is accompanied by medical disorders, and in all there is an interaction between physical and psychological factors. Pica is common: 20% have cravings for inedible substances. Geophagia (eating earth or clay) can lead to iron deficiency anaemia and bowel obstruction. Hyper-emesis can lead to Wernicke's encephalopathy (Dupouy and Courtois 1930; Selitzky 1925). Pre-eclamptic toxaemia is more common in first-time mothers; its dreaded complication was eclampsia, which was sometimes followed by confusional or manic psychoses (see below).

3.1.1 Denial of Pregnancy

Failure to recognise pregnancy is common in the early stages, especially in those pregnant accidentally or for the first time; in a few it continues until delivery (Brezinka et al. 1994). One must distinguish between the following:

- Those who are obese or near the menopause – who simply do not notice the pregnancy
- Those who conceal it
- Those who, against all the evidence, remain obstinately unaware of it

Among the psycho-social factors which predispose, isolation is important because there is no-one to notice and comment on the change in appearance. Another is a moral climate antagonistic to extra-marital sexual relations. Low intelligence may contribute. The psychological mechanisms which enable pregnancy to remain unacknowledged include denial and dissociation. There may also be the belief that the baby had died.

The late discovery of an unwelcome pregnancy carries a small risk of suicide. The mother is also at risk of all those complications of delivery which, with modern obstetrics, have become rare. For the child there are increased hazards at the time of the birth, including neonaticide.

3.1.2 Prenatal Attachment

Recently it has been realised that the mother "bonds" or "affiliates" to the unborn child in a way analogous to the formation of the mother–infant relationship after birth (Arbeit 1975; Cranley 1981; Leifer 1977). She begins to have fantasies about the baby and often talks affectionately to him or her. She may engage the husband and other children in "playing" with the child. She begins to imagine what it will be like to assume responsibility for baby care.

There is a pathology of the affiliative stage. In some mothers, there is minimal attachment even at term. The foetus is viewed as an intrusion, whose movements annoy or distract the mother, disturb her sleep or make her feel ill. When the mother's attitude to the pregnancy is obstinately rejecting, therapists can direct attention to the relationship with the child.

3.1.3 Foetal Abuse

When a mother deeply resents her pregnancy, she may try to harm the foetus. This occurs, with determined intent, in self-induced abortion. It may be a manifestation of rage against the infant within. Condon (1987), who described this phenomenon, stated that it aroused the same incredulity as did child abuse in the 1950s.

It is not only the mother who may "batter" the foetus. Domestic violence is common. Abuse may increase during pregnancy, when kicks and blows are directed at the abdomen, rather than the face. The main factors are sexual frustration, unreadiness for

fatherhood, jealousy, the mother's irritability and substance abuse.

3.2 Mental Illness During Pregnancy

3.2.1 Anxiety

For many mothers, pregnancy is a time of considerable anxiety. The first trimester may involve an anguished decision whether to continue or terminate. Women who have previously miscarried or suffered infant loss reach a peak of apprehension at the time the earlier pregnancy ended. In the third trimester, there is an escalation of anxiety, centred on three main themes – the fear of parturition (tocophobia), of foetal abnormality and of not coping with motherhood.

These anxieties will usually be managed by ventilation and support, but anxiolytic medication can be used cautiously. Benzodiazepines are contraindicated in the last stage, because they can cause prolonged foetal intoxication ("the floppy infant syndrome"), especially in premature infants. Propranolol is best avoided, because of reports of intra-uterine growth retardation and neonatal cardiac and respiratory symptoms.

3.2.2 Depression

Although pre-partum depression has not aroused the same interest as post-partum depression, it is no less common (Cooper et al. 1988). Depression is common in all women in the reproductive age-group, and its frequency during pregnancy may be no more than this general tendency. It can be recurrent: there are at least ten reports in the literature of mothers who have suffered four to 12 attacks with successive pregnancies; some have recovered promptly at delivery, and there is an association with puerperal mania (Brockington 1996).

The frequency of suicide during pregnancy is a vexed question: there are problems about the accuracy of the data – not all suicides are reported to the coroner, not all have necropsies and not all necropsies include an examination of the uterus. Both suicide and pregnancy are often concealed. Nevertheless, there seems to be a difference between studies which appeared at the beginning and end of this century, with higher rates in the first quarter. These showed that about 13% of female suicides were pregnant – rather a high figure, suggesting that pregnancy was a risk factor when illegitimate pregnancy was considered so shameful. More recent studies show lower rates. The study by Weir (1984) outweighs all others in its thoroughness. Weir studied all the depositions for 1696 suicides in central London between 1943 and 1962: 3.9% were pregnant; 40 out of 66 pregnancies were conceived outside marriage – about six times the illegitimacy rate in London at the time. His data suggest that the crisis of adjustment to an unwanted pregnancy was still a factor in suicide in the mid-twentieth century.

Severe prenatal depression is sometimes left untreated, because of fears for the effect of drugs on the foetus. These have been exaggerated. No antidepressive drug is known to have teratogenic effects, nor any other effects on the growing foetus. There are occasional reports of side-effects or withdrawal symptoms in neonates, including heart failure, seizures, hypothermia, laryngeal spasm and retention of urine, so medication is more to be avoided in the last trimester. It is too early to reach conclusions about the safety of the recently introduced serotonin reuptake inhibitors. Electroconvulsive therapy (ECT) is safe, provided that the mother is competently oxygenated during the brief period of anaesthesia. Pregnant women should be screened for rare syndromes of pseudo-cholinesterase deficiency before receiving ECT.

3.2.3 Alcoholism

Pregnancy has a beneficial effect on alcohol addiction, but, if heavy abuse continues, there are severe effects on the foetus. Ethanol is teratogenic – causing the "foetal alcohol syndrome" (Lemoine et al. 1968), whose features include facial dysmorphism due to maxillary hypoplasia. Alcohol's main effect, however, is intra-uterine growth retardation (Ulleland 1972). Exposed infants may have withdrawal symptoms. Learning difficulties are a long-term consequence.

3.2.4 Other Addictions

Cannabis is commonly abused by pregnant women, but probably has no major effects on the foetus. Lysergic acid diethylamide (LSD) may have teratogenic or mutagenic effects. Phencyclidine addiction leads to withdrawal symptoms.

Narcotic addicts, like alcoholics, have multiple emotional and social problems, and most do not seek antenatal care. The infants may be affected by maternal malnutrition and infections such as venereal disease, hepatitis, endocarditis and acquired immune deficiency syndrome (AIDS). Narcotics are not teratogenic, but a high proportion of the infants are of low birth weight, partly explained by prematurity, and partly by

intra-uterine growth retardation. A withdrawal syndrome develops in most babies. The perinatal mortality rate and frequency of sudden infant death (SID) are increased.

In the management, all mothers should have social case work. Other drugs of abuse should be gradually withdrawn. If it is decided to withdraw heroin, this should be done in the second trimester, replacing it by methadone. Naloxone should only be given to save life after an overdose, because it precipitates a foetal abstinence syndrome. After birth, the infants should be kept in hospital for 14 days. Respiratory depression can be treated by naloxone, seizures and withdrawal symptoms by diazepam.

Cocaine may be teratogenic, causing genito-urinary abnormalities, but the evidence is conflicting. Its main effects are cardiovascular. It causes uterine vasoconstriction, and this can lead to abruptio placentae (separation of the placenta from the uterine wall). There is intra-uterine growth reduction, and premature labour is common – even commoner than with other addictions. The infants may suffer cerebral infarction. There is a withdrawal syndrome, but this is less severe than with narcotics. There is evidence of an increased risk of SID.

3.2.5 Eating Disorders

There are psychological and somatic reasons for an antagonism between pregnancy and anorexia nervosa; nonetheless, the majority of women with anorexia nervosa recover, with return of menstruation when the weight reaches about 80% of the standard weight. There are numerous case reports and several long-term studies establishing the fact that many women with a history of anorexia nervosa give birth to children in the normal way. The overall effect on fertility has been quantified by a 12-year Danish study: the average number of children (0.6) was about one third the usual figure (Brinch et al. 1988). A minority become pregnant while in the throes of the disease. If the mother continues to restrict her diet, the foetus may suffer from malnutrition, with reduced abdominal girth and low birth weight. Occasionally, it has been necessary to rescue the infant by elective caesarian section. When mothers are actively anorexic, their children may be affected by their attitudes to feeding, suffering stunted growth.

Bulimia nervosa is often improved by pregnancy (Morgan et al. 1999). The pressure of the enlarging uterus on the stomach may make bulimia more difficult. Some mothers report that the presence of the baby inhibits bingeing. About half relapse after delivery. Bulimic mothers also sometimes show deviant mothering, ignoring their children while overeating or vomiting, or restricting food supplies.

3.2.6 Obstetric Factitious Disorder

Self-induced illness behaviour can extend into the obstetric domain (Goodlin 1985; Jureidini 1993). Women may induce bleeding to simulate threatened miscarriage, placenta praevia or post-partum haemorrhage. They may simulate rupture of membranes in order to precipitate an early delivery. Others have been caught manipulating instruments, e.g. the external tachodynamometer. Two patients even attempted to simulate hydatidiform mole, by adding human chorionic gonadotrophin to blood samples.

3.2.7 Pre-partum Psychosis

Numerous asylum surveys have testified to the lower frequency of psychosis during pregnancy than after delivery. This has been confirmed by two large surveys. Paffenbarger, in his study of patients admitted to hospital in Ohio (Paffenbarger and McCabe 1966) found an overall rate of 0.7 per 1000 population per year, compared with 4.0 per 1000 for post-partum psychosis and 3.6 per 1.000 in non-child-bearing women. Kendell, in Edinburgh, had the advantage of linking obstetric and psychiatric case registers (Kendell et al. 1987). A study of 54,087 births showed rates for psychosis of 2.1 per month before conception, 2.0 during pregnancy, 51 in the first post-partum month, 25 in the second, 13 in the third and four thereafter; thus the risk of admission with psychosis was unchanged during pregnancy and much lower than after childbirth.

Pregnancy probably has no effect on chronic delusional states, but there is a beneficial effect on menstrual psychoses, and possibly bipolar and cycloid psychoses. Acute manic and cycloid episodes occur during pregnancy, and some seem remarkably similar to puerperal psychosis. Indeed, they have been observed in women with a history of typical puerperal psychosis (Brockington 1996).

It is, on the whole, safe to prescribe neuroleptic agents during pregnancy. Phenothiazines and butyrophenones are not teratogenic. The main (but infrequent) hazard is the appearance of sedation and extra-pyramidal symptoms in the newborn. Lithium is relatively dangerous. It may cause cardiac malformations: at least 12 cases of the rare Ebstein's anomaly have been reported. As delivery approaches, reduced renal clearance can result in toxicity on normal doses: five cases of alarming blood levels (up to 5 m*M*/l) have been reported, with coma and convulsions in the

mother. Even at normal blood levels, babies exposed to lithium have suffered lethargy, hypotonicity and other effects. Carbamazepine has been associated with rather high rates for congenital abnormality, and sodium valproate with spina bifida.

3.2.8 Obstetric Liaison Services

In view of the complexity of the psychological response to pregnancy, and the frequency of anxiety, depression and other psychiatric disorders, comprehensive obstetric and psychiatric services should include a liaison between the two specialities. In addition to the diagnosis and treatment of the pre-partum psychiatric disorders described above, the high level of supervision in the antenatal clinics can be exploited to detect those vulnerable to post-partum illness. Since many women wish to avoid the stigma of psychiatric referral, it may be best to employ specially trained midwives, whose role would be to detect and treat milder disorders and to refer those with more serious illness or vulnerability.

3.2.9 Psychopathology of Parturition

Childbirth can be one of the severest of human ordeals, and it would be surprising if its torments did not result in acts of desperation. They are fully described in the older literature. They are much rarer now, but may still occur where obstetrics is primitive, or pregnancy denied. Auto-caesarian section has been described. There are several reports of completed suicide, by defenestration, drowning, hanging or coal gas poisoning. Rage attacks are also described. They can endanger the foetus and may be a factor in some cases of neonaticide. Confusional states are rare, but well documented (Engelhard 1912; Kirchberg 1913; Sarrat 1911).

3.3 Infant Loss

The child may be lost under a wide variety of circumstances:

- Termination of pregnancy, at the behest of the mother
- Miscarriage, ectopic pregnancy and late termination of a wanted child for medical reasons
- Foetal death in utero, stillbirth, neonatal death and SIDS
- Relinquishment to adoption

3.3.1 Termination of Pregnancy

Termination of pregnancy is condemned by the Roman Catholic Church and Islam. During this century, and especially the last 30 years, there has been a general movement towards liberalisation.

The indications include the following:

- Medical grounds – to preserve the health and life of the mother
- Humanitarian grounds – when pregnancy has resulted from rape or incest
- Genetic or eugenic grounds – where there is a risk of congenital abnormality
- Psychiatric grounds – e.g. to prevent suicide
- Social grounds – because pregnancy is untimely and disruptive, to the disadvantage of the unborn child
- On demand – in some nations, it is believed that women should be free to decide on pregnancy and maternity

There has been an intense debate on the validity of psychiatric indications; this turns on the psychiatric consequences of a refusal to terminate. Suicide threats are common, but are rarely carried out; nevertheless, there can be no doubt that unwanted pregnancy is a factor in completed suicide. A history of puerperal psychosis is not an indication, because episodes are equally likely to follow abortion. There are other, arguably more serious, puerperal complications such as mother–infant relationship disorders, which are more common after unwanted pregnancy. These can be avoided by adoption, but the psychological effects of relinquishment are not negligible.

The psychological effects of termination have been thoroughly explored. Most of those who voluntarily abort suffer no adverse effects, either in the short or long term. There is often relief, even euphoria, and a reduction in anxiety, depression, anger, guilt and shame. A minority experience regret and self-reproach over the "murder" of the baby; some feel like criminals, worry about punishment or the nemesis of sterility or future congenital malformations. A few develop clinical depression (Edelberg and Galant 1925), which may ensue after the next pregnancy. There is evidence that manic or cycloid episodes, similar to puerperal psychosis, occur after abortion (David 1985).

In order to minimise the psychological risk, prudent decision-taking is of the essence, and counselling has a valuable role. The most difficult part of the experience is loneliness and isolation. Many do not inform their parents and, when they do, endure negative responses and unwelcome pressure. The attitude of the child's father is crucial. It is axiomatic that a woman should make her own decision – one of the most difficult that

she will ever take, with profound long-term consequences. It often has to be taken hastily, in an atmosphere of conflict and turmoil. The best outcomes are found when a woman makes her decision in a context of respect and support from partner, parents, friends or counsellor.

3.3.2 Miscarriage

Miscarriage is a common event and occurs in perhaps 40% of all conceptions, but only 10% after pregnancy becomes apparent through amenorrhoea or other signs. Its emotional consequences are not trivial, but comparable to foetal death in utero or perinatal death – less severe, because there has been little time for attachment to the newly conceived, but still the loss of greatly desired child. The event itself, with the clots and foetal tissue passed suddenly and painfully, may be disturbing. Some of the psychological symptoms may resemble post-traumatic stress disorder, with perseverative and intrusive re-experiencing ("flashbacks") and nightmares. There is a sense of failure, guilt and anger. The incidence of depression is four times the rate found in the general population (Friedman and Gath 1989). There may be depressive episodes at the time of expected delivery, anniversary reactions and an increased risk of post-partum emotional disorder after a later normal delivery.

Helping a mother who has suffered a miscarriage is a variant of grief therapy, in which the intense distress can be shared, and the sadness, guilt and anger ventilated with support. Mental health workers should never imply that spontaneous abortion is anything but a significant loss.

Late termination for medical reasons, although a deliberate intervention, is psychologically similar to miscarriage and to foetal death in utero. The pregnancy has advanced beyond the stage of quickening. These mothers experience intense anxiety at the time of the tests and require a more radical surgical intervention. Depression is common, and grief long-lasting (Iles and Gath 1993; Lloyd and Laurence 1985). All these women required counselling, before and after the termination.

3.3.3 Foetal Death In Utero, Stillbirth, Neonatal Death and Sudden Infant Death

Reactions to foetal death in utero, stillbirth, neonatal death and SID are generally more severe than to miscarriage, and each has its special characteristics. When the baby dies in late pregnancy, the mother carries a corpse within her and must also undergo a futile labour. If it dies during labour, the loss is sudden and shock pronounced, with a strong sense of unreality (Bruce 1962). When the child dies in the first week, the parents have to endure a period of great anxiety, with dwindling hope; they may be involved in the decision to switch off the respirator and witness the child dying. The later death of an infant, when the maternal response is fully developed – especially SID – is at the very top of the catalogue of calamities; there is no warning or preparation, and the death is followed by a forensic investigation (Cornwell et al. 1977; Smialek 1978).

When helping the parents, the principles of therapy are as follows:

- Honesty and openness in communication. The admission of errors is delicate, but the parents' guilt should not be reinforced by refusal to accept responsibility. Recrimination, litigation or querulant reactions are common. Staff should accept this as normal and try not to be defensive. Repeat interviews are recommended because the parents may be too stunned to register the first time.
- The mother will often be helped by seeing and holding the dead baby. A photograph should be taken and kept, as well as other mementoes.
- After stillbirth, most mothers prefer segregation, e.g. in a single room with their husband, and early discharge. The postnatal examination should be private.
- The mother should be visited by a member of the primary care team. A lactating mother may need bromocriptine or to donate milk to a milk bank. Hypnotics may help mothers troubled by insomnia. The doctor should be alert for secondary depression.
- The bereaved mother needs to share her distress with a sensitive and sympathetic person, with the time and interest to listen and guide. This support will often come from husband, family and friends. If they are unable to help, professionals, especially chaplains or nurses, should step in. The aim is to help the mother to grieve and accept her loss. After SID, the parents need much support during the police interrogations, forensic tests and inquest. Self-help groups and voluntary agencies are invaluable for some mothers.
- All parents want to know why the baby died. A simple, rational explanation will relieve fear, misconception and guilt. The necropsy can help, but parents should be warned that often no explanation is found. Necropsies in SID are specialised: the pathologist can play a vital psychological role and should be available for discussion.

- The dignity of naming and a burial ceremony are often helpful. The dead child remains one of the family and, in imagination, continues to grow up.
- No doctrinaire advice can be given about the timing of the next pregnancy, which is a personal decision. Increased anxiety during pregnancy and the puerperium can be expected.
- To helping the grieving sibling, the routine and rhythm of family life should be disturbed as little as possible. The parents should not be afraid to show their emotions – it is best to acknowledge how sad they feel and how much they will miss the baby. They should try to give a factual account of what happened, avoiding euphemisms. It is important to reassure the children that they are not responsible, that they will not lose the love of the parents and that neither they, nor their parents, are in imminent danger of death. The child can be helped to grieve by looking at pictures of the dead sibling, attending the funeral and visiting the graveyard.

To avoid these severe and prolonged psychological effects, a relinquishing mother needs counselling during the pregnancy (Harvey 1977). The aim is to emerge from the experience with self-respect and dignity. After delivery, the mother should be encouraged to see, hold and even breast-feed the infant; this facilitates the grieving process. Photographs of the infant should be filed. The mother should not normally be housed with mothers who are keeping their babies. Follow-up counselling should be continued for at least 6 months. The mother may wish to be put in touch with a society for relinquishing parents. Adoptive parents should accept any gift or token of the natural mother's love. Information on the outcome of the child should be available. Some birth-mothers wish to provide up-to-date information about themselves, so that the child knows that they are now respected citizens. A recent innovation is the practice of "open adoption", in which both sets of parents meet. There is even "continuing open adoption", which means that they remain in contact over the course of the child's development.

3.3.4 Relinquishment

Adoption is an ancient custom, allowing parental rights to be transferred from the birth-mother to another woman. It used to be the main way of satisfying the longing for children and dealing with accidental pregnancy; but there has been a great social change in the last 20 years. In spite of the huge increase in extra-marital births, the number of adoptions is falling steadily. This is not due to spectacular improvements in the treatment of infertility, reducing the demand, nor to the relaxation in the abortion laws, reducing the supply, but a new tolerance of single motherhood.

Relinquishment can be one of the most stressful events, comparable to bereavement and divorce, and may lead to intense depression and sadness (Rynearson 1982). Instead of understanding and support, there is often loneliness and ostracism. Time is no healer of the grief over a surrendered child. The sense of loss fluctuates – worse at anniversaries and at the birth of later children. Some harbour deep, unresolved feelings for years. There is often a fantasy of reunion or restitution. As time goes on, there is a new component: the mother knows that the adult child may seek to find her, and there is the hope that this event, which she cannot influence, may happen. Adopted children often seek out their parents and the wish for reunion is reciprocated by many birth-parents, as shown by the growth of organisations for relinquishing parents, helping them to trace their offspring.

4
Psychiatry of the Post-partum Period (I.F. Brockington)

4.1
Normal Puerperium

For many or most mothers, giving birth is a supreme moment, and euphoria or elation is common. Some may be too excited to sleep. These feelings of peace, fulfilment and accomplishment help to sustain mothers during the weeks of strain which follow. Prolonged euphoric reactions, lasting a week or more, are probably mild episodes of puerperal mania and are often followed by depression.

Newly delivered mothers have to face a number of challenges, including the following:

- Physical exhaustion and painful sequelae of pelvic trauma.
- Breast-feeding, which has many advantages, but is often difficult to establish.
- Insomnia. Sleep deprivation is a cause of irritability and increased volatility.
- The maternity blues. About half experience a brief period of dysphoria, usually lasting a few hours, occurring between the third and the fifth day. Mothers may become sensitive to minor rebuffs and are surprised and puzzled by their uncharacteristic weeping.

- Recovery of normal figure and attractiveness, which may be threatened by weight gain and stretch marks.
- Loss of libido. Episiotomy and vaginal trauma often cause dyspareunia; nevertheless, sexual relations are usually resumed within 1–3 months, though reduced in frequency and with a delayed return of orgasm. For this and other reasons (e.g. jealousy), the marriage may come under strain.
- Social privation, including loss of employment, income and leisure, confinement to the house, and boredom.

With this background of rapid biological, social and emotional transition, it is not surprising that a wide variety of psychiatric disorders occur in the puerperium. Indeed, the psychiatric complications of childbirth are more numerous and complex than in any other human situation. They fall into four main groups – psychosis, disturbances of the mother–infant relationship, various anxiety, obsessional and stress-related "neuroses" and depression.

4.2 Post-partum Psychoses

4.2.1 Classification

A variety of different psychoses can begin after childbirth. There are a group of rare organic disorders which occur soon after delivery. They include the following:

- Idiopathic confusional states, similar to those seen during parturition
- Exhaustion to the point of stupor (Tott 1844)
- Delirium tremens
- Post-eclamptic delirium – usually an acute organic syndrome followed by profound amnesia (Kutzinski 1909; Olshausen 1891), but occasionally with manic features
- Infective delirium

Other psychoses include the following:

- Psychogenic psychosis, e.g. delusional jealousy, which can arise as an understandable reaction to changing relationships and the quiescence of sexual life. Psychogenic psychoses have also been reported in fathers and adoptive mothers (Trixler and Jádi 1981).
- Manic, cycloid or depressive psychosis.

The term "puerperal psychosis" (synonyms: "puerperal insanity", "puerperal mania") usually refers to this last group. The first clear description was written in 1797 by the German obstetrician Osiander. Since Fürstner's description of *hallucinatorische Irresein der Wöchnerinnen* (Fürstner 1875), it has always been recognised that acute psychoses of cycloid type ("amentia") are associated with the puerperium.

4.2.2 Clinical Features of Puerperal Psychosis

Puerperal psychoses are acute, rapidly reaching a climax of severity. The onset is usually between 2 and 14 days after delivery. There is no specific symptom, syndrome or course, but there is evidence of a close relationship with manic depressive (bipolar) disorder:

- About 35% of episodes meet criteria for manic or schizo-manic illness (Brockington 1996).
- The bipolarity of the illness is often seen in the course of the episode or recurrences.
- There is a high puerperal attack rate in women with a history of non-puerperal mania – about 20% (Bratfos and Haug 1966; Kendell et al. 1987; Reich and Winokur 1970).
- There is often bipolar disorder in the families.

Mania is particularly severe, often with "schizo-affective" features. The delusions cover the whole gamut of morbid ideas. Verbal hallucinations, thought insertion, echo phenomena, thought broadcasting and "made" impulses may occur, accompanied by ideas of control or possession. Catatonic features are common. There is often an apparent confusion, bewilderment, perplexity or "dreamlike delirium". Occasionally this is seen in pure form – Marcé's (1858) "transitory intellectual enfeeblement".

4.2.3 Therapy and Prevention

In the days before modern therapy, the median duration was about 6 months, but since ECT and neuroleptic medication, it has been reduced to a few weeks. Neuroleptic agents should be used with caution, because of severe extra-pyramidal side effects, including the neuroleptic malignant syndrome. Lithium has been used increasingly, since the link with manic depressive psychosis was recognised. There is evidence, from retrospective studies, for its prophylactic value in women at high risk (Stewart et al. 1991). It may have adverse effects on breast-fed infants, though there is only one reported instance of a transient adverse reaction. ECT is effective in manic as well as depressive patients.

The location of treatment is an issue. Hospitalisation can have serious effects. Even in the nineteenth century, thoughtful clinicians urged that this disorder be treated at home, where the patient can maintain her role as wife, homemaker and mother and her relationship with the newborn. If hospital admission is

necessary, there are great advantages in conjoint mother and baby admission.

4.2.4 Aetiology

The frequency is about 1 per 1000 pregnancies at a threshold of hospital admission within the first trimester (Kendell et al. 1987; Terp and Mortensen 1998). The distribution is worldwide. There is no link with twin pregnancies, breast-feeding, single parenthood or stillbirth. Episodes have occurred after short gestation (22–28 months).

Puerperal psychosis belongs to a group of biological brain disorders with high heritability and an inborn tendency (diathesis) to develop psychotic episodes throughout life. Thus the problem of its causation can be broken down into three subsidiary questions:

1. What is the nature of the diathesis?
2. What determines the clinical polarity – mania, depression, cycloid features or switching from one to another?
3. What is the trigger which provokes the episode?

The first two questions are not unique, but concern the larger problem of bipolar disorder. The third is pertinent – indeed, this is where the study of reproduction-related illness can make its special contribution. The clinical facts, however, suggest not one, but several, pregnancy-related triggers (Brockington 1996):

- Abortion
- Pregnancy itself, especially the last trimester
- The early puerperium, especially the first 10 days
- Post-partum menstruation
- Menstruation in general (see menstrual psychosis)
- Weaning

These triggers can be added to the list of other biological events which trigger bipolar episodes, including surgical operations, adrenocortical steroid treatment and seasonal climatic changes. There are instances of the combination of these triggers in the life-history of individual women (Esquirol 1818).

The evidence for a link between puerperal psychosis and menstruation implicate the steroid hormones. Cortisol, oestrogen and progesterone are structurally related. Oestrogen has many interactions with neuro-transmitter systems, including dopaminergic, noradrenergic, adrenergic, serotonergic and cholinergic receptors. Progesterone also interacts with neurotransmitter amines. Many other hormones are greatly affected by pregnancy, including gonadotrophic hormones, prolactin, oxytocin and neurophysin, thyrotropin, corticotrophin and corticosteroids, renin, angiotensin and human placental lactogen. It is too early to determine which hormone and receptor is involved. Neuro-scientific studies of this psychosis are in their infancy, but this is one of the few psychoses whose onset can be predicted within a short time interval, so that it is feasible to study its pathogenesis.

4.3 Mother–Infant Relationship Disorders

Just as the emerging relationship with the foetus is an important pre-partum psychological process, so the growth of the mother–infant relationship is a vital post-partum development. In popular parlance, this is often called "bonding". The mother–infant and infant–mother relationships are two different things, the infant's attachment coming later, after 7–8 months. The mother–infant relationship consists essentially of ideas and emotions, aroused by the sight, sound, feel and memory of the infant, which find their expression in affectionate and protective behaviour. Its immense power is revealed in self-sacrifice and the pains of separation. The mother's emotional response enables her to maintain a never-ending vigilance and endure the exhausting toil of the nurture of the newborn.

There is no "critical period" in the development of the maternal response – no special magic in immediate contact with the newborn. Close proximity from the start ("rooming-in") confers confidence in mothering skills. In the development of maternal emotions, the infant plays an important part. While in the womb, hearing is acute (Peiper 1924). Within a month of birth, babies can discriminate speech. From 6–12 weeks, they react preferentially to human speech and singing (Bühler et al. 1927). At birth, they are programmed to respond to the human face. At 36 hours, they will imitate facial expressions, and by 3 weeks this is advanced. Eye-to-eye contact mediates the interaction (Robson 1967), and gazing becomes an absorbing activity on both sides. The baby's smile is another catalyst; by about 6 weeks, it is linked to the human face, and the mother will devote time to bringing it out. Even before infants can babble, videotape studies have shown how they contribute to a dialogue. At an early stage, mother and infant learn to stimulate and reinforce one another – "to dance together".

Sometimes the maternal response is immediate, primed by her pre-partum affiliation, but often there is a delay, which may worry the mother. For the first 3–4 weeks, many mothers feel bruised, tired and insecure, and their babies seem strange and distanced. This phase may end when the baby begins to smile and look at her. Thereafter there is an incremental growth, until, by the end of the third month, mothers felt pangs of conscience on leaving their babies.

The term "mother–infant relationship (or bonding) disorders" covers a spectrum of clinical states. These disorders are common in mothers referred for psychiatric help, e.g. 22% of post-partum referrals and 29% of those presenting with "postnatal depression" (Brockington 1996). They are poorly recognised by medical practitioners and psychiatrists. Yet they are the disorders most specific to childbirth and an important part of the work of peri-partum mental health teams. It is these disorders, rather than uncomplicated depression, which are likely to have long-term effects on the behaviour, mood and cognitive development of a child.

In the mildest form, the maternal emotional response is lacking. The mothers complain of a lack of warmth towards the infant and may feel estranged – the baby does not seem to be their own. Their reaction varies: some seek reassurance or counsel from their own mothers or confidantes, but others conceal their feelings. Shame is an important reason why these disorders seldom come to medical attention and impedes diagnosis. Failure to diagnose is regrettable, because treatment is easy – often explanation and reassurance suffice.

At a severe level, there is hostility and rejection of the infant (Oppenheim 1919), which may be covert or overt. The mother may try to persuade her own mother or another relative to take over or may demand that the infant is fostered or adopted. Some mothers try to escape, leaving home for hours on end, sometimes repeatedly. The most poignant manifestation of rejection is the secret wish that the baby "disappear" – be stolen or die. Rejection is often associated with pathological anger, with its risk of child abuse.

Seeking the causes, it seems certain that unwelcome pregnancy is a factor. Unfortunate events at the time of childbirth, e.g. death of a twin, previous stillbirth or a painful and unpleasant delivery may contribute. There is much evidence that the infant's social contribution is important. Sick infants, or those delayed in their social responses – handicapped or premature – may be at risk. Persistent crying, failure to sleep, feeding difficulties, vomiting and a difficult temperament put a mother under severe strain. Post-partum depression may be primary. Indeed, mothers may lose an established "bond" for the duration of an inter-current depression. In other cases, the relationship disorder precedes and seems more severe than depression.

In the diagnostic assessment, an interview is usually sufficient, but in-patient observation yields valuable information, to which each member of the multidisciplinary team contributes. The crucial assessments of maternal behaviour are made by psychiatric nurses, who keep a shift-by-shift record of salient incidents, reporting the mother's statements about the baby, her competence and skill, her affectionate behaviour and her response to crises. The long period of 24-h observation is invaluable in obtaining an accurate overall view.

This is a difficult disorder to manage successfully. Depression is sometimes severe, whether as cause or consequence. The mother experiences extreme guilt and may be exposed to criticism. Family relationships deteriorate, leading to severe, prolonged and irreconcilable conflicts. With skilled treatment, however, there can be optimism about a successful outcome. The principles of management are as follows:

- When hostility and rejection are prominent, the primary decision is whether to attempt treatment at all. The child has no need to be reared by the birth-mother. The mother must be given freedom of choice – it is dangerous for her to feel trapped in a tunnel of unwelcome motherhood. At the same time, the father also has his rights. The option of relinquishing the infant must be openly acknowledged and fully discussed with both parents. Usually the mother opts for treatment.
- Antidepressant treatment should normally be given, in the form of psychotherapy, drugs or ECT.
- The specific element of therapy is working on the dyadic relationship. It is a mistake to separate mother and baby – this merely compounds the problem by adding an element of avoidance. If there is any hint of abuse, or if she is troubled by aggressive impulses, she must never be left alone with her infant. She must be relieved of irksome burdens of infant care. When the baby is calm and content, and the mother feels at ease, she is encouraged and helped to interact with him – to cuddle, talk to him, play and bring out his smile and laughter. The aim and essence of treatment, therefore, is to create the circumstances in which mother and child can enjoy each other. Participant play therapy and baby massage are the key therapies. A panel of recovered mothers, who can instil hope in those still in trouble, is an important resource.

Treatment can take place in various settings:

- Home treatment can be successful, provided there is enough support to relieve the mother of night care and stressful duties.
- Day hospital treatment can provide individual support and group discussion, as well as specific therapies.
- With the most severe and refractory cases, the proper setting is an in-patient mother-and-baby unit.

4.4
Anxiety, Obsessional and Stress-Related Neuroses

4.4.1 Post-traumatic Stress Disorder

After long, hard and excessively painful labours, some women suffer the repetitive intrusion of images and memories, similar to those which occur after the harrowing experiences of war and natural disaster (Bydlowski and Raoul-Duval 1978). If they become pregnant, the symptoms may return, especially in the last trimester, with terrifying nightmares and insomnia. They may develop a secondary tocophobia, with avoidance of child-bearing.

This disorder can be treated by ventilation and cognitive/behavioural psychotherapy.

4.4.2 Querulant Reactions

Another reaction to a severe labour experience is pathological complaining (*querulantenwahn*). These women complain bitterly about their delivery, especially the "dehumanisation" of modern obstetrics, and their humiliation by procedures involving the most intimate parts of their bodies. This disorder can be treated by a psychotherapeutic approach which distracts the mother from her grievances and reinforces productive child-centred activity.

4.4.3 Puerperal Panic

Some mothers are incapacitated by anxiety in the early puerperium, overwhelmed by the fear that they will not be able to cope with their helpless infants (De Armond 1954). The panic and agitation seen in these extreme examples is merely an exaggeration of the feelings that many women, especially first-time mothers, experience when they confront their responsibility. This disorder can often be handled by the family, without invoking professional help. All difficulties are avoided if the mother's own mother or other members of the extended family are at hand.

4.4.4 Exaggerated Fears for the Health and Safety of the Infant

In some women, motherhood can lead to a persistent state of over-arousal, as described by Moll (1920) under the title of *maternitätsneurose*. The mother is anxious about banal tasks which put the baby at risk (e.g. bathing) and sensitive to the slightest indication of illness. These symptoms are prominent in mothers whose children have been born after years of infertility or recurrent miscarriage. In some, the over-concern about the infant's health resembles an adult Briquet's syndrome – hypochondriacal neurosis by proxy. Another cause of post-partum anxiety is the fear of SID (Weightman et al. 1999). These mothers are insomniac, because they lie awake listening to the baby's breathing; they may check the infant 20–30 times every night or even wake them to ensure they are alive. This results in excruciating tension and exhaustion.

A mother may be helped by ventilation of these fears and explanations about the rarity of SID and the infant's resistance to asphyxia. Devices to monitor the infant's breathing should be installed. The vicious cycle of insomnia and hyper-vigilance can be interrupted periodically by involving relatives or friends, so that the mother can sleep under sedation. Anxiety management and cognitive therapies may help.

4.4.5 Phobic Avoidance of the Infant

A mother who suffers from excessive anxiety, whatever the cause, may develop a phobia for her infant and become unable to approach him or her at all (Sved-Williams 1992). The same is true in maternal obsessional disorders involving intrusive filicidal thoughts.

The treatment is similar to that of other post-partum anxiety disorders. The mother may need antidepressive or sedative medication, but the main approach is behavioural, gradually desensitising her to her fear of the infant.

4.4.6 Obsessions of Child Harm

Obsessive-compulsive disorder may present in the puerperium, with extravagant thoughts, images or impulses of child harm. These mothers fear being left alone with their children and may take extraordinary precautions to avoid attacking the child. Post-partum obsessional states may also have the content of child sexual abuse.

Ventilation and explanation are an important part of the treatment, but are rarely sufficient. All these mothers require psychotropic medication, either in the form of antidepressant agents or neuroleptics. It is important to discourage avoidance of the child and to encourage interaction, strengthening positive maternal feelings. Cognitive/behavioural treatment can help her to achieve mastery over irrational impulses.

4.5 Depression

Puerperal melancholia was one of the first post-partum psychiatric disorders to be identified – in merchants' wives in Portugal (1551) and Belgium (1608) (De Castelo Branco 1551/1620; Castro 1617). Patients with up to eight attacks were later described. When, in the 1950s, attention turned to milder, more common disorders, post-partum depression was found to be common. A major contribution was made by the Gordons in New Jersey (Gordon and Gordon 1959). They reviewed the literature, studied 100 normal mothers, made a controlled study of aetiological associations, conducted a follow-through study and showed that social casework was superior to psychoanalytic explorations. Postnatal depression soon become a household word.

The scientific value of this concept must be examined with some scepticism. Depression after childbirth is similar to any other depression (see Brockington 1996, pp. 172–174) and only slightly more frequent than at other times in the lives of women during the reproductive years. The term "postnatal depression" has the danger of introducing into the minds of the unwary the mirage of a homogeneous disorder with a single cause. The causes of post-partum depression are numerous and much the same as those which cause depression in human beings of all ages.

In mothers with recurrent puerperal depression, we would expect to find specific factors. There is no consistent association with parity, dystocia or breast-feeding, but there is some evidence for a link with caesarian section, earlier miscarriage, menstrual mood disorder and the maternity blues. Unwanted pregnancy has been found to be a predictor of peri-partum depression. It has been suggested that the burden of child-rearing, rather than child-bearing, is a factor, but this has been challenged: the twin study by Malmquist and Kaij (1971) and the suicide study by Høyer and Lund (1993) showed that parous women have a lower risk of depression.

The effects of post-partum depression on family life, and on the emotional climate in which children are reared, is of great concern. These effects depend on the degree and duration of maternal depression and the extent to which it involves interactions with the child. A growing child needs not only care, but also emotional support, approbation, attention and stimulation. The mother is his or her primary environment, and her mood dominates the child's world. Even very young infants are disturbed by deviant social behaviour in the mother. In the long term, poor communication may affect the acquisition of speech, language and social skills, and through the pervasive influence of language, other educational deficits (Murray et al. 1996). Nevertheless, these are not universal and inevitable effects: some depressed mothers are sustained by the interaction with their children, and some are warm and stimulating, putting in a tremendous effort, in spite of their distress and symptoms (Pound et al. 1988).

Treatment begins with effective diagnosis. Many more mothers are depressed than ever make their way to their family doctor's surgery. The reasons for the failure to seek help are not fully understood. It can be guessed that some recover early, some do not realise they are ill and others are ashamed or apprehensive about confessing their symptoms. Primary care teams miss many cases. In such circumstances, a screening procedure with high sensitivity and specificity is required. The Edinburgh Postnatal Depression Scale (EPDS; Cox et al. 1987) meets this need. Patients identified by screening, or self-referral, require a full psychiatric examination, exploring the symptoms and course of the illness, and its setting in the context of the mother's life-history, personality and circumstances, especially this pregnancy. Her relationships with her spouse, baby, other children and family of origin must be explored and the available supports established. The diagnosis of depression is relatively easy, provided that the clinician is alert to the possibility, but it is equally important to identify the factors which contribute to vulnerability and the specific components of post-partum disorders. The initial interview should be held at home. This is partly because it is difficult for mothers to attend a clinic while fettered with the care of young children. A domiciliary assessment also has the advantage of meeting the mother in her own environment and has a quality which cannot be achieved in the office.

4.6 Services for Mentally Ill Mothers

The outline of a utopian service is slowly emerging. Its aims are to prevent disorders in those who are vulnerable, to make an early and accurate diagnosis and to intervene rapidly and effectively with minimal disruption of family life.

This requires the following:

- A specialist multidisciplinary team capable of treating severe and intractable illness and undertaking service development, treatment innovations,

training of medical, nursing and paramedical staff and research into the cause and cure of parapartum disorders.
- A community service which provides domiciliary assessment and home treatment, with minimal disruption of family life. Home visits by community nurses are an ideal method of continuing care.
- Day care, which is a rich source of support, bringing the mother into contact with other mothers with similar difficulties, with minimal family disruption. There are group discussions, one-to-one meetings with staff and specific therapies – play therapy, baby massage and anxiety management, as well as motherhood classes, occupational therapy and drama therapy.
- In-patient facilities for mothers and infants, including toddlers. Mother-and-baby conjoint admission was pioneered in 1948 by Dr. T.F. Main. There has been a dissemination of joint admission facilities throughout Britain and also in Australia, Canada, New Zealand, France, Holland, Belgium, Norway and Israel. There are a few specialised units with eight to ten beds or facilities to admit a family; these offer economies of scale, greater safety and an appropriate milieu.
- An obstetric liaison service capable of detecting illness and vulnerability during pregnancy.
- Links with other agencies providing services for mothers, especially the social services, midwifery and primary care teams.
- A network of voluntary organisations, working independently, but with close cordial ties with the professional service.
- Medico-legal expertise to deal with child abuse, infanticide and the custody of children by mentally ill mothers.

5
Psychiatry of the Abuse and Murder of Children (I.F. Brockington)

5.1
Child Abuse

Cruelty to children has long been a shameful feature of human life, which was eventually condemned. The vicious maltreatment of helpless infants has only recently come to the attention of the profession and the public. Its recognition began with French experts on legal medicine, especially Tardieu in 1860. His brilliant insights were unwisely overlooked, and it was necessary to rediscover child abuse through clues from pathology and paediatric radiology, especially bilateral subdural haematoma, retinal haemorrhages and subperiosteal haematomas (Caffey 1946). In 1955, Woolley and Evans made the crucial observation that, when the infants were removed from their homes, no new lesions developed. These discoveries were publicised by Kempe et al. in 1962, 100 years after the original discovery.

The frequency of major abuse is about 6 per 1000 births (Baldwin and Oliver 1975), but much higher in high-risk groups, such as premature infants. Abuse can be subdivided into non-accidental injury, neglect and sexual abuse (not dealt with here).

5.1.1 Non-accidental Injury

The injuries include the following:

- "Battering", resulting in widespread bruising, testifying to the rage or fanaticism of the punitive parent. It may result in rhabdomyolysis, fat embolism, visceral injuries or hypo-volaemic shock.
- Head injuries, caused by direct blows, or swinging the baby by its legs. These cause more severe damage than simple falls and result in multiple, complex fractures and brain injury.
- Fractures, due to jerking the limbs or gripping the thorax while shaking the child. There may be different lesions in several locations, at different stages of healing. They are often multiple and tend to be more severe than accidental fractures.
- Shaking, which is believed to cause subdural haematoma without direct trauma, through rupture of veins under the skull. It also causes retinal haemorrhages.
- Bites, burns and scalds, e.g. by deliberately immersing the infant in scalding water.
- Split lips, lacerations of the mucous membrane or torn frenulum, due to rough use of the feeding bottle.
- Suffocation to suppress crying. This accounts for a *small* proportion of SID (Emery 1989).
- Poisoning by drugs or table salt. Parents may also deprive the child of water or force fluids.
- Fabricating or causing illness, e.g. infections. Recurrent suffocation, poisoning and factitious illness are grouped under Munchausen's syndrome by proxy (Meadow 1977).

5.1.2 Neglect

Neglect includes the following aspects:

- Emotional neglect, resulting in infantile depression and failure to thrive

- Deliberate starvation
- Sequestration – prolonged imprisonment in confined quarters

5.1.3 Causes

The causes of child abuse and neglect include, as background, maternal youth and poverty, lack of social support and the burden of large families. There may be a history of abuse in the parent's own childhood ("the cycle of familial violence"; Oliver 1993). There is often some form of psychiatric disorder, e.g. learning difficulties, depression, substance abuse or extreme sleep deprivation, rarely psychosis. There is frequently a disorder of personality, especially explosive irritability, callousness and cruelty. Factors in the infant are important, including prematurity, illness, handicap and a difficult temperament. Excessive crying, failure to sleep, diarrhoea or refusal to feed may push a mother to the limit of her endurance.

Most of these have an indirect effect. The proximate causes are found in the interaction between mother and infant. Injury results from the mother's anger at a time of crisis, neglect from hatred of the child. The motivation for Munchausen's syndrome by proxy is enigmatic, but perhaps results from maternal anxiety and its deviant expression. The mother's behaviour is governed by the quality of her relationship with the child, her self-control, her experience and her resources in terms of maternal stratagems.

5.1.4 Treatment

The management begins with investigation. Silverman, who obtained some of the first confessions (Silverman 1953), and other pioneers (Ounsted et al. 1974) have advised on how to elicit the history of injury. Interrogation should be sympathetic and quiet, not angry or hostile. It is wise to delay until the physical and radiographic findings are conclusive; with Munchausen's syndrome by proxy, this requires much investigation. The physician interviews the parent privately and indicates his confidence that the injuries must have been inflicted by an adult, and everyone has an obligation to avoid repetition. He would welcome the parents giving him the full story. It is useful to go over each violent act in detail. He will ask about sources of worry, stress or tension and about the baby's behaviour and the parents' upbringing. He should to make clear to the parents that all of us, given adequate provocation, could batter babies. The aim is to understand – not to look back, but to look forward to the future and the positive steps which can be taken.

Although the law differs from one country to another, it is generally mandatory immediately to involve the police and the agencies with a responsibility to protect the child. There is often a duty of notification. The investigation should be handled by a stable, experienced team including a doctor, police and specialist social workers. The position should be made clear at the outset in front of a witness. The parents may deny noticing the injury or give an implausible explanation. In disputed cases, it is necessary to question the spouses independently and other relatives.

Having established the diagnosis, the first duty is to protect the child. There is a high risk of recurrence, and other children in the family are at increased risk. The paediatric hospital provides a sanctuary for a time. Often the only safe remedy is to separate the child from its parents. If it returns home, its condition must be carefully monitored. A play group or day nursery is invaluable, because some infant care can be taken over, and the infant's health monitored unobtrusively. Family centres can provide a setting for many-sided non-residential support. Supervised accommodation in mother-and-baby homes, run by the social services or voluntary agencies, provides shelter and an opportunity to learn maternal skills. The mother needs practical advice and prolonged, protective (not punitive) support from social workers, home helps or lay counsellors, assisting and directing her in her responsibilities. Limits must be set, with frequent visits to ensure that acceptable standards are reached. Child abuse occurs at moments of crisis, and an important intervention is an emergency "hot line".

The mother needs psychotherapy. Child abuse is one of those disorders for which psychotherapy is not just important and indispensable, but virtually the only treatment. It is essential that the counsellor is not involved in the supervision of the baby's health and can give all their attention to the mother. These mothers have a deep sense of helplessness and inferiority and feel worthless and devalued, as underlined by society's rejection of them now. They have intense dependency needs. Punishment and criticism are useless. Lay counsellors ("foster grandparents") may be of particular value. Many, however, have commented on the difficulty in reaching the mothers. Their treatment requires the prolonged efforts of an experienced outreach service, involving a resourceful team of therapists who support each other and are fully aware of the resistance of these mothers.

The children also need therapy. They have been physically damaged and often show obvious signs of fear. As Tardieu (1860) wrote:

One is struck by the facial appearance of these poor children, exposed to ill-treatment and privation. Their

faces breathe sadness. They are timid and fearful. Sometimes their eyes are dull, but often express a burning resentment. It is amazing how rapidly their physiognomy changes, when they are rescued and put under protection.

Ounsted et al. (1974) used the term "frozen watchfulness" to denote a hyper-vigilant child, quiet, slow to move and respond, showing reduced interest in things or people, carefully avoiding gaze fixation and crying only in extremis.

Others have stressed their depression – "a profound apathy to the point of stupor" (Baldwin and Oliver 1975). Older children may show a superficiality of relationships or an anxious reversed solicitude for the mother – the child turned therapist.

5.2 Infanticide

The term "infanticide" covers the killing of infants and children in a wide variety of circumstances, broadly divided into "neonaticide" (killing of the newborn) and "filicide" (the later murder of a child).

5.2.1 Neonaticide

Suppression of the neonate (especially female infants) has been customary in many societies, as an official policy or "grass-roots" custom to control population growth. An entirely different phenomenon is anomic (lawless) neonaticide, in which a desperate mother, who has concealed her pregnancy, kills the infant immediately after parturition. This was a major public health problem in Europe during the nineteenth century. During this century, the frequency has fallen dramatically (Wilkey et al. 1982). Contraception and a relaxation of the abortion laws have played a part, as have the development of social work and the support of single mothers.

Neonaticide is a challenge to forensic pathology. The evidence comes from three sources – signs of recent parturition, proof that the infant was born alive (i.e. had breathed at least once) and evidence of the means of death. Tardieu (1868/1880) detailed the methods of killing and their relative frequency: suffocation is by far the commonest, followed by drowning, head injury and strangulation; wounds, poisoning and neglect are infrequent. Concealment of the cadaver is a problem for the mother, especially difficult for urban dwellers.

Little is known about the mental state of mothers who kill the newborn. Deliberate planned murder of the newborn, sometimes aided and abetted by the father, is probably rare. In the great majority of cases, the explanation of the crime is to be found in the circumstances of concealed pregnancy which were fully elucidated by Jörg (1837) in his classic monograph *Die Zurechnungsfähigkeit der Schwangern und Gebärenden*. Most are immature girls, too passive to resist intercourse or terminate the pregnancy (Gummersbach 1938). All factors conspire to force them into crime – "the scoff and scorn of a taunting world" and economic necessity. There is no-one to turn to, because it is dangerous to consult. A tendency to deny the fearful reality, to retreat into wishful thinking may occupy some weeks or months. They can hope for a miscarriage, or a stillbirth, or even their own death in labour. The birth is awaited as if a miracle could avert it. But in the end, they must endure, in secret, an agonising first delivery, without the support of a midwife, making superhuman efforts to suppress the slightest murmur of complaint. No-one can imagine the extremes of depression, fear and desperation of these girls. They are eventually faced with a crying baby and respond by silencing it, killing the child out of fear and perplexity. Most of the assaults, employing suffocation or drowning, are compatible with panic. A minority, which involve head trauma or stabbing, testify to rage and hatred.

There has been much debate whether the defence of insanity can be invoked. It is probable that most of these babies die when the mother is in the grip of an emotional crisis – seized by fear, despair or fury. The emotional extremes experienced by these women, in their pain, exhaustion and lonely peril, put the definition of insanity under strain; but *emotional* crises are not generally acceptable in law as evidence of insanity, which requires a *cognitive* factor. The medico-legal problem centres on the fact that impaired consciousness undoubtedly occurs in labour, though rarely. The causes include confusional states, eclampsia, syncope due to loss of blood and exhaustion to the point of stupor. If the burden of proof is with the defence – i.e. the prosecution must prove *actus reus* and *mens rea*, but the defence must prove insanity – there can be no valid evidence in unattended deliveries, because the diagnosis of confusion and syncope require an eye-witness. Some jurists, however, have been concerned about the possibility of a miscarriage of justice – that a mother who killed her baby when her consciousness was clouded could be wrongly condemned.

We know little of the psychological consequences of neonaticide. The long-term effects are likely to resemble those of criminal abortion, but the horror of the event is of a different magnitude. Post-traumatic stress disorder and depression can be expected, and there is a lifetime of coming to terms with an atrocious crime.

5.2.2 Filicide

A parent may kill a child in a variety of different mental states. These can be grouped under sane filicides, child abuse, depression, psychosis and trance states. The majority of murdered children are killed by their parents, and the majority of female murderers kill their own child.

Occasionally, children are killed by parents who are not mentally ill. An unwanted child may be killed "in cold blood". Euthanasia is another setting – a sane mother may kill a beloved child to relieve its suffering – Perrussel's "homicide through pity" (Perrussel 1923). The "Medea complex" is the name given to vengeful child murder, which may be an element in some filicides and some neonaticides.

Child abuse is a relatively common cause of filicide. Death results from ill-tempered assaults or over-zealous punishment, without homicidal intent. In the Queensland study (Wilkey et al. 1982), 18 out of 49 child murders were due to non-accidental injury. In various surveys, the rates have been about 1 per 100,000 children. The death rate in children already subjected to abuse and returned to their families is much higher. Fathers play a major part in punitive child abuse.

Depression is the commonest cause of filicide. Studies of convicted mothers underestimate the frequency of depressive filicide, because many mothers do not survive; e.g. in Denmark, 82 out of 92 parents who poisoned their children completed suicide (Harder 1967). Depressive murder is often committed in the belief that the child's best interests are being served – delusional altruism or mercy-killing (libericide). Often the mother kills to spare the child the misfortune of being motherless after her suicide. In contrast to those who kill an unwanted child, mothers surviving depressive filicide make no attempt to conceal the crime: typically, they confess and request punishment. Mothers may kill more than one child. Unlike filicidal males, few women attack their husband or cohabitee – family murder is rare in women. Men also kill their children during an attack of depression, and family murder seems more common. Family suicide was a peculiarly Japanese institution: Komine (1938) unearthed the staggering total of 4323 cases between 1930 and 1938.

Filicide during puerperal manic or cycloid illness is rare. It may occur in chronic delusional psychosis, especially if the morbid ideas involve the child, or through command hallucinations. There are several instances of filicide in menstrual psychosis. Delirium tremens is an occasional cause. Post-epileptic delirium or epileptic automatism can result in motiveless filicide. The same is true of somnambulism.

6 Psychiatric Aspects of Hormonal Contraception (M. Lanczik)

6.1 Introduction

Contraception with "the Pill" is in widespread use and more than 99% effective. It has both positive and negative somatic effects and may also have undesired psychotropic effects, or even desired ones. Thus the physician is confronted by psychosyndromes provoked by the use of oral contraception, but may also, in other cases, use it successfully to treat mental disturbances, such as mood disorders.

A total of 15% of women who discontinue oral contraception do so because of "mental side effects" (Milsom et al. 1991), and mood alterations, usually depressive, are present in one third of all women who use oral contraception (Cullberg 1972; Clare 1985). The risk of mental side-effects from oral contraception is significantly increased in women who suffer from pre-menstrual dysphoric syndrome (Hammarbäck and Bäckström 1989). It has been stated that women with severe pre-menstrual dysphoric syndrome are more likely to develop mood disturbances when taking oral contraceptives, while women with a "mild" peri-menstrually occurring psychosyndrome are more likely to experience an improvement of mood (Bäckström et al. 1992).

Because most oral contraceptives are combined preparations containing varying amounts of androgens, oestrogens and progesterone, it is difficult to tell in individual cases which component hormone is responsible for causing a mental disorder or a possible "psychotherapeutic" effect. It is much easier to trace the somatic effects of these preparations, both desired and undesired, to their individual components.

6.2 Anxiety Disorders and Depression in the Setting of Oral Contraceptive Use

A number of relatively old studies revealed a relationship between the use of oral contraceptives (in higher doses than now usual) and depressive mood disorders, and even panic attacks (Wagner and Berenson 1994). More recent studies reveal no such relationship when low-dose contraceptives are used. Nonetheless, oral contraceptives have been reported to lead to relapses of phasic endogenous depression and pre-menstrual dysphoric syndrome in women with a past history of these disorders (Kendler et al. 1988; Bancroft and

Sartorius 1990). Triphasic preparations are clearly related to pre-menstrual dysphoric syndrome and recurrent menstrual depression (Bancroft et al. 1987b; Bancroft and Rennie 1993).

The extent to which oral contraceptives may induce milder, i.e. subclinical depressive mood disturbances is still controversial (Parry and Rush 1979; Kendler et al. 1988; Bancroft and Sartorius 1990). It is clear that they generally reduce sexual interest and that preparations with high progesterone activity in particular, including depot preparations, may lead to easy fatigability and sad mood disturbances and promote lethargic behaviour (Graham and Sherman 1992; Westhoff et al. 1995).

According to a number of anecdotal reports, oral contraceptives not only improve physical well-being, e.g. by alleviating pre-menstrual oedema and breast pain, but also improve the mental manifestations of pre-menstrual dysphoric syndrome (Graham and Sherman 1992). Prospective studies of this question, however, have yielded inconsistent findings.

Vitamin B_6 supplementation, used to treat the functional vitamin B_6 deficiency that accompanies oral contraceptive use, has also been reported to help improve mild depressive mood disturbances (Winston 1973).

In conclusion, much more research is necessary regarding the mental effects of oral contraceptives, both desired and undesired, from the point of view of both psychopathology and endocrinology.

7
Peri-menopausal Dysphoric Syndrome and Depressive Illnesses in the Peri-menopausal Period (M. Lanczik)

The term "peri-menopause" refers to the 5–7 years preceding the last menstrual period (the menopause), a time of life in which ovarian function progressively ceases and, as a result, the plasma concentrations of the oestrogens, progesterone and the androgens decline. The increasing deficiency of these hormones is paralleled by a rise of gonadotropin activity. The initial consequence of these hormonal changes is a disturbance of the menstrual cycle, i.e. the menses become rarer and less regular and ultimately stop. The beginning of the post-menopausal period is endocrinologically defined by an oestrogen level below 40 pcg/ml and a follicle-stimulating hormone (FSH) level above 25 μ/ml. Most women have multiple physical symptoms in the peri-menopausal period, and some also have mood disturbances reaching psychiatric intensity.

7.1
Clinical Features and Classification

There is controversy over whether endogenous depression appearing peri-menopausally differs in its psychopathological features from that appearing at other times (Winokur 1973; Schmidt et al. 1996). It is characteristic of peri-menopausal affective illnesses that they are always accompanied by multiple somatic manifestations.

We distinguish two characteristic types of disturbance on the basis of their psychopathologically relevant manifestations. Most patients suffer from a so-called hyperaesthetic-emotional asthaenia, which is clinically indistinguishable from post-partal dysphoria (maternity blues, post-partum blues) and from many cases of pre-menstrual dysphoric syndrome. This syndrome is characterised by sleep disturbances (50%), disturbance of concentration (53%), lability of affect (64%), increased irritability (70%), anxiety (67%), tearfulness (70%), sad mood disturbance (61%), lack of interest (56%), easy fatigability (53%; Schmidt and Rubinow 1991; Schmidt et al. 1997) and decreased libido (10%–85%; McCoy and Davidson 1985; Cutler et al. 1987).

The affective syndrome of the second group of patients is characterised by a severe, sad mood disturbance with hopelessness, life-weariness of occasionally suicidal intensity, diminished initiative, lack of interest, volitional and cognitive inhibition, self-reproach (up to a severe delusion of guilt) and, as in the first group, sleep disturbances. These manifestations are no different from those of endogenous depression appearing outside the peri-menopausal period.

It is quite obvious that two characteristic types of peri-menopausal affective disorder are to be identified diagnostically as such and that they differ not only in their clinical features, but also in their aetiology, pathogenesis and course. The first type, which may be called peri-menopausal dysphoric syndrome, is directly caused by hormonal changes. The second type, peri-menopausal depression, represents the initial manifestation, or a relapse, of endogenous depression in patients with the appropriate genetic predisposition, for which the hormonal changes of the peri-menopausal period act merely as a trigger mechanism. The lack of distinction between these two clinical entities at least partly explains the conflicting epidemiological data on this mental disorder that may be found in the literature.

A total of 80% of all peri-menopausal women experience vasomotor disturbances such as hot flushes and cold sweats, which mostly occur at night and thereby disturb sleep. The more severe these vasomotor

or hormonally induced manifestations are, the greater the risk that a depressive, dysthymic or dysphoric syndrome will develop. When the somatic manifestations subside, the psychic manifestations do also.

Because many women of this age also complain of tachycardia, vertigo and shortness of breath, hyperthyroidism and panic disorder must be included in the differential diagnosis.

7.2 Aetiology

Both neuroendocrine and psychosocial factors have been invoked as causes of these disorders.

7.2.1 Endocrinological Aspects

Baischer et al. (1995) found a negative correlation between the Hamilton Depression Score and the concentration of 17-β-estradiol in peri-menopausal women with depressive and anxious mood disturbances. Huerta et al. (1995) found an elevated FSH concentration in patients with these disorders. Thus affective disorders in the peri-menopausal period may also be considered the result of oestrogen withdrawal.

It is therefore reasonable in any case for women over age 40 suffering from an affective psychosyndrome of depressive, dysthymic or dysphoric type, or from anxiety disorders, to be screened for the possibility of peri-menopausal or menopausal manifestations by the measurement of 17-β-estradiol, thyroid parameters and FSH.

7.2.2 Psychosocial Aspects

Not only these neuroendocrine factors, but also psychosocial factors play an important role in the causation and maintenance of the disorder. Divorced, widowed or separated women are more likely to suffer from peri-menopausal affective disturbances than women with partners (Avis and McKinlay 1991). Women with lesser degrees of education also seem to have an elevated risk for these disorders (O'Connor et al. 1994; Avis and McKinlay 1995; Huerta et al. 1995). On the other hand, there is no elevated risk associated with the death of parents or with children moving away from home (Kaufert et al. 1992).

7.2.3 Risk Factors

Women who have had pre-menstrual dysphoric syndrome, endogenous depression, post-partal mood disturbances or a dysphoric syndrome related to the use of oral contraceptives have a significantly elevated risk of developing a dysphoric or depressive illness once again in the peri-menopausal period (Stewart and Boydell 1993; Hay et al. 1994; Pearlstein 1995). The longer the peri-menopausal period lasts, the more likely a mood disturbance will occur (Avis et al. 1994).

7.3 Epidemiology

It remains a matter of debate whether the peri-menopausal period is associated with an elevated risk of developing a depressive illness (Weissman et al. 1988). Kessler et al. (1993) even report a diminished prevalence of depressive syndromes severe enough to be classified as endogenous depression in this age-group. On the other hand, it is recognised that depressive syndromes may occur as a consequence of hysterectomy, with or without oophorectomy (Kritz-Silverstein et al. 1993; Oldenhave et al. 1993).

7.4 Treatment

The first distinction that must be drawn is that between depressive syndromes rising to the intensity of an endogenous depression on the one hand and dysphoric syndromes on the other. Our differential therapeutic recommendations are largely based on this dichotomy. There are essentially three strategies for the treatment of peri-menopausal affective syndromes: (1) medical antidepressant therapy, (2) hormone supplementation therapy and (3) combined therapy, i.e. both antidepressant and hormonal therapy.

7.4.1 Hormonal Therapy

Controlled studies have shown oestrogen monotherapy to be ineffective for the treatment of peri-menopausally manifesting depressive syndromes that fulfil the diagnostic criteria for endogenous depression (Schmidt et al. 1996).

Oestrogen supplementation therapy is particularly useful in patients who have not only mental, but also physical manifestations of hypo-oestrogenism, e.g. nocturnal hot flushes and sweats. Patients suffering from mood disorders after hysterectomy and oophorectomy (i.e. iatrogenic menopause) have been found to respond well to oestrogen supplementation (Sherwin 1988).

Anxiety states in the peri-menopausal period, which may be of vasomotor origin, also respond better to

hormone supplementation therapy than to anxiolytics or antidepressants.

7.4.2 Psychopharmacotherapy and Its Application in Combination with Hormonal Treatment

Thymoleptic medical therapy is the treatment of choice for patients with peri-menopausal relapses of endogenous depression, or peri-menopausal dysphoric syndromes.

A combined treatment with both thymoleptics and hormone substitution is particularly helpful in patients with peri-menopausal relapses of endogenous depression, who suffer from an oestrogen and progesterone withdrawal syndrome with both mental and physical manifestations (Zweifel and O'Brien 1997).

The increased sweating that characteristically occurs in the peri-menopausal period is further exacerbated by the use of antidepressants. Clonidine may be used to counteract this undesired effect (Feder 1995).

An increase of libido may be achieved by androgen (testosterone) supplementation (Sherwin et al. 1985).

Culture-Specific Mental Disorders

Translator: E. Taub

1 Introduction

1.1 Comparative Cultural Psychiatry

At the beginning of the twentieth century, Emil Kraepelin announced the birth of a new scientific discipline that he named "comparative psychiatry" (*vergleichende Psychiatrie*), which he predicted would play an important role in both general psychopathology and ethnopsychology (Kraepelin 1904). We now know that Kraepelin, in his later years, attached special importance to sociocultural factors in the generation, manifestations, and distribution of mental illnesses (Jilek 1995). He died suddenly in 1926 before he could work out the definitive formulation of the discipline he had inaugurated, which would best be called "comparative cultural psychiatry," but is now generally known as "transcultural psychiatry," "cross-cultural psychiatry," or "ethnopsychiatry."

In accordance with Kraepelin's conception, H.B.M. Murphy, in his basic text on this discipline (Murphy 1982), identified its principal concerns as the identification, verification, and explanation of the links that exist between mental disorders and the different psychosocial characteristics of peoples and cultures. The term "culture" here comprises "the ideas, values, habits, and other patterns of behaviour which a human group consciously or unconsciously transmits from one generation to another" (Murphy 1982, p. 10).

1.2 Cultural Relativism and Universalism

The diverse views of what constitutes psychopathology have extended, from earliest times, over a continuum ranging from extreme cultural relativism to extreme universalism. Radical psychiatric universalism maintains that mental disorders are essentially the same all over the world, while radical cultural relativism is summed up by the motto: *on est fou par rapport à une société donnée*, i.e. "one is mad in relation to a given society" (Beguin 1952). The debate over cultural relativism and universalism in relation to psychopathology has been stimulated, since 1977, by the proclamation of a so-called new transcultural psychiatry, whose proponents accuse the supposedly old transcultural psychiatry of having subjugated itself to biologically and organically oriented psychiatry (Kleinman 1977, 1988; Littlewood 1990; Lewis-Fernandez and Kleinman 1994). The champions of this so-called new transcultural psychiatry criticize well-known comparative psychiatric research projects, including those of the World Health Organization (WHO), for allegedly having been designed from their outset to find greater similarity than diversity in the cultural comparison of psychopathological phenomena, so that, beneath the obscuring layers of cultural particularity, the postulated biological core might be found. A further error of the "old" transcultural psychiatry is said to be the application of "Western" psychiatric categories in areas of non-Western culture, which supposedly constitutes a category fallacy. In contrast, the "new" transcultural psychiatry stresses the specific cultural meaning of psychopathological phenomena, which must always be understood in the context of the culture in question, for which reason ethnographic methods are preferred to epidemiological methods in the area of research. The "new" transcultural psychiatry demands special consideration of indigenous notions of causality and of explanatory models based on folk beliefs, i.e. the culturally immanent or "emic" standpoint is given priority over the culturally overreaching or "etic" perspective of the scientific observer (these current terms of American anthropology were formed in vague analogy to the linguistic terms "phonemic" and "phonetic"). It is hardly of assistance to cross-cultural psychiatric research, however, when such apparent antagonisms are carried to the extreme on theoretical grounds; instead, the culturally immanent and culturally overreaching perspectives ought to complement each other (Pfeiffer 1994). These tendencies of the so-called new transcultural psychiatry reflect the pronounced cultural relativism that exerted great influence on twentieth-century Anglo-American anthropology, while French anthropology, represented by the works of Claude Lévi-Strauss, strove to extract the basic and universal structures of human thought processes out of cultural diversity.

Some radical cultural relativists characterize psychiatric diagnoses as European-American folk categories and consider it futile to design a generally applicable diagnostic classification scheme (Patel and Winston 1994) or else define modern psychiatry as a culturally constructed Western folk system (Gaines 1992). The great majority of psychiatrists involved in transcultural research reject the ideological position of extreme cultural relativism and recognize that the pioneers of transcultural psychiatry always tried to discover differences in psychopathological phenomena across cultures and to explain these by means of sociocultural factors – without, however, overlooking the universal elements of human behavior that transcend individual and ethnic/cultural differences.

2 Cultural Influence and Psychopathology

Sociocultural factors influence, to different degrees, all aspects of mental disorders, including their generation, symptom profile, course, and prevalence (Marsella 1988; Fabrega 1993). The same is true of normal psychological functions, even those that are known with certainty to have a neurophysiological basis: with respect to color perception, for example, we now know that the spectrum is divided in entirely different ways by different cultural/linguistic groups (Berlin and Kay 1969). Castillo (1997, pp. 268–270) summarizes neurobiological research findings of relevance to cultural learning and comes to the conclusion that the sociocultural environment of the individual becomes physically structured in the neural network of the brain over the course of his or her enculturation.

A *pathoplastic* effect of sociocultural factors, i.e. an effect that forms the clinical picture, is generally accepted, no doubt because of the extremely large number of unambiguous examples. Recent evidence was provided by the findings of the Determinants of Outcome of Severe Mental Disorders (DOSMED) projects of the WHO: the relative frequency of certain symptoms in schizophrenic patients in highly developed and developing countries was very different (Sartorius et al. 1986; Jablensky et al. 1992); significant differences in schizophrenic manifestations were also found when probands in Agra, India, and Ibadan, Nigeria, were compared, and the local researchers found that the content of psychotic symptoms identified critical concerns of the culture in question (Katz et al. 1988). An analysis of psychiatric symptom formation in members of three ethnic minority groups in British Columbia (Salish Indians, Russian Doukhobortsi, and Low German Mennonites) revealed that cultural factors were the most important distinguishing criteria, more so than gender or socioeconomic status (Jilek-Aall et al 1978). The pathoplastic influence of ethnic and cultural identity is also greater than the influences of geographical proximity, historical relations, ethnolinguistic relatedness, and religious connection: recent comparative psychiatric studies show that there are significant differences in schizophrenic manifestations between Malta and Libya (Maslowski 1986), Japan and China (Fujimori et al. 1987), Korea and China (Kim et al. 1993), and Pakistan and Saudi Arabia (Ahmed and Naeem 1984). The International Pilot Study of Schizophrenia (IPSS) and DOSMED global research projects, carried out in international cooperation by the WHO Mental Health Division, revealed an extremely important finding for comparative cultural psychiatry: the course and outcome of schizophrenic psychoses were clearly and uniformly better in project sites in non-Western countries than in the centers of the highly technologically developed Western countries (Jablensky et al. 1994). Cultural influence was listed as an important determinant of this finding, but could not be defined any more precisely (Jablensky et al. 1992). In this connection, longitudinal studies of schizophrenic psychoses in Japan, Hong Kong, and Singapore appear to be relevant, as they revealed favorable prognoses comparable to those seen in the developing countries in the WHO projects (Ogawa et al. 1987; P.W.H. Lee et al. 1991; Tsoi and Wong 1991). These research findings come from highly technologically developed countries, but from cultures that are still very different from those of modern Western societies. The critical difference in relation to the course and outcome of schizophrenic disorders, and probably other psychiatric disorders as well, thus seems not to be that between more and less technologically developed countries, but between modern Western societies and non-Western populations that have largely succeeded in preserving important elements of their traditional culture.

A *pathogenic*, i.e. disease-causing, effect of sociocultural factors is most easily demonstrable in psychopathological conditions of organic/toxic origin that occur in the context of certain sociocultural factors (Jilek 1982). These include, for example, neuropsychiatric disorders of genetic origin, promoted by culture-typical marriages between cousins or perinatal brain injury through certain customary childbirth practices, and especially the sanctioning of alcohol consumption in societies such as Western society, inevitably opening the way to alcohol abuse, with its well-known psychosocial and psychiatric consequences. The rapid and overwhelming westernization ("modernization") of small, tribal societies is accompanied by pathological psychosocial phenomena, as Murphy (1961) was able to show as early as 1959 in a review of data available at the time. Since then, an accumulation of research findings has confirmed the pathogenic psychosocial effects of the forced and rapid transformation of traditionally grown communities to the modern mass society. The consequences of such a social upheaval are mostly not a general acculturation or new cultural creation, but rather marginalization and deculturation of broad segments of the population, associated with critical levels of alcohol and drug abuse and their psychiatric complications, as well as youth suicide. Such behavior after the loss of culture is often a manifestation of *anomic depression* based on anomie, confusion of cultural identity, and relative deprivation (Jilek 1974, 1981). Psychopathological sequelae following excessively rapid culture change have been documented for indigenous populations in North America

(Jilek 1974; Jilek-Aall 1974, 1988; Kraus and Buffler 1979; Hochkirchen and Jilek 1985; Kirmayer 1994), Greenland (Thorslund 1990), and Oceania (Jilek 1987a; Rubinstein 1992; Hezel 1993). In Africa, similar societal changes also cause an increased frequency of transient psychoses and psychosis-like conditions (see below).

3 "Culture-Specific Disorders" or "Culture-Bound Syndromes"

3.1 Development of the Concept

Kraepelin was convinced that the characteristics of an ethnic group also find their expression in mental illness. The eighth edition of his textbook (Kraepelin 1909, 1913) is probably the first comprehensive psychiatric text mentioning disorders known today as "culture-bound syndromes," namely *latah*, *amok*, and *koro*, with which he became familiar during his travels in Asia (Jilek 1995). He did not assume, however, that entirely new types of mental illness would be found in other cultures, and he considered the conditions mentioned to be variants of well-known clinical pictures. In the *American Handbook of Psychiatry*, Arieti and Meth (1959) were the first to address culture-bound syndromes under the heading of "exotic psychotic syndromes," mainly relying upon a survey by Yap (1951). It was also Pow Meng Yap who introduced the concept of "culture-bound" clinical conditions to the psychiatric literature, first in the form of "atypical culture-bound psychogenic psychoses" (Yap 1962) and ultimately as "culture-bound reactive syndromes" (Yap 1967, 1969). According to his definition, which is still the clearest to date, culture-bound syndromes are culture bound only in the sense that their symptom patterns are unusual and are determined in form and frequency by cultural factors (Yap 1974). Yap (1969) was the first to point out that a culture-bound syndrome need not be "exotic," but may also arise under the cultural conditions of modern Western society, e.g. anorexia nervosa – the first, that is, if we set Devereux aside, who construed schizophrenia as an "ethnic psychosis of the Occident." The term introduced by Yap was at the focus of the debate in the 1980s and 1990s between "cultural relativists" and "universalists" in transcultural psychiatry, and this influenced the manner in which it was interpreted. The interpretation of Simons (1985a) may serve as an example of a universalistic interpretation. He considers culture-bound syndromes to be indigenously defined folk illnesses that are strongly influenced by the social and cultural realities of the society in which they occur, although this in no way implies that biological factors are irrelevant to the formation of these syndromes. In the same multi-author text on the subject (Simons and Hughes 1985), Carr (1985) defines culture-bound syndromes from the culture-relativistic point of view as the result of a social learning process that is legitimated as illness within the indigenous system. Littlewood and Lipsedge (1985) prefer to restrict the application of the term to certain locally occurring, temporally limited, and nonbiologically caused patterns of behavior for which the affected individuals are not considered responsible as usual. Decidedly culture-relativistic interpretations were proffered mainly by North American ethnologists. Ritenbaugh (1982), for example, states that culture-bound syndromes can be understood only in a specific cultural context, and the indigenous etiological theory, which symbolizes the essential meaning and behavioral norms of the culture, must be taken into account; diagnosis and successful treatment should be based on culture-specific ideology and technology. Other researchers have aimed at a more neutral definition of terms. Tseng and McDermott (1981) speak of culture-related specific psychiatric conditions that occur with some frequency in certain culture areas, possess special and unusual characteristics, and have manifestations that are closely related to that particular culture.

Prince and Tcheng-Laroche (1987) prefer to keep indigenous explanatory models out of the definition; they see culture-bound syndromes as groupings of clinical signs and symptoms that, because of their special psychosocial characteristics, appear in only a limited number of cultures. In view of the often ideologically motivated disputes over these definitions, some authors have proposed less controversial designations, such as "folk diagnostic categories" (Levine and Gaw 1995) or "folk psychiatric disorders" Hughes (1985a). Hughes (1985b) compiled a long list of 168 "culture-bound or folk psychiatric syndromes," containing a great number of locally used, indigenous names of generally occurring conditions. H.B.M. Murphy (1982), in his basic text on comparative psychiatry, discusses the known culture-bound syndromes without subsuming them under this title. Meanwhile, the term coined by Yap has been sanctioned, so to speak, by the official diagnostic manual of American psychiatry, DSM-IV (APA 1994).

3.2 Delimitation of the Concept

In Annex *2* of the Research Edition of the International Classification of Mental and Behavioral Disorders,

ICD-10 (WHO 1993), it is correctly stated that the culture-specific disorders have two common features:

1. They are not easily accommodated in an international psychiatric classification system.
2. They were first described in, and then considered in close relation to, a certain population group or cultural region.

For this Annex, 12 examples of widely varying importance were drawn from the great number of culture-specific disorders and briefly discussed. The American diagnostic manual DSM-IV contains a "glossary of culture-bound syndromes" with 25 entries, of which, however, only a few concern distinct syndromes. The DSM-IV glossary also contains wholly nonspecific expressions such as *locura*, the Spanish colloquial term for insanity or folly, or *mal de ojo*, Spanish for the "evil eye," to which many tradition-directed populations ascribe a general, magical, disease- and misfortune-producing effect (Hauschild 1982). Possession by the *zar*, which is listed in the same glossary, is not a pathological phenomenon, but a healing cult (Jilek 1993). The DSM-IV glossary also includes general pathological conditions that are regionally known under certain folk names. In the present chapter, the term "culture-specific disorders" refers to locally recognized, specific symptom patterns that can be plausibly brought into relation with the sociocultural emphases and stresses typical of a given population.

3.3
Attempts at Nosological Classification

In view of the bewildering profusion of various local and regional disease names, it is no wonder that early attempts were made to classify culture-bound syndromes in a generally recognized diagnostic system on the basis of the symptoms that the investigator held to be most important. Yap provided, at the same time as his new term, a diagnostic classification system for the culture-bound reactive syndromes. He divided these into three main categories (Yap 1967, 1969): paranoid syndromes, emotional syndromes, and syndromes with disordered consciousness. These categories were further subdivided into primary fear reactions, rage reactions, culture-specific nosophobia, and trance dissociation and later (Yap 1974) modified to include fear reactions, rage reactions, and reactions based on "mental obfuscation." The first English-language textbook of transcultural psychiatry (Kiev 1972) contained a division of the culture-bound mental disorders into anxiety states, obsessional compulsive neuroses, hysterical disorders, phobic states, depressive reactions, and dissociative states. With all due respect to these attempts to seek "unity in the diversity" of culture-bound syndromes (Sartorius 1979), it can only be concluded, from the perspective of transcultural psychiatry, that harmonization of indigenous ethnic terminology with a psychiatric diagnostic system is not possible (Pfeiffer 1980, 1994; Littlewood and Lipsedge 1985). A nosologic classification is neither scientifically nor clinically satisfactory, as the diagnosis-determining manifestations of most culture-bound syndromes overlap, and the indigenous disease terms are semantically overlaid with traditional meanings and interpretations of folk medicine that significantly influence both the illness behavior of the affected person and the reactions of others. It thus seems somewhat artificial when Simons (1985a) sorts the culture-bound syndromes into "taxa," for which he postulates the same or similar neurophysiologically based behavior patterns; for most of these syndromes, no neurophysiological basis can be demonstrated. Pfeiffer's method (1980, 1994) of considering culture-specific stress zones, behavioral forms, and coping styles, while taking into account the interpretations of folk medicine, seems to be of greater heuristic value and clinical utility. This chapter contains an exposition of culture-typical emphases and stress situations that may provoke specific mental disorders in affected individuals. To satisfy the statistical demands of clinical practice and research, the local disease terms will be supplemented, wherever possible, with the corresponding ICD-10 classifications. As may be inferred from the above discussion, an exact agreement between psychiatric diagnostic categories and indigenous concepts of illness cannot be achieved.

4
Folk Idioms for General Emotional Distress

Susto, Espanto **(ICD-10: F43; ?F45.1)**

Heterogeneous combinations of symptoms are regarded by some authors as a culture-bound syndrome only because a single, commonly accepted popular diagnosis is applied, even though the patients so designated have diverse sociocultural identities and lifestyles and their complaints may be quite different. A good example of this phenomenon is *susto*, also called *espanto*, *espasmo*, or *miedo* – Spanish terms that all connote a frightening experience. These disease designations are found among Spanish-speaking populations almost everywhere in the Western hemi-

sphere, and individuals are diagnosed in the city and in the countryside without regard to gender, age, social class, or ethnic origin – European, Amerindian, or African (Rubel 1964; Rubel et al. 1985; Hollweg 1997). Diverse symptoms that often resemble neurotic and somatoform syndromes, but may also include definitely organic diseases (Sal y Rosas 1958; Tousignant 1979), are given the folk diagnosis of *susto* or one of its equivalents under the following conditions:

1. The symptoms are related by their sufferers to a frightening experience, generally in the manner of a rationalization (O'Nell 1975).
2. This frightening experience is assumed to lead to a separation of the soul from the body, either spontaneously or through the action of chthonic or demonic powers (Sal y Rosas 1958; Logan 1979; Tousignant 1979), which decidedly weakens the resistance of the sufferers to disease-inducing influences.
3. The diagnosis of *susto* or equivalent is confirmed by a folk healer; this does not, however, rule out the consultation of a modern physician as well for treatment of the individual symptoms.

The folk-etiologic theory of loss of the soul is reminiscent of shamanic ideas of Paleolithic origin, which the Latin Americans adopted from the indigenous Amerindian population – an example of "reverse acculturation." The authors encountered the same conceptions in healing ceremonies of North American Indians (Jilek 1990) and Southeast Asian mountain tribes (Jilek and Jilek-Aall 1990).

Nervios, **Nerves (ICD-10: F32.11; ?F48.0)**
The psychosocial stress placed on postmenopausal women by marital conflicts, family problems, loneliness, and the suffering of emotional and material deprivations and losses may lead, in many, very diverse cultures, to a chronic, dysphoric mood state with somatic manifestations. The Hispanic population of the Caribbean, Central America, and North America and rural Anglo-American groups refer to such symptoms, in accordance with outdated academic medical conceptions, by the Spanish term *nervios* and the English term *nerves* (Low 1985; Nations et al. 1988).

Ataque de Nervios **(ICD-10: F43; ?F44)**
A direct, acute reaction to traumatic emotion-laden experiences in Hispanic women of the Caribbean and Central American area, and also in North America, is known as an *ataque de nervios* (Guarnaccia 1993; Guarnaccia et al. 1989; Oquendo 1994; Oquendo et al. 1992), an ictally appearing, uncontrolled behavior of brief duration and generally favorable prognosis, frequently a dissociated state that may resemble a *grande ataque hystérique*, in other cases an event resembling a panic attack (Liebowitz et al. 1994).

Hwa-byung **(ICD-10: F34.8)**
Korean women of mature age in Korea and North America, as well as women in other cultures, may react to continuous stresses in marriage, family life, and social situation, and to life situations perceived as unbearable, with somatic symptoms in an anxious and depressive mood state similar to *nervios* or *nerves*, but in the Korean case accompanied by pronounced feelings of anger and, frequently, by the sensation of a (nonexistent) epigastric mass. This chronic depressive condition is designated *hwa-byung*, "fire disease," in accordance with the conceptions of traditional Chinese and Korean medicine, and is correspondingly treated by specialized, shamanic healers, most of whom are women (S.H. Lee 1977; Lin 1983; Lin et al 1992; Min 1989; Min et al 1990; Pang 1990).

5 Culture-Typical Reactions to Extreme Environmental Conditions

"Arctic Hysteria"
"Arctic hysteria" is a collective designation for several conditions, some of them with dramatic manifestations, that have been observed and described among the indigenous population of arctic and subarctic regions, first by explorers and later by ethnologists, physicians, and psychiatrists. These brief reactions are provoked by a stressful situation in which the affected individuals, while experiencing acute anxiety, develop a temporary state of dissociated consciousness. The extreme climatic conditions of the arctic winter expose the inhabitants of these areas to physical deprivations and mental stresses that provide the ecological background for the various patterns of "arctic hysteria" (Novakovsky 1924). The survival of the small group, living together in a very crowded space, requires frictionless cooperation and thus demands of the individual, from earliest youth onward, the strict control of aggressive, competitive, and sexual impulses and emotions. In the traditional Eskimo culture, shamanic séances, in which the entire group actively participated, often provided an opportunity for the indirect expression of intense emotions in dissociated states of consciousness, e.g. in prolonged, ecstatic drum songs leading to a *pivdlerorneq* (Inuit, "drum dance fit") (Holtved 1967). These practices facilitated the occurrence of dissociative states of so-called arctic

hysteria in anxiety-producing situations (Foulks 1972). The best-known phenomena of this type are *pibloktoq* (Inuit, "crazy") and *kayak-svimmel* (Danish, "kayak dizziness").

Pibloktoq **(ICD-10: F44.7; F44.88)**
Pibloktoq-type attacks were observed among Eskimo groups in Greenland, Canada, Alaska, and Siberia and described by several authors in essentially similar terms (Brill 1913; Czaplicka 1914; Gussow 1960; Wallace and Ackerman 1960; Holtved 1967; Foulks 1972): the affected individual, usually a fairly young Eskimo woman, seems to be anxious and irritated, withdraws from group interaction, and starts to sing or to imitate bird or animal calls. Suddenly, she lapses into a state of wild agitation, tears the clothes from her body, and rushes – while screaming loudly – into the snow or ice, sometimes even into icy water. In most cases, however, the affected person remains within a certain range of safety, so that she can be easily saved. Violent actions directed against others or herself are rare. The usually brief stage of motor arousal ends with collapse, sometimes also with convulsive movements, followed by a deep sleep from which the affected person awakens with no clear memory of the event and without any sequelae whatsoever. The traditional culture generally ascribes the attack to possession by an evil spirit. In addition to the above-mentioned combination of ecological and psychosocial factors, the hypothesis has been advanced that *pibloktoq*-like conditions are caused by inadequate and unbalanced nutrition, leading to deficits of calcium and vitamin D_3, or to excessive amounts of vitamin A (Wallace and Ackerman 1960; Wallace 1972; Landy 1985). In the last few decades, in the course of rapid westernization, the small tribal societies of the arctic, subarctic, and Pacific region have been flooded with imported alcoholic beverages (Jilek 1987a). Under the influence of alcohol, the phenomenology of stress-induced reactions in the indigenous population of northernmost North America has changed: the traditional manifestations of arctic hysteria have now given way, under the influence of acculturation, to much more dangerous episodes of acting-out while intoxicated, in which, however, certain traditional behavior patterns can still be discerned (Foulks 1985).

Kayak-svimmel **(ICD-10: F41.0)**
In traditional seal hunts, the Eskimo often has to spend hours in a state of social isolation and sensory deprivation, sitting motionless in his kayak, surrounded by the monotonous loneliness of the Arctic, waiting for a seal to appear. Approximately 10% of seal hunters suffer an attack of *kayak-svimmel*, also known as kayak-angst, in such situations (Meldorf 1900; Bertelsen 1940; Ehrstrom 1951; Gussow 1963, 1970). Attacks of kayak-angst begin with dizziness, lightheadedness, and the feeling of a disturbance of balance. A sensation of cold rising from below makes the hunter fear that the kayak is filling with water. Anxiety increasingly grips him: he trembles and breaks out in sweat, and he may sustain a panic attack with inability to move and illusional perceptions. If help arrives in time, the affected individual may reach shore again, by himself or with assistance. Attacks of kayak-angst are accompanied by vegetative symptoms and may return with increasing intensity until the affected person gives up hunting in a kayak altogether. Now that the Eskimos have largely abandoned their traditional way of life, kayak-angst has become rare.

Windigo, Witiko, Witigo **(ICD 10: F32, in the Current Indigenous Meaning)**
The so-called *windigo* psychosis of the northern Algonquin tribes of Canada, especially the Ojibwa and Cree, has been mentioned under various diagnostic labels in practically all discussions of the culture-specific disorders ever since Linton (1956) referred to "cannibalistic insanity" as an example of a so-called primitive psychosis. Typically described as an obsessive and impulsive, murderous desire for human flesh as the result of delusional possession by, or transformation into, a mythical cannibalistic monster (*windigo*), the *windigo* phenomenon was long a favorite subject of psychodynamically inclined American anthropologists (Hallowell 1934; Landes 1938; Linton 1956; Parker 1960; Hay 1971). The periods of famine in winter which, when extreme, may have led to cannibalism out of necessity, despite the disgust it generally produces, were the ecological and historical background of the Indian myth of the *windigo* – the cannibalistic hibernal monster with a skeleton and a heart of ice. More recently, *windigo* behavior has been regarded as symptomatic of "classical depression" (Kiev 1972) or as a melancholic delusion, the content of which is based on tribal mythology and the struggle for survival in a subarctic climate (Shore and Manson 1981). The expression *windigo* is used today by the northern Ojibwa more generally to denote a state of sorrow, deep worry, or hopelessness (Marano 1982). Teicher (1960) reviews the literature on the *windigo* myths and phenomena in aboriginal North America as far back as the seventeenth century and identifies, on the basis of mostly anecdotal reports, 70 cases of *windigo* psychosis. Critical examination of these reports (Honigmann 1967; Marano 1982) could not confirm a single case of cannibalistic compulsion; in addition to sporadic earlier cases of cannibalism out of necessity, many of the individuals suspected of *windigo* were, in fact, victims of an epidemic of witch fear that struck several northern Canadian Indian

tribes during the first traumatic culture change after the European intrusion (Honigmann 1947; Marano 1982). The *windigo* phenomenon is now mainly of historical interest.

6
Mental Disorders as the Expression of Culture-Typical Emphases and Culture-Typical or Acculturative Stress Situations

6.1
Acculturative Stress Situation: Studying in a Culture-Alien Milieu

Brain Fag (ICD-10: F43.2; F48.0)
Mental stress and crises occasioned by the demands of academic study, particularly in connection with examinations, are frequently encountered in Western and East Asian cultures, despite centuries-old literary traditions and general familiarity with a school system based on reading and writing and typified by formal, competitive testing. Such academic demands place a much greater burden on schoolchildren and university students in developing countries, which have often made a rapid transition, in a single generation of "modernization," from a preindustrial, communalistic tribal society with oral traditions and cooperative, practical initiation learning to an individualistic, competitive education system imported from the West, with an emphasis on theoretical knowledge acquired from books. This type of knowledge often bears no relation to the daily life of the older generation, which, however, places heavy pressure on the younger generation to produce the academic successes which are expected to result in socioeconomic advancement in the new society – and this, in turn, further reinforces the students' mental stress. This situation is particularly typical of African students under acculturation pressure and is often associated with the development of a symptom complex known, since its first description and later delineation by Prince (1959, 1960, 1985, 1989), by the term "brain fag," coined by Nigerian university students. The clinical picture is characterized by the following:

- Unpleasant sensations in the head and body, especially of heat, burning, and crawling
- Eye and visual symptoms, especially blurry vision and tears while reading
- Inability to concentrate on books and lectures and to understand them
- Impairment of retention and memory
- Daytime fatigue and feeling of weakness, with frequent disturbance of night-time sleep

English-language abilities may suffer a transient decline (Boroffka and Marinho 1963). The intellectual capacity of affected individuals is not below average – indeed, the opposite is often true, as was mentioned by several observers and confirmed in a controlled study (Morakinyo 1985). Intercurrent organic illness of the affected students can be excluded as a cause by reason of the high prevalence of the disease; 50%–70% of Nigerian high-school and university students complained of typical symptoms when interrogated by questionnaire (Prince 1962; Jegede 1983). The brain fag syndrome has also been described in schoolchildren and university students in other African countries, including Uganda (German and Arya 1969), Ivory Coast (Lehmann 1972), Liberia (Wintrob 1973), Tanzania (Harris 1981), Malawi (Peltzer 1987; 1995), and Swaziland (Guinness 1992). These studies confirmed the relatively high frequency of the syndrome as well as the aspects in which brain fag differs from the anxiety states and depressive reactions evoked by academic stress in the West:

- Symptoms caused by the mere effort of reading
- The physical sensations of burning heat and crawling, often experienced as if there were insects crawling on – or worms beneath – the skin

In Africa, these symptoms form a part of the common, popular conception of being ill. Worms or reptiles in the head and body are often considered to be causes of disease in African folk medicine, whether the problem consists of stereotyped psychophysiological complaints (Makanjuola 1987) or an unambiguously organic condition, e.g. epileptic seizures (Orley 1970; Jilek-Aall 1979). Parasitic infestation is quite common in tropical Africa; in cases of helminthic infestation, the worms may be activated by fever, cause skin irritation, and emerge from bodily openings such as the nose and mouth (ascaris) or the conjunctiva (filaria).

6.2
Culture-Typical Stress Situation: Fear of Magical Persecution

***Bouffée Délirante*-Type Reactions (ICD-10: F23)**
Bouffée délirante, a term introduced in French psychiatry by Magnan (1893), was applied by French-speaking clinicians in West Africa (Aubin 1939; Vyncke 1957; Rainaut 1958; Salles 1961; Collomb 1965) and the Caribbean (Bustamante 1969a,b; Constant 1972) to acute transient psychotic or psychosis-like reactions evoked by a frightening experience, in the context of culturally accepted beliefs in magic, witchcraft, and the ever-present possibility of magical persecution or retribution. The symptoms consist of intense fear, dream-like confusion, unsystematized

paranoid delusions, and, frequently, visual and auditory hallucinations, usually accompanied by emotionally charged, dramatic, and sometimes dangerous acting-out behavior. A complete remission follows after a relatively short time, either spontaneously or after sedation with medications or medicinal herbs. The experience is usually sealed off by "amnesia" or denial of the event, for which the sufferer, in traditional cultures, is not held responsible. In a small number of cases, the episode may be repeated under similar conditions.

Reactions corresponding to *bouffée délirante* in English-speaking Africa are known under various diagnostic terms designating acute paranoid reactions. Lambo (1960) described an acute, agitated anxiety reaction, similar to a hysterical twilight state, that often occurs in the context of fear of bewitchment, under the name of "frenzied anxiety" and equated this reaction to *bouffée délirante* (for a review of transient psychoses in Africans, see Jilek and Jilek-Aall 1970). In the last decade, such psychotic reactions were also reported in Zimbabwe (J. Stevens 1987), Swaziland (Guinness 1992), and Egypt (Okasha et al. 1993). As several authors have stressed, most cases of *bouffée délirante* have no organic or infectious cause. Transient psychotic or psychosis-like reactions evoked by the acute fear of being affected by magic are in no way a specific phenomenon of African cultures; they have been described with some frequency in other parts of the world, including Indonesia (Pfeiffer 1994) and Tonga (Jilek 1988) as well as in southern European migrant workers (Labhardt 1963; Risso and Böker 1964). In their manifestations and course, *bouffée délirante*-type conditions are reminiscent of two nineteenth-century disease entities: the "transient amentia" of the Vienna School (Meynert 1889) and *folie hystérique*, the "hysterical psychosis" first described by Morel (1860) in Paris, a diagnostic concept revived by American authors in the 1960s with special reference to transient psychotic reactions in non-Western cultures (Hollender and Hirsch 1964; Langness 1967; Hirsch and Hollender 1969). The special significance of *bouffée délirante*-like conditions for transcultural psychiatry lies in their particularly frequent occurrence in previously tradition-directed indigenous societies undergoing a rapid transformation to modernity, in which the individual is exposed to loss of status and role confusion. This was stated as early as 1965 by Collomb (1965), repeated by later authors, and, most recently, confirmed by thorough analyses in Swaziland (Guinness 1992). The common feature of affected individuals coming under acculturation pressure in various lands is that they are still adhering to a traditionally derived, premodern world view to such an extent that they view magic and witchcraft as real threats, while at the same time having lost the protective, compensating resources of their old culture.

6.3 Culture-Typical Emphasis: Procreation and Fertility

Koro, Suo-yang (ICD-10: F48.8)

Psychoanalytical authors thought that they had found a real-life manifestation of oedipal castration anxiety in the form of the "genital disappearance" syndrome, *koro* (Kobler 1948; Devereux 1954). Yap (1965) elevated *suo-yang/koro*, which he viewed as a depersonalization, to the status of a paradigmatic example of a culture-bound syndrome (a term he had coined; see above). Among the many culture-bound syndromes, *koro/suo-yang* is the only one to have occurred in mass epidemics – indeed, on several occasions. We shall thus discuss this phenomenon in greater detail.

The Malay word *koro* is generally used today for an acute state of anxiety, accompanied by vegetative symptoms, in which the affected person believes that he or she can perceive, if he is male, the shrinking and disappearance of his penis or, if female, the shrinking of her breasts and/or labia; it is assumed not only that this process leads to impotence and/or sterility, but also that complete retraction of the external genitalia will inexorably be followed by death. This explains the "life-saving" emergency treatment practiced by folk healers in Asia when confronted by the frequently panic-like *koro* attacks, consisting of holding the penis in place, either manually or with special instruments (see the figure in Van Wulfften Palthe 1934). The term *lasa koro*, "penis shrinking," first appeared in print in Sulawesi in 1874, in Matthes's dictionary of the Buginese language. Indonesian colleagues have informed the authors that, in Sulawesi, the retraction of the head of a tortoise (Malay *kuro*) is viewed as analogous to the *koro* syndrome. Western medicine became aware of this syndrome at the turn of the century through the scientific reports of Dutch physicians in what is now Indonesia (Blonk 1895; van Brero 1897b; Voustman 1897), followed, in the 1930s, by ethnomedical analyses (van Wulfften Palthe 1934, 1935, 1936; Slot 1935; Mulder 1935). In the meantime, Western interest in classical Chinese medical theory had also made *suo yang* known to the West, specifically meaning "shrinking of the penis," or more generally "reduction of the male principle *yang*." The resulting excess of the female principle *yin* disturbs the health- and life-sustaining *yin–yang* equilibrium of the organism. Deficiency of *yang* and excess of *yin* lead to a state of "cold" that calls for the vitalizing remedies of traditional Chinese medicine; thus *suo-yang* is an indication for *yang*-strengthening remedies (Rin 1965). *Suo-yang* was already mentioned in the *Canon of*

Internal Medicine of the Yellow Emperor, Huang Di, compiled approximately 600–400 B.C., a classic work in which the *yin-yang* theory is explicated (Tseng 1973). A precise description of the *suo-yang* syndrome from the viewpoint of Chinese medicine was provided by the *New Collection of Remedies of Value* compiled by Bao in 1834 (Gwee 1968). Individual cases studied by Chinese psychiatrists in Taiwan (Rin 1965), Singapore (Gwee 1963), and Hong Kong (Yap 1965) mostly concerned insecure younger men whose *koro*-like anxiety attacks arose in connection with acute or chronic sexual problems and, in a few cases, in the context of a paranoid or depressive psychosis. Yap attempted to show that the popular conception of *suo-yang,* based on traditional Chinese medical theory, itself causes these *koro*-like symptoms to arise, under certain conditions, in susceptible individuals in the Chinese cultural sphere. He assumed that the syndrome was bound to Chinese culture and that it was exported to Indonesia by Chinese immigrants. This argument overlooks the fact that *koro* has long been endemic not only in Moslem, Christian, and animist ethnic groups of Sulawesi and Kalimantan, but also in populations that are not under Chinese cultural influence, such as the aboriginal tribes of the island of Flores (El Fakharani 1980) and of the interior of Mindanao, in the Philippines (J.W. Edwards 1985), not to mention its epidemic occurrence in non-Chinese cultures.

Kraepelin (1913) had already mentioned the occurrence of *koro*-like delusions in manic-depressive patients in Germany. With the growing interest of European and American clinicians in transcultural psychiatric literature, there are now more reports of isolated *koro*-like cases in Western countries (J.W. Edwards 1970; Dow and Silver 1973; Ang and Weller 1984; Berrios and Morley 1984; Smyth and Dean 1992; Adeniran and Jones 1994). What distinguishes these *koro*-like cases of Western patients from culture-typical *koro* or *suo-yang* in Asia is, first of all, that the *koro*-like symptoms are merely a part of a larger neurotic, psychotic, or toxic disorder; second, more importantly, that the patients develop the idea of genital disappearance on their own, and this idea is not shared by their cultural group, i.e. the idea is autistic rather than culture specific. These differential diagnostic features were pointed out years ago (Jilek and Jilek-Aall 1985) and later recommended for inclusion in the DSM-IV classification (Bernstein and Gaw 1990).

In Africa, *koro*-like conditions have been described chiefly in Nigeria. In these conditions, the affected individuals – usually men – were convinced that they had been robbed of their genitals by magical means, typically by strangers whom they had chanced to meet in the market, usually members of another tribe whom members of their own tribe generally distrust. Even when the "robbing of genitals" was belied by inspection, many affected individuals nonetheless believed that their sexual function and reproductive ability had been damaged by magical powers (Ilechukwu 1988). In Nigeria, in addition to sporadic cases of *koro*-like conditions (Ifabumuyi and Rwegellera 1979), there have also been small-scale epidemics of "magical robbing of genitals." These were stirred up by rumors and media reports to the effect that unscrupulous politicians or bankers had organized magical robbing of genitals in order to exploit the forces residing in the genitals, according to cultural tradition, for the magical enhancement of their own power or wealth (Ilewchukwu 1992). Modern Europeans to whom such ideas appear bizarre should be reminded that common popular opinion in the late Middle Ages assumed that a man was continuously liable to lose his virility, and his *membrum virile,* as the result of witches' magical attacks. The Dominican scholars Sprenger and Kraemer Institor (1487), devoted an entire chapter of their *Witches' Hammer* to this complaint, which was not infrequently voiced by young men at that time.

Koro Epidemics

The typical *koro/suo-yang* syndrome, consisting of a subjective perception of the shrinking or disappearance of the genitals or breasts with accompanying fear of death, has occurred in several times and places in epidemic fashion. The first European report of a *koro* epidemic in China was written by a French physician who observed it among young students in Szechuan in 1907; he remarked that this "Asiatic psychosis" could arise either individually or collectively, was of short duration, and was associated with the fear of being unable to procreate, "terrifying to the Chinese" (Legendre 1908). The principal site of *koro* epidemics in China is the southern part of the province of Guangdong (Leizhou and Hainan), where the mass occurrence of *suo-yang* is documented as early as 1865 and, in this century, in 1948, 1955, 1966, and 1974 – all years of particular political tension and socioeconomic turmoil in China. The last major epidemic, in 1984–1985, was thoroughly investigated by psychiatrists (Jilek 1986; Tseng et al. 1988, 1992); it struck several thousand people with typical *suo-yang* attacks, most of them male adolescents and young men, but also girls and young women. The authors had the opportunity to visit the region toward the end of the epidemic and, with the aid of Chinese colleagues, to interview affected individuals, their families, and their healers (Jilek 1986). Common among the sufferers were the feeling that their genitals or breasts were shrinking or retracting and the accompanying fear of death, with the corresponding psychomotor and autonomic/vegetative concomitants. Despite decades of Marxist indoctrination, the traditional belief still prevailed that

possession by female fox spirits caused disappearance of the genitalia. Fox spirits transforming themselves into *femmes fatales* are a classic theme of Chinese literature; the fox symbolically unites the dark domain of *yin* with the bright world of *yang* (Buber 1946). The traditional treatment of *suo-yang* victims consisted of holding the "shrinking" organ firmly and of exorcism rituals in which the fox spirits were to be "knocked out" of the body; images of the classical demon expeller Zhong Kui, or sometimes of Mao Zedong, who was identified with him, were used as prophylactic measures.

In 1967, the male Chinese population of Singapore was stricken by a *koro* epidemic affecting approximately 500 people. Because the symptoms followed the classical *suo-yang* pattern, the investigators (Koro Study Team 1969; Ngui 1969) concluded that indoctrination with the traditional Chinese medical theory of *suo-yang* had been an essential causal factor, although only one quarter of the affected individuals had prior knowledge of it. In fact, the epidemic was provoked by rumors of the deliberate poisoning of pork. The epidemic unfolded during a historical period of intense political and ethnic conflict between the Moslem Malays, who eat no pork, and the pork-eating Chinese, who felt threatened by the Malays after the British occupation forces withdrew (Murphy 1982). Psychiatric observers found no Chinese cultural influence in the *koro* epidemic in Thailand in 1976 (Jilek and Jilek-Aall 1977a,b; Suwanlert and Coates 1979). This epidemic of typical *koro* attacks began in provinces bordering on Vietnam, moved to other parts of the country, and ultimately affected more than 2000 individuals, most of them peasants, about a third of them women and children; all were Thai, and not a single one belonged to the Chinese minority. In a time of widespread fear of aggressive actions of the then victorious communist Vietnam, the Vietnamese were suspected of a malevolent attack on the reproductive capability of the Thai people by means of mass poisoning of food, drink, and tobacco. The rapid spread of the epidemic was aided by sensational news reports and stopped only by a vigorous explanatory campaign by Thai colleagues.

A few sporadic cases of psychosis with *koro* symptoms have been reported in India (Shukla and Misra 1981; Chowdhury 1992). In the summer of 1982, the "genital disappearance syndrome" attracted a great deal of attention in India through its rapid epidemic spread through Assam, West Bengal, and Meghalaya. The condition was known locally under the Assamese name *jhinjhini bimari*, "prickle disease," because a prickling feeling over the entire body preceded the *koro* symptoms. More than a thousand people of diverse ethnic, religious, and social origin – Hindus of all castes, Moslems, and animists – were involved, though not a single person of Chinese origin or under Chinese cultural influence. Indian investigators studied several hundred patients and identified them as having classic *koro* syndrome (Dutta et al. 1982; Nandi et al. 1983; Chakraborty 1984; Sachdev 1985). The affected individuals were mostly young men and male adolescents; it was estimated that one quarter of the sufferers were women. Another massive *koro* epidemic occurred in West Bengal in 1985 (Chowdhury et al. 1988; Chowdhury 1991), in the northern region of the state, an area whose ethnic and religious diversity is continually reinforced by immigration. The affected individuals this time included Hindus of Indian and Nepalese origin, Moslems, and mountain tribespeople. Women were represented in all affected ethnic groups and were the subject of a first special study (Chowdhury 1994); they complained mainly of retraction of the nipples and flattening of the breasts. The Indian *koro* epidemics came at a time of heightened social and interethnic tension in the stricken regions and were brought about by the collective fear of the rural population that they would be inundated with land-hungry immigrants (Chakraborty 1990).

In conclusion, the *koro/suo-yang* syndrome can be considered neither as a paradigm of pathogenic cultural indoctrination, nor as a manifest example of an oedipal castration complex. It is, rather, an expression of individual or collective fears, provoked by an assumed threat to reproductive ability, in cultures in which reproductive ability is a major determinant of a young person's worth.

Shen-k'uei, Dhat, Jiryan, Sukra Prameha
(ICD-10: F48.8; F45.34)

In traditional Chinese medicine, the "semen loss" syndrome carries the name *shen-k'uei*, "vital weakness of the kidneys" (Tseng 1973; Wen and Wang 1981); in Ayurvedic medicine, it is known by Sanskrit-derived designations, thus in India *dhat* (Wig 1960) or *jiryan* (Carstairs 1956), in Sri Lanka *sukra prameha* (Obeyesekere 1976). The "semen loss" syndrome is widespread on the Indian subcontinent, but has only been a subject of scientific investigation in recent decades (Malhotra and Wig 1975; Chadda and Ahuja 1990; Bhatia and Malik 1991; Paris 1992; Chadda 1995). This syndrome, in which the person supposedly suffering semen loss fears for his virility and reproductive ability, is closely related to *koro/suo-yang*, with which it may occur in combination (J.W. Edwards 1983; Bhatia et al. 1992). The patients, mostly young men, complain of a general decline of strength, loss of energy, exhaustion, disturbances of sexual function, vague bodily complaints, difficulty concentrating, and anxious-dysphoric mood. They attribute these symp-

toms to the loss of sperm in the urine or in nocturnal pollutions. Despite the hypochondriacal quality of the complaints, the patients' fears of loss of sperm must be taken seriously, because sperm, in both Chinese and Indian culture, is considered a precious, vital elixir that the organism must laboriously distill from the blood, just as the blood is distilled from food and drink. Ayurvedic tradition holds that sperm is the most valuable of the seven *dhatu*, or essential body substances. There are many Western parallels to the supposed consequences of sperm loss, ranging from Greco-Roman medical philosophy to the academic medical theories of the eighteenth and nineteenth centuries (Bottero 1991; Raguram et al.1994). Even today, true spermatorrhea would certainly arouse concern anywhere, but the *dhat* syndrome and its equivalents are distinguished by the fear of losing one's life-giving elixir in a society that places supreme value on male generative power.

6.4 Culture-Typical Emphasis: Making a Pleasant Impression on the Other Person in Interpersonal Relations

Taijin Kyôfu (ICD-10: F40.1)

Western psychiatry uses the terms "anthropophobia" or "social phobia" (*phobie sociale*, Janet 1903) for *taijin kyôfu*. There are a number of features common to Western social phobia and *taijin kyôfu*, particularly with respect to the manifestations of anxiety that are evoked by certain actual or anticipated contact situations. The Japanese conception of social phobia, however, is different from the Western one, as will be shown below. *Taijin kyôfu*, described by Morita (1921) as a subtype of the "constitutional nervous temperament" (*shinkeishitsu*), is in no way a general fear of human contact, but rather "a fear of the other person, the person one is facing, a fear of a particular interpersonal situation" (Kimura 1995, p. 135). Accordingly, Kasahara (1987) proposes the term "phobia of interpersonal relations" and shows that the interpersonal situation that arouses intense fear is one in which the other person is neither a complete stranger nor a member of one's intimate circle, but a person whom one knows to some extent. *Taijin kyôfu* is not a uniform disease type, but rather a group of structurally similar phobic anxiety conditions, including the following (Kimura 1972, 1995; Yamashita 1993):

- Fear of blushing in front of others (erythrophobia)
- Fear that others will be bothered by being looked at, resulting in avoidance of all eye contact (eye contact phobia)
- Fear that one's own, supposedly offensive body odor will disturb others (own-body-odor phobia)
- Fear that one has a particularly unattractive face or a repulsive physical defect (dysmorphophobia)
- Fear that one will tremble or make a face

The sufferers' conviction that they possess defects that they actually do not sometimes makes these phobias hard to distinguish from delusions that may also appear as temporary components of a schizophrenic mental disorder. The diagnosis of *taijin kyôfu* therefore requires the exclusion of the presence of other psychotic symptoms. The anthropophobe's relation to his human environment is fundamentally different from that seen in schizophrenic delusions of reference.

Anthropophobia of the Japanese type is a fear of presenting oneself (Iwai 1982). In severe cases, the affected individuals insist on the surgical correction of their supposed physical defect (Aoki 1981). If they have a certain degree of insight into their condition, those suffering from *taijin kyôfu* believe they are unable to master interpersonal relationships because of a "nervous weakness," as in Morita's concept of *shinkeishitsu*; they then seek help in one of the clinics that practice Morita therapy, often successfully. The theory of neuroses proposed by Morita and the Morita psychotherapy based on it are discussed in an extensive specialized literature in Japanese, which is summarized in several reviews (Suzuki and Takemura 1966; Kondo 1976; Kitanishi 1990; Goddard 1991).

According to a number of statistical determinations, social phobias are more common in Japan than in Western countries; they account for 6%–19% of neurotic patients in Japanese university outpatient clinics and a much higher percentage in private clinics (Kitanishi and Tseng 1988; Takahashi 1989). In earlier times, most *taijin kyôfu* patients were male adolescents or young men, but, in recent years, the number of female and older patients has risen, as has the number of serious cases, particularly of own-body-odor phobia and eye contact phobia. A number of Japanese authors attribute these changes in symptom prevalence and distribution to sociocultural change in the wake of industrial expansion, which influences interpersonal relationships negatively through emphasis on aggressive competition (Russell 1989).

Although *taijin kyôfu* shows parallels with the social phobia (DSM-IV: 300.23) diagnosed in North America, there is at least one major difference: the Japanese *taijin kyôfu* patient fears that the interpersonal encounter will disturb or insult the other person, while the American social phobia patient fears that such an encounter will be humiliating or embarrassing to him- or herself, i.e. although they have similar symptoms, the East Asian type of phobic anxiety is "allocentric," the American type "egocentric," in accordance with the characteristic features of each culture (Chang

1997). In their clinical analyses of *taijin kyôfu*, several authors adduce ethnographic data on the specifically Japanese cultural background of these anxiety states (Kasahara 1974; Kimura 1995; Takahashi 1989; Kirmayer 1991; Yamashita 1993). In fact, the *Tale of Genji*, written by Lady Murasaki Shikibu in 1001–1015 (Murasaki 1970), already tells of a young girl with symptoms similar to those of *taijin kyôfu*, as well as of the great importance generally attached to a pleasant body odor.

Doi (1982) analyzes the Japanese need for *amae*, the confident, imposing feeling of trust that a child has in his or her parents, and the desire to experience *amae* in interpersonal relationships with significant others; he attributes the phobic anxiety conditions discussed here to frustration of the need for *amae*. Kimura, in his semantic-phenomenological discussion of what he calls Japanese social phobias, comes to the conclusion that the self of these patients consists exclusively of the self perceived by other people. He proposed that social phobias are particularly common in Japan because "among the Japanese, the self does not contain the basis of its existence within itself" and because "in the structures of Japanese ego consciousness, the question of who one is is not answered within oneself" (Kimura 1995, p. 137).

Kirmayer (1991) stresses that *taijin kyôfu* is based, not only on specifically Japanese beliefs about the self, but also on cultural norms and rules of social interaction. His claim that there would be no *taijin kyôfu* without the medium of Japanese culture seems excessive, however, considering the relatively frequent occurrence of typical *taijin kyôfu* symptoms in Korea, particularly in young people of either sex (S.H. Lee 1987; S.H. Lee et al. 1994). The characteristic features in Korea are the same as in Japan, as is the allocentric orientation of the patient's anxiety. The first cases of "social phobia" reported in China, unlike the typical Japanese and Korean cases, show an egocentric orientation, as in North American social phobia (Yu and Prince 1991). New comparative psychiatric studies of university students in Japan, South Korea, and China show that *taijin kyôfu*-like anxieties in interpersonal situations are much more commonly found in Japanese and Korean students than in their Chinese counterparts, whose anxiety also has other contents (Kitanishi et al. 1995). Despite the shared Buddhist and Confucianist cultural heritage, the *taijin kyôfu* anthropophobias in Japan and Korea are different in type and frequency from social phobias in China, perhaps because China has undergone a different type of historical and political development.

6.5 Culture-Typical Emphasis: Propensity to Dissociation and Imitative Learning

Latah-Type Reactions (ICD-10: F48.88)

The peculiar *latah*-type reactions will be dealt with in some detail in this chapter because of their special importance for psychopathology (alternative interpretations of identical manifestations as exceptional behavior in normal psychology, a phylogenetic mechanism, an organic brain disorder, or a psychotic or neurotic disorder) and because of the central role that *latah*, like *koro*, plays in the controversy over the culture-relativistic or biopsychological orientation of transcultural psychiatry. The complete *latah* symptom complex consists of the following types of behavior:

1. Abnormal startle response with elevated general sensitivity to being startled, depending also on the individual- and culture-specific nature of the tactile, acoustic, and/or visual stimulus, and the status of the person provoking the startle response.
2. The startle response then induces the typical hypnoid alteration of consciousness, or dissociation, which can also be induced by fascination or other affective stimuli.
3. Next, there is decomposition of speech – production of unformed sounds or inarticulate words; impulsive, repeated utterance of sexual terms (coprolalia or, more accurately, pornolalia), sometimes in abbreviated or euphemistic fashion, occasionally progressing to obscene and aggressive verbal abuse.
4. Echo symptoms: echopraxia and echomimia, i.e. imitation of movements and facial expressions of the provoking person; echolalia, exact repetition of forms of address and greeting, even of words and sentences in languages of which the affected person is ignorant; and, sometimes, imitation of noises.
5. If the hypnoid alteration of consciousness is advanced, automatic obedience to commands may occur, often providing a source of merriment at the expense of the hapless *latah* sufferer.
6. In some cases, there is also cataleptic rigidity.

Areas in which the full *latah* reaction occurs include:

- Southeast Asia, the Malay-Indonesian culture area (van Brero 1895; Ellis 1897; Gimlette 1897; Abraham 1912; van Loon 1927; Yap 1952; Pfeiffer 1968; 1994; Geertz 1968; Kenny 1978; Winzeler 1995), including the Dayaks of Sarawak and the Rungus of Sabah (Chiu et al. 1972; Doolittle 1991; Winzeler 1991; Simons 1996), also Thailand (Suwanlert 1972),

Burma-Myanmar (Still 1940; Yap 1974), and the Philippines (Musgrave and Sison 1910; Simons 1996).
- Northern Eurasia, Ainu in Hokkaido and Sakhalin (Sakaki 1905; Uchimura 1935; Winiarz and Wielawski 1936; Ohnuki-Tierney 1980); Mongols (Aberle 1952), aboriginal peoples of Siberia (Hammond 1884; Jochelson 1908, 1910; Czaplicka 1914; Shirokogoroff 1935).

Recently, Minevitsch (1993) observed *latah*-type reactions among the Buryats of the Baikal region, as did Korolenko in 1996 during religious ceremonies of the Church of Christ in Novosibirsk (Professor C. Korolenko, personal communication, 1997). In the past, *latah*-type reactions, so-called Lapp panic, were described among the Sami and Skolt Lapps in northern Russia and northern Scandinavia (Collinder 1949). Cultures to which *latah* reactions are endemic have specific indigenous names for it: among Malay peoples *latah*, "nervous, ticklish," from the Sanskrit *lata*, "fool;" among the Thai *bahtschi*, "tickle-crazy;" among the Burmese *yaun*, *young-dah-te*, "ticklish;" among Filipinos *mali-mali*, and among the Ainu of Hokkaido and Sakhalin *imu*, "startle fright." In Siberia, *latah*-type reactions (Russian *miryachit*) occur among the Tungus (*olon*), Yukaghirs (*irkunji*), and Koryaks (*meryak*).

In the *latah* zones of northern Eurasia and Southeast Asia, *latah*-type reactions occur mostly in women. These peoples of northern Eurasia and Southeast Asia were not in historical contact with each other, have different types of social organization, and display no linguistic relatedness. What they have in common, however, is a cultural emphasis on the propensity to dissociation, practiced from youth onward in religious, social, and therapeutic ceremonies, shamanic séances, or trance rituals. These cultures also emphasize learning by imitation, often also by identification with the role model, and mastery of situations by copying a person behaving in a superior way.

Among the factors that may contribute to the formation of latah reactions in Malay culture, Murphy (1976) named, above all, child-rearing practices promoting dissociation and suggestibility; these result in rapid, but mechanical learning of behaviors and capabilities through passive-submissive obedience to instruction. Geertz (1968) wrote similarly about the upbringing of Javanese children. In Java, many women have an "initial dream" of sexual content some time before their first *latah* reaction (van Loon 1927; Pfeiffer 1968). This dream is culturally stereotyped and is popularly considered to provide an etiological explanation for *latah*, in addition to the action of spirits and vague notions of soul loss. In the Malay-Indonesian culture area, *latah* is regarded more as a personal trait than as an illness and is generally not thought of as an indication for traditional healing treatment. However, thorough history-taking often reveals that the first occurrence of *latah* was at a time of particular mental stress and/or was associated with a depressive reaction (Pfeiffer 1994).

The occurrence of *latah*-type reactions outside the *latah* zones of northern Eurasia and Southeast Asia has been documented for the following countries and peoples: South Africa, among the Bantus (Gilmour 1902); Eritrea and Yemen, among Yemenite Arabs (Infurna 1928; Sarnelli 1934), Libya, among the Senussi (Natoli 1937); Southern and Western Sahara among various ethnic groups (Repond 1940). Apart from the South African cases, these cases of *latah*-type reactions all occur among male members of the Arab-Islamic culture area, in which the *latah* syndrome is only partly developed, with startle and echo symptoms, but without coprolalia or automatic obedience to commands. In fact, since the studies by Landis and Hunt (1939) and later studies in human ethology, the startle response has been shown to be a universal human reaction pattern. Apparently no less universal is the imitative behavior of indigenous populations coming into close contact with Europeans for the first time, who, upon being surprised by the strangers' unfamiliar behavior, may fall into a trance and, without any sign of psychopathology, manifest extreme and prolonged echopraxia and echolalia. This was already observed by Darwin (1840) among the Indians of Tierra del Fuego; more recently, Gajdusek (1970) described similar experiences during the first contact with indigenous groups in South America and Melanesia, and Jilek-Aall (1979) during her encounter with Bantu women in a remote bush village in Tanganyika. Echo symptoms and compulsive imitation have been observed in practically all *latah*-type cases; it is thus not without reason that French psychiatry designates *latah* reactions as *névroses d'imitation*. The common occurrence of startle patterns, imitative behavior, and dissociation led Simons (1980, 1985b) to designate *latah* as *startle matching taxon* or *startle matching syndrome* (Simons 1996) and to define it as a culture-specific exploitation of a neurophysiological potential common to all human beings, indeed to all mammals.

The sporadic occurrence of *latah*-type manifestations in Europeans is occasionally mentioned in the old reports from Siberia; it affected Russian settlers who had close contact with aborigines suffering from *miryachit*. No European *latah* cases are known from Southeast Asia, where, in the colonial era, Europeans sometimes entertained themselves with the *latah* attacks of their servants. A European anthropologist who married into a Malay family with 37 *latah* cases in

1990, and has experienced this "family habit" regularly ever since, has so far remained immune to it (Bartholomew 1994). A Dutch woman in the Netherlands did, however, display *latah* symptoms, albeit without imitative behavior; she had never had any contact with the Malay-Indonesian culture (Jenner 1990). The best-known Euro-American example of a *latah*-like reaction is the so-called jumping syndrome among the rural French-speaking population of certain areas of Maine, New Hampshire, and Quebec. The jumping syndrome was described in the nineteenth century by Beard (1878, 1880) at meetings of the American Neurological Association as a trance state of brief duration induced by a sudden startle, in which the affected person jumps up, drops any object he happens to be holding, throws it away, or strikes out blindly with it, repeats words and sentences spoken to him, even in unfamiliar languages, and obeys any command given, even if nonsensical or dangerous. The jumping syndrome affects lumbermen of French Canadian descent, begins in early childhood, and runs in families. As in the Arab-Islamic cases mentioned above, these Catholic "jumpers" do not manifest pornolalia. Sporadic cases of jumping have been described in modern times as well (H. Stevens 1964, 1965; Kunkle 1967). Even though Beard (1878) stressed that this was a psychological trance state rather than a neurological disease, Gilles de la Tourette (1884) cited Beard's lectures on jumping in a *revue critique* together with the reports by O'Brien (1883, 1884) on *latah* and by Hammond (1884) on *miryachit* and defined these conditions as exotic variants of the syndrome that Charcot had named after him. The similarity of Gilles de la Tourette syndrome, an autosomal dominant neurological disease characterized by multiple motor and vocal tics, as well as coprolalia and complex mental symptoms, to *latah*-type reactions has been pointed out time and again thereafter (Mazur 1953). Recently, an attempt was made to explain this similarity by the hypothesis of common neurophysiological and neurochemical mechanisms (Howard and Ford 1992). Nonetheless, the different geographical distribution and sex-based prevalence of *latah* and Gilles de la Tourette syndrome are strong evidence against a common origin. Like Gilles de la Tourette, the earliest medical writers on the subject interpreted *latah*-type reactions as neurological or neuropsychiatric illnesses of a hereditary nature, such as petit mal epilepsy (Ellis 1897) or "provoked imitatory impulsive myospasia" (van Brero 1895) or else as a hypnotic reflex phenomenon (Gimlette 1897). The similarity of hypnotic and *latah* states was apparently demonstrated by the hypnosis experiments performed by Fletcher (1908), in which uncharacteristically aggressive behavior was produced in a female *latah* patient. The Siberian *miryachit*, too, was first regarded as an organic nervous disease (Hammond 1884) and evaluated as such when found, in indigenous recruits, by military physicians of the Tsar's army (there was a disciplinary case, originally reported by a Dr. Kaschin, among the Trans-Baikal Cossacks, who continually repeated the commands and curses of their colonel in loud echolalia; Czaplicka 1914). Nonetheless, the well-known Russian neurologist Tokarsky (1890) diagnosed *meryachenie* as a nonorganic condition. Kraepelin (1904), during his travels in Asia, felt that *latah* reminded him of observations in "hysterics." Later authors, too, regarded *latah* reactions as belonging to the sphere of hysterical phenomena, but interpreted them psychodynamically and related them to the repression of sexual impulses (Galloway 1922; van Loon 1927; Murphy 1976, 1982). In his comprehensive treatise, Yap (1952) characterized *latah* as essentially a fright neurosis, hysteriform only in the sense of Kretschmer's biological conception. Kretschmer (1958, pp. 20–24) explained his "set hypobulic reaction" with reference to the *imu* syndrome of Ainu women on Hokkaido (Uchimura 1956), in whom a culture-typical key stimulus, a snake or merely the word "snake," releases the *latah*-like "primal phylogenetic instinctual reaction." In contrast to these phylogenetically and biologically based explanations of the *latah* phenomenon, Murphy (1973) tried to show, in a comparative historical study, that *latah* first appeared in the mid-nineteenth century at a time of consolidation of the European colonial system in the Malay-Indonesian area and spread rapidly among the populations then under direct European influence. More recently, according to his thesis, the *latah* phenomenon spread from these centers to remote areas, the male cases that had appeared earlier stopped appearing, and the intensity of the attacks abated. Murphy thus considers *latah* not as an expression of the Malay cultural tradition, but as a transitional product of the interaction between this tradition and modernizing influences. In his main opus, Murphy (1982) extended this sociological hypothesis to the aboriginal Siberians, to the Francophone jumpers of Maine, and to *latah*-type behavior in general: a rapid increase in *latah* behavior always occurs when relatively powerless and indigent peoples come in contact with more powerful and wealthy groups and then seek to acquire the advantages of the latter by imitating those apparently superior and obeying their orders, without, at first, understanding them. Later, when it is realized that automatic obedience and imitative learning are less productive than understanding the principles underlying the model, the method of learning changes, and *latah* behavior becomes rarer. In the last two decades, *latah*-type reactions have been at the center of the discussion concerning the priority of universal

biopsychological or culture-specific factors in psychiatric syndromes in general, and in so-called culture-bound syndromes in particular. The debate was mainly led, on the cultural relativists' side, by Kenny (1978, 1983, 1990) and, on the side of the biopsychological universalists, by Simons (1980, 1983, 1985b, 1996). Pfeiffer (1994) recognizes the importance of both the general biopsychological and the culture-immanent perspectives; he considers the argument over priority to be futile and argues for consideration of the personal and family situation in each individual case.

6.6 Culture-Typical Emphasis: Propensity to Dissociation and Male Conflict Resolution Through Discharge of Aggression

Amok-Type Reactions (ICD-10: F68.8)

Today the word *amok*, with local variations, may be found in the dictionaries of all major languages and is generally used to denote an episode of apparently unprovoked, randomly aggressive, and homicidal behavior, ultimately ending either in suicide or in complete exhaustion and limited recollection of the event. Along these lines, *amok* is defined in the ICD-10 Annex *2* as a culture-specific disorder. In the American DSM-IV glossary, *amok* is referred to as a culture-bound syndrome; the classification "culture-specific explosive behavioral disorder" was originally suggested (Gaw and Bernstein 1992). The word *amok* comes from the Portuguese version, *amuco*, of the designation commonly used in the Hindu states of India for warriors who, like the *morituri* of ancient Rome, swore to attack and annihilate the enemy while holding their own death in contempt. Malay and Javanese warriors took over the Indian expression and the intimidating battle cry, "amok! amok!" (Shaw 1972). The heroic deeds of the *amok* warriors were exalted in popular legends such as the Malay epic *Hikayat Hang Tuah* (German translation by Overbeck 1986), in which individual *amok*-runners are glorified who heroically overcome shame or slights by carrying out mass murder with the traditional *kris* and then, ultimately, seeking and finding their own death (Pfeiffer 1994).

The word *berserkr*, occurring in the Old Norse sagas with the meaning "warrior clad in bearskin," underwent a similar semantic shift to that of *amok*. It originally designated the swordsmen in the service of medieval Scandinavian princes, who put themselves into an ecstatic state of furor in order to fight with superhuman strength. Some also wore wolfskin and were called *ulfhednar*, "wolf-heads," later "werewolves;" the shamanic idea of possession by wild animals, through donning bear- or wolfskin, plays a role here. The sagas tell not only of heroic troops of Scandinavian berserker warriors (who, incidentally, were also employed as mercenaries by Byzantine emperors), but also of individual *berserksgangr*, ecstatic fits of berserker rage, in which the storming berserker murdered at random (Weiser 1927; Laiblin 1965). In modern English, the expression "going berserk" generally denotes any type of aggressive frenzy.

In the Malay-Indonesian cultural sphere, the introduction of Islam in the fourteenth century converted running *amok* against the "infidels" to an act of religious fanaticism, and death suffered through such an act, unlike suicide (forbidden to Moslems), was considered pleasing to Allah. This tradition found its continuation in the so-called "Aceh murders" of Dutch colonists by Moslem fanatics among the Aceh of Sumatra until the end of the colonial period (Pfeiffer 1994) and also in the *amok*-like indirect suicide ritual (*juramentado*) of the Moslem Moros of the southern Philippines in the nineteenth century (Ewing 1955). Another motivation of *amok*-like behavior in the Malay-Indonesian tradition was social protest; thus enslaved debtors, for example, sought an honorable death through random murderous attacks as early as the fifteenth century (Murphy 1973). The culturally sanctioned threat of running *amok* in response to gross injustice served as a certain check on the abuse of power by rulers and wealthy men (Gullick 1958).

From the seventeenth to the nineteenth century, *amok* attracted much attention in the West through the reports of European observers and was identified with Malay-Indonesian culture, especially because no lesser figure than Captain Cook wrote from Java on the "prevailing practice" of running *amok* (Teoh 1972), and an exiled Javanese ran *amok* in Cape Town in 1786 (Prince 1991). *Amok* was often assumed to be a mental disorder caused by opium or other drugs (Pfeiffer 1994). This was claimed of *amok* by mid-nineteenth century physicians as well, along with somatic causes such as gastrointestinal diseases, febrile delirium, or dementia (Murphy 1973). Later, psychiatric diagnoses were increasingly applied: melancholy and other mental disorders (Swettenham 1889) or "epilepsia larvata" (Ellis 1893); notably, no explanation was offered for the lack of female cases. Van Brero (1897a) conceded the possibility of a "transient mental illness" with subsequent amnesia, or the claim of having seen animals or devils in the *amok* victims; nonetheless, he cautioned against calling an act insane simply because one thinks only a madman would be capable of it. Gimlette (1901) emphasized four diagnostic criteria that are still recognized as valid today:

1. Prodromal depressive brooding over actual or imagined slights.
2. An explosive homicidal outburst.

3. Persistent homicidal activity without apparent motivation.
4. Claim of amnesia for the event.

Van Loon (1927) reverted to the previous thesis of infectious delirium, stating, however, that the "peculiar psychic nature" of the Malays – pathoplastic factors – made the symptoms manifest themselves in an entirely different form than in Europe and, in general, favored the appearance of confusional states. A decade later, Amir (1939) found that most hospitalized patients were suffering not from infectious diseases, but from chronic organic brain disease or schizophrenia. Van Wulfften-Palthe (1933), who collected information about *amok*-runners among the rural population of Java and Sumatra, saw *amok* as a twilight state with sudden, unmotivated, and undirected acts of violence, which can also occur in otherwise normal individuals if the emotional stimulus is strong enough. In the 1960s, the few hospitalized patients suffering from *amok* in West Malaysia all had schizophrenic symptoms (E.S. Tan 1965, quoted in Teoh 1972). In Sarawak, East Malaysia, Schmidt et al. (1977) studied 24 *amok*-runners, including, besides Malays, also Dayaks and other aborigines, who apart from *amok* were all psychiatrically diagnosable as having organic psychosyndromes, endogenous psychoses, or neurotic disorders. Murphy (1973) documented the change of significance and function of *amok* behavior in the Malay-Indonesia area, from a glorified warrior ethos to a sanctioned means of social control and social protest which, after the establishment of the European colonial system and a modern justice system, became criminalized and unsuited to its purpose. *Amok* behavior was then transformed from a consciously motivated act to a dissociative reaction, and at present *amok* behavior is found in the Malay culture area usually as an episode in the course of a chronic mental disorder. After the Second World War, *amok* appeared on the Malay peninsula among Chinese as well as Malays (Teoh 1972). Pfeiffer (1994, p. 135) characterizes *amok* in Indonesia as an exceptional dissociative state and distinguishes the following phases:

1. Dysphoric-neurasthenic preliminary phase in the context of difficulties with the social environment, chronic illnesses, loss of social rank, or lessening of personal prestige.
2. Triggering by a sometimes trivial event that leads to decompensation of the state of heightened tension.
3. Meditative brooding, alteration of the state of consciousness, and changes in visual perception – the outside world becomes dark (*mata gelap*, "eye dark") or red, the affected person feels surrounded by threatening figures and experiences fear or rage.
4. The affected person is suddenly seized by a storm of hypermotility, the *amok*-run begins and leads to random aggression, killing, and destruction.
5. This finally ends in suicide or self-mutilation; if the affected person survives, the attack ends in deep sleep or stupor, followed by depressed mood. Amnesia is claimed for the *amok* deeds.

Yap (1951) argued for a distinction between the "true *amok*" of the Malays from other paranoid-homicidal reactions; he later classified *amok* among his culture-bound reactive syndromes as "disordered consciousness" and "rage reaction" (Yap 1967, 1974). Carr (1985) takes an unequivocally culture-relativistic position. He discusses how the major characteristics of the traditional Malay conceptual system relating to notions of value, status, and health contribute to the *amok* phenomenon, and he concludes that a significant prevalence of *amok* can only be found in a population with Malay concepts and behavioral norms. Earlier still, Carr and Tan (1976) had concluded, after study of 21 hospitalized patients with "true *amok*" in Malaysia, that *amok* is not a disease per se, but rather a "prescribed form of violent behavior" in Malay culture, released by many different factors, traditionally sanctioned as an appropriate behavior under specific conditions. Two arguments against this are that *amok*-runners are usually marginal figures, and not typical representatives of Malay-Indonesian culture, and that *amok* is extremely rare in areas of this culture that are still highly traditionally oriented (Pfeiffer 1994). The thesis of the specific Malay character of the *amok* reaction is cast into further doubt by the not infrequent observation of the *amok* syndrome among non-Malay populations. There was only one Malay among the Indonesian patients extensively documented by Pfeiffer (1994, p. 137); one can, of course, view the non-Malay ethnic groups of Indonesia as being under Malay cultural influence. With certain restrictions, this may also be true of the Philippines, where 25 soldiers were arrested between 1946 and 1956 for *amok* acts committed with firearms (Zaguirre 1957). These cases were very similar in their psychosocial aspect to the "grenade *amok*" seen in Laos during the Indochinese war between 1959 and 1970. Westermeyer (1972, 1985) reported 18 cases of *amok* attacks by young soldiers in Laos, who, in an impulsive anger reaction after a personal experience of loss or of loss of prestige, threw a hand grenade into a crowd. These soldiers killed an average of ten wholly innocent people; the majority had drunk alcohol, and half of them simultaneously committed suicide. In his attempt at a transcultural epidemiological analysis, Westermeyer (1973) comes to the conclusion that *amok* homicide waxes and wanes periodically, becoming particularly frequent at times of internal armed

conflicts and rapid social change; *amok* behavior can be "transmitted" from one ethnic group to another, contiguous one. It is typically found in alienated, relatively uneducated young men. Aubin (1939) described analogous *amok*-like attacks by Senegalese soldiers in West Africa as *état de fureur*, and Carothers (1947) described them in Kenya als "frenzied anxiety." Sir B.G. Burton-Bradley, who served as a psychiatrist in Papua New Guinea for many years, often had occasion to study surviving *amok*-runners forensically and to interview eyewitnesses to multiple homicides. His detailed description of the *amok* behavior of probands of highly differing ethnolinguistic groups, some of them still on the developmental level of the Stone Age, are entirely in agreement with the classical descriptions from Malaysia and Indonesia, except as regards visual symptoms (Burton-Bradley 1968, 1975, 1989). *Amok* must be distinguished from pseudo-*amok*, which was widespread among the population of the Highlands of Papua New Guinea. Rage mimicking that of an authentic *amok* attack, with dramatically threatening, but not murderous behavior, reminiscent of theatrical bravado, has been described in different tribes and variously interpreted as acute hysterical psychosis (Rodrigue 1963; Langness 1965), "wild man behavior" (Newman 1964), or a state of possession (Koch 1968). Pseudo-*amok* has also been attributed to the consumption of supposedly hallucinogenic mushrooms in accordance with native tradition (Reay 1960, 1965), but this was soon refuted by the eminent mycologists Heim and Wasson (Reay 1977). Pseudo-*amok* in New Guinea also serves the functions of individual catharsis and collective entertainment (Clarke 1973); the participation of costumed female "*amok*-runners" in such displays (Aufenanger 1973) offers an almost parodic contrast to the overwhelmingly male type of authentic, murderous *amok* behavior seen in New Guinea and elsewhere in the world.

In a historical study, Kon (1994) arrived at the conclusion that *amok* is not a culture-bound syndrome. It is certainly no longer possible to speak of *amok* as a specifically Malay-Indonesian phenomenon, in view of the steadily accumulating reports, in recent decades, of *amok* behavior by men of European extraction in the Western cultural sphere. In his comparative analysis of such cases, Arboleda-Florez (1979) concludes that typical *amok* behavior can arise anywhere under conditions of a rapidly changing society among individuals with feelings of social alienation and a simultaneous need for demonstrative self-assertiveness. In this connection, mention may be made of the current Western zeitgeist, propagated by mass media, which contributes to the popularization and secret admiration of macho Rambo and other "killer" types (Tan 1989). An increased prevalence of dissociative alterations of consciousness and widespread use of psychoactive substances are also features of the contemporary North American scene. This is of prognostic importance, because dangerous *amok* behavior is largely determined by an uncontrolled propensity to dissociation and a tendency toward disinhibited violence.

6.7
Culture-Typical Emphasis: Thinness in Women

Anorexia Nervosa (ICD-10: F50.0)

Immediately after formulating his concept of the culture-bound reactive syndromes, Yap (1969) proposed classifying anorexia nervosa as a Western culture-bound syndrome. Religiously motivated fasting has, of course, been seen as legitimate from time immemorial in many cultures, particularly in the Judaeo-Christian and Hindu-Buddhist spheres, and should not be interpreted as psychopathological (Banks 1992), nor should fasting for the accomplishment of political or social aims (Mahatma Gandhi!) been seen as such. Refusal of food because of lovesickness is known from Greek culture as early as the fourth century B.C. and is a classic theme in world literature, as in the Persian epic of Leila and Majnun (Pfeiffer 1994). Fasting cures for therapeutic or general "health-promoting" purposes are often recommended by both academic and "alternative" medicine. The phenomenon of refusal of food that arose in the nineteenth century among the daughters of the Western bourgeoisie and is today known as anorexia nervosa had nothing to do with religious, political, or even romantic motives. This clinical picture was first mentioned in North America by Chipley (1859) under the name *sitomania*, "dread of eating" (Vandereycken and Lowenkopf 1990). It was then described in Europe by Gull (1874) as anorexia nervosa and by Lasègue (1873) als *anorexie hystérique*, with essentially the same symptomatology now familiar to every clinician. These pioneers of psychiatry showed an impressive insight into the psychosocial causation of the syndrome, in contrast to some later authors, who postulated an organic endocrine etiology and occasionally confused cause and effect. The fascinating history of the anorexia nervosa phenomenon is discussed in detail by Brumberg (1988) and in summary form by DiNicola (1990a). Analysis of currently available epidemiological data clearly shows the decisive role of sociocultural factors in the genesis of this phenomenon (Garner and Garfinkel 1980; Prince 1985; DiNicola 1990b; Gordon 1990; Diedrichsen 1991; Garner 1991; Iancu et al. 1994; Pfeiffer 1994; Toro et al. 1994; Weiss 1995). On the basis of these data, anorexia nervosa has been shown to be a disease of modernity, without any bio-organic cause, predominantly affecting young

female members of relatively well-to-do families under the influence of idealized fashion images. Anorexia nervosa occurs primarily, and with steadily increasing incidence, in the Western cultural sphere, and recently also in upper-class girls of non-Western cultures heavily exposed to modern Western influences. The rise of anorexia nervosa (and the often associated "other side of the coin," bulimia) to a "social epidemic" (Gordon 1990) among female adolescents of the Western world was made possible by the economic and social consequences of full industrialization and of the modern consumer society, which led not only to widespread material affluence, but also to nuclearization of the family, with increasing family conflicts. In Europe, the number of cases of anorexia nervosa declined dramatically during the war years and the immediate postwar period, in which food was scarce; many chronically anorexic patients abandoned their symptoms. In today's consumer society, however, extreme slimness is the dominant ideal of feminine beauty, created by fashion, in paradoxical contrast to the enormous supply and consumption of foodstuffs. With the rise of the general standard of living, and under the influence of the visual mass media, anorexia nervosa spread from the upper and middle classes to the working class, and from western and northern to southern Europe; the disappearance of traditional family relationships played an important role in the latter development (Selvini-Palazzoli 1985). In recent decades, North America, too, has seen a remarkable increase in the incidence of anorexia nervosa, which has doubled or trebled in some areas since 1960. It has been shown that this disease became dramatically more common when the mass media promulgated the fashionable ideal type of the thin, infantilized female body type (Garner and Garfinkel 1980; Jones et al. 1980; Garner 1991; Lucas et al. 1991). Curiously, the weight tables used by American physicians from 1960 onward also show a progressive decline in female "ideal weight," so that it appears that supposedly culture-free biomedical standards have been adapted to fit popular trends in modern Western society (Ritenbaugh 1982). In Spain, where modern Western lifestyles were not adopted by most people until the 1980s, the same pathogenic effect of fashionable thinness, propagated by the advertising media, can be observed today (Toro et al. 1994; Caballero 1995). Alongside the diet-and-slimming industry, which earns high profits from countless proffered publications and therapies, a new medical and paramedical eating disorder industry (Shorter 1994) has now arisen in the Western world that also does its part to keep this fashionable illness (in both senses) in the public eye. In many traditional cultures of Asia, Oceania, and Africa, as in Europe, too, in the more distant past, good health, high social rank, and even attractiveness in young women was generally identified with a more adipose nutritional state. Since the 1980s, there have been several reported cases of anorexia nervosa in non-Western populations (DiNicola 1990b; Davis and Yager 1992; S. Lee 1996), e.g. in Japan, Hong Kong, Taiwan, Singapore, China, India, Malaysia (Chinese and Indian ethnic groups), and even in Nigeria. With the exception of Japan (Mizushima and Ishii 1983; Suematsu et al. 1985), classical anorexia nervosa in non-Western countries is still relatively rare compared to Europe and North America, predominantly arising in female students in large cities, as distinct from symptomatic anorexia in the course of a physical illness or depression (Nigeria: Ebigbo and Okunna 1986/87). Many of the non-Western patients probably lack the specifically Western symptom of fear of obesity and the obsessive idea of being fat, which was already recognized in 1880 by Charcot in Paris (Habermas 1991). The majority of Chinese anorexia nervosa patients in Hong Kong, for example, had no "fat phobia" of this type. An increasing frequency of this diagnostic criterion is, however, to be expected as non-Western societies become increasingly westernized (S. Lee et al. 1993); questionnaires given to female students in Hong Kong already show a break with traditional Chinese ideals of beauty in favor of the modern fashion for thinness (S. Lee 1993). The occurrence of anorexia nervosa among young women belonging to all classes of Western society, and the appearance of this pathological phenomenon in non-Western population groups under the influence of westernization, as well as its frequent occurrence among young female immigrants under Western acculturation pressure, are all compatible with the characterization of anorexia nervosa as a "culture change syndrome" (DiNicola 1985). This syndrome is to be understood as an individual reaction to modern Western culture's typical demand for feminine thinness, which, since the nineteenth century, has spread from the wealthy upper class to all social strata of the West and has now also begun to affect non-Western cultures.

7 Culture-Appropriate Diagnosis: Differentiation of Culture-Specific Disorders from Institutionalized Culture-Congenial States

In the preceding discussion, culture-specific mental disorders were presented as expressions of culture-typical emphases or as a result of stressful situations that may arise in a given culture or in a situation of culture change.

It is important for clinical practice to distinguish these culture-specific disorders from exceptional states that are institutionalized in a particular culture. To make such a differential diagnosis, the clinician must possess certain general prerequisites of transcultural psychiatric assessment (Tseng and Streltzer 1997), especially sensitivity for cultural particularities, understanding of the patient's culture and religion, and awareness of cultural variations of psychopathology.

One may generally state of the culture-specific disorders that occur in non-Western cultures that they (a) do not appear in the framework of ritualized behavior and (b) are recognized by indigenous healers as abnormal or morbid, and can often be treated successfully through traditional practices which have been found to be therapeutically effective in many cases of reactions caused largely or entirely by psychosocial factors (Jilek 1993).

7.1 Altered States of Consciousness

Altered states of consciousness are dissociative phenomena that also appear in a number of culture-specific mental disorders. Such states, in other forms, are institutionalized in tradition-directed cultures as nonpathological dissociations and are considered acceptable behavior when tied to culturally defined ritual conditions, in which they are induced and manifested. Altered states of consciousness are associated with characteristic changes of attention, sensory perception, affectivity, and the experience of time, and also with hypersuggestibility and culturally or religiously conditioned feelings (Ludwig 1966). In these states of consciousness, the everyday feeling of personal identity is experienced as specifically changed or as replaced by another entity. In the religious systems of tradition-directed cultures, such altered states of consciousness are thought of as extraordinary modalities in which the affected individual (a) believes himself or herself to be in special contact with a perceived being of variable provenance, identified as divine or demonic, as the spirit of a dead person, protective spirit from the animal world, etc., or (b) believes that he or she is possessed by a supernatural being whose power operates through the possessed individual; the acts of the possessed thus imply no personal responsibility and are sealed off by amnesia. These two fundamental variants of altered states of consciousness were designated by Bourguignon (1973) as (a) "trance" and (b) "possession trance" and have been reported to occur in many different cultures. The differences between these states are culturally defined and not founded in psychology or neurophysiology.

7.2 Religious Ecstasy and Demonic Possession

In traditional Christianity, trance states conforming to the belief system, such as religious ecstasy and experiences of revelation, are sanctioned at any given time according to the preference of the particular church in question, today not uncommonly in the framework of charismatic movements and fundamentalist religious communities. In the religious exercises that often precede ecstatic experiences, one may note the presence of suggestion and other somatopsychic factors that, in general, facilitate the induction of altered states of consciousness, such as fasting, dehydration, sleep deprivation, sensory deprivation, and monotonous auditory stimulation. In Judaeo-Christian tradition, the expression "possession" is reserved for possession by demonic spirits and is diagnosed and treated (by exorcism) by some ecclesiastical authorities even today (Lhermitte 1963; Rodewyk 1963; van Dam 1970).

7.3 Trance Rituals and Possession Cults

There are institutionalized trance rituals and possession cults in many non-Western cultures, because "possession," in cultures not influenced by Christian tradition, may also be thought of as positive. Ritualized trance and possession states are learned and practiced in the framework of a ceremonial for religious and/or therapeutic purposes. This happens, for example, in Amerindian initiation rites, in which altered states of consciousness are induced in motivated candidates without the effect of drugs by means of direct and indirect suggestion and rhythmic acoustic and kinetic stimulation alternating with sensory deprivation, sleep deprivation, fasting, dehydration, hyperventilation, and other induction methods (Jilek 1987b). Many of the collective trance and possession cults practiced in non-Western cultures have demonstrable psychohygienic, therapeutic, and social integrative functions. (For a global overview of these ritualized group therapies, see Jilek 1993, 1994.) A few examples may be named here: The *zar* cult is a ritual therapy for female patients with affective and psychosomatic symptoms in northeastern Africa and the Near East. The female possession cult *zebola* has a similar function in the Congo region. West African trance and possession rituals such as *orisa*, *rab*, and *lup* have historical connections to the Afro-Caribbean (*vodun*, *santeria*, *shango*) cults and to the Brazilian *umbanda*, currently the numerically largest form of religious group therapy, which syncretistically unites African

traditions, Western spiritism, and Amerindian culture elements. Indonesian trance rituals and the ecstatic self-imposed ordeals of the Hindu *taipusam* similarly have religious and psychohygienic significance, as do the revived cult dance rituals of North American Indians.

7.4
Eurocentric and Positivistic Fallacies

Western or Western-trained observers risk committing a eurocentric fallacy through the pathology labeling of institutionalized and ritualized conditions in non-Western cultures, without paying due regard to the behavioral norms and traditional explanatory models of the culture in question.

A positivistic fallacy is committed when one considers ideas and behaviors to be irrational and abnormal because they do not fit into the framework of logico-experimental science. Ritualized trance and possession states, like other religious acts, are primarily "manifestations of sentiments" (Pareto 1935), and not generally indicators of psychopathology.

Psychiatry in Developing Countries

1 Introduction

The decision as to whether a country is to be called a developing country depends on a number of criteria. Some of them seem straightforward: in general, such countries have a low per capita income, their communication systems are deficient (thus preventing the efficient transport of people, goods and information), health indicators testify to an unnecessary loss of life (e.g. as a result of high child mortality) and high rates of disease, and the level of education of their populations as a whole is low. When all of these and a number of other signs of the same kind are present, it is easy to reach agreement that the country is lagging behind in development or – if most of the indicators show that the country is in a very difficult situation – to decide that it belongs to the category of "least developed countries". At present, there are some 40 countries in the latter category. However, their populations are relatively small and together they represent only a modest proportion of the total population of the world or of the developing countries. The remaining countries outside Europe, the United States, Canada, Australia, New Zealand and Japan are less easy to place within a category, and the United Nations recently proposed splitting this group into two categories (rapidly developing countries and developing countries) and placing Eastern European countries and the countries of the Community of Independent States into a separate group because it has characteristics that distinguish it from the rest of the European countries.

However, this apparently convenient division of the world into developing and developed countries does not hold up under scrutiny.[1] Firstly, in many of the so-called developed countries, there are parts (or population groups) that in all respects resemble the countries of the developing world. Secondly, in most developing countries, there are now parts (or population groups) that have achieved a high standard of living and can be favourably compared with the average of the developed world. Thirdly, some of the developing countries are lagging behind in some aspects (e.g. health criteria), while, in terms of other criteria (e.g. per capita income), they are close to or better than some of the developed countries. Fourthly, countries are continually changing, and what could be called a developed country today might tomorrow, in most respects, become close to a developing country, and vice versa. Fifthly, economic development is not necessarily the final goal of human existence, and if the world is categorized according to non-economic criteria (e.g. in terms of tolerance, non-aggression, and human interdependence), it becomes necessary to redistribute countries among the developed and the developing categories.

In view of all this, it would seem wiser to avoid dividing the world into a small number of rigidly limited categories and to consider instead smaller groups of countries (or even groups of one), recognizing that each nation has its own cultural, economic, intellectual and emotional traditions and characteristics that make it to a significant degree unique. It is possible and more desirable to describe countries in terms of a number of relevant criteria, even if this takes a little more space and time or, if grouping is necessary, to do this bearing in mind that there are many differences between the countries in the group and that most countries in the world are mosaics of developed and developing regions, of modern and traditional parts and of noble and ignoble components. Just how much of each of these is present will vary with time and from one country to another.

Medicine and science reflect the above situation. Even in very poor countries, there are institutions engaged in research and service of outstanding quality (e.g. the Institute of Psychiatry in Mexico City); on the other hand, in the developed world, there are areas in which health care is poor (e.g. in slums or remote areas), a situation made worse by the fact that there is enough money available and that a lack of governmental resources cannot be blamed for the scenes which can be observed.

The differences within and between countries are part of the reason why it is illusory to hope that a comprehensive description of mental health programmes in the developing countries can be produced in a single book chapter. Other reasons that reduce the chances of producing a detailed and well-documented description include the scarcity of data resulting from well-conducted studies of the mental health situation in many of the developing countries and the rapidity of sociocultural, economic and other changes that are present in most of them.

2 The Problems

Four groups of problems beset psychiatry in developing countries: (1) the low value given to mental health by individuals and by society, (2) the high prevalence of mental and neurological problems, (3) the disre-

[1] At various times, other terms were proposed to distinguish these two groups of countries: Third World countries, non-industrialized countries, the countries of the South. None of these designations is convincingly better than others. In this chapter, the simplest terms – developing and developed – will be used, despite their imperfection.

gard for psychosocial aspects of various health and development projects and (4) the chronic lack of resources.

2.1 Low Value Given to Mental Health

The value which individuals and societies give to mental health and the normal functioning of the mind is of decisive importance for the development of mental health programmes. Where mental health lies low on the scale of values, it is difficult if not impossible to initiate or maintain mental health programmes. The low value of mental health finds its reflection in the low priority given to mental health activities within general health programmes, in the difficulty of recruiting the best postgraduate students to psychiatry, in the feeble, if any, participation of the population in mental health activities and campaigns and in the continuing disregard for opportunities to enhance mental health programmes. At the individual level, the low value of mental health finds its expression in people's willingness to put their mental health and sanity at risk by taking drugs, in the neglect of measures that would protect or enhance the mental health of children and in a variety of other ways. In most developing countries, mental health is not seen as being without any value: rather, it is considered as less precious than many other things or acquisitions ranging from material wealth to sexual attractiveness. Countries are not monolithic in this respect; however, although population groups vary in their appreciation of mental health, few place mental health and mental life among their top priorities.

There may be many reasons for this, probably including the vagueness of the definition of mental health and mental illness. Although mental health can, at best, be a component of health (the other equally non-independent component being physical health), the term is used to describe the state of feeling well, the absence of mental illness, normal mental functioning, equanimity, coping capacity and spiritual equilibrium. The vagueness of the concept makes it difficult to rally support for it as an objective of health service programmes and makes educational programmes supposed to help in the promotion of mental health nebulous; this in turn leads to mental health slipping even lower on the scale of values. The loose boundaries of the term also allow various disciplines – ranging from theology to marketing science – and various organizations to produce and promote definitions of mental health to suit their own purposes. Groups of population at large accept one or the other of these definitions (or create another one of their own), which diminishes or removes the pressure on health services to do something about mental health.

Another reason for the low position of mental health on the scale of values is the uncertainty about the limits of mental illness. In industrialized countries, the boundaries between mental illness and simulation, possession states, laziness, personality variants, artistic creativity, ideological originality and numerous other forms of behaviour and states of mind are somewhat clearer because of the efforts of the medical profession and because of the pressure of insurance systems to make a distinction between what is a medical condition (i.e. for which treatment has to be paid for by the insurance) and a non-medical condition (for which the health insurance does not pay for treatment).

In developing countries, neither of these two types of pressure are at work. Mental health care workers are often not numerous and often tend to adhere to illness categories created on the basis of experience in other countries. If these do not fit, vague, general terms ("psychotic state") are used. Insurance systems cover only a minute proportion of the population and do not have much weight or interest in precise definitions.

While there is now no doubt about the ubiquity and similarity of the incidence of severe mental disorders such as schizophrenia, there are other psychological disorders whose incidence and prevalence seem to be different in different sociocultural settings. Most of those conditions can be placed into the categories of major classifications of mental disorders (e.g. the International Classification of Diseases, ICD), but there are some that cannot: people who suffer from them, however, seek help from both traditional healers and modern doctors. These differences in frequency and the so-called culture-specific disorders contribute to shaping the image of mental illness in the setting in which they occur and can contribute to the notion that psychiatry is a branch of medicine that has a blurred focus, that the diseases which it is supposed to treat are not real diseases (there are no culture-specific forms of cardiovascular disease and these "real" non-communicable diseases are thought to respond to the same treatment in the same way, everywhere) and that the practitioners of psychiatry are closer to spiritual advisors (or traditional healers) than to real doctors.

Culture-specific ways of describing problems, and the abundance of influential traditional health practitioners who contribute their own terms and explanations, further blur the boundaries and concepts of mental disorder. This is good and bad: good because, in many instances, such vagueness of borders diminishes the probability of rejection and stigma because of mental illness, but bad because some of those who have a recognizable and treatable mental illness do not come to seek help from qualified services even if they are provided at a cost that the patient and the family could well afford.

It could be argued that, in some particularly disadvantaged areas, it might be better for the population to continue to consider some of the diseases from which it suffers as an inevitable part of the human condition rather than as disease states for which they could obtain treatment if only their government were to provide them with a better health service or with more money that would allow them to purchase good health care. The limitations of this kind of reasoning are dangerously close to a thoroughly unethical position in which ignorance is regarded as an ally diminishing the probability of revolt and postponing changes in the prevailing socio-economic order. This is particularly so in situations in which active involvement of the population (regardless of the state of the country's health services) could prevent the occurrence of diseases or diminish the problems of those who have them. Psychiatry is an excellent example of a field of work in which much could be done even under conditions of poverty and poor health services; it is all the more deplorable that this happens so rarely.

Yet another reason for the low priority given to mental health is probably the fact that, for a very long time, there were no effective methods of medical treatment of mental disorders. While the rest of medicine achieved victory after victory and produced or declared revolutionary advances in its practice, psychiatry still used a variety of treatment methods that did not yield convincingly good results. Some of the methods used were logical in the light of the limited knowledge about mental functioning, while others were innovative; still others were closer to folk healing and religious rites than to medicine. The impression that psychiatry does not have a solid scientific basis and that it is inefficient (and that it should therefore not be given any support except insofar as it can serve to control socially unacceptable behaviour due to mental disorder and impairment) have prevailed in many countries; in the developing world, however, that image of psychiatry in the face of continuously higher demands of the efficient medical disciplines and diminishing resources at the disposal of the health care system have pushed psychiatry lower and lower on the list of priorities. Lack of support has made mental health care facilities deteriorate, has decreased the quality of psychiatric training and has increased the attractiveness of other disciplines that are more lucrative and more interesting for students of health professions.

2.2 Frequency of Mental Disorders in Developing Countries

The notion that mental disorders in developing countries are less frequent than in the industrialized world was popular among psychiatrists and other medical specialists until relatively recently. Various reasons were put forward for this contention, including the apparently more leisurely pace of life thought to characterize developing countries, the absence of those stresses seen in highly organized industrialized countries, stable and strong family relationships, healthy air and nutrition without artificial additives. For certain mental disorders, the difference was explained by physiological differences: Carothers (1947, 1953), for example, thought that depression would not affect Africans because they have smaller frontal lobes than the white population. Some of these convictions had to do with prejudice and prevailing social order: Prince (1967) examined publications about the frequency of depression in African countries and reported that, before the early 1960s, there were very few articles stating that African patients had depressive disorders as often as people elsewhere: the majority of papers stated the opposite. In later years – after African countries became independent – the findings changed: depressive disorders were reported to be seen as frequently in Africans as in other citizens of the world. Prince and others felt that this could be related to the change in the way in which doctors were viewing patients (and patients were viewing themselves) before and after gaining political independence. The diagnostic labels that were previously used only for diseases of colonial officers or citizens then became available to everyone.

Gradually, the myth of differences in the incidence of mental disorders between developed and developing countries begun to lose strength. It became clear and admitted that stresses exist in all cultural settings, villages as well as towns, and that mental disorders are frequent regardless of the level of industrial development (e.g. Leighton et al. 1963; Sethi et al. 1972). The studies coordinated by the World Health Organization (WHO) – the International Pilot Study of Schizophrenia (WHO 1975b), the Study of Determinants of Severe Mental Disorders (Jablensky et al. 1992), the studies of depression in different countries (Sartorius 1983) – all seemed to indicate that differences in the frequency of mental disorders, whenever they are reported to exist, are more probably due to methodological reasons rather than to a real difference in incidence.

While mental disorders do not seem to vary in incidence among countries, it would not be surprising to find that there are differences in the prevalence of mental disorder. This difference could result from lesser survival chances of the mentally ill in many developing countries or from other factors, e.g. the better prognosis of mental illness in the developing than in the developed countries (WHO 1979) that has been reported on several occasions. Some of the epidemiological studies of severe mental disorders in

developing countries have shown a lower prevalence of these disorders (e.g. Cooper and Sartorius 1996), but it should be noted that the size of the differences between the findings of the studies in developed countries and those in developing countries often seems to be similar to that found between studies done in the same (developed) country. The differences in the clinical syndromes of diseases such as schizophrenia have been described as well as culture-specific disorders (see Chap. 14, Vol. 2, Part 1) but, on the whole, the differences between mental disorders in different cultures seem to be less pronounced than the similarities, particularly in the instance of severe forms of mental illness. Differences in patterns of alcohol and drug abuse (e.g. between Islamic and other countries) that were found can most probably be attributed to reasons other than the level of economic development (e.g. religion). In general, it could be said that poverty and its consequences (e.g. lower education) influences the form and course of mental illness and that the numbers of poor people in developing countries is higher than in the developed world.

The poor foundations of the myth of the happy savage – of the lower frequency of mental disorders in developing countries – crumble even more convincingly when the conditions due to early or later brain damage because of poor perinatal care, frequent infections, malnutrition and under-stimulation are also considered in the assessment of the burden that mental and neurological problems might present in developing countries. Mental retardation related to iodine deficiency disorders, for example, still appears frequently in many areas of the developing world. Conditions such as short, acute psychotic states due to high fever and psychological impairment due to cerebral malaria and encephalitis are also more frequent in the developing world, but often go unreported. Mild degrees of cognitive impairment are probably higher in those developing countries in which the control and correction of sensory deficits such as poor vision is sporadic or non-existent (see Chap. 8, Vol. 1, Part 2). The all too frequent comorbidity of mental and physical diseases unfortunately continues to obscure the real numbers of people with mental illness because of the tendency to report only one (usually physical) illness per contact and because of the higher mortality of the mentally ill due to co-existent physical illness and malnutrition.

The separation of psychiatry from neurology that happened in many countries in the past four decades – useful as it may have been in many instances – has also been detrimental to the assessment of the importance of psychiatry (and of neurology) in developing countries and to the determination of the priority that mental health programmes should have. The notion that psychiatry's field of action are the functional psychoses such as schizophrenia, manic depressive illness and various neurotic states, while various types of damage of the central nervous system (regardless of the presence of psychiatric symptoms), mental retardation, learning difficulties and behavioural disorders should be the domain of the neurologists and other specialists (often not existing in the developing countries) has decreased the estimates of the magnitude of mental and neurological problems in the eyes of the health system authorities and diminished the priority that might have been given to these disorders had they been grouped together. A second, more subtle negative consequence of the division between neurology and psychiatry was that the image psychiatry might have had by dealing with mental disorders due to such organic brain damage has been lost and that the prevention of these disorders did not become an obligatory part of mental health programmes. A third consequence is related to the image of psychiatry that is portrayed as a discipline dealing with states without pathological substrates and is therefore a discipline that should not be given the same respect (or resources) as other medical disciplines.

For many health decision-makers in developing countries, the findings that mental health problems are frequent in general health care services were surprising. The notion that the frequency of communicable diseases and consequences of trauma are so high in health services that mental disorders will constitute only a small proportion of those who come forward seeking help proved to be wrong. Study after study found that as many as 10%–20% of those contacting primary health care services in developing countries have psychological problems of varying severity. In rural Senegal, for example, 17% of the 545 children and 16% of the 933 adults who were examined had such problems, although these were not necessarily recognized as such by the general health care service workers. In other African countries, the situation was similar (see, e.g. German 1987; Ndetei and Muhangi 1979). Other parts of the developing world have reported similar findings. In South India, general practitioners estimated that 10% of their patients came to them primarily because of psychological problems (Gautam et al. 1980) and a multi-centric study coordinated by the WHO also confirmed these results (Sartorius and Harding 1983; Harding et al. 1983a,b), as did a number of other studies (Sartorius et al. 1990). More recent studies have shown that the situation is similar today and that mental health problems represent a major part of the burden of general health services (Üstün and Sartorius 1995).

Unfortunately, this is not all. There are good reasons to believe that the prevalence of mental disorders will continue to increase. The main reasons for this include demographic changes and longer life expectancy: as

more and more people survive into their early twenties, the group at higher risk for schizophrenia will increase. Similarly, survival into the age of heightened risk for depressive disorders will increase the prevalence of depressive disorders in the population of developing countries, survival into old age will increase the prevalence of dementia and so on. It might of course happen that better conditions of life and better health services will decrease the numbers of preventable neurological and psychiatric problems due to early trauma, malnutrition and other ills besetting developing countries today; however, it is not easy to predict which will be quicker – the decrease in the incidence of mental and neurological disorders due to brain damage or its increase due to better survival chances.

Another reason for the probable increase of prevalence of mental disorders is the improvement of chances of survival of people suffering from chronic diseases likely to be accompanied by mental disorders such as depression. The dictum that each of our successes in terms of better medical care and saving lives has to be paid for by an increase in risks for other diseases and problems (Gruenberg 1977) was true when first said and might, regrettably, remain true in the future. The longer life expectancy of people who have a mental disorder may have the same effect on increasing the prevalence of the disorders even if incidence stays the same or slightly diminishes.

Whether the rampant pollution that accompanies industrialization in developing countries will have neuropsychiatric consequences that will increase the incidence of mental disorders is also difficult to foresee; what is more likely, however, is that man-made accidents will happen more often in developing countries and will lead to an increase in the numbers of people with mental disorders (see Chap. 17, Vol. 2, Part 1). By way of illustration, of the approximately 3 million people affected by disasters in the 1967–1991 period, more than 95% were living in the developing countries in Asia and Africa (Desjarlais et al. 1995).

Although it is likely that some of the communicable diseases that can be accompanied by mental disorders will diminish with the improvement of health care and of the health education of populations, other diseases with mental health consequences might appear and be difficult to control for years to come. If this happens, developing countries will suffer more than their developed counterparts because they cannot easily deploy additional resources to counter the new perils. A good example is infection with the human immunodeficiency virus (HIV): if the current estimates of the frequency of psychological problems associated with HIV infection and acquired immunodeficiency syndrome (AIDS) are correct, within two decades there will be more people affected by AIDS-related dementia in Africa than there are hospital beds for all inpatient care on the continent. In many developed countries, the AIDS epidemic is almost under control, but in developing countries it is still on the rise.[2] In the instance of AIDS, the psychological problems are not only the dementias appearing late in the course of the disease, but also the early reactions to the infection (Maj et al. 1993; see also Chap. 16, Vol. 2, Part 2) and the problems arising in orphaned children and devastated families.

A further contribution to the burden of mental disorders in the developing world are the mental health consequences of violence on a mass scale (e.g. wars, insurgencies, civil strife) and on an individual level (e.g. crimes), the latter particularly in urban settings. Both forms of violence are incomparably more frequent in the developing world and have taken on epidemic proportions in recent years. Although suicidal behaviour is not necessarily a psychiatric problem, it is necessary to note here that suicide is more frequent in some developing countries than in most developed countries. Sri Lanka, for example, had the second highest suicide rate in the early 1990s, and suicide among young rural women in China is among the highest in the world (Desjarlais et al. 1995).

2.3 Disregard for Psychosocial Aspects of Health and Other Development Programmes

A third obstacle to the development of mental health programmes in developing countries is the restrictive definition of psychiatry as a discipline whose competence and task is to deal only or mainly with the most severely mentally ill. Since psychiatrists often accept this definition and they are the people who run mental health programmes, such programmes will also concentrate on the most severely ill and impaired (and on their inpatient care). The education of medical students – future health care decision-makers – will foster the same image of psychiatry and make changes towards a more enlightened view of mental health and psychiatry difficult for years to come.

The restriction of mental health programmes to activities related to the most severe forms of mental disorders also decreases the importance and relevance of mental health programmes. If defined in this way, mental health programmes deal with a small proportion of the population, and their significance for the

[2]For example, a recent report summarising the findings of the annual survey in the Republic of South Africa gives the figure of 50,000 new cases of HIV infection per month.

improvement of the health of the population is minor. If, on the other hand, mental health programmes were to be seen as having to deal with human behaviour, it would be logical that they assume a position in the mainstream of public health efforts and receive significantly more support and emphasis.[3]

Psychiatrists are often reluctant to assume responsibility for the development of broadly conceived mental health programmes which encompass the prevention of mental disorders, the promotion of mental health, the delivery of contributions that psychiatry and behavioural sciences can make to the resolution of psychosocial problems and the treatment and rehabilitation of people with mental illness and impairment. Postgraduate psychiatric training does not prepare psychiatrists for such an array of tasks, and they are rarely willing to devote all their time to the development of mental health programmes. They are also reluctant to see other professionals running such programmes: as a consequence, in most developing countries mental health programmes are narrowly conceived, and the people running them are either reluctant to see them be expanded to include the areas outlined above or find it difficult to gather sufficient support to put broad mental health programmes into operation.

And yet it is logical that the role of psychiatrists in most developing countries should be different from that of their counterparts in the industrialized world. In a country such as Ethiopia, there is one psychiatrist for every 5 million population; even if that person were to spend all of his or her time treating the mentally ill people, he or she would be able to help only a minute proportion of the mentally ill in the country. Initiating and building a mental health programme that will involve a wide variety of professional and non-professional helpers might have an immeasurably more useful effect for the same investment of time and energy. It can be argued that this is not what psychiatrists are for, but the counter-argument is that the identity and tasks of any professional depend on the context, on the setting in which they exercise their profession, and that the role of the psychiatrist in a developing country therefore has to be different. Top officials in developing countries do recognize the need to develop programmes that deal with psychosocial aspects of health and development. They might be inclined to support such programmes if there were qualified individuals willing to commit their time and effort to the development of such programmes.

[3]The bad effects of the separation of psychiatry from neurology at the organic end of the spectrum described above are also significant to these considerations.

The two most important consequences of the broad conception of mental health programmes are that, firstly, these programmes would gain in importance because they would deal with problems of major importance for health – such as the promotion of healthy behaviour – and secondly, that postgraduate training in psychiatry would have to include a section that would be fundamentally different from what is currently included in postgraduate courses in most developing and developed countries. The reorientation of postgraduate education in psychiatry in order to produce sufficient numbers of leaders of national and regional mental health programmes in developing countries does not mean that the need for psychiatrists with a predominant interest in clinical psychiatry would disappear; the investment in training, however, would have to be differently weighted to allow for the development of mental health programmes and for the growth of services for people suffering from mental illness.

The WHO has promoted the notion that mental health programmes have to be comprehensive and broad if they are to be seen as an important part of the public health enterprise (Sartorius 1978; WHO 1981, 1992a). The arguments put forward were that, firstly, many mental health problems can only be resolved if the health sector as a whole is involved, secondly that many of the public health problems could be resolved more easily if technology developed by mental health programmes (e.g. concerning change of attitudes, humanization of medicine) were to be used in general health care, and thirdly, that health programmes cannot make a contribution to the overall socio-economic development unless they incorporate a mental health component. Broad mental health programmes in the form recommended by the WHO have come into existence in a number of developing countries, but are not yet the model programme accepted by all.

2.4 Scarcity of Resources

The fourth major reason for the slow development of mental health programmes in developing countries is their chronic lack of resources. Annual expenditure for health in some of the least developed countries is a few dollars – as much as one thousand times less than in countries in the industrialized world. The scarcity concerns most of the resources that are necessary for health programmes – qualified staff, facilities, medicaments, laboratories, means of transport. Salaries, if paid at all, are so low that staff have to seek other sources of income – work abroad, private practice or other occupations – often of the most surprising

nature. The scarcity of resources is often combined with an almost total neglect of peripheral health care workers, resulting in burn-out, which is increasingly seen as the chief reason for the continuous deterioration of health care in developing countries. Inpatient facilities (antiquated mental hospitals) still represent most of the resources that mental health programmes have. These institutions, which are usually in a dire state, provide a vastly insufficient number of beds for the country; in many African countries, the number of psychiatric beds is in the region of 0.5–5 per 100,000 population. In Asia, the numbers of psychiatric beds are somewhat higher, but still low in comparison with richer countries (e.g. Vietnam, 0.78/100,000; China, 0.73/100,000; the Philippines, 1.13/100,000). In the richest of the developing countries, the situation is somewhat better: even there, however, the low position that psychiatry has in the eyes of decision-makers results in a disproportionately low amount of resources for mental health care and other mental health activities. The numbers of psychiatrists vary from 1:5,000,000 in Ethiopia (Alem 1997) to 1:200,000 in Korea (Shinfuku 1993), but their distribution is uneven and most of them are practising in urban areas. The number of psychiatric nurses is also low, although here the situation is less distant from numbers in developed countries. Psychiatric social workers are rarely available. Psychologists are more numerous and often face the difficulty of finding employment in mental health care services which traditionally have not included posts for psychologists. In Latin America, the numbers of psychologists are particularly high, and many among them will seek to open a private practice or work in sectors that have nothing to do with health.

Funds for the treatment of those with mental illness are scarce and their availability irregular. The resources necessary for the maintenance of inpatient institutions, patients' food, clothing and other necessities are often not available. Distances between health service centres and the population groups are often large in developing countries, and effective transportation is of essential importance, yet vehicles are few and there is no money for fuel and maintenance and no replacement parts. The distribution of funds between mental health care services and other services is not even, and the low priority of mental health programmes is reflected in a variety of ways when it comes to budgetary provisions, new posts, fellowships, library supplies and other material. The unjust distribution of resources does not only affect the care of patients; it also has negative effects on the morale of the staff working in mental health care services. Many leave the service, and those who can be recruited are often not of the best quality.

An indicator of the state of mental health programmes is the legislation. A recent survey of legislation in 45 countries demonstrated that, in 12 of them, there was no special mental health law and the admission of patients, their treatment and other aspects of the mental health care services were governed by some informal system; a number of these countries belonged to the developing country category. The same survey established that mental health laws in the poorer countries had not been updated as recently as the laws in richer countries. In another analysis, the survey showed that, in a number of countries, mental health laws were incompatible with a policy of integration of people with mental illness into the community; all of the six countries that belonged to that category were in the developing world (see Chap. 15, Vol. 1, Part 2).

3 Possible Solutions

The difficulties alluded to above have not prevented the establishment of mental health programmes in the developing world. Often, such programmes were built around an individual excelling in energy and charisma; there are, however, also programmes that have grown in the absence of such individuals.

Although none of the developing countries has established, consistently maintained and evaluated a comprehensive mental health programme, many have adopted progressive programmes and are implementing them. The elements such programmes comprise are described below.

3.1 Promotion of the Value of Mental Health

The promotion of mental health is best understood as the process of moving mental health up on the scale of values of individuals and societies (Sartorius 1992, 1998). Mental health promotion should thus not be equated with the improvement of the mental health status of the population; improvement will be achieved by programmes of prevention and treatment of mental disorder and by various other means, e.g. better nutrition. Placing mental health high on the scale of values is, however, important for the improvement of mental health because it provides the motivation to undertake preventive and curative measures which will result in better mental health and functioning.

Since the promotion of mental health is a process of changing values, it cannot be the exclusive task of mental health care services or indeed of health services in general. Values are shaped during the upbringing of

children, at home and in school, through the media, by examples and models and in other ways. Mental health programmes in the developing countries should see the promotion of mental health (understood in this sense) as their highest priority, because success in placing mental health higher on the scale of values is essential for all other activities in the mental health field. Action concerning promotion will require multiple links and alliances with those who have a role to play in this process; the consequence of this is that mental health programmes must consider partnership with many groups with whom they have not had contact before.

Psychiatrists will usually not be in charge of mental health promotion programmes; it is important, however, that they should participate in them and advocate them, because the success of such programmes will help in the development of programmes of care and rehabilitation of people with mental illness. Sometimes, they can initiate such programmes; in Pakistan, for example, the department of psychiatry of the University of Islamabad has been the driving force behind a programme designed to promote mental health in schools (Mubbashar 1999). In other settings, mental health promotion activities have been embedded in programmes of general health promotion and community development (Badura and Kickbusch 1991; Trent 1992).

3.2
Primary Prevention of Mental Disorders

Primary prevention of mental disorders has long been considered an impossible task. When the Director-General of the WHO presented the results of an analysis of possibilities for the prevention of mental, neurological and psychosocial disorders (WHO 1986) at the 39th World Health Assembly, the assembled ministers and other top health officials were both astonished and pleased. A resolution was adopted requesting countries to take action and urging the Director-General to assist countries by preparing appropriate guidelines for action. Most of the measures presented in the report of the Director-General of the WHO have to be undertaken by sectors other than the health care sector, some have to be carried out by the health care sector but not by mental health care services (e.g. the improvement of perinatal care) and very few by mental health care workers. The latter, however, have a central role in bringing about preventive action; firstly, they have to advocate the development of preventive programmes; secondly, they have to continue to stimulate general health services and other social services to do what is necessary; and thirdly, they have to monitor the effects of the interventions undertaken.

Possibilities for the primary prevention of mental disorders are mentioned above, and more details can be found in the chapter by Eisenberg (see Chap. 8, Vol. 1, Part 2). In general, it should be stressed that, in developing countries, possibilities for the primary prevention of mental disorders (e.g. due to early damage of the central nervous system) are particularly numerous but are usually neglected (Sartorius and Henderson 1992).

3.3
Treatment of Mental Disorders

Using data from the Global Burden of Disease publication (Murray and Lopez 1996), M. Phillips (personal communication) has recently estimated that, of the 80% of people with depressive disorders living in developing countries, only 5% receive treatment. The situation is probably similar for other types of mental illness. The report by Murray and Lopez and a number of other papers have provided new ammunition for the request to introduce mental health components into primary health care – a recommendation often repeated by the WHO and numerous other bodies (WHO 1975a, 1990).

There are a number of examples of countries or areas in which mental health care has been provided through general and primary health care agents (Murthy 1996; WHO 1984, 1990). The effects have, on the whole, been rewarding. The results have indicated an increased coverage of care for people with serious mental illness and an increased satisfaction of general health care workers trained to deal with mental illness. In some developing countries, e.g. Thailand and Uganda, the treatment of mental disorders and the promotion of mental health have been included in national health care plans as one of the priorities for action. A large number of manuals enabling general practitioners and primary health care workers to deal with mental disorders have been produced and used in training programmes in many countries (WHO 1992b). The WHO has even complemented its the tenth revision of ICD (ICD-10) by a classification for use in primary health care (ICD-10 PHC). This document has been produced in order to facilitate reporting about mental illness in primary health care facilities. The PHC version of ICD-10 has a sharply reduced number of categories – only 22 categories versus more than 600 categories (see Table 1) and in some even further simplified versions only nine categories. These were selected on the basis of the frequency of diagnosis made at the primary health care level, paying attention to including only those categories which primary health care workers will be able to use with minimal instructions (and for most of which treatment is available).

Table 1. Mental health categories in the primary health care version of ICD-10 (ICD-10 PHC)

F00	Dementia
F05	Delirium
F10	Alcohol use disorders
F11	Drug use disorders
F17.1	Tobacco use
F20	Chronic psychotic disorders
F23	Acute psychotic disorders
F31	Bipolar disorder
F32	Depression
F40	Phobic disorders
F41.0	Panic disorder
F41.1	Generalized anxiety
F41.2	Mixed anxiety and depression
F43	Adjustment disorder
F44	Dissociative disorder
F45	Unexplained somatic complaints
F48.0	Neurasthenia
F50	Eating disorders
F51	Sleep problems
F52	Sexual disorders
F70	Mental retardation
F90	Hyperkinetic disorder
F91	Conduct disorder
F98.0	Enuresis

Classifications are often not used; to increase the attractiveness of ICD-10 PHC and to make it more widely used, the WHO, in collaboration with non-governmental organizations (e.g. the organizations representing general practitioners and psychiatrists), has also produced specific instructions on how to recognize the conditions to be classified and how to treat people who have them once they are recognized. The classification was produced in the late 1980s and released for test use in a number of countries. It was finalized once the results of these tests became available and published in 1996 (WHO 1996).

The introduction of mental health components into primary health care has not always been fully supported by psychiatrists. Some of them feared that the treatment of mental illness in general health care might have untoward consequences for the patient, others that the devolvement of responsibility might decrease the numbers of patients who would come forward as their clients. Neither of the two fears proved justified. General practitioners and primary health care workers can provide effective treatment to a significant proportion of patients, particularly if there are possibilities for referral and if general health care workers receive short practical training. In developing countries, other needs also have to be satisfied, including the need to ensure a regular supply of psychotropic medication and possibilities for the transportation of health care workers to remote areas and of patients for referral, for example. In both developing and developed countries, the introduction of primary health care concepts could actually have a positive effect on psychiatry, increasing its importance in the framework of public health action (Sartorius 1997) and improving its performance.

In developed countries, the treatment of mental disorders in the general health care system is, to a certain degree, a matter of choice of those concerned – the patients, their families, the general practitioner and the psychiatrist. In developing countries, it is not: if mental health care is not provided through the general and primary health care worker, it will not – for an immense proportion of the population – be provided at all.

The treatment of mental disorders, particularly those that are likely to produce a lasting impairment, has to be linked to a process of rehabilitation. In developing countries, a very small proportion of the most severely ill are inpatients in the mental hospitals, mainly built in the colonial times. Most of the remaining patients who were not rejected by their families (because the family could not afford to feed them or could not tolerate their socially unacceptable behaviour) used to stay with them and were partly integrated into the life of the family and the community. Families have thus played a central role in the life of patients during and after the disease. Current processes of urbanization and the nuclearization of families diminish the capacity of families to provide long-term care to their sick members; at present, most of the developing countries have not found an answer to the challenge of such care under conditions of the dwindling capacities of families to help.

The life of those suffering from a severe mental illness is difficult in all types of countries. In developing countries, the situation is the same or worse. While the families and communities of people who suffer from mental illness show compassion and understanding at the beginning of the illness (unless the behaviour of the mentally ill is very disturbing, bringing shame to the family or community or endangering the life of others), their capacity to care and look after these individuals is usually soon exhausted. Sometimes, those with a severe mental illness are ejected from their setting and become vagrant psychotics; sometimes, they remain hidden in some dark corner of the house for many years; often, they die a premature death because of the increased risks to their health,

their diminished capacity to cope and their lesser ability to request or obtain medical help. The introduction of psychiatric services, in collaboration with and through general health services, is therefore a life-saving operation in addition to being a process of bringing people with mental illness relief and support.

4 Conclusion

The forms of the most frequent mental disorders are similar in developing and developed countries. There are culture-specific forms of mental illness, but these represent only a small proportion of all mental illness. Most of the differences between developed and developing countries result from poverty and the many ways in which it impacts on people, on health care and on diseases.

Poverty also affects the chances for the application of knowledge to help people with mental health problems; nevertheless, the development of mental health programmes is possible and, particularly in poor countries, highly desirable. At the same time, however, it is important to realize that the reluctance of the mental health care professions to change and accept new definitions of their roles often figures highly among the obstacles to creating or improving mental health programmes.

Mental health programmes must be an integral part of general health care programmes, which, in turn, are inextricably linked to socio-economic development; however, this does not mean that change within the field of health or mental health can only happen if developing countries catch up with the industrialized world. Much can be done for mental health in developing countries today, and too little of it is undertaken. In this respect, psychiatry in developed countries has an important, often neglected role to play. Many psychiatrists from the developing world are trained in industrialized countries, and much of the technology and new knowledge is generated in these settings; it would be immensely useful if the differences that exist between countries were to be systematically considered in postgraduate medical education everywhere. This would be one way of exchanging information about ways of organizing services and providing care, but all other occasions and opportunities should also be used so that experience from countries at different stages of development can be shared and judiciously used in educating mental health care professionals and in building relevant and useful mental health programmes.

Psychiatric Problems Arising in Extreme Environmental Circumstances

1 Introduction

Human exposure and mastery of extreme environmental conditions inevitably resulted in a number of newly described psychiatric phenomena for which our mind and body remain phylogenetically and ontogenetically unprepared. As we continue to master harsh environments of the Arctic, Antarctic, mountain peaks, ocean depths, and space, we come upon new discoveries about human behaviour and the psyche in the process of forced adaptation to these altered, extreme conditions.

We continue to challenge the human body and mind with various professional activities under unfavourable conditions which ultimately stress human psychophysiology. For example, some professional activities require sustained maintenance of the highest degree of visual and auditory acuity in a setting of emotional and cognitive stress. It is well known that psychological and physiological factors have a direct effect on the overall functional state of an individual. There are several examples of this. Desynchronosis is a sleep irregularity due to a change in the usual circadian rhythm and is seen in shift workers and participants of lengthy expeditions. These subjects frequently demonstrate emotional instability and pronounced physical and emotional fatigue. Likewise, prolonged work under the conditions of the polar night commonly results not only on psychological stress, but also in a disruption of normal neurovegetative functions in the body. Lengthy submarine travel and work also require a special artificial illumination schedule to enable sailors to work.

There are other environmental stressors which we associate with disruption of normal bodily functions. These include chronic exposure to vibration, noise and electromagnetic radiation from power plants. As a further example, modern-age space travel and work require adaptation to zero gravity conditions for which humans are clearly unprepared by evolution on Earth.

2 Mental Health Problems

Isolated exposure to any one of these extreme environments may not necessarily produce a mental disorder. However, the amalgamated action of the untoward environmental effects presents new issues to add to our current psychiatric phenomenology, diagnosis and treatment. One such issue is the problem of psychological compatibility between members of very small teams who perform shift work or participate in lengthy expeditions in a confined space isolated from their habitual social environment and support.

We continue to face problems with professional selection for such missions, as methods are borrowed from the field of psychology that have been developed to address human behaviour under conditions that are more familiar to us. For example, there are only few data about latent interpersonal conflicts among the members of small groups of explorers who avoid meeting one another after they return home (Lebedev 1989).

It worth mentioning another known phenomenon observed in the setting of environmental isolation and extreme stress. Similar to the illusion of experiencing something double, a person may visualize his or her own double and experience other auditory, visual and tactile hallucinations and distortions of reality. Such brief and transient conditions are fully reversible and appear to be related to the attempt to adapt to an extreme situation in which reality testing and functional ability remain preserved; the individual quickly returns to an asymptomatic state.

Extreme environmental conditions may also have their effect on large populations. Ecological psychiatry is concerned with the relationship between the physical, chemical and other environmental pollutants and mental health in large groups of people. Unlike an individual's adaptation to extreme conditions, a larger group responds to ecological stressors in a more complex way and with numerous intertwined, biopsychosocial and cultural pathogenic factors.

3 Ecological Psychiatry

The new field of ecological psychiatry continues to develop along with the demand for its clinical and research applications in the recent past. However, the future areas of development in ecological psychiatry remain unclear and will require future study. Overall, ecological psychiatry may be defined as an area of complex scientific inquiry into mental health and illness in the setting of unusual, anthropogenically produced or naturally occurring environmental conditions (Krasnov et al. 1993a; Krasnov 1995).

Areas of interest include individual and public health issues related to the various effects of the psychological and social environment of mental health and illness. An area of major importance is thus the mental health of individuals who work in prolonged sensory and psychosocial isolation with forced disruption of their circadian rhythm in unusual geoclimatic

situations. Of special interest is the study of individual adaptive reactions within a small group during prolonged isolation (see above).

Epidemiological vectors address the specific features and variants in mental health and psychosomatic diseases as a result of living and working in large, new technological and industrial settings. These may include newly populated areas in the Far North of Russia and Canada, where native and non-native populations may significantly differ in their social and physical adaptation styles (Korolenko et al. 1991; Semke 1992; Krasnov 1995).

Moreover, it is important to continue research and clinical efforts related to the problems of refugees, forced migrant populations and victims of wars, torture, violence and imprisonment throughout the world (see Chaps. 18–21, this volume).

Finally, ecological psychiatry continues to promote areas of research into immediate and delayed consequences of great natural and man-made environmental disasters. For example, the Chernobyl disaster of 1986 dramatically promoted the development of ecological awareness in Russian medicine. The Chernobyl harmful exogenous factors affected millions of people and continue to remain a major health hazard. The sequel of the disaster called attention to other previously ignored large-scale technological accidents and calamitous environments. It is precisely because of the immediate and specific consequences of Chernobyl that the field of psychiatry had to re-evaluate its traditional and narrow nosography and to look for new approaches to diagnosis, evaluation, treatment and rehabilitation of the victims (Krasnov et al. 1993a,b, 1995; Krasnov et al. 1995; Viinamäki et al. 1995; Nyagu and Loganovsky 1997; Havenaar et al. 1997). This may present an area of joint inquiry for industrial and ecological specialists within psychiatry.

However, the methodology of ecological psychiatry remains largely undeveloped. It is clear that it will require biopsychosocial and cross-cultural approaches to study the role of environmental factors in human health and social functioning. The future areas of methodological development will most likely evolve around individual and group psychobiological responses to various negative and positive environments. In addition, new methods in appropriate psychiatric rehabilitation must be considered.

In recent years, a number of publications have addressed psychosomatic and non-psychotic mental disorders which are developing with increasing frequency in many hazardous industrial settings (Simon et al. 1990; Krasnov 1991, 1995; Andresen et al. 1993). These include sleep–wake cycle disturbances, severe emotional and cognitive stress, perceptual disturbances and similar conditions. The afflicted workers are found among air traffic controllers, submarine sailors, space workers and astronauts (Weybrew 1963; Hauty and Adams 1966; Tenfiord 1966; Serxner 1968; Offerlend and Roos 1969; Berry 1970; Bennet 1972; Lindsley 1972; Takla et al. 1994). Current scientific literature appears to group these conditions with other psychogenic neurotic disorders. However, this seems partly unjustified. Unlike neurotic conditions, the phenomena of adaptation appear to preserve a healthy motivation for work and do not demonstrate maladaptive interpersonal symptomatology. It is obvious that unusual, brief, reactive psychological phenomena may occur under extreme conditions. However, these experiences appear to result from the process of adaptation to the extreme conditions and do not necessarily cause particular problems or hinder work. A number of vivid descriptions of such interpersonal adaptation phenomena and latent conflicts during lengthy polar expeditions and other travel in isolation can be found in current (mainly in non-professional) literature (Byrd 1932; Slocum 1956; Law and Bechervaise 1957; Bombard 1958; Heyerdahl 1959; Mullin and Connery 1959; Serxner 1968; Leonov and Lebedev 1971; Gunderson 1973; Rivolier et al. 1988; Sandal et al. 1996).

Occasional interpersonal difficulties and conflicts appear to be related to asthenic, affective and neurovegetative conditions which tend to develop under prolonged stress and in total or partial isolation. These asthenic neurovegetative symptoms frequently include progressively increased fatigability, irritability, sleep disorders, dysphoria, anxiety, dizziness, headaches, tachycardia, unpleasant somatic sensations, vegetovascular instability, hyperaesthesia and hypervigilance. The above-mentioned phenomena are highly nonspecific and tend to occur in small expedition groups and during prolonged isolation and sensory deprivation. When the extreme conditions persist unremittingly for an extended period of time, bona fide psychiatric disorders do tend to develop as well, as documented by a number of authors (Ritter 1900; Byrd 1932; Slocum 1956; Bombard 1958; Burns and Kimura 1963; Lebedev 1989; Cooper 1993).

Various sensory and perceptual disturbances, illusions and the specific phenomena of depersonalization and derealization can frequently be observed under specific extraordinary environmental conditions. Depersonalization and derealization appear to be specifically provoked by desynchronosis, sleep deprivation, prolonged isolation and monotony under experimental conditions. Unlike similar known psychiatric conditions, these phenomena are transient, situation specific and do not affect the individual's sense of self-control.

For example, in the setting of zero gravity, depersonalization is a common experience. Proprioception and the sense of one's own position in space become impossible, since there are none of the usual terrestrial

gravity cues available. Under such conditions, the process of adaptation requires an astronaut to rely almost exclusively on visual perception in order to estimate his or her position in space. Similar adaptation may take place during a space walk outside the spacecraft, where orientation in space is aided by the Earth, the nearby spaceship, the sun and the stars (Leonov and Lebedev 1971). Nevertheless, depersonalization and derealization in space are experiences with total preservation of reality testing and without feelings of morbidity.

Numerous experimental designs have been utilized in order to study sensory and cognitive deprivation and isolation. The studies have been carried out in the laboratory and in space in zero gravity. Common findings included asthenia, somatoform conditions, brief and transient illusions, hallucinations and cognitive mistakes. At the same time, reality testing always remained intact and allowed for necessary corrections while performing specific tasks and assessing unusual situations (Heron et al. 1956; Burns and Kimura 1963; Sharpe 1969; Leonov and Lebedev 1971; Daniel and Vining 1983; Lebedev 1989).

Similar psychological phenomena have been reviewed in detail in the literature dealing with sensory deprivation (Bexton et al. 1954; Heron et al. 1956; Davis et al. 1960; Mendelson et al. 1961). Sensory deprivation and monotony appear to stimulate the human need for external stimuli and emotionally rich responses also known as "sensory hunger". Thus perception and mental images acquire additional vividness, but do not affect one's ability to distinguish them from images of real objects. This type of compensatory imagination is inseparably connected to the adaptation activity of the mind and body. The longer the period of solitude and isolation, the greater the need for social contact becomes. The psychological phenomena of this social need may be manifested by assigning personal meaning to inanimate objects, talking out loud to oneself or to one's diary and responding to internal stimuli. In solitude and isolation, a human being sometimes visualizes his or her own double and communicates with it. However, a clear distinction between reality and fantasy is always preserved. In addition to such pseudoautism, prolonged solitude and isolation produce peculiar patterns of overvalued ideas of inventiveness, reformation and religious and philosophical contemplation about the world and the purpose of existence. Ideation of this nature completely remits upon discontinuation of isolation and return to normal life and does not recur.

At the same time, comparable adaptation mechanisms may take place under monotonous and isolated conditions of some asthenizing and exhausting industrial labour environments. Not much is known about the subject except for some documented occupational hazard factors (Burns and Kimura 1963; Serxner 1968; Lindsley 1972; Sandal et al. 1996). Although sanitary and hygienic norms have been established for most physical and chemical work environments, most researchers have not studied the complex interaction between occupational hazard factors and their cumulative effect on an individual and his or her ability to adapt. Moreover, some hazardous occupational settings already exist within unsafe ecological environments. Such conditions arise at several plants in the oil industry, mining and non-ferrous metallurgy north of the polar circle, in the north of Russia and in Siberia, for example. Therefore, we face a complex research problem of resolving the interplay of multiple variables involved in the mental hygiene of industrial labour. These variables include technological factors, the industrial environment, individual and group emotional and cognitive reactions and the overall ecological background.

Human adaptation to certain specific conditions of professional activity has become a real problem for modern medicine. Frequent, lengthy geographic and military expeditions, space exploration and aeronautics, disruptive shift labour on submarines and similar work environments increasingly require humans to perform complex functions in an artificial space–time environment and isolation. Under such conditions, the perception of space and time is modulated by complex high technology, but humans are expected to perform with the highest degree of concentration, attention and alertness. Space perception and information related to operations in space and time come from the instrument panels and not from the usual perceptual cues. Operation of modern machinery, such as airplanes and ships, is made possible by indirect measurements by the instruments. Frequently, there is a discordance between individual's subjective perception and the information provided by the technological devices. For example, an object may appear to be far away when viewed through a porthole, but it is much closer according to the instruments on a boat or a spaceship. More recent errors in rendezvous between inhabited space modules and a supply aircraft and accidents with in-flight refuelling are examples of such mistakes.

4 Dynamics of Subclinical and Clinical Adjustment Reactions

However, mental disorders do arise as a result of work under extreme conditions. These disorders are typically limited to asthenic syndromes with emotional lability and neurovegetative disturbances accompanied

by inappropriate aggressive and demonstrative behaviours. Recent research efforts have enabled us to isolate and describe some of the common features of psychiatric sequelae after exposure to extreme conditions. Our early work dealt with mental disorders in members of marine vessels on long-term self-contained missions (Kokhanov and Krasnov 1986). The factors under consideration included vibration, noise, excessive humidity, change in temperature, desynchronosis, excessive cognitive demands on vision and hearing and everyday life inconveniences, isolation from the family, information deficiency and a restricted circle of personal and professional contacts. The duration of the working period and observation was up to 6 months. All individuals in the study were male and aged from 20 to 46 years old. A total of 149 individuals were studied, and a standardized structured interview was used to assess and monitor the mental state changes. Clinical findings were quantified using a specially developed psychiatric symptoms assessment scale with 60 clinical entities, including asthenic, affective and neurovegetative symptoms and signs. In addition, changes in vital signs and orthostatic blood pressure were also monitored.

The study allowed us to understand changes in mental status over the period of observation and to reveal certain patterns of behaviour associated with the gradual development of affective and neurovegetative symptoms. It became apparent that some symptoms such as asthenia and dysthymia eventually developed into stable clinical conditions. During the first month of work, 39 men (26.2%) revealed episodic disturbances, asthenia and neurovegetative signs. These findings were revealed only in the setting of a structured interview and had no influence on observed behaviour and work productivity. By the end of the study, after 6 months, 76 individuals (51%) revealed similar symptoms with asthenia and mild depression. Transient initial dysphoric reactions were excluded from these figures, as such reactions were clearly due to the initial adjustment to a new work routine and adaptation to a new social environment.

The asthenic disturbances were characterized by a gradual increase in psychological and cognitive deterioration, irritability, hyperaesthesia and sleep problems. The latter were limited to initial insomnia, insufficient depth of sleep and waking up frequently. Later sleep disturbances were marked by hypersomnia and dysphoria upon awakening. The end of the working day was typically marked by low mood and dysphoric responses to others. Subjects reported physical and emotional fatigue, headaches, excessive sweating, tachycardia, tremor and dyspnea. Vegetative findings were accompanied by aches, paraesthesias and general physical discomfort with hypochondriac and phobic ideation.

During the final 2 months of observation, mental status findings were more consistent with the development of depressive disorders with a complex association with asthenia. Overall deterioration in activity was noted during the day and especially in the morning, when most subjects had difficulty initiating most activities. Psychomotor retardation and speech slowing and poverty were also increasingly noticeable. There were significant problems with attention and memory tasks on cognitive mental status examination.

The development of emotional problems acquired a predictable pattern of earlier tension and irritability progressing to frank apathy and social withdrawal, which did not appear to affect work-related activities. Apathy was complicated by increasing signs of depression and episodic anxiety. Emotional instability was marked by intrapunitive reactions and introversion. Occasional external expression of dysphoria was accompanied by self-criticism and feelings of regret. A tendency towards low self-esteem was also discovered. Somatoform symptoms became more clearly localized to the chest, epigastric and head areas and became stable. Individuals also woke up early in the morning.

Thus a complex of depressive signs and symptoms was observed to evolve according to a specific pattern. Initial occasional asthenic and neurovegetative symptoms gave a way to dysphoria and apathy and eventually to a stable depressive disorder.

The clinical nature of mental disorders seen in long-term sailing appears to be truly multifactorial, with psychosocial and physical hardship stressors being of equal importance in symptom formation. This can be seen in the phenomenology of the depressive disorders, which include both psychological and biological manifestations such as hyperaesthesia and dysphoric mood, memory and attention problems and somatic complaints, which are usually intertwined in one complex observable pattern. At the same time, the above-mentioned depressive disorders are strikingly similar to neurotic depression and atypical depression with an organic substrate. Diurnal mood variations with early morning dysphoria, dysphoric reactions, somatoform features and neurovegetative signs seen in sailors after 6 months are non-specific symptoms of depression which are most likely related to underlying physiological and chronobiological disturbances.

It is important to note that subjects' ability to perform work-related functions remained relatively unaffected, and depression did not make it any more difficult to follow routine operations that did not demand independent decision-making. In spite of the obvious decrease in motivation, most subjects continued work activity as directed. This is most likely due to innately high motivation to preserve the upkeep of the

inner resources of an individual. Moreover, most symptoms completely remitted after the period of convalescence at the end of the 6 months. Depressed mood remitted first, followed by a brief period of euphoria and remission of the asthenic phenomena.

The vital signs were consistent with increased sympathetic tone during the period of initial asthenia and with vagal parasympathetic tone during the late stage of depressive disorder. Heart rate values were 78 ± 2.1 and 63 ± 1.8, respectively ($p < 0.001$).

Other significant studies have been conducted to investigate environmental effects on the human psychological state. Thus, in 1991, Krasnov and his colleagues studied changes in mental state in the personnel of a large airport. In this study, 402 individuals were examined using an anonymous questionnaire in order to determine the prevalence of psychiatric disorders. Stable and recurrent asthenic and psychovegetative disorders were identified in 207 subjects (51.5%). The most common symptoms included headaches, irritability, problems with concentration and attention, eye strain, daytime sleepiness, increased meteorotropic sensitivity, episodic tachycardia, arterial blood pressure changes and chest pain. These findings do not necessarily indicate separate clinical entities, but seem to be the result of work stress and psychophysiological adaptation. Most interviewed subjects revealed no family conflict, felt good about their work and the workplace and had no other apparent life stressors. At the same time, the significant symptoms appeared to be considerably more prevalent among air traffic controllers who are exposed to chronic noise and desynchronosis compared to the rest of the group.

Another example of a protracted and persistent mental disorder related to a specific environmental exposure is mental and psychosomatic syndrome in rescue team workers who dealt with the Chernobyl disaster aftermath in 1986 (Krasnov 1993a,b). The extreme psychological stress was combined with exogenous toxins and produced a peculiar clinical syndrome. The syndrome of the so-called liquidators is characterized by its symptomatic heterogeneity and multiple patho-aetiologies with the final amalgamated clinical presentation of asthenia, somatoform symptoms, dysthymia and cognitive dysfunction combined with vegetative dysregulations, psychosomatic disorders (e.g. gastritis, ulcer, asthmatic bronchitis, arthritis, arterial hypertension) in conjunction with vegetative-vascular dysregulation (varying from arterial hypotonia to hypertension), and not infrequently also with combined somatic dysfunctions (cardiovascular, gastrointestinal, osteomuscular, metabolic) and non-specific neurological disturbances of the dyscirculatory encephalopathy type. This syndrome developed a few years after the disaster, and affected individuals usually present with non-psychotic symptoms but have a tendency to develop a psycho-organic syndrome. Primary radiation disease may be ruled out, since most individuals were exposed to relatively low radiation doses (0.1–0.3 Gy), while radiation disease develops at irradiation in doses of not less than 1 Gy for a short period of time. Nevertheless, in the general context of harmful effects (e.g. aggressive components of decontamination agents, fluctuations in the external temperature around miners digging a tunnel under the destroyed reactor, desynchronosis, psychological stress), we cannot ignore the role of low and moderate doses of radiation in the development of the conditions discussed above.

5 Conclusion

In conclusion, psychiatric phenomena arising under extreme environmental conditions can be either normative pseudopathological adaptive mechanisms or bona fide psychiatric disorders with complicated long-term biopsychosocial sequelae. Pseudopathological normative adaptation phenomena may include sensory distortions, personification of inanimate objects, vivid mental images, illusions and even visual hallucinations of one's double, whereas reality testing is always completely reserved. Such phenomena appear to play an adaptive role in accommodating an individual to an extreme condition and tend to remit under normal circumstances. Pre-flight training of astronauts in Russia shows that presence of such phenomena during the training period usually prognosticate a swift adaptation to real flight conditions (Lebedev 1989).

On the other hand, psychiatric disorders do develop under unusually severe environmental conditions. According to ICD-10 (World Health Organization 1993) and DSM-IV (American Psychiatric Association 1995), such disorders are usually adjustment disorders, acute stress disorders and post-traumatic stress disorders. The new complex polymorphous disorders of multiple aetiologies such as the Chernobyl disaster victims syndrome have yet to be formally classified (Krasnov 1995).

Psychiatric Problems Related to Natural and Human-Made Disasters

1 Introduction

Extreme events, such as natural and human-made disasters, often have short- and long-term psychological impacts that far exceed the degree of medical morbidity and mortality that ensues. Indeed, Lechat (1979) defined a disaster as a "disruption exceeding the adjustment capacity of the affected community" (p. 11). Since World War II, a number of studies have assessed the emotional consequences of a variety of natural disasters, such as hurricanes, tornadoes, floods, volcanic eruptions, and earthquakes, as well as technological and human-made catastrophes, such as the nuclear power plant accidents at Three Mile Island (TMI) in the United States and Chernobyl in Ukraine (Bromet and Dew 1995; Havenaar et al. 1996; Raphael 1986; Weisæth 1993), the Nazi Holocaust (Robinson et al. 1994), and the Cambodian massacre (Kinzie et al. 1989). Studies aimed at describing the prevalence of psychological impairment or disorders in populations exposed to disasters are best conceptualized as epidemiologic in nature. Within this rubric, they represent a special case of the classic cohort paradigm, focusing on incidence, prevalence rates, risk factors associated with onset, and short- and long-term impairment.

Before 1980, beliefs about the effects of disasters on mental health were based primarily on case reports or data from surveys of nonrepresentative and/or small samples. The study groups were typically samples of convenience, such as disaster victims seeking monetary compensation, injured persons, litigants, or volunteers. Such research was often criticized for having poor response rates, no control group, nonstandardized assessment tools, and no conceptual framework guiding the design, measurement, and analysis. With the 1980 publication of the third edition of the *Diagnostic and Statistical Manual* (DSM-III; American Psychiatric Association 1980), psychiatric epidemiology began to adopt new methodologies to assess mental disorders and symptom complexes, and disaster research soon followed suit. This entailed the widespread use of standardized diagnostic and subclinical measures in disaster research, such as the Diagnostic Interview Schedule (DIS; Robins et al. 1981), the General Health Questionnaire (Goldberg 1972), the Symptom Checklist-90 (Derogatis 1977), and the Impact of Events Scale (Horowitz 1990). For many of these instruments, normative population data are available. In addition, with the introduction of operational criteria for post-traumatic stress disorder (PTSD) and structured interview guides, a number of studies began to examine the occurrence and persistence of PTSD and post-traumatic stress symptoms in disaster-exposed compared to control populations. Greater attention has also been given to including representative samples and a comprehensive array of risk and protective factors. However, with some notable exceptions, such as the TMI nuclear power plant accident (Dew and Bromet 1993) and the Buffalo Creek flood (Green et al. 1990, 1994), the majority of disaster studies continue to be cross-sectional, assessing adjustment at a single, often arbitrary, point in time within 1 month to 3 years postdisaster. We therefore have a somewhat limited understanding of the evolution of symptoms over time and the extended long-term effects of natural and human-made disasters.

While epidemiologic designs provide a more rigorous methodology for understanding community-wide stress, pre-event baseline data are unavailable in most studies. The exceptions can be thought of as "natural experiments." Such exceptions have occurred in situations in which a population was studied for some other purpose prior to a catastrophic occurrence, and researchers were able to conduct a prospective follow-up and identify predictors of postdisaster adjustment. For example, data were collected for a psychiatric epidemiologic study modeled after the Epidemiologic Catchment Area (ECA) study (Robins and Regier 1991) in Puerto Rico in 1984 (Canino et al. 1987). In 1985, torrential rains hit the island, causing extensive mudslides and leaving 180 people dead, 4000 in shelters, and 19,000 with serious property damage. In 1987, the investigators reevaluated a group of disaster survivors ($n = 77$) and controls ($n = 298$) using a Spanish-language version of the DIS Disaster Supplement (Robins and Smith 1983). The results showed that, after adjusting for demographic variables and previous symptoms, depressive, somatic, and PTSD symptoms were significantly, albeit modestly, increased after the disaster (Bravo et al. 1990; Canino et al. 1990; Escobar et al. 1992). A methodologically different example of a "natural experiment" occurred in conjunction with a major earthquake in Italy. Trevisan et al. (1992) were in the midst of conducting a 5-year follow-up of workers participating in a coronary heart disease risk factor study when the earthquake struck. Compared to workers whose evaluations were completed before the earthquake, those whose examinations were performed afterward had significantly higher heart rates, serum cholesterol levels, and triglyceride levels. However, these elevations were not seen at the next follow-up assessment 7 years later.

Because of the uniqueness of each disaster and the different methodologies employed in each study, it is difficult to summarize the findings across the diverse events that have occurred. Moreover, the methodolo-

gies contain numerous sources of bias that constrain the inferences that can be drawn about symptoms and behaviors. The sources of bias include selective mortality (only survivors are assessed), difficulties assembling a representative sample when the disaster victims are scattered and subsequently relocated, difficulty gaining cooperation when populations are under stress and/or angry about delays or inadequacies in relief programs (Frederick 1980), and recall bias or faulty memory. Disaster studies are also subject to interviewer bias when the interviewers themselves reside in the affected areas. Finally, whether consciously or not, investigator bias can arise in analyzing data and interpreting findings either because investigators are influenced by how they themselves coped with their own life-threatening experiences or because of constraints imposed by the agencies sponsoring the research. The sources of variability in disaster research can be summarized as follows:

1. Disaster characteristics
   a) Natural versus human-made
   b) Suddenness of onset
   c) Duration of impact
   d) Extent of damage
   e) Number of deaths
   f) Evacuation
   g) Relocation
   h) Potential for recurrence
   i) Organizational response
   j) Sociocultural context
2. Methodological issues
   a) Sample differences (general population, litigants, help-seekers)
   b) Low response rates
   c) Interviewer bias
   d) Recall bias
   e) Timing of assessments
   f) Choice of measures
   g) Cross-sectional versus longitudinal

This chapter emphasizes findings on mental health effects from epidemiologic research, drawing mostly from studies using systematic methods for sampling and assessment. Three issues are discussed: the psychological problems that have been identified in adults and children; the risk factors for adverse outcomes in these populations; and the personal, situational, disaster-related, and treatment intervention factors that can mediate potential deleterious effects. As in a previous review (Bromet and Dew 1995), this chapter gives more weight to studies using representative samples of 50 or more survivors, because multivariate analyses of such samples are statistically more reliable. Although the review is limited to studies published in English, the disasters themselves occurred all over the world.

2 Rates and Types of Psychological Impairment

The most detailed and statistically sophisticated analysis of postdisaster prevalence of psychological morbidity was performed by Rubonis and Bickman (1991) in a meta-analysis of 52 mental health studies connected with natural and technological disasters. They calculated that the average excess psychological morbidity was 17%. Similarly, Weisæth (1993) estimated that the 1-year prevalence of psychological morbidity following a disaster was about 20%. However, he noted that the rate could range to as high as 50%. Indeed, by treating all disasters as equal, the average rates obscure the rates of suffering of survivors of prolonged, intense disasters, such as the Chowchilla bus kidnapping (Terr 1983) and the Nazi Holocaust, which approach 100%.

The 20% figure given in the reviews published before 1995 reflect research conducted primarily in North America and Europe (Bromet and Dew 1995). In fact, many of the world's worst disasters occur in developing countries (Lima et al. 1990b; Weisæth 1993) and in the former Soviet Union. Recent studies published after these reviews appeared suggest that the average rate may be considerably higher. For example, the rates of psychiatric morbidity reported in recent studies of natural disasters in Sri Lanka, Colombia, and India were 75%, 55%, and 59%, respectively (Sharan et al. 1996).

The specific rate of impairment or disorder varies widely with the type and magnitude of the disaster, the measures chosen for study, the populations evaluated, and the timing of the data collection. Four studies of earthquake survivors illustrate this issue. In the first study, de la Fuente (1990) administered a questionnaire containing the DSM-III criteria for PTSD, generalized anxiety, and depression to victims housed in shelters after the 1985 earthquake in Mexico. The rates for men ($n = 163$) were 18% for PTSD, 9% for anxiety, and 7% for depression; the rates for women ($n = 395$) were 38%, 24%, and 16% for each disorder, respectively. In the second study, Wood et al. (1992) determined the rate of nightmares among students at Stanford University and San Jose State University after the 1989 San Francisco Bay Area earthquake by asking them to keep written records every morning for the 3-week period after the earthquake; 40% recorded one or more nightmares, compared to 5% of controls in Arizona. The third study, by Maj et al. (1989), assessed survivors from three Italian communities who had contacted their general practitioners for physical health problems after an earthquake. They used a two-stage design, in which the 30-item Italian version of the General Health Questionnaire (Goldberg 1972)

was administered in the first stage, and the Comprehensive Psychopathological Rating Scale and ICD-9 were completed on the basis of a psychiatric evaluation in the second stage. The reported prevalence rates of psychiatric disorder (mostly neuroses) for the three communities ranged from 41.9% to 54.4%. The last study, by Goenjian (1993), assessed the effects of the 1988 earthquake in Armenia. Psychiatric evaluations were conducted on 582 individuals who had sought mental health treatment 3–6 months after the earthquake. Based on DSM-III-R (revised) criteria, 74% were diagnosed with PTSD and 22% with major depressive disorder. Thus, although all four studies focused on victims of major earthquakes, they differed substantially with respect to the magnitude, socioeconomic, and sociocultural contexts of each event, the study design (one-stage versus two-stage, types of samples, timing of data collection), and measurement (type of symptoms, approach to measurement). While the rates of psychological morbidity were clearly elevated across all the studies, it is very difficult to assign a precise numerical value, or even a reasonable range, from studies with such extensive methodological variation.

The most frequently reported symptoms in adults in the aftermath of natural disasters are somatic complaints, depression, anxiety, and post-traumatic stress symptoms, particularly intrusive and avoidant symptoms. The clustering of such symptoms is sometimes referred to as the "disaster syndrome." Escobar et al. (1992) used the phrase "disaster-reactive psychopathological repertoire" (p. 966) to describe such symptoms. It has been argued that these symptoms do not reflect separate disorders (Deering et al. 1996) but rather represent "complex somatic, cognitive, affective and behavioral effects of psychological trauma" (van der Kolk et al. 1996, p. 90).

Significant elevations of these symptom domains have been reported in studies of adult survivors of earthquakes (e.g. Cardena and Spiegel 1993; Carr et al. 1997; de la Fuente 1990; Freedy et al. 1994; Goenjian 1993; Goenjian et al. 1994; Karanci and Rustemli 1995; Maj et al. 1989; Murphy 1988; Nolen-Hoeksema and Morrow 1991; Sharan et al. 1996; Wood et al. 1992), floods (e.g. Cook and Bickman 1990; Kaniasty and Norris 1993; Ollendick and Hoffmann 1982), hurricanes (Norris and Uhl 1993), volcanic eruptions (Shore et al. 1986a,b), mudslides (Canino et al. 1990; Escobar et al. 1992), cyclones and tornadoes (Madakasira and O'Brien 1987; Milne 1977a; Parker 1977; Patrick and Patrick 1981; Penick et al. 1976), and a mass food-poisoning epidemic (toxic rape-seed oil; Lopez-Ibor et al. 1985). Elevations in these same symptom domains, as well as aggressive behavior and enuresis, were also reported in studies of children exposed to floods (Durkin et al. 1993), hurricanes (e.g. Garrison et al. 1995; Hardin et al. 1994; Lonigan et al. 1994; Shannon et al. 1994), cyclones and tornadoes (Bloch et al. 1956; Milne 1977b), a bushfire (McFarlane et al. 1987), and a blizzard (Burke et al. 1982; girls only: Burke et al. 1986).

These same symptom domains have also been shown to be elevated following human-made catastrophes (Bromet 1989). In fact, one of the earliest descriptions of post-traumatic stress syndrome in a civilian population was the detailed report of Hiroshima survivors by Lifton (1967) based on a series of in-depth interviews he conducted in Japan in 1962. Strictly speaking, the generalizability of the findings is open to question because of both the unstructured format of the interview and the selected nature of the sample, i.e. survivors from an unspecified population pool willing to talk at length about highly personal matters with a psychoanalytically oriented American psychiatrist. Nevertheless, Lifton's descriptions of psychic numbing (originally referred to as "psychological closure"), i.e. the loss of feeling from the extreme agony that resulted from witnessing mass death and dying and being unable to respond to calls for help, as well as other cardinal symptoms of intrusive and avoidant thinking, became criterion symptoms for the classification of PTSD in current nosological systems.

There are two unique mental health findings from studies of technological events that distinguish their aftermath from that of natural disasters: the protracted nature of the mental health problems and the fear of contracting an exposure-induced disease. With respect to its enduring effects, long-term follow-up studies of Nazi concentration camp survivors show persistent psychiatric and somatic symptoms enduring through the survivors' lifetime in spite of adequate occupational and family role functioning (Robinson et al. 1994). Even relatively lower impact events, such as the accident at TMI and the Buffalo Creek dam collapse (Green et al. 1990), led to long-term sequelae. For example, Baum and Fleming (1993) conducted a 6-year, longitudinal panel study of a carefully selected sample from the 5-mile radius of the TMI nuclear power plant in central Pennsylvania. The comparison groups included residents living near another nuclear reactor, near a coal-fired plant, and more than 5 miles from any power plant. The TMI group had significantly higher rates of a very wide range of symptoms, including somatic complaints, anxiety, depression, hyperarousal, intrusive thoughts about the accident, avoidance of reminders of it, elevated blood pressure, and elevated levels of urinary norepinephrine, epinephrine, and cortisol. In a similar vein, the Bromet study of mothers of young children living within 10 miles of TMI found that depression and anxiety symptoms were persistently elevated up to 10 years

after the accident, with 35% of the women exhibiting consistently high levels of distress over the period of observation (Dew and Bromet 1993).

In addition, technological events, particularly those that involve radiation exposure (Slovic 1991), lead to another enduring symptom, fear of acquiring cancer or another exposure-related disease. This fear is reinforced when cancers and other illnesses occurring among survivors are attributed, rightly or wrongly, to the exposure. For example, Misao and colleagues (1961) showed that the level of anxiety about developing "A-bomb" diseases was 75% higher in two large samples of Nagasaki survivors compared to controls. It is interesting to note that the persistent fears of radiation disease in people affected by Chernobyl have been given the disparaging label of "radiophobia" (Ginzburg and Reis 1991).

In sum, at least 20% of an exposed population will exhibit symptoms of anxiety, depression, somatization, and/or PTSD, and in some cases these symptoms may persist for years. The rates of disaster-related psychopathology range from 20% to 50%. However, there are some important risk factors associated with its expression. The next section describes both personal and disaster-related risk factors.

3 Risk Factors

Three sets of factors affect adjustment following natural or human-made disasters (Davidson and Foa 1993; Freedy et al. 1993; Table 1): (1) predisaster factors, including gender, psychiatric history, and prior traumatic stressors, (2) within-disaster factors, such as degree of exposure to horror and death, and cognitive appraisal of control, and (3) postdisaster experiences occurring during the recovery process, including informal and formal crisis support.

Table 1. Psychiatric risk factors

Period	Risk factor
Predisaster	Female sex
	Prior psychiatric history
	Prior traumatic experiences
During disaster	Severity of exposure
	Death of loved one or close friend
	Physical threat
	Perceived lack of control
Postdisaster	Inadequate practical support
	Inadequate emotional support
	Inadequate professional intervention

With respect to predisaster variables, a number of studies have shown that women have higher rates of disaster-related psychopathology than men. For example, Shore et al. (1986b) reported that, after the Mount St. Helens (northwestern United States) volcanic eruption, the 1-year onset rates of generalized anxiety, major depression, and/or PTSD were approximately twice as high in exposed women (20.9%) as in men (11.1%). Garrison et al. (1995) also found higher rates of PTSD in adolescent girls during the first few months after Hurricane Andrew (in the southeastern United States) compared to boys (9.2% versus 2.9%). It should be emphasized, however, that gender differences have not been reported consistently across disaster studies (Gibbs 1989), even though in epidemiologic research PTSD, depression, and anxiety are more prevalent in women than in men (e.g. Gruen 1993; Kessler et al. 1994, 1995). To some extent, the gender differences in disaster studies may also be due to the types of measures administered. Although women are more likely to endorse affective and anxiety symptoms, men have higher rates of substance-related problems and disorders (Kessler et al. 1994). Substance problems are often not recorded in disaster studies, even though it is well established that, in men, PTSD is comorbid with substance use disorders. Their consideration might provide a more balanced view of how men and women react to disasters.

A life history of mental disorder, or predisaster mental health status, represents a well-documented risk factor in disaster as well as other types of outcome research and constitutes a crucial vulnerability factor in most stress models (Bromet and Dew 1995; Bromet and Schulberg 1987; Solomon 1992; Gruen 1993; Rabkin 1993). For example, Nolen-Hoeksema and Morrow (1991) studied depressive and post-traumatic stress symptoms in Stanford University students 10 days and again 7 weeks after the Bay Area earthquake. A subsample of them had completed a similar battery of questionnaires 2 weeks before the earthquake. Pre-event symptoms proved to be among the strongest predictors of postevent symptomatology. In our TMI research, preaccident depression and/or anxiety disorder based on the Schedule for Affective Disorders and Schizophrenia–Lifetime (SADS-L) interviews and research diagnostic criteria (RDC) was the most important predictor of depression and anxiety disorders over the 1 year following the accident. In a follow-up of victims of a paint factory fire, Weisæth (1989) showed that, while acute PTSD was linked to the initial intensity of the exposure, outcome 4 years later was influenced more by pre-exposure psychological functioning. Similarly, McFarlane (1988) found a significant association between a history of psychiatric disorder and chronic PTSD in a large group of firefighters in Australia assessed after a major

bushfire. Finally, studies of PTSD in the general population have also found that prior history of psychopathology is a significant risk factor (Breslau et al. 1991; Bromet et al. 1998; Davidson et al. 1991).

Another important set of predispositional risk factors is prior exposure to traumatic life experiences and enduring high levels of strain at the time of the event. The evidence suggests that individuals with prior traumas are more vulnerable to the impact of a natural or human-made disaster (Carr et al. 1997). Indeed, the general population studies of PTSD have also consistently reported that prior traumatic experiences are associated with increased rates of PTSD following subsequent trauma exposure (Breslau et al. 1991; Bromet et al. 1998; Davidson et al. 1991). In general, epidemiologic studies have shown that individuals exposed to both ongoing strain and an acute stressor will be at increased risk for adverse mental health outcomes (Turner et al. 1995). It should be noted that a debate exists as to whether prior exposure to trauma is a risk factor or a protective factor (stress inoculation theory). The weight of the evidence thus far implicates prior exposure as a vulnerability factor.

Far less is known about the effects of predisaster risk factors on the psychological morbidity of children (March and Amaya-Jackson 1993). Recent reviews of the available evidence suggest that the level of distress increases with the child's age and with pre-event mental and physical health problems of the child or his or her parents (Aptekar and Boore 1990; Saylor 1993; Vogel and Vernberg 1993), although the results have not been entirely consistent. For example, in a study of American children exposed to Hurricane Hugo in the southeast United States, Lonigan et al. (1994) found that younger rather than older children were more likely to develop PTSD-like reactions. In contrast, March et al. (1997) did not find that age was a risk factor for post-traumatic symptomatology after the industrial fire in the same region.

It has also been hypothesized that mothers' response to a disaster is not only an important risk factor for the child (Bloch et al. 1956), but for some events, it may be a better predictor of post-traumatic phenomena in young children than direct exposure itself. The extent to which exposure factors, rather than parental reaction, directly predict the psychological response may depend on the age of the children and on the degree of their direct involvement in the disaster. For example, in the study by Pynoos et al. (1987) of elementary school children in the Los Angeles area exposed to a fatal sniper attack on their playground, proximity to the violence was the most important predictor of type and number of PTSD symptoms. In a subsequent study of the Armenian earthquake, Pynoos et al. (1993) demonstrated a similar correlation between proximity to the epicenter of the quake and severity of children's post-traumatic stress reactions. March et al. (1997) showed a clear dose–response effect, with the greatest PTSD symptoms reported by children who witnessed an industrial fire and had a relative or friend hurt or killed, followed by those with a relative or friend who was hurt or killed (only), those who witnessed the event (only), and the lowest level among those with neither exposure. On the other hand, several other disaster studies (Vogel and Vernberg 1993), including our TMI work on very young children (Cornely and Bromet 1986) and school-age children (Bromet et al. 1984) as well as the study by Laor et al. (1997) of preschool children after the Scud missile attack on Tel Aviv, found that mothers' response was the more significant factor. Thus the age of the sample and the nature of the event will influence the findings on risk factors in children.

Turning to the characteristics of the disaster itself, the severity of the exposure is the primary risk factor for the development of postdisaster psychiatric morbidity (Bromet and Schulberg 1987; Green 1994). The intensity derives from the magnitude of the destruction (realized or anticipated as in the case of a nuclear power plant accident), stressors incurred during the evacuation and/or relocation (Milne 1977a), sudden death of a loved one, severe physical harm, cognitive appraisal of lack of control, and predictability and personal threat or worry over future similar events (Freedy et al. 1993; Green 1994). This pattern is illustrated by findings from a study of survivors of a rail accident in England, showing that those who were trapped, witnessed death, or felt at risk of death experienced more PTSD symptoms than other survivors (Selley et al. 1997). In general, the more severe the exposure, the greater the likelihood of psychological impairment in the wake of such events.

Perhaps the most powerful and enduring of the stressors occurring in the immediate aftermath of a disaster is the untimely death of relatives and close friends. Kohn and Levav (1990) commented that, in this circumstance, grieving may be complicated by the other aspects of personal chaos with which disaster victims must cope. As noted earlier, perhaps the most graphic and poignant description of survivors' coping with death and dying is Lifton's (1967) descriptions of the survivors of Hiroshima. Specifically, he vividly depicted the loss of feeling survivors experienced from the extreme agony of witnessing mass death and dying and being unable to respond to calls for help, a phenomenon referred to currently as psychic numbing. This phenomenon and other cardinal symptoms Lifton described have also been observed in other disaster victims and, as noted above, ultimately became criterion symptoms for the classification of DSM-III PTSD. The concepts of intrusive and avoidant thinking also were operationalized in the Impact of

Events Scale (e.g. Horowitz 1990), which has been widely used in disaster research to capture aspects of the disaster syndrome.

In the postdisaster recovery period, practical and perceived support have important relationships to mental health outcomes (Fleming et al. 1982). The theory from stress research, based primarily on studies of individual life event experiences, is that social support should serve to buffer the adverse effects of stress (in this case, from a disaster) on mental health. However, social support can also be considered an aspect of the recovery environment (e.g. Green 1995) or a dynamic variable that can itself be affected by a disaster (Kaniasty and Norris 1993). It is interesting to note that, in many studies, social support is treated as a trait measure (predispositional variable) that presumably is stable over time (Gibbs 1989). Adding to the conceptual confusion is the fact that the findings on the precise role of social support in disaster research (as well as life events research) have been inconsistent. In other words, a few studies have reported that social support buffered some aspects of postdisaster morbidity (e.g. Cook and Bickman 1990; Fleming et al. 1982), while others found direct effects rather than a buffering effect (e.g. Bromet et al. 1982; Murphy 1988). In addition, within a given study, the findings on social support have also been inconsistent across demographically defined risk groups. For example, in a study of the Exxon Valdez oil spill in Alaska, Palinkas et al. (1992) found that perceived family support buffered the effects of exposure on depressive symptoms (assessed by the Center for Epidemiologic Studies Depression scale; Radloff 1977) in Euro-Americans but not in Native Alaskans. In a similar vein, Solomon et al. (1987) reported that spouse support reduced disaster-related symptoms in exposed men but not in women. In our TMI research, we found no evidence of a buffering role for social support in the sample of mothers, but found that a positive family milieu buffered the effects of TMI stress on the current mental health of school-age children (Bromet et al. 1984).

The importance of understanding how different aspects of social support operate in various demographically defined groups cannot be underestimated given its potential role in alleviating the deleterious effects of stress caused by disasters. There is growing evidence that "crisis support" (e.g. people who listen and provide practical and emotional support) promotes aspects of psychological recovery after disasters. Both naturalistic follow-up studies of disaster victims and clinical studies of traumatized patients support the therapeutic value of crisis support. The theory is that repeated discussion about the traumatic memories lessens the feelings of fear and anxiety attached to them. Consistent with this formulation, Dalgleish et al. (1996) showed that greater crisis support when the Herald of Free Enterprise ferry sank predicted fewer avoidance symptoms at 6-year follow-up.

Another consequence of many disasters is the creation of temporary shelters. Far less is known about the impact of temporary settlements on mental health, even though many recent disasters have produced large refugee populations interned in camps without adequate sanitary conditions, nutrition, privacy, or safety (Bromet 1996; Jackson 1991). Survivors of Hiroshima and Nagasaki and those evacuated from the area around Chernobyl were also subjected to social stigma by both health care professionals and lay members of the community. This aspect of the postdisaster experience has not been adequately studied or discussed, although existing data from some interned populations would suggest that the rate of PTSD stemming from this experience might be substantial (Bromet 1996).

4 Implications and Conclusions

This review makes it clear that psychiatric sequelae occur among significant proportions of affected populations and that these clinical manifestations may endure for long periods of time. While some have argued that the psychological effects of disasters are negligible (Perry and Lindell 1978; Quarantelli 1985) or short-lived (e.g. Milne 1977b), the majority of studies conducted since the introduction of DSM-III show that disasters engender substantial morbidity, particularly during the first few years (e.g. McFarlane 1993; Rubonis and Bickman 1991). Moreover, in some instances, such as disasters involving prolonged persecution or radiation exposure, the level of morbidity either did not decrease or indeed increased with time (Chamberlin 1980; Lima et al. 1990a; McFarlane et al. 1987). Logue et al. (1981a,b) lamented more than 15 years ago that few empirical studies of disasters utilized epidemiologic methods. As we have seen, there has been considerable progress in the design of psychiatric disaster research, and the findings on high levels of morbidity have been confirmed in a number of disaster populations.

Unfortunately, there is a dearth of disaster studies with longitudinal designs or extended, long-term follow-up. Thus, while high-risk groups in need of short-term services can be identified, we still have little knowledge of the relationship between short-term and long-term adjustment. Specifically, we have little knowledge of the evolution of disaster-related symptoms and syndromes and the risk factors associated

with course (as opposed to onset) of these disorders in men and women of different ages and different socioeconomic and national backgrounds. Conversely, it is imperative that we learn more about the variables that promote health and protect against adverse mental health outcomes after disasters. Such knowledge can then be used in the formulation of potentially successful interventions.

Several types of intervention strategies following disasters have been implemented. These include public information, community education, crisis counseling, individual and family outreach, and recovery counseling (Lebedun and Wilson 1989). The World Health Organization's Division of Mental Health provides training material and professional services when disasters strike, with the long-term goal of increasing self-reliance in coping with the needs of disaster victims (World Health Organization 1992). Other specific materials are also available from international agencies (see Danieli et al. 1996 for available resources).

The role of the mental health professional in disaster management programs has traditional and nontraditional elements. Such roles can range from assisting with public education and media responses to bolstering indigenous support networks, supporting family members who have lost a loved one, and working with the Red Cross and other relief organizations to provide psychological first aid (Green and Lindy 1994). In addition, new forms of psychological and pharmacotherapeutic treatments are being developed and tested with survivors of trauma (Brady 1997). It should be emphasized that the complex nature of disasters (disasters involve multiple factors acting simultaneously, including physical exhaustion and physical illness, dislocation, unavailability of basic resources) and disaster-induced psychopathology (e.g. comorbidity of PTSD, depression, anxiety, substance use disorders, and somatization, along with the chronicity of these disorders) challenge the design of clinical interventions. Research is currently being conducted on a number of issues. For example, should symptom-specific treatments be administered sequentially or simultaneously? Should medications be combined with cognitive-behavioral treatment from the outset, or should they be added as needed? How effective are the different modalities for children, e.g. debriefing, pharmacological interventions, individual psychotherapy, family therapy (Vernberg and Vogel 1993)? It is clear though, based on the retrospective data from the National Comorbidity Survey (Kessler et al. 1995), that professional intervention can shorten the duration of symptoms by about 2 years.

Finally, as Vernberg and Vogel (1993) note, prevention of psychological trauma requires rapid and appropriate crisis responses from the mental health community. The U.S. military established four principles for treating psychiatric casualties: immediacy (early intervention), expectancy (the attitude that the patient will return soon to duty), simplicity (in the forms of treatment), and centrality (of facilities). Some conceptually similar, important new work on preventing the onset of PTSD is being tested in rape victims, in which they are educated about what symptoms to anticipate, taught relaxation techniques, taken through the traumatic experience, and given home work assignments (Foa 1997). Preliminary results suggest that this combination of straightforward techniques is effective in reducing the onset of PTSD symptoms. If it proves successful, this type of intervention has widespread utility for many disaster situations. While it is difficult, if not impossible, to prevent all psychiatric sequelae from occurring after disasters, our goal should be to reduce the prevalence and severity of the morbidity and the long-term adverse effects.

Psychiatric Problems Related to Persecution and Refugee Status

1
Development of a Diagnostic Concept to Measure the Impact of Persecution

Patterns of psychological distress following traumatic experiences have been described for many years prior to the inclusion of post-traumatic shock disorder (PTSD) in DSM-III in 1980 (American Psychiatric Association 1980). For example, "shell shock," "combat fatigue," formulations denoting a presumed organic basis for trauma-related psychological symptoms, were used during the two World Wars. Kardiner (1941) noted that sufferers from "traumatic neuroses" develop an enduring vigilance for and sensitivity to threat and stated that the nucleus of the neurosis is a physioneurosis. He also noted that the "pathological traumatic syndrome" consists of an altered conception of the self in relation to the world, based on being fixated on the trauma and having an atypical dream life, with chronic irritability, startle reactions, and explosive aggressive reactions. Central in Kardiner's thinking, similar to Janet and Freud, was the fact that "the subject acts as if the original traumatic situation were still in existence and engages in protective devices which failed on the original occasion. This means in effect that his conception of the outer world and his conception of himself have been permanently altered" (Van der Kolk et al. 1996).

After World War II, many psychiatrists in the United States and the United Kingdom tried to apply Kardiner's lessons in the combat theater. They discovered group stress debriefing as well as the use of group psychotherapy and the therapeutic community. Both war and disasters made mental health care professionals aware that, under extreme conditions, the group rather than the individual is the basic unit of study and treatment (Van der Kolk et al. 1996).

After World War II, the long-term effects of trauma were studied in survivors of the holocaust and the Japanese concentration camps. The concepts of "concentration camp syndrome" or "*KZ Syndrom*" were developed, which included not only the symptoms listed under PTSD, but also personality changes which are now referred to as complex enduring personality change after catastrophic experience (ICD-10) or complex PTSD (appendix, DSM-IV). The studies on concentration camp victims showed that extreme trauma had severe biological, psychological, social, and existential consequences, including a diminished capacity to cope with both psychological and biological stressors later in life.

Other diagnoses previously used for the disorder included "adjustment reactions" and "pathological" grief responses. During the process of developing DSM-III, a number of meetings eventually led to the inclusion of PTSD (American Psychiatric Association 1980). All the different syndromes – war sailor syndrome, trench foot, rape trauma syndrome, battered women syndrome, Vietnam veterans' syndrome, and abused child syndrome – were included in the new diagnosis.

Relative to the conceptualization of other psychological disorders, that of PTSD appears to represent a step forward, in that a direct linkage between a known causal agent (a traumatic event) and a resultant syndrome is assumed. Thus, at least in theory, PTSD is an ideal diagnosis; it exceeds the level of a phenomenological description of symptoms.

It has also brought rapid progress to the field of post-traumatic stress studies and interventions. However, interpreting trauma as a disorder prevents us from understanding mass trauma and community stress. We should shift our attention from the debilitating or disturbing aspects to include aspects of normal processing of traumatic events and even of potential growth (Tedeschi et al. 1998).

1.1
Long-Term Effect of Persecution

Krystal (1988) studied the long-term outcome of massive traumatization in concentration camp victims. He suggested that the core experience of being traumatized consists of "giving up" and accepting death and destruction as inevitable. He noted that the trauma response evolves from a state of hyperalert anxiety to a progressive blocking of emotions and behavioral inhibition. In his view, trauma leads to a "dedifferentiation of affects." Traumatized patients come to experience emotional reactions merely as somatic states, without being able to interpret the meaning of what they are feeling. They become prone to undifferentiated affect storms and psychosomatic reactions. Most of the initial studies on the effects of World War II were conducted by investigators who had participated in the war or had survived concentration camps (see Dohrenwend 1998).

Lomranz (1995) reviewed the research literature on the holocaust and came to the conclusion that most studies have the following limitations:

1. They are anchored in a psychoanalytic or psychodynamic theoretical orientation.
2. They are limited mainly to intrapsychic dimensions.
3. They are seldom empirical.
4. They use extremely small samples and clinical case studies.

5. They disregard the importance of sample selection procedures.
6. They have patients as their subjects.
7. They overinclude and do not specify the exact nature of the trauma (e.g. concentration camp, hiding).
8. They lack control groups.
9. As their major focus of investigation, they have themes concerning deficiency, symptomatology, or psychopathology.

Lomranz mentions that the more recent empirical studies have underscored the remarkable adaptive capacities of survivors, revealing minimal, if any, differences with nonsurvivor control groups. In his view, the studies show that survivors experience well-being and satisfaction in their work, marriage, and family and enjoy social interactions. In some aspects of adaptation and well-being, survivors sometimes score even higher than those who did not experience the holocaust. The studies with a positive outcome quoted by Lomranz date from the 1980s. Other studies from a somewhat later period are more pessimistic; they confirm the clinical impression that survivors of World War II are at risk of a delayed onset or worsening of post-traumatic symptomatology during the later phases of the life cycle, sometimes after decades of adequate coping. This pertains to survivors of Nazi persecution, military veterans, former members of resistance movements, and war sailors. For example, Op den Velde et al. (1993) studied former members of the Dutch resistance during World War II and found that the time of onset of the first symptoms of PTSD was highly variable. The first occurrence of symptoms suggestive of PTSD followed in 31.7% of the studied population immediately or almost immediately after World War II. In 50%, PTSD was first manifested more than 20 years after the end of the war. Hovens (1994) found that, 45 years after the war, 56% of these male Dutch resistance fighters appeared to have current PTSD according to the Structured Clinical Interview for DSM-III-R (SCID). Only 4% of the sample was symptom free. It was found that veterans with PTSD had longer periods of resistance work and subsequent imprisonment. This suggests that the actual duration of the stressful circumstances may have contributed substantially to the occurrence of PTSD.

Tennant et al. (1993), in a controlled follow-up study with former Australian servicemen who were interned in Japanese prisoner-of-war camps, showed a significant increase of psychiatric disorder when the target group was between 46 and 66 years of age. A similar trend was noted in several other studies (see Aarts and Op den Velde 1996).

1.2 Transgenerational Traumatization

The late sequelae of World War II are still visible today, both among patients and in art and literature related to that period. Concentration camp survivors, resistance fighters, combat veterans, and civilian victims often struggle with the prolonged consequences of the violence and abuse inflicted by the war. It may be expected that these victims and survivors could not adequately comply with the needs and wishes of their children born after World War II, the so-called second generation. Numerous clinic-based observations have suggested that some of the effects of the persecution of parents were transmitted to their offspring. The traumatization suffered by the survivors – with its prolonged psychopathological and psychosocial after-effects, including familial losses, often of spouse and children, the frequent hastily contracted marriages upon liberation, and problems arising from resettlement – among other factors, were thought to impair parenting abilities (Levav 1998). A number of clinical studies reporting on the influence of the war on survivors have been summarized along three lines (Van der Velden and Kleber 1999):

1. *Unbalanced interaction between parents and children.* This unbalanced interaction manifested itself in several ways. First, it became apparent in difficulties in separation and individuation. Parents had experienced so many losses and separations during the war that they felt threatened by the idea that their child was growing into an independent, autonomous individual. They felt as if they were losing their child. Not being able to support the child's need for independence might lead to an "anxious attachment" between parent and child (Bowlby 1981). This anxious attachment can manifest itself in difficulties with small separations (e.g. going on a short holiday, playing at friends' houses) as well as in overprotection or overinvolvement (Russel 1980). Second, it was shown in lack of emotional support. Parents were often so occupied by the reminiscences of the war that they could not be empathetic to the emotional needs of their children or provide affection and support. A third problem was "parentification." The memories and intrusions of World War II made the parents psychologically vulnerable. Children easily register the distress and vulnerability of their parents, even if these are masked. As a result, children may feel responsible for their parents' well-being, which may result in a reversal of family roles. The parent assumes the dependent role, while the child

acquires the caring and supporting role and becomes parentified (Sigal et al. 1973).
2. *Management of emotions, in particular aggression.* Feelings of rage and hostility were often difficult to handle for those who survived the ordeals of the concentration camps of World War II. Violence was omnipresent in the camp, but at the same time a prisoner had to control his or her feelings with the utmost care in order to survive. Against such a background, aggression can become a difficult emotion in postwar life. Anger and aggression therefore often manifest themselves as extremes on the poles of a continuum. They may become extremely inhibited, sometimes resulting in outbursts of anger, or manifest themselves frequently.
3. *The burdensome theme of war in the family.* War-stricken parents often hardly discuss their war memories with their children. Their reluctance can be motivated by the wish to protect their children from the atrocities and horrors of the war. This attempt may paradoxically result in the opposite. The child does not dare to ask questions and tries to fill the gaps with his or her own imagination. The silence with regard to war memories is indicated as a conspiracy of silence (Danieli 1985) or as a family secret.

The issue of transgenerational traumatization is subject to debate. Children of victims, exposed to their parents' symptomatology without themselves undergoing violence, persecution, or war, may show the characteristic traumatic stress symptoms of intrusion, hyperarousal, and enactment similar to their parents. Parental reactions to the experience play a crucial role in the child's responses, at times determining the child's reaction to the traumatic event. Trauma clearly has a contagious effect (Steinberg 1995). Nevertheless, the child's resilience and available supports may modify the impact. In a study on the long-term effects of the Vietnam war, Kulka et al. (1991) found that children with a veteran parent suffering from PTSD had significantly more behavioral problems than did children of veteran parents without PTSD. These findings may help explain the transmission of post-traumatic stress to offspring who were spared the actual traumatic experiences.

In a study of the children of U.S. prisoners of war held during the Vietnam war, McCubbin et al. (1977) found indications of the transgenerational effects of captivity. The long-term strains of internment affected parent–child relationships and children's functioning in general, as was shown, for example, in school performance and dysfunctional symptoms of the child. A longitudinal analysis of 42 families showed factors that could account for these effects:

1. The severity of the mental abuse suffered during internment
2. The severity of physical abuse
3. The wife's relationship with her parents
4. The wife's involvement in the activities of the former prisoners of war

The father's involvement in preparing the family for separation was found to be a positive factor in subsequent family relationships. Children of survivors of the Nazi holocaust are a well-documented group with regard to the indirect effects of violence on children. For example, Rakoff et al. (1965) found that Holocaust survivors exhibited negative effects due to the traumatic experiences of their parents. Mooren and Kleber (1996) did two studies, one on the children of Jewish World War II survivors and one on children whose parents survived the Japanese camps in the former Dutch Indies during World War II. These studies do not confirm previous studies in which no significant differences between survivor and control group children were found. The findings of Mooren and Kleber (1996) indicate that only a few differences exist in health and parenting styles between the second generation and the comparison groups they studied. The problems of the second generation are related to the coping disturbances of the parents due to the war. Their data confirm the results of a double-blind research design that was used in Israel (Brom et al. 1994). Both studies demonstrated a small and significant difference between the offspring of holocaust survivors and their peers. These and other empirical studies (Solkoff 1992) made clear that there are some long-term aftereffects of the war in the offspring of war survivors. However, in contrast to clinical observations, studies conducted in the community did not show evidence that the offspring of concentration camp survivors have more psychopathology than controls (Levav 1998). It appears that the concept of transgenerational traumatization is rather inappropriate (Figley and Kleber 1995). The children of concentration camp survivors have not themselves experienced traumatic events. It is their upbringing that is hindered by war memories and their parents' feelings of guilt and loss. The disturbances in the offspring of war survivors are not as much an issue of transmission of trauma as an issue of a specific socialization.

These studies have several implications for clinical workers, either in the West or in low-income countries, where man-made or natural disasters are much more prevalent than in the West. Clinicians are confronted with the subtle task of unraveling a patient's history to find out whether and to what extent the parents' war experience has an impact on the life of their patients.

1.3
Cultures of Fear

The state production of fear has led researchers to speak of "cultures of fear" or "frightened populations" (Corradi et al. 1992). Salimovich et al. (1992) have identified three core features of persistent fears among the Chilean population: (1) a sense of personal weakness, vulnerability, and a feeling of powerlessness; (2) sensory perceptions remaining in a permanent state of alert; and (3) the impossibility of testing subjective experience against reality. Cultures of fear are not only produced by states in Latin America, but also by (para)militia or police forces, e.g. in the former Yugoslavia, the Caucasian republics, or Sri Lanka, as well as by cults of violence and counterviolence, e.g. in Mozambique, Uganda, Liberia, or Sierra Leone (Jeyaraja Tambiah 1992; K.B. Wilson 1992; Allen 1991). During and after a war, the "culture of fear" may interact with the chronic sequential war traumas and with the daily difficulties of living in a devastated area, a refugee camp, or a repressive environment. This leads to a continuous traumatic stress syndrome showing similarities with complex PTSD or enduring personality change after catastrophic experience. These individual diagnoses show a striking similarity to the above-mentioned core features of the "cultures of fear." We know little about the consequences of this interaction, and on the personal level empirical research hardly exists (Shresta et al. 1998). On a community level, it is tempting to hypothesize a relation between this continuous traumatic stress and the occurrence of recurrent violence as a temporarily "effective" but in the long run adverse collective coping strategy, e.g. in the Middle East, southern Africa, Algeria, Latin America, or the former Soviet Union. It is also tempting to postulate that the violence in Israel and Palestina or in the South African townships, for example, is to some extent a rebound phenomenon of a rebellious younger generation which is no longer willing to endure the humiliations or a perceived lack of resistance in their elders. The prevailing fear and suspicion weave their way into society and affect mutual support structures, personal commitments, belief in justice, and belief in democratization and human rights.

2
Refugees and Displaced Persons

2.1
Scope of the Problem and Its Geographical Distribution

The number of refugees has grown enormously over the last decades. In 1960, there were estimated to be 1.4 million refugees worldwide. By 1978, there were 4.6 million refugees seeking (international) assistance and protection. Grant (1979) estimated a total of 13 million worldwide in 1979, and Cohon and Westermeyer mention a total of 16 million refugees in 1981 (Cohon 1981; Westermeyer 1989). By the beginning of 1993, the United Nations High Commission for Refugees (UNHCR) reported a total of 18.2 million refugees and estimated the number of internally displaced people (refugees within the borders of their own countries) conservatively at 24 million (Long 1992; UNHCR 1993). The United States Committee for Refugees (USCR) (1992) mentions a current estimate of 20 million refugees covered by the 1951 UN Convention on the Status of Refugees and 20 million internally displaced persons. Many of these refugees are destitute people from poor countries who travel within or to other impoverished countries. This displacement can destabilize the host countries, aggravate regional tensions, and increase rates of environmental degradation. In Mozambique alone, for instance, the number of internally displaced persons was estimated at four million and the number of refugees at more than one million out of a total population of 14 million. Meanwhile, established nations that have traditionally offered asylum are increasingly unwilling to open their doors to massive refugee flows (Desjarlais et al. 1995).

The total number of refugees is increasing as the number of people seeking refuge is growing faster than the number of refugees whose plight is resolved through repatriation or resettlement. For every legally defined refugee, there are many more internally displaced people who suffer no less psychosocial trauma and who may not formally be identified, but who are vulnerable to similar mental disorders as refugees. Studies of the dynamic flow of uprooted populations confirm that groups may be refugees yesterday, repatriated today, and internally displaced tomorrow. In addition to the approximately 20 million official refugees, there are countless other economic and environmental refugees in the world today. More than 70 million people around the world have left their native countries, primarily in search of work. At least 10 million of these have fled from environmental decline, land degradation, and diminishing agricultural and water resources (Desjarlais et al. 1995).

The regional distribution of the refugee problem is far from even. According to Leopold and Harrel-Bond (1994), Africa contains about 30% of the world's refugees and perhaps half of the internally displaced. Europe accounts for about 3.75% and North America account for about 10.25% (including an estimated 2 million refugees from the former Yugoslavia), and the Middle East and South Asia for about 50%. Clearly, these figures are subject to fluctuation due to the volatility of national and international relations, for

example in Burundi, Congo, Rwanda, Sri Lanka, Ethiopia and Eritrea. In Africa, 70% of the refugee burden is borne by 12 countries. All 16 of the least-developed African countries are affected by the refugee problem.

Western countries spend US$ 5–7 billion on less than one million refugees in the West, while a mere US$ 340 million is spent by the UNHCR on the 17–19 million refugees in the rest of the world (Harrel-Bond 1991).

Both disasters and wars have a differential impact in low-income countries. In the period 1967–1991, an average of 117 million people living in developing countries were affected by disasters each year, as compared to about 700,000 in developed countries (a striking ratio of 166:1). War represents the most ancient and the most important form of human-made violence in terms of the magnitude of its effects. Since World War II, there have been 127 wars and 21.8 million war-related deaths. The Red Cross estimated a total twice as high, i.e. about 40 million people killed since WW II. All but two of the 127 wars have taken place in developing countries (McFarlane and de Girolamo 1996).

2.2 Psychosocial and Mental Health Consequences

Forced migration and the refugee status are often consequences of circumstances of degradation, violence, dehumanization, and torture. As was just mentioned, this is particularly true in low-income countries, where the combination of low-intensity warfare and high-intensity lethal weaponry is one of the major causes of displacement of large numbers of people, especially women and children. The militarization of these countries, which may even nowadays be the arena for conflicts between the superpowers, is a major cause in the present-day global refugee problem (Jablensky 1994).

All aspects of the refugee's ordeal take their mental and physical toll: the events precipitating the act of relocation (war, persecution, hunger, disaster, death), the process of relocation (upheaval, a long journey on foot under mental and physical strain), and the often temporary settlement in a refugee camp (discomfort, uncertainty, oppression). The resulting long- and short-term mental health and psychosocial consequences are many and varied.

2.3 Risk Factors and Mental Disorders

Jablensky et al. (1994) discuss more specific risk factors that are implicated in the development of mental disorders in refugees. These include the following: marginalization resulting in loss of self-esteem and self-confidence; socioeconomic hardship resulting in poverty, deprivation, and unemployment; poor physical health due to poor sanitation, poor nutrition, or crowding; head trauma and other physical injuries; collapse of social networks resulting in anomie, alienation, and isolation; and mental trauma due to torture, death, loss, and fear. Sartorius (1994) mentions factors which may help to mitigate several of these risk factors: opportunity to promote cohesion (versus active dispersion); continuity of life span (versus neglecting life span); promotion of initiative (versus punishing it); clear knowledge about the future (versus an uncertain future); job opportunities (versus unneeded or obligatory work); fostering a social network (versus no social network); rules of conduct (versus rules by accident); and setting goals in life (versus living from day to day).

The general effects of trauma are varied but can be described by some combination of the following: feelings of extreme vulnerability, helplessness, or despair, intense, panic-level arousal and negative emotion, a sense of being stunned, numb, and depleted, and an altered consciousness or awareness that entails a sense of derealization and depersonalization (also referred to as dissociation) (Litz and Roemer 1996). More specific mental disorders observed in refugees and attributable to their circumstances include PTSD (Friedman and Jaranson 1994), depressive disorders (Silver and Iacono 1984; Westermeyer 1986), substance abuse (Keehn 1980; Peak et al. 1981; Westermeyer 1985), panic disorder, generalized anxiety, phobia, antisocial and other personality disorders, psychosis (Yesavage 1983), childhood developmental problems, organic brain syndrome (especially in victims of violence), and associated medical and social problems (Corcoran 1982).

2.4 Morbidity Among Adults

PTSD is currently the focus of public and scientific interest. However, few epidemiological estimates exist of the overall prevalence of PTSD (regardless of exact cause) in the general population and especially in those areas of the world where wars are highly prevalent.

The Epidemiological Catchment Area survey found a lifetime PTSD rate of 0.5% among men and 1.3% among women. The number of those who showed some symptoms after a trauma was substantially higher, i.e. 15% among men and 16% among women, with an average of 2.4 symptoms (Helzer et al. 1987).

A number of studies have assessed the prevalence of PTSD among Vietnam combat veterans. The National

Vietnam Veterans Readjustment Study (NVRRS) appears to be the most validated epidemiological study of the prevalence of PTSD among Vietnam combat veterans in the general population. Current prevalence rates (6 months prior to assessment) for men and women were 15.2% and 8.5%, respectively. Lifetime prevalence rates of PTSD for men and women were 30.6% and 26.9%, respectively (Kulka et al. 1991). A study of over 2000 monozygotic twin pairs found a prevalence of PTSD of almost 17% in twins who served in South-East Asia compared to 5% in co-twins who did not do their military service in Asia (Goldberg et al. 1990).

Kaličanin et al. (1993) studied 384 war veterans in 21 psychiatric institutions in Serbia between 1991 and 1993. The most frequent diagnoses among war veterans were adjustment disorder (34%) and PTSD (27%). Among refugees the diagnoses that were encountered most frequently were adjustment disorders (27%), mixed anxiety and depressive reaction (25%), and acute and transitory psychotic disorders associated with stress (40%). The most frequent stressors related to these problems among refugees were separation from loved ones (15%), loss of property (15%), and the combination of several stressors (45%).

Rundell et al. (1990) reviewed all controlled studies of psychiatric disorders reported to be associated with war and other traumatic events. They mention four studies of concurrent psychiatric disorders in combat veterans with PTSD. Additional psychiatric diagnoses are alcohol abuse or dependence (41%–80% of PTSD patients), depression (8%–72%), and drug abuse disorders (16%–50%). Antisocial personality disorder has been reported in 3%–40%, social phobia in up to 50%, and bipolar disorder in 10%–25%.

De Girolamo and McFarlane (1996) provide an overview of the epidemiology of PTSD. Two groups of studies in their overview pertain to the consequences of persecution. The first consists of ten studies on prisoners of war and other types of prisoners, generally those imprisoned for political reasons. These studies were conducted in the United States, Germany, Turkey, Australia, and France. In all these studies, the PTSD rate varied between 50% and 70% or sometimes more. There were patients who suffered from PTSD symptoms for the first time decades after the end of their imprisonment; many others were still suffering decades after the end of detention and the first appearance of the disorder. Some studies have found an association between the appearance and the severity of PTSD and the length and the severity of imprisonment, the latter being mainly evaluated by the experience of torture and by the percentage of body weight lost. The second group of studies in their overview consists of 12 studies assessing the rate of PTSD among samples of refugees. Nine of the 12 studies were carried out among samples of resettled refugees, mostly South-East Asians. Looking more closely at some of these studies reveals the following picture. South-East Asian refugees in the United States and Canada show high rates of psychiatric disorders. According to Westermeyer (1988), 44% of Hmong adults in a 10-year follow-up in the United States qualified for an axis I disorder (13%) or chronic adjustment troubles plus depressive symptoms (31%). Among Cambodian, Hmong, Laotian, and Vietnamese psychiatric patients in the United States, Mollica et al. (1987) found that 50% of the patients suffered from PTSD. Except for one patient, the diagnosis of PTSD was consistently associated with another psychiatric diagnosis, primarily major affective disorder. Patients with PTSD had experienced twice as many traumatic events as patients with other psychiatric diagnoses. On average, the refugee patients had experienced ten traumatic events such as lack of food, water, or shelter, imprisonment, war injury, sexual abuse, or witnessing death or murder. They also witnessed an average of 1.6 instances of torture. Kinzie and Manson (1983) and Nguyen (1984) report similar data. In a study among Somalian refugees in Europe, 38% of the refugees suffered from PTSD, and an additional 60% from partial PTSD (Roodenrijs et al. 1998).

The remaining three studies are the only studies carried out among victims of wars or refugees in the afflicted areas in low-income countries. Mollica et al. (1993) studied 993 Cambodian refugees on the Thai–Cambodian border. During the Khmer Rouge regime (1975–1979), more than 85% reported lack of food, water, shelter, and medical care, brainwashing, and forced labor; 54% reported murder of a family member or friend; and 17% reported rape or sexual abuse. During the refugee period (1980–1990), most of these figures decreased to some extent; during the same period only reports of murder, head injury, and rape/sexual abuse decreased to 5%. Fifty-five percent qualified for a depression, and 15% for PTSD. Summerfield and Toser (1991) conducted a study in Nicaragua. Since they interviewed a small sample of convenience with the General Health Questionnaire, which was not validated for Nicaragua, firm conclusions can hardly be drawn from their data. Ramsay et al. (1993) looked at a sample of torture victims that found refuge in Great Britain. This means that only one of the three aforementioned valid epidemiological surveys carried out so far was in a low-income country (Mollica et al. 1993). El Sarraj et al. (1996) found prevalence rates of 20% or more among 550 torture survivors in Gaza. Shresta et al. (1998) studied 526 Bhutanese torture survivors and a matched control group in Nepal. A diagnosis of PTSD was significantly more common in the tortured group (14%) than in the nontortured group (3%). Significantly more tortured

refugees had high anxiety scores (43% versus 34%) and high depression scores (25% versus 14%).

In Africa, a few descriptive studies have been done to assess psychosocial and psychiatric problems among various populations such as refugees and displaced persons. So far, no valid epidemiological studies have been published.

Based on these studies, it may be concluded that, in general, PTSD rates among victims of wars and persecution are 50% or higher, that these victims often suffer from additional psychiatric disorders, and that they have usually faced very difficult circumstances (e.g. torture, starvation, witnessing killings) and are a highly traumatized population.

2.5 Traumatic Stress and Its Consequences for Children, Adolescents, and Families

Tens of millions of children are victims of persecution or misfortune, becoming refugees, displaced persons, child soldiers, or casualties of war. Of the above-mentioned 43 millions refugees and displaced persons in the world, 70%–80% are mothers with children (Forbes Martin 1992). The current increase of refugee populations, both in low-income and in high-income countries, creates a causal chain of disruption of communities and families. Women, children, and the elderly are particularly vulnerable according to the literature (Desjarlais et al. 1995). However, based on our own experience among the Lhotsampa refugees from Bhutan in Nepal, Sudanese refugees in Northern Uganda, or refugees in the shelters surrounding Addis Ababa, for example, men are afflicted at least as seriously as women; both peasants and white-collar workers mostly lack the opportunity to pursue their profession, which impairs their social identity. Women on the other hand maintain a social role raising their children, doing household chores, or engaging in petty trade. However, this accumulation of tasks, their sense of responsibility for their idle husbands, and the risk of being raped do make women a vulnerable group.

The surviving elderly often carry a heavy responsibility in the transmission of cultural values. This transmission often takes place during elaborate rites of passage, which can be inhibited in the refugee camps due to high costs, the long duration of the rituals, or restrictions imposed by camp authorities.

The hardship of children is compounded by their dependence on parents and by their mental and physical vulnerability. In (post)war conditions, parents may themselves suffer from mental or psychosocial problems, which in turn affect their children. If both parents have died or are lost, as often happened in Rwanda, for example, the children may be left to fend for themselves. Crude death rates among refugees and internally displaced persons soar to levels as high as 50 times the baseline crude death rate in their home areas. Most of these deaths occur among young children. During periods of displacement, the mortality rate can be as much as 60 times the expected rates (Toole and Waldman 1993). Among displaced Kurds in northern Iraq, 63% of the deaths occurred among the 17% of the population younger than 5 years (Yip and Sharpe 1993). In addition, children are especially at risk for developmental attrition, aggressive and antisocial behavior disorders frequently associated with substance abuse, and seizure disorders (Westermeyer 1989; Desjarlais et al. 1995). Developmental attrition results from the failure to reach normal developmental landmarks, so that cumulative defect becomes even larger. It is the result of inadequate intake of nourishment vital for body and mind: proteins, calories, and micronutrients; perceptual and cognitive stimuli; and social relations and interactions. Attrition manifests itself in three ways: physically, as height and weight well below norms for age; in school settings, as learning failure and retarded mental development; and behaviorally, as psychiatric disorder and social deviance. The disadvantages to which poor children are subjected – especially when they are exposed to manmade disaster – start during pregnancy. Poor nutrition and limited health care during pregnancy increases the likelihood of poor outcomes. If children born of a complicated pregnancy are reared under adverse social conditions, they will suffer long-term retardation in cognitive development (Desjarlais et al. 1995). These children are also at risk of developing schizophrenia later in life, whereas children with pellagra have a higher risk of developing dementia in adulthood.

Children need familial support and must live in communities rather than in orphanages or resettlement camps. The wars in Mozambique, Zimbabwe, Eritrea, Rwanda, Congo, and Sudan have led to the orphaning or dislocation of thousands of children who have been witness to the bloody conflict. One of the priorities for abandoned children is family reunion. In addition to the usual ways of family tracing by means of photographs or radio messages, the present author was interested to learn of the way Sudanese children were supported in a refugee camp in North Kenya. For about 5 years, this group of nearly ten thousand children had been fleeing forced circumscription by either the northern Sudanese army or one of the guerrilla movements of southern Sudan. Each plot in the refugee camp had a large sign of one of the southern Sudanese cities so that children could try to find one of their family members back. Children who did not find a family member lived under the supervision of an adult who received a modest per

diem for his or her work. Fifty children living in ten huts in a circle cooked their own meals, visited schools, and had leisure activities under the supervision of their tutor. This kind of solution is preferable to orphanages that are often set up with the best of intentions but with questionable results. Children in orphanages in Mozambique often appear withdrawn, apathetic, regressed, and fearful. Orphanages for girls often turned into a breeding place for prostitution, whereas orphanages for boys easily resulted in banditry.

Children are not only easy victims of the violence, but they are also actively drawn into the violence. During the drafting of the Declaration of the Rights of the Child, several low- and high-income countries opposed to the minimal age of participating in a war being increased to 16 years. In a number of African, Latin American, and Asian countries, children are forced into a military training and service. Many boys are forced to serve as porters or to serve in a (rebel) army, whereas young girls are forced to serve as housemaids or are sequentially raped as "partners" of soldiers. This was a common fate in Mozambique, and it still is for children and adolescents in northern Uganda if they are abducted by the Lords Resistance Army or by one of the rebel movements. Insubordination, be it refusal to follow orders or an attempt to desert, can result in summary execution. Many children were forced by RENAMO to kill a parent or an inhabitant of their own village to make it impossible for them to return to their home village and so to transform them into willing tools of war (Minter 1989; Geffray 1990; Vines 1991). These and similar atrocities, such as cutting off body parts in Mozambique, equal those committed by the Lords Resistance Army or Holy Spirit Movement in Uganda, the Khmer Rouge regime in Cambodia, or in Sierra Leone.

Violence can become a dominant way of being in the world. Acts of violence can work their way into the practices of everyday life. Violence relates both to effective ways of acting in a community and to a reworking of the moral sensibilities that define those ways of acting.

As a consequence of trauma and violence, children may show symptoms of silent withdrawal or hyperactivity accompanied by violent behavior. Regression to earlier developmental stages is common. Preschool children may show frequent or continuous crying, pathological behavior involving clinging, bedwetting, and loss of bowel control, thumb and finger sucking, frequent nightmares and night terrors, as well as unusual fear of actual or imagined objects.

Children of early school age display similar behavior and are overtly unhappy, nervous, restless, irritable, and fearful. Self-stimulation such as rocking or head banging may be observed. In addition, refusal to eat and physical complaints with a psychosomatic basis (headache, dizziness, abdominal pain) are frequent. These children may also display behavior appropriate of much younger children, such as prolonged muteness and bed-bound incontinence or clinging behavior. They frequently have specific fears, e.g. of being left alone in a room or of situations which remind them of traumatic events. Such reactions may be limited to a couple of days or weeks or may persist over a period of months or years. Many of these children become victims of a continuous strain trauma. Such trauma can result in personality disorders and even have knock-on effects in descendants, as was mentioned before.

War-related fears weave their way into the mental lives of exposed children. A study of 3- to 9-year-olds in Lebanon indicated that war was the major topic of conversation in 96% of the children, of play in 80%, and of drawing in 80% (J. Abu-Nasr, unpublished). The drawings of Ugandan refugee children indicate their preoccupation with their experiences of violence, death, and starvation. Drawings depict soldiers shooting their mothers, infants bleeding to death, decapitations, dogs eating human corpses, and people crouching in the forests with jutting ribs and swollen bellies. In a follow-up after 1 year, these children were still producing such drawings (Harrel-Bond 1986). A study of child refugees in Mozambique showed that 77% of the children had witnessed murder and 51% had been physically abused or tortured. A total of 64% of the children were abducted, and of these 75% were forced to serve as porters and 28% were trained for combat (Boothby et al. 1991). Sudanese refugee children in North Uganda suffered significantly more from the war than the Ugandan children in the same area: 94% of the families lost their property, 81% lost a family member, 92% suffered from a lack of food or water, 62% had no medical care when illness occurred, 28% of the children had been tortured, and 25% been lost or kidnapped. Compared to the Ugandan children, the Sudanese children reported significantly more PTSD complaints such as trouble sleeping, nervousness, traumatic memories, behavioral problems, depressive symptoms, and psychosomatic complaints. Despite these adversities, the plight of these children has not come to an end, since the situation in these camps – as in many other refugee camps – is extremely difficult. The Sudanese children experience considerably more daily difficulties than the Ugandan children. This is mainly caused by the poverty in the camps. The refugee children report lack of food, lack of clothes, lack of school materials, poor sanitation, and lack of medical care. They also have to contribute to household tasks, mainly because their mothers spend a great deal of time obtaining water and firewood (Paardekooper et al. 1999).

Straker et al. (1992) carried out a 3-year follow-up study of 60 young people in South-Africa. They wanted

to find out the extent to which exposure to political violence and violent conduct within that context can become generalized in behavior in other situations. All the adolescents had been abused by the police. Despite their adverse backgrounds, their militancy, and their endorsement of violence as a political tool, they did not see violence as an end in itself. Only a minority saw violence as a means to further personal gain and revenge.

Dawes (1990) studied women and children who were involved in riots in South Africa. A total of 52% of unmarried and 69% of married women suffered from PTSD. Nine percent of children suffered from PTSD, and the symptoms were most common among children whose mothers suffered from PTSD. Macksoud (1993) studied 220 children between the age of 6 and 16 years in Greater Beirut. A total of 83% had been exposed to shelling, 63% to combat, 60% to a change of residence, 55% deprived of food, 53% had their house bombarded, 11% witnessed a killing of an extended family member or other, and 9% witnessed a panic reaction in an extended family member. She also found that the number of traumatic events experienced ranged from 0 to 20, with an average of 5.75. In their study on the effects of the Gulf war in Irak, Dyregrof and Raundalen (1993) found that 90% of children had lost an average of four friends. Pynoos and Nader (1993) found that, among 51 Kuwaiti children within the age range of 8–21 years, 86% knew people who had been captured, 76% people who had been injured, 65% saw injured or dead people, 31% reported severe post-traumatic reactions, 40% moderate, 29% mild, and 4% of children reported no reaction.

Punamäki (1982) found that 35% of a sample of Palestinian children had symptoms of fear, 22% showed withdrawal behavior, 27% difficulties sleeping, 92% nightmares, and 80% were afraid that the Israeli army would attack their homes. She later found that strong ideological commitment in children between the age of 10 and 16 had a moderating effect on anxiety, insecurity, and depression (Punamäki 1996). The more the mother is socially embedded, politically active, and ideologically (or religiously) committed, the better her mental health and that of her children (Punamäki 1989).

Baker (1990) explored the effect of violence on a sample of 796 Palestinian children. A total of 80% started out fighting each other, 25% exhibited destructive behavior, one third suffered headaches, and one third difficulties sleeping, 12% bit their nails, and 43% felt depressed. Qouta et al. (1995) studied Palestinian children aged 11–12 years and found that the more traumatic experiences they had and the more they participated in the intifada, the more concentration, attention, and memory problems they had. Rosenbaum and Ronen (1992) studied 277 Israeli children to explore the effects of violence. They found a high rate of anxiety, especially in the evening, which was very high in the first weeks, but started to decrease in the fifth week. Females were more anxious than males, and there were similarities between the perception of the child and his or her parents concerning the danger. Solomon (1994) compared Israeli children in a high-exposure area with a low-exposure area. Children from the shelled area reported more coping activities than children in a nonshelled area. Children focusing on threat reported more psychological stress than children who focused on avoidance. In a study on the psychological sequelae among Angolan adolescents 6 months after the 1993 war, Ventura (1997) studied three adolescent groups differing in their degree of war exposure. The results show that the prevalence and symptoms of PTSD were greater in the refugee group (90%), followed by the nonrefugees living in Lubango (82%), and the Angolans who at the time of the study had resided for more than 1 year in Portugal (22%). There was a relationship between increased war exposure and an increase in anxiety, depression, adjustment, and behavioral problems and a decrease in intellectual functioning and self-concept. It is praiseworthy that – in contrast to adults – so many studies on children have been carried out in the afflicted areas.

However, in comparison to adults, a limited number of studies exist on children and adolescents who became refugees in a host country. Kinzie et al. (1986, 1998) found a 50% prevalence rate of PTSD in 40 Cambodian adolescents living in the United States who had been exposed to war trauma. They found that the prevalence of PTSD and depression continued to persist for years after their initial diagnosis in these refugees who were traumatized as children. Arroyo and Eth (1985) found that one third of 30 Central American refugee children (17 years or less) met criteria for PTSD. Mghir et al. (1995) found that 34% of 38 adolescent and young adult Afghan refugees in the United States met criteria for major depression, PTSD, or both.

Mahjoub (1995) provides a summary of our knowledge about the psychosocial consequences of wars among children and adolescents. Children appear to suffer less from wars than adults for the following reasons: children forget easier, are less concerned and too young to understand the horrors, and have the future to distract them from the past. Mahjoub's second conclusion is that, in addition to the short- and medium-term effects that have been studied so far, the long-term effects of wars on children need additional attention. Third, the traumatic syndrome among children has not yet been well defined. One of the reasons for this is that the presence of symptoms depends

on the measurements used (e.g. asking the mothers instead of the children about anxiety or depression). Fourth, although the differences in symptoms between boys and girls are virtually nonexistent, certain age-groups are less vulnerable than others (e.g. until the age of 2–3 years and during the latency period). Fifth, the stress of children is mediated through their environment; the role of the family has been shown in the British studies after World War II as well as in studies in kibbutzim and among Palestinians, for example.

2.6
Reaction of the Donor Community

The position of bilateral or multilateral donors is often ambivalent with respect to mental health care among refugees. Most refugee programs are emergency oriented in material and logistic terms, emphasizing food and shelter. So far, little attention has been paid to the psychological state of refugees within their cultural context. Refugees have often been reduced to mindless or psyche-less individuals whose only recognized needs are material and physical. This attitude is partially due to the perception that the degree of trauma suffered by refugees is such that their problems are too overwhelming to address. Therefore, until recently, only a few relief and development agencies included psychosocial problems on their agendas. In this way, they unwittingly contributed to a "conspiracy of silence and denial," as it has been described in the literature on the post-holocaust era, for example. The argument is often advanced that it is impossible to do anything substantial or meaningful. This results in an avoidance of the issues of the individual psychological suffering and of the attendant economic consequences. At the same time, this reaction of the (Western) donors seems to be a repetition of its own postwar coping style.

Discussions that the present author has had with Africans from various socioeconomic backgrounds have indicated that the issues of individual and collective grief and bereavement are much more important – both in terms of personal and economic consequences – in Africa than in the West. Asians seem to take an intermediate position in this regard.

The increase in refugee populations implies a progressive disruption of the natural social life of communities or families living in camps, which easily become "total institutions" in Goffman's sense. Learned helplessness and a "dependency syndrome" may develop (von Buchwald 1994). This is especially likely to happen in camps incorporating the same type of authoritarian regimes. Dependency may be reinforced by the international donor agencies that see refugees as helpless and vulnerable people, without considering the possibility that their very survival is due to ingenious coping strategies and resilience.

3
Interventions for Survivors of Persecution

3.1
Interventions for Adults and Children

In a rational world, the development of services for both adults and children should be based on public mental health considerations. The selection of treatment priorities in a society coping with the massive consequences of human-made violence would ideally take place with the help of the public mental health criteria leading to interventions discussed below.

3.1.1 Prevalence

The first criterion is the *prevalence* of the problem, preferably determined with the help of a culturally sensitive epidemiological survey. A survey is important to distinguish individuals who, once exposed to the traumatic events, have developed a disorder from those who have not. Epidemiology is also valuable in the design of services, because it provides prevalence estimates of the affected populations. Moreover, epidemiology can provide information on chronic symptoms as a result of type II trauma or continuous traumatic stress as well as on disability. Chronicity is a critical issue in arguing for secondary and tertiary prevention. As has been mentioned before, until now only three epidemiological studies have been performed in lower-income countries where violence is highly prevalent. Since probably less than 10% of the traumatized population seeks treatment, it is difficult to determine the size and the nature of psychosocial and mental health problems that have to be addressed by service providers. Finally, epidemiological research can generate information on risk factors and protective factors by studying sociodemographic and economic variables, gender, coping style, social network, and structural and functional social support, for example. Modification of these factors is an important objective of an effective intervention and prevention program as long as primary prevention in the form of putting an end to war is seen as an unrealistic option.

Ideally, an epidemiological survey should include a study on help-seeking behavior. Most studies on traumatic stress focus on populations under treatment. However, in order to understand the dynamic process

of adaptation to traumatic stress, one must not only look at those who seek treatment. This is even more important in war-affected areas, where "treatment" in the Western sense is often absent. In other words, to develop curative and preventive interventions, we need information both on the prevalence of disorders and on the way these disorders are distributed over a certain area. Studying help-seeking behavior provides information on the indigenous and allopathic services where people try to get support or, conversely, where they do not try to do so.

3.1.2 Community Concern

Community concern can be hard to assess in postwar circumstances. Victims may have been deprived of basic human needs such as shelter, water, or food for a considerable amount of time. They may be accustomed or even conditioned to ask for material help from (non)governmental organizations (NGOs). They may also be so accustomed to the effects of traumatic stress that a distortion has taken place of the population norm with regard to normality and deviancy. For example, during focus groups discussions in a war-ridden area in East Africa, the mothers stated that their children were not affected by the war. Since the results seemed hard to believe, the focus group discussions were repeated. It turned out that all children had night terrors and that all children up to the age of 12 were wetting their bed in an area where being potty trained at the age of 1 year is not exceptional. In addition to qualitative techniques such as focus groups or key informant interviews, community concern can be assessed by looking at the type of problems that people present to community services or health services in the affected areas. Their presentation of specific problems provides insight into their concerns which is complementary to the results of the aforementioned epidemiologic study or the research on help-seeking behavior. For example, in our work among Sudanese refugees in Uganda, the main problems presented by the refugees are poverty, forced marriage, violence within the family, suicide (attempt) and homicide, mental disorder and epilepsy, magic–religious illness such as Jok-Jok (spirit possession), alcohol abuse, acquired immunodeficiency syndrome (AIDS), rape, infertility, and "misled youth." Although most of these problems are related to the war activities and the daily problems in the refugee camps, and although many of the problems concur with epidemiologic data, these presented problems give vital information on intervention priorities as seen by the community. Another indication for community concerns are the requests being forwarded by community leaders among the refugees. These requests can be transmitted by district or provincial authorities to the government and subsequently to international agencies or organizations (see Sect. 3.1.7 on "Political Acceptability").

3.1.3 Seriousness

In postwar situations, general distress and minor psychological disorders may affect almost the whole population. These problems may thus be a priority based on the first criterion of (point) prevalence. However, the management of these psychosocial problems needs to be in balance with serious psychiatric disorders that are brought forward by the population. After a war, an increase in the incidence of major psychiatric disturbances is often seen, primarily caused by the absence of services during the war period. In addition, several groups among the population may show a different response if mental health services are offered. For example, when setting up mental health care services in Cambodia, we found that in areas with high concentrations of returnees from the Thai border camps, the consumption of mental health care services was many times higher than in areas that had never known any allopathic mental health care service over and above the services that were delivered by the local healers and monks. The reason for the difference was that, although both groups regarded mental disorder as a serious predicament, only the returnees from the border camps knew from their previous experience in Thailand that such a thing as allopathic treatment for mental disorder exists (Somasundaram et al. 1999).

3.1.4 Susceptibility to Management, Treatability, or Feasibility

The criterion of susceptibility to management, treatability, or feasibility is important both with regard to the question of whether people with certain problems get support from their environment and whether there are sufficient resources in terms of personnel, time, and funds to treat specific problems. For example, in some areas of Africa and Asia, the prevalence of epilepsy is as high as 3.7%–4.9% and it is often presented to psychiatric and primary health care services (Adamolekun 1995). In addition, especially in situations of massive stress, a large number of people show symptoms of dissociation varying from individual possession as an "idiom of distress" to classical fugue states and epidemics of mass psychogenic illness with or without psychogenic fits (de Jong 1987). While setting up services, it has to be considered which health care sector is best equipped to deal with the high prevalence of all kinds of convulsions.

Offering treatment to those with epilepsy is a feasible option. A total of 95% of a sample of West African patients with generalized epileptic convulsions were correctly diagnosed and treated with phenobarbital by primary health care workers who received a couple of hours of training; the average seizure frequency decreased from 16 to 0.34 per month (de Jong 1996). On the other hand, dealing with the equally highly prevalent dissociative states often requires sophisticated and scarce psychotherapeutic skills. In many cultures, adequate management for both groups implies triage of the epileptic patients and referral of those with dissociative states to the local healers or possession cults. A similar problem exists with regard to the treatment of complex PTSD as a result of type II trauma in war-affected areas. In the West, the psychotherapy of complex PTSD requires a long-term commitment from both therapist and client. In most war-affected areas, psychotherapists are not or hardly available and long-term therapy is mostly alien to the local culture. This is one of the reasons why mental health care professionals often have to resort to short therapies, limiting themselves to the stabilization phase of the three-phase model of Janet, for example (Van der Kolk et al. 1996; Meichenbaum 1997).

3.1.5 Sustainability

The sustainability of a program will depend primarily on the institutional capacity and the creation of enough human resource capacity to continue the interventions. To guarantee continuation of the activities after repatriation, the program should train as many (para)professionals as possible from the refugee community. (It is obvious that this type of empowerment also has a preventive effect on the community.) Sustainability is also important with regard to the provision of psychotropic drugs. As mentioned before, populations of refugees, displaced persons, or returnees will often contain individuals with serious psychiatric disorder or epilepsy that present to the mental health services. When setting up a program, it has to be remembered that these patients need to continue their medication after resettlement or repatriation.

In our view, donors should abstain from engaging themselves in mental health care services without a long-term commitment. Some donors customarily fund subsequent project phases on a 6-month basis. From an ethical point of view, one wonders how these donors expect mental health care professionals to assist traumatized people with psychosocial interventions, psychotherapy, or maintenance treatment if they have to disrupt their work every 6 months hoping for new funds to arrive.

Another aspect promoting the sustainability of a program is to take a politically neutral stance while implementing the program (see Sect. 3.1.7 on "Political Acceptability").

3.1.6 Knowledge, Skills, and Availability of (Mental) Health Care Professionals

Before setting up an intervention program on an intersectoral basis, the number and types of mental health care professionals, general health workers, and other possible trainees from other sectors such as education or social services should be assessed. This assessment should answer questions regarding their ability to handle different types of psychosocial and mental health problems, their normal duties and responsibilities, and what kind of training and supervision they need in order to be able to deal with the consequences of man-made violence. It should also determine the extent to which the trainees themselves have been traumatized by the war. Training should address their traumatic experiences, and after the training a second assessment should be carried out to find out whether the trainees are able to deal with the traumas of others. Group and individual debriefing, supervision and intervision, and job rotation are useful measures to prevent burnout.

3.1.7 Political Acceptability

It is important to find out the (hidden) agenda of policy makers and their opinion on the possible implications of the work. For example, both in epidemiological research and in stress research, it is important to measure traumatic stressors and life events before, during, and after the human-made disaster in order to measure the effect of these independent variables on psychosocial well-being and psychopathology. The results of this type of research play a central role in designing culturally appropriate interventions. However, the same data can also be used for other purposes, such as human rights work or advocacy against repressive government practices at home or in a guest country. Governments may therefore be ambivalent toward this kind of psychosocial and research activity. On the one hand, the activities may stimulate democracy, respect for human rights, and psychosocial support. On the other hand, governments may be afraid of being exposed as repressive. They may try to hinder a psychosocial program or, conversely, welcome human rights activ-

ists in case they themselves are imprisoned after a coup, thus needing the benefits of human rights that their previous enemies achieved.

3.1.8 Ethical Acceptability

The possible harm that might be inflicted on others, e.g. by carrying out research that lacks cultural sensitivity or by carrying out research that does not result in provision or improvement of services, should be considered. All too often scholars are eager to collect psychodiagnostic or psychometric data to be published without questioning whether the data will help in formulating preventive or curative interventions for the affected population.

Western-style informed consent with signatures on an elaborate consent form has to be discussed thoroughly before being applied. As Bromet (1995) argued after the Chernobyl accident, such forms may be perceived with distrust and suspicion. The procedure may evoke fear, e.g. of being disowned by one's country, as we found out in countries such as Cambodia, Ethiopia, or Gaza.

Another ethical consideration is the above-mentioned sustainability of the project. Psychosocial and mental health assistance requires a long-term commitment. In lower-income countries, it may take 5–7 years before a local training of trainers (TOT) group has been trained itself and before it has subsequently trained and supervised sufficient secondary- and tertiary-level staff to ensure continuity of the work.

3.1.9 Cultural Sensitivity

Culture defines reality for its members. It defines the purpose of the life of the individual and the group and prescribes and sanctions proper behavior. The beliefs, values, and behaviors of a culture provide its members with personal and social meaning, learned through tradition and transmitted from generation to generation. Culture serves two functions. It is integrative, i.e. represents the beliefs and values that provide individuals with a sense of identity. It is also functional, i.e. furnishes the rules for behavior that enable the group to survive and provide for its welfare, while supporting an individual's sense of self-worth and belonging. These two functions are analogous to the warp and woof of a tapestry (Kagawa-Singer and Chi-Ying Chung 1994). The weaving technique is universal, but the patterns that emerge from each culture are particular. A thread can be taken out and compared cross-culturally, but its function can only be understood within the cultural fabric from which it came.

As a result, each aspect of a public mental health intervention has to be tested for its cultural assumptions and consequences. For example, Green (1993) has suggested eight generic dimensions of trauma: (1) threat to life and limb; (2) severe physical harm or injury; (3) receipt of intentional injury/harm; (4) exposure to the grotesque; (5) violent/sudden loss of a loved one; (6) witnessing or learning of violence to a loved one; (7) learning of exposure to a noxious agent; (8) causing death or severe harm to another. Some of these dimensions (e.g. 1–3) can be regarded as universal stressors, but others are perceived differently in specific cultures. For example, in Uganda we found that group rape of abducted women can be dealt with by a collective purification ritual under the aegis of the elderly, whereas in Algeria, Cambodia, Nepal, or Namibia the shame caused by rape can lead to suicide or marginalization of the victim. Violence in the family is regarded as a serious consequence of continuous traumatic stress in many cultures, but some cultures are lenient toward battery violence, whereas in other cultures it is found to be unacceptable. Loss of an older loved person (dimension 5 and 6) who has children and some accumulated wealth can be acceptable in African animist cultures, since the person will travel to the reign of the ancestors. On the other hand, the death of a child in the same culture is a disaster, even though some Westerners think that parents suffer less in cultures with high exposure to child mortality. An individual who is a perpetrator (dimension 8) may be regarded as a hero if he is a (child) soldier in some West African countries or in the Middle East. Even exposure to the grotesque can be mediated by religious convictions such as the role of karma in Buddhism in Asia. These culturally determined subjective components are important in determining subsequent psychopathology. Therefore, the development of scales to quantify the severity of traumatic exposure is a complex issue necessitating collaboration with cultural informants and social scientists. The role of culture is equally important in the design of any psychosocial, psychotherapeutic, or psychiatric intervention, be it curative or preventative. This mean that local mental health care professionals – especially if they were trained abroad – should "indigenize" their knowledge and expertise in order to provide services to the victims of violence who often have a different cultural background and reside in peripheral rural areas. In my opinion, Western mental health care professionals who are equipped with the best of intentions but without work experience in low-income countries or without extensive experience in working with refugees in their home countries should be extremely cautious in offering their Western

culture-bound expertise in conflict-ridden areas elsewhere.

3.2 Translating Public Mental Health Priorities into Program Priorities

Organizations, either governmental or nongovernmental, usually choose a model to implement psychosocial and mental health care interventions in postwar situations. Their choice is often determined by the model which was consciously or unconsciously established by the psychiatric services in the area before the disaster took place. Siegler and Osmond (1974) distinguished eight possible models: the medical, moral, invalidity, psychoanalytic, social, psychedelic, conspiracy, and family interaction models. The models implemented in a specific area are often determined by social or colonial history and often need thorough transformation to be effective in postwar circumstances. For example, the Soviet approach, with its emphasis on medical authority, hospital-based care, and the conspiracy model, is an obstacle for adequate interdisciplinary community-based interventions in countries such as the former Yugoslavia, the Caucasian republics, Cambodia, or Vietnam. The centralized custodial care in Portugal's former colonies Mozambique and Angola does not provide a model to set up mental health care services in the rural areas afflicted by the war. The French psychoanalytic model which is en vogue in Algeria does not equip its mental health care professionals to do outreach work in the communities suffering from the sequelae of the violence and human rights violations. Similar considerations play a role in the treatment of refugees with mental problems in high-income countries. Some countries prefer to set up special or category-based services for refugees, other countries opt for integrated care, and in some countries refugees use the general psychiatric services but may be referred to services with a specialization in complex cultural psychiatric and psychotherapeutic problems.

In addition to the role of local models, the international (donor) community plays an important role in the choice of a specific approach. For example, because many Westerners can identify themselves with the suffering of people in the former Yugoslavia and because it is a politically sensitive area, it seems that currently more money is spent on the psychosocial consequences of the war in ex-Yugoslavia than in the rest of the world. If more funds are available, more mental health care professionals can be hired or trained, which easily results in a more or less classical dyadic or group psychotherapeutic approach within existing institutions or facilities with the possible disadvantage that large parts of the afflicted population do not receive proper care. If funds and professional manpower are limited, as in most lower-income countries, governments or NGOs often have to resort to cheaper public mental health care solutions with the possible flaw that semiprofessionals with limited training have to support large numbers of people suffering from serious sequential traumatization. The choice of a specific model is further complicated by the preferences or capacities of professionals or organizations. For example, there are large numbers of medical doctors worldwide who are well trained in public health but have little knowledge of psychotrauma treatment, while most psychiatrists and psychotherapists find it difficult to translate their professional expertise into a public mental health care perspective. Social scientists often hear that they are still so committed to time-consuming participant observation that the results of their inquiries lag behind in the turmoil of postwar areas. The choice of a model is also determined by organizations working in the field who have their own opinions on the implementation of mental health care services. The public discourse of all kinds of organizations is often quite different from their behavior in the field. For example, one of the United Nations (UN) agencies involved in helping refugees in Uganda had limited knowledge of current views on integrating different types of services within a horizontal public health care approach. When we started establishing mental health care services in the area, we were obliged to spend almost a million dollars to set up our own logistic infrastructure, including transport and telecommunication, to convince the UN agency that we would not "use" others to implement our work. In other words, we added another vertical program to a variety of initiatives in the medical field. After this investment, we had shown that we might be serious partners. This enabled us to begin dismantling our infrastructure in order to set up a suitable horizontally integrated public health care system sharing logistics with other organizations providing medical or social services.

3.3 Outline of a Public Mental Health Model for Massive Traumatization

The international multisite program of the Transcultural Psychosocial Organization (TPO or "Peace of Mind"), a World Health Organization (WHO) Collaborative Centre, is active in Algeria, Burundi, Cambodia, Congo, Ethiopia, Gaza, India (Tibetans), Kosovo, Mozambique, Namibia, Nepal, Sri Lanka, Uganda, and the Netherlands. The outline of its approach will be

described here as an example of how mental health care services can be set up in conflict areas. The TPO program is based on an interdisciplinary approach combining public mental health care, psychology, psychiatry, social science, psychotherapy, and epidemiology. Within a comprehensive approach, each discipline contributes to finding practical solutions for the complex problems of transcultural diagnosis and to designing effective, community-oriented interventions. This outline illustrates our multimodal approach, which can be used in a rather eclectic way. In this approach, three aspects of transcultural public mental health care programs are emphasized which, if neglected, may hamper the effectiveness of interventions. First, cultural variables and the context in which behavior occurs have to be studied both on the population and on the individual level in order to understand normal and deviant behavior. Second, the use of Western quantitative research instruments which are not based on culture-specific qualitative data should be avoided. This lack of cultural validation of instruments perpetuates the so-called category fallacy, in which indigenous diagnoses are overlooked and Western categories imposed where they have no cultural validity (Kleinman and Good 1985). Third, the long-term outcome of programs is often primarily determined by the original design. This is not realistic with a view to the major changes that may occur among the target population. The TPO model is a combination of an ecological, traumatic stress, and stress diathesis model (Lazarus and Folkman 1984). It uses a methodology which captures the idiomatic description of mental health problems that fit local cultural illness experiences in order to bolster indigenous coping strategies. Each project in the different countries develops its own culture-specific approach within this general outline or blueprint.

TPO generally recruits long-term professional expertise from abroad if local expertise is scarce. Local and foreign staff form an intercultural and interdisciplinary TOT team. Local staff may have little formal training, since most of the low-income countries where the program is active only have a few psychologists, psychiatrists, or social scientists. Even if these local professionals are available, they usually need additional training in topics such as psychosocial and mental health care interventions, group and individual trauma treatment modalities, crisis intervention, prevention, and human rights violations in order to cope professionally with the consequences of war, oppression, or civil unrest. Our intervention strategy uses a combination of Western and local methods. We exchange knowledge between the local members of the TOT group and the expatriate trainers. We try to prevent neocolonization of the non-Western mind by the uncritical use of Western trauma treatment techniques such as cognitive-behavioral or psychoanalytic approaches. Instead, we carefully build on local coping strategies and on healing techniques that match local expectations and practices by healers. In this way, syncretistic therapy methods are developed combining universal "common factors" (Frank and Frank 1993) or nonspecific therapy variables (Garfield and Bergin 1986) with culture-specific healing methods. This enables technology transfer about the consequences of trauma to a wide number of local practitioners and beneficiaries. We alleviate the psychological consequences of massive organized violence through the management of identified cases – both adults and children – and through the empowerment of the community. Collaboration is sought with local and international organizations in rural development, vocational skills training, and income-generating activities. Participatory action/research is carried out in order to evaluate and monitor our programs in each country, at the same time involving local staff to ensure a future capacity to evaluate the progress of programs once TPO leaves.

The program objectives are realized through a number of activities. Psychosocial and mental health problems are identified and assessed by means of a multimethod approach combining qualitative, ethnographic methods with quantitative epidemiological and psychometric methods. Using this specific approach (Agar and Murdoch 1994), we are able to detect priority problems within the communities and the different categories of people who will be trained by the program. This helps to elicit indigenous coping strategies; explanatory models on the level of the population and the individual, local idioms of distress; folk illnesses and culture-bound syndromes; proverbs, metaphors, and somatizations related to distress; and culturally mediated protective factors. The latter are used for training and reinforcing self-management and self-help activities within the framework of a psychosocial intervention program. The research and the training sessions produce additional culture-specific material on grief, trauma, and coping. This material is used to adapt the existing training manuals, e.g. for health care workers, teachers, relief workers, and healers. Part of the training is based on the WHO/UNHCR book on the *Mental Health of Refugees* (de Jong and Clarke 1996). Culturally appropriate adaptations of this book are produced for South-East Asia and East Africa. The material is also used to design preventive interventions in the field of psychosocial assistance and mental health (de Jong 1995). One of the preventive empowering strategies is to support local

authorities and camp managers in rural development based on a primary care approach emphasizing intersectoral collaboration. In addition, the program is monitored and the effectiveness of the interventions is improved by using variables developed during the action research.

Each country or participating area tailors the program to suit local circumstances while following the outline. Both research and interventions are essential. In order to constantly monitor and improve local program implementation, each project uses a combination of qualitative and quantitative research techniques such as participant observation, focus groups, key informant interviews, and epidemiologic surveys with psychodiagnostic and psychometric instruments. The outcome of the interventions is assessed with an effectiveness methodology. The results are fed back as a cybernetic loop in the ongoing intervention projects.

Each intervention model chosen by an organization or a government has to address the restoration of shattered assumptions. Janoff-Bulman (1992) mentions that we all have a culturally determined set of assumptions – or schemata – that guide our cognitions of reality and our plans and actions. A basic aspect is the illusion of personal invulnerability, which protects us from stress and anxiety but also from adopting preventive behavior. A second assumption is that we live in a meaningful world. By following certain rules and by behaving in a worthy way, we protect ourselves against misfortune. A third assumption is that we are decent and worthy people. We possess a positive self-image and self-esteem. When overwhelming trauma occurs, our social reality is often disrupted and our personal schema is also completely shattered. This results in strong emotions such as powerlessness, anger, and anxiety or, conversely, in their denial. Coping with stress implies coming to terms with the new reality and trying to fit new assumptions about the world with its harsh facts and with ourselves. Culturally defined coping strategies may serve to come to terms with shattered assumptions about the world and ourselves. This may happen by trying to redefine the traumatic event to make it consistent with previous reality or by making sense of the event by finding a purpose in it or by restoring the belief in an orderly world with the help of religion or by involvement in a democratization process. Alternatively, a survivor may try to change his or her behavior to regain autonomy and control. A person may seek social support, set up self-help groups, or decrease his or her dependency on authorities or organizations. This chapter has tried to provide guidelines to support survivors in finding a new homeostasis in times of war and persecution.

Psychiatric Problems Related to Torture

1 Introduction

Torture is a widespread human rights problem practised in 115 out of 215 or in 53.5% of all countries (Amnesty international 1997). The medical and psychological after-effects on its victims and their families now constitute a public health problem demanding concerted efforts from the health systems in all parts of the world. A special concern for mental health care providers in European countries are the mental health needs of traumatised torture survivors among refugees granted asylum after wars and persecution from repressive regimes in Europe and elsewhere (e.g. the former Yugoslavia, Eastern Europe, Turkey, the Middle East, south-east Asia). Baker (1992) estimated that between 5% and 35% of the world's 14 million refugees had suffered at least one experience of torture. Research on torture and its consequences is needed for several important reasons.

Torture is the most abhorrent form of human rights violation. The aims of torture have always been to destroy the personality of the victim and at the same time set an example for the rest of the community (Genefke and Vesti 1998; Basoglu et al. 1997). Scientists can contribute to turning society's and the media's attention to the health problems connected with the issue, thus raising public awareness and bringing pressure to bear on governments and international organisations to combat the practice of torture. Studying the trauma of torture as a deliberate attack aimed at destroying an individual's identity gives us valuable insights into the effects of extreme stress and the processes of traumatisation and coping. Thus the study of torture trauma and its mental health implications contributes to developing methods of psychiatric assessment and classification of trauma-related symptoms and to refining stress theory.

Following the introduction of the diagnosis of post-traumatic stress disorder (PTSD) in DSM-III in 1980, a generic theory unifying previous approaches to the long-lasting psychological effects of trauma was proposed. According to this theory, different types of traumata such as combat experience, child abuse, sexual abuse and torture may provoke similar psychopathology. However, PTSD as diagnostic category has been shown to be inadequate to encompass the entire symptomatology of torture survivors (Shresta et al. 1998; Arcel 1998).

This chapter will present the current knowledge of psychological and psychiatric problems in torture survivors world-wide. Within this frame, it will discuss whether symptoms following torture constitute a specific syndrome qualitatively different from other stress response syndromes (Rasmussen 1990; Genefke and Vesti 1998). The chapter will furthermore give a clinical description of how torture trauma affects emotion, consciousness, memory, self and interpersonal relationships. Finally, treatment principles for torture-related psychiatric problems will briefly be reviewed.

2 Definition and Types of Torture

A widely accepted definition of governmental torture is stated in the United Nation's Convention against Torture and Other Cruel, Inhuman or Degrading Treatment or Punishment (United Nations General Assembly 1992):

> The term torture means any act by which severe pain or suffering, whether physical or mental, is intentionally inflicted on a person for such purpose as obtaining from him or a third person information or a confession, punishing him for an act he or a third person has committed, or is suspected of having committed, or intimidating him or coercing him or a third person, or for any reason based on discrimination of any kind, when such pain is inflicted by or by the instigation of, or with the consent or acquiescence of a public official or other person acting in an official capacity.

Torture affects not only the individual victim, but also the entire community by creating a culture of fear that intimidates and terrorises. In repressive cultures, the mere fact that an individual has been detained and tortured is enough to stigmatise that individual, creating mistrust for his possible disloyalty (Turner and McIvor 1997). Relationships in families that have been tortured together at home or during detention are burdened with strong and contradictory feelings of shame, guilt, aggression and humiliation on the one hand and compassion and identification on the other. Often torture is a secret that families share.

High-risk target groups as regards governmental torture are members of the political opposition, human rights activists, ethnic minorities, refugees, labour union leaders, student leaders, journalists, criminals or ordinary civilians when arrested and interrogated.

We differentiate between primary victims, i.e. those subjected to direct torture, and secondary victims, i.e. their families. The torturers are soldiers, police officers, prison officers and militia. Torturers are

trained in a variety of techniques of physical and psychological abuse.

2.1 Prevalence

As no large epidemiological studies exist in the community, the rate has been measured as the number of torture survivors in refugee populations, recognising that refugees are high-risk populations. The percentages vary between 20% and 70% according to the selection of the groups. It was 20% in a random sample of 3000 of the 10,000 asylum seekers who arrived in Denmark in 1986 (Jepsen 1988). Typically, the prevalence is higher in refugee populations referred to psychiatric clinics, e.g. 70% in males and 31% in females in a selected outpatient psychiatric clinic in Norway between 1991 and 1995 (Lavik et al. 1996). Montgomery (1998) found 30% tortured in a sample of Middle Eastern asylum seekers, and 20% were tortured in a Bosnian refugee population of 2023 included in a psychosocial programme in Croatia (Arcel et al. 1998).

2.2 Torture Methods

For practical reasons, methods have been divided into physical and psychological, although this division is artificial, as many of the psychological methods, e.g. water, food and sleep deprivation, involve not only psychological but also physiological sequelae, and many physical methods, e.g. sexual torture, involve psychological elements too.

The most common physical methods of torture are blunt violence, "falanga" (persistent beating of the soles of the feet), suspension (by the arms or legs), strapping of body or body parts with rope or handcuffs, electrical torture, suffocation, sexual torture carried out by humans or animals, insertion of foreign bodies into body openings, cuts with sharp instruments, teeth torture, immobilisation in forced positions, detention in cells smaller than the human body, burns with cigarettes or acidic liquids, "telephono" (beating on the ears with cupped hands), cold-water showers, pulling of hair and exposure to extreme heat or extreme cold.

Psychological methods include blindfolding and isolation, severe humiliation, sexual torture, forced nakedness, death threats, verbal abuse, mock executions, witnessing torture of others or family members, solitary confinement, exhaustion, deprivation of food, water and sleep and being forced to listen to high-pitched sounds or music. As the knowledge of physical torture increases, more sophisticated, mainly psychological methods of torture are being developed by torturers in order to prevent documentation through physical sequelae.

3 Physical Sequelae

Physical torture methods leave symptoms and physical signs. Certain types of torture are related to specific symptoms and signs. Chronic and late sequelae are related to the severity of the applied method. These sequelae are often the basis for a documentation of physical torture. It is important to examine the victim close to the time of torture, as traces may disappear with time. In contrast, the psychological symptoms described later in this article are persistent. (For a detailed listing of physical sequelae related to methods of torture, see Skylv 1992; Holtan 1998.) As torture is a violent attack on the body, many torture victims have poor physical health and many medical complaints and initially describe physical rather than psychological symptoms. It is therefore important to mention here a few physical sequelae.

The sequelae can be fresh or badly healed fractures, ostitis, periostitis, nerve and vessel injury, fibrosis in muscles fasciae and connective tissue, injury to tendons and ligaments, distortions and scars from beatings, whippings, cuts with a knife or other sharp instruments, burns or electrical torture. Other symptoms may include sexual dysfunction, damaged teeth, the whiplash syndrome, punctured eardrums and hearing loss. In survivors of falanga, we find smashed heels, and the rate of walking is slow and the distance limited. Alopecia is found following electrical torture. Torture survivors' chronic pain and tension influences the general tension of the musculature, resulting in fibrositis, fibromyalgia and myofascial pain. Former prisoners of war who have been subjected to torture are reported to have increased cumulative incident rates of chronic disorders of the peripheral nervous system, joints and back and an increased rate of peptic ulcer (Nice et al. 1996). There is increasing recognition of the chronic nature of many of the sequelae, in particular chronic pain.

Sexual torture may leave traces in the musculoskeletal system, structural injuries, functional disturbances and dysfunction of the pelvic joints in women. These women often have low lumbar pain, complain about pains in genitalia, menstrual disturbances and sexual problems. Sexual dysfunction and testicular atrophy in men are seen following electrical torture on genitals.

4 Medical Assessment

Important themes in the medical assessment preceding psychiatric assessment and treatment include the following:

- The medical assessment of the torture victim is an important part of the entire diagnostic process and preparation for the psychological treatment. Chronic medical conditions or distracting physical symptoms should be identified and assessed before any psychological treatment is initiated. Differences in type of injury following torture are small between different parts of the world despite the fact that particular forms of torture may prevail in certain cultures. Specialities such as traumatology, sports medicine, forensic medicine, neurophysiology and rheumatology provide the basis for the diagnosis and treatment of sequelae of physical torture.
- Torture victims have many medical complaints. Pains in the head, back, abdomen or chest are often the major complaints. Pain can recur years after torture and must be addressed. However, the complaints require physical evaluation in a slower, more deliberate and less invasive approach in torture victims than in others because the pain may be a manifestation of a primary psychiatric problem.

  In a study of 50 victims, Juhler and Smidt-Nielsen (1995) found that there was a discrepancy between the large number of physical complaints and the small number of objective medical findings, with the exception of musculoskeletal findings, as shown in Table 1.

  The survivors may feel reassured to know that their symptoms are organically unfounded, as they often fear that the torture has inflicted damage on them.

Table 1. Discrepancies between percentage of physical complaints and medical findings in 50 victims of torture

Type of complaint	Complaints (%)	Findings (%)
None	0	4
Neurological	86	22
Cardiopulmonary	74	14
Gastrointestinal	68	24
Urological	34	4
Sexual/genital	54	16
Musculoskeletal	92	92

- As some examinations may resemble the torture situation, medical procedures must be discussed with the survivor. Especially vulnerable are patients with a history of electrical torture or teeth extraction.
- The physical evaluation can document the history of torture and the methods used.
- The role of the primary care physician is less threatening for the survivor, thus creating a bridge of trust for further psychiatric care. When a patient is being treated for urgent physical symptoms or medical conditions, psychotherapy can begin.

5 Psychological Sequelae

During the last two decades, an increasing body of research and theory has been produced in many, mainly Western countries where torture victims among refugees have been investigated. Terms such as complex PTSD (Herman 1992), chronic organic psychosyndrome (Petersen et al. 1985) and torture syndrome (Genefke and Vesti 1998) have been used to denote the complexity of torture trauma. Important questions that need to be addressed include whether torture constitutes a specific syndrome, i.e. whether it evokes a predictable constellation of signs and symptoms. Initially, attempts to identify the key features of the effects of torture were subsumed under the heading of "torture syndrome" proposed by Danish doctors (Amnesty international, Danish Medical Group 1977). This proposal was based on a combination of thorough medical examinations of the physical indications of torture in most of the major organ systems and a psychiatric examination of the short-term and long-term psychological effects of both physical and psychological torture in treatment seekers.

At an early stage, it was concluded by the Rehabilitation and Research Centre for Torture Victims (RCT) in Denmark that the worst sequelae of torture were psychological, as confirmed by other international studies (Allodi 1980; Kordon et al. 1988; Rasmussen 1990). Researchers in favour of a distinct torture syndrome claim that the issue of infliction of deliberate violence on one human being by another with the aim of destruction has a decisive influence on the formation of symptoms (Somnier et al. 1992). Gelinas (1993) supports this point by differentiating between "facticity" (e.g. breaking a leg in an accident) and "agency" as causes of trauma. According to Gelinas, it is the malevolent intention of the perpetrator that causes the

most extreme trauma. So far, the answers are inconclusive, primarily due to major methodological problems in research.

Many studies do not differentiate sufficiently between symptoms connected with the difficulties of being a refugee in exile and symptoms related to the torture experience. As very few epidemiological studies exist, investigations are hampered by selection bias by investigating treatment seekers. The definition of torture varies from investigation to investigation, and the degree of severity is not adequately operationalised. Severity measured by the number of incidents is too crude a measure (Holtz 1998). Head trauma as a possible aetiological factor in symptoms is rarely examined, and impairment may thus be interpreted as psychologically founded. Personality traits, e.g. resilience, ego strength, attachment style and others important for coping with torture trauma, are very rarely investigated. The numerous health problems caused by physical torture are not clearly differentiated from psychosomatic symptoms. The importance of other traumatic events, e.g. dramatic loss of family members, divorce, unemployment, exile and separations as additive to torture stress, is often not investigated.

However, it has now been established that torture is a very important life stress event that causes numerous other stress events. The survivors may lose their physical health, work, family, status in the family and in society and finally, if exiled, their country, language and cultural environment (Mollica et al. 1987). The most commonly reported psychiatric and psychological symptoms in many different parts of the globe include anxiety, depression, irritability, emotional instability, cognitive memory and attention problems, personality changes, behavioural disturbances, neurovegetative symptoms such as lack of energy, insomnia, nightmares, and sexual dysfunction even if the person has not been sexually tortured (Mollica and Caspi-Yavin 1992; Cunningham and Cunningham 1997; Holtz 1998).

In Table 2, we present the most frequent psychiatric symptoms observed by the RCT psychotherapists. The classification of the symptoms in the DSM-IV diagnostic categories (American Psychiatric Association 1994) is shown.

Nine of the most common symptoms are encompassed by the diagnostic criteria for PTSD. It is interesting to note that symptoms "change in personality" and "survivor's guilt" are included in the revision of PTSD in DSM-IV (American Psychiatric Association 1994) under the heading of associated descriptive symptoms. They are mentioned among a number of symptoms that are more commonly seen in association with an interpersonal stressor in criterion A.

In the WHO International Classification of Diseases of 1992, it is emphasised that post-traumatic stress disorder may show a chronic course over many years and a transition to an enduring personality change. The diagnostic guidelines emphasise that the change must be present for at least 2 years and should not be attributable to a pre-existent personality disorder or to a mental disorder other than PTSD.

The personality change includes inflexible and maladaptive features with impairment in interpersonal, social and occupational functioning.

6 Post-traumatic Stress Disorder and Co-morbidity

The introduction of PTSD has shifted the focus of investigators away from demonstrating the presence of a unique syndrome and given impetus to substantial research on torture documenting in most investigations that PTSD is found in a significantly higher degree in refugees with torture experiences compared to refugees without (Shresta et al. 1998; Holtz 1998; Priebe and Esmaili 1997). In connection with tortured individuals, it is important to consider the neurobiological aspects of PTSD, as the threat to the organism leads to the activation of multiple neurobiological systems. It has been shown that, among individuals with PTSD, a higher level of adrenaline and noradrenaline is found than in non-traumatised individuals. Another finding is the increased activity of the autonomic nervous system, with abnormal sleep architecture and elevated blood pressure and heart rate (Kaplan et al. 1994). The numbing phase often seen in PTSD may be partly explained by repeated depletion of catecholamines (Saporta and van der Kolk 1992). The same authors claim that noradrenergic dysregulation might explain the difficulty in modulating aggression found in PTSD victims.

Van der Kolk and Greenberg (1987) suggest that autonomic arousal mediated by the locus coeruleus may account for the increase in flashbacks and nightmares in PTSD victims.

There is an increasing recognition of the importance of neurological factors in understanding the connections between PTSD and trauma. At the same time, PTSD has been shown to be inadequate when it comes to encompassing the entire symptomatology seen in torture trauma victims. Co-morbidity is the rule and in most investigations includes the diagnoses of anxiety disorder, major depression and somatoform disorder (Shresta et al. 1998; Holtz 1998). It has additionally been shown that different forms of torture produce different PTSD symptoms (Ramsay et al. 1993). The majority of symptoms reported by individuals who suffered isolation or blindfolding, impact torture and

Table 2. Twelve major symptoms seen by psychotherapists at the Rehabilitation Centre for Torture Victims (RCT) in Denmark and location of symptoms within diagnostic categories of DSM-IV

PTSD criterion	Symptom (DSM-IV)[a]	Description or comment
Emotional lability	D2, D4	Irritability or outbursts of anger, hypervigilance
Sleep disturbances	B2, D1	Nightmares, difficulty falling asleep or staying asleep
Disturbances in ability to concentrate/remember	C3, D3	Psychogenic amnesia, difficulty concentrating
Avoidance of thoughts or feelings associated with torture experience	C1	
Avoidance of activities or situations that arouse recollections of torture experience	C2	
Diminished ability to establish personal relationships	C5, 6	Feelings of detachment or estrangement from others, restricted range of affect
Markedly diminished interest in several significant activities	C4	
Sense of foreshortened future	C7	
Sudden acting or feeling as though torture situation were recurring	B3, 4	Flashbacks occur after exposure to events or environmental stimuli that symbolise or resemble aspect of torture experience
Change in personality		
Survivor guilt		
Anxiety		Anxiety that is specific to torture experience and is neither neurotic nor psychotic

Empty cells indicate that there is no associated DSM-IV diagnostic category or no description/comment.
PTSD, post-traumatic stress disorder.
[a]B1, recurrent and intrusive distressing recollections of the event, B2, recurrent and distressing dreams of the event; B3, acting or feeling as if the traumatic event were recurring; B4, intense psychological distress at exposure to internal or external cues that symbolise or resemble an aspect of the traumatic event; B5, physiological reactivity on exposure to internal or external cues that symbolise or resemble an aspect of the traumatic event; C1, efforts to avoid thoughts, feelings or conversations associated with the trauma; C2, efforts to avoid activities, places or people that arouse recollections of the trauma; C3, inability to recall an important aspect of the trauma; C4, markedly diminished interest or participation in significant activities; C5, feeling of detachment or estrangement from others; C6, restricted range of affect; C7, sense of a foreshortened future; D1, difficulty falling or staying asleep; D2, irritability or outbursts of anger; D3, difficulty concentrating; D4, hypervigilance, D5, exaggerated startle response.

other forms of physical torture were PTSD intrusion symptoms, whereas individuals who had been sexually tortured described more avoidance phenomena. This may suggest that PTSD is not a uniform syndrome in tortured individuals. Vesti and Kastrup (1995) concluded that a substantial proportion of survivors developed symptomatology close to the entity of PTSD, whereas others did not. Current results indicate that the strongest predictors of PTSD symptoms are the perceived severity but not objective severity of torture and the impact of the captivity experience on the family and the quality of social support in post-captivity, as shown by Basoglu et al. (1994a), who compared tortured political activists with non-political tortured victims in Turkey. Threats and humiliation and being forced to watch others being tortured were factors predicting PTSD among resettled refugees in Australia (Cunningham and Cunningham 1997).

The largest investigation of torture survivors to date world-wide, comparing tortured with non-tortured Bhutanese refugees in Nepal, found the diagnoses of PTSD, depression and anxiety to be significantly more common in the tortured group (Shresta et al. 1998). The total number of torture techniques experienced was the only significant predictor of PTSD and depression. The presence of PTSD, depression and anxiety leads the authors to propose the classification "disorders of extreme stress - not otherwise specified" as being a better way to describe the sequelae of torture than PTSD. Their investigation identified symptoms of shame, mistrust, concerns, unexplained pain, the conviction of being permanently injured, many medical complaints, loss of appetite, sleep disturbances and loss of sexual desire.

Political involvement, being prepared for torture, spirituality and an inner locus of control during torture and imprisonment appeared to play an active role in the development of protective coping methods

(Basoglu et al. 1997; Shresta et al. 1998; Holtz 1998; Qouta and el Saraj 1997). PTSD symptoms were associated with severe physical torture combined with a lack of effective support in male refugees from Iraq staying in the United Kingdom (Gorst-Unsworth and Goldenberg 1998). The prevalence of obsessional symptoms in the group was 20%. Poor social support rather than severity of trauma was a predictor of depression in the long term. Feelings of meaninglessness and "existential dilemmas" were widely reported in the study group.

In conclusion, there is now agreement that simply describing torture survivors as having PTSD is an inadequate description. PTSD in torture survivors is not inevitable, but genetic factors such as vulnerability to stress or resilience, proneness to anxiety, developmental deficits, previous psychiatric history, incapacitating physical sequelae, quality of social environment and individual coping efforts play a decisive role. It is beyond doubt that torture exposes people to the risk of developing psychiatric symptoms and thus social problems. The more prolonged, repeated, and unpredictable the experience of torture is, the more traumatic it is and the more serious the psychiatric symptoms are.

The complexity of the torture trauma means that neither PTSD nor a single torture syndrome can provide an adequate diagnostic basis. Connections between the general stress theory, head injury literature and results on torture symptoms need to be correlated in theoretical models of diagnosis and treatment.

7
Torture as Extreme Stress

Stress research has highlighted the universal human automatic response of "fight or flight" under threat accompanied by the emotions rage and fear, which have common physiological similarities (Cannon 1953). The "fight or flight" response is triggered not only in the original traumatic situation but also by memories. When the mind detects a threat, the sympathetic nervous system is activated and the individual is instantly prepared to fight back or, if he or she considers the danger to be too great, to flee. Inability to either fight back or flee before, during and after torture or when re-experiencing the traumatic memories leaves the individual in a state of extreme physiological arousal and with the emotions of fear and rage that cannot find an outlet. Mental images of the torture create arousal in the brain and other body parts, with accompanying feelings of rage and fear. The physiological activation causes anxiety despite the fact that a threat no longer exists. It is therefore more accurate to talk about traumatic reactions as psychosomatic reactions, as there is no psychological stress without involved physiological stress. There is no doubt that extreme traumatic experiences alter the central nervous system and the physiological system generally, which can explain the symptom of hyperarousal in torture victims. As Basoglu also emphasises, "no other trauma seems to come closer to the experimental paradigms used to explore the processes of traumatisation in animals and humans" (Basoglu et al. 1997).

The hypothesis from the stress theory about the "dose-response" relationship is well confirmed by torture research. However, the results on the protective factors mentioned earlier show that the subjective interpretation of the objective experience contributes to the development of trauma. The more life-threatening the torture situation is experienced as, the more traumatising it becomes, and, similarly, the more helpless a person has felt while subjected to torture, the more traumatising the effect will be. Of all the variables examined in a study comparing political victims and non-political victims of torture, it was shown that the fact that the non-political victims were less psychologically prepared for torture was by far the strongest predictor of psychological problems (Basoglu et al. 1997).

The literature on severe stress, trauma and coping gives us valuable insights into the impact of torture on attachment, emotion, consciousness, memory, self and interpersonal relationships (Allen 1995; Lazarus and Folkman 1984; Lazarus 1991). Disturbances in these areas create vicious circles and expose the individual to the risk of developing psychiatric symptoms.

7.1
Attachment

Torture disturbs attachment to other people, as it disturbs the sense of safety and trust. Behnia (1997) emphasises that distrust in torture victims makes rehabilitation and resettlement a difficult and painful process. Attachment developmentally has the function not only to protect the individual by care-giving, but also to regulate physiological arousal, as Bowlby (1973) has shown. Gradually, the regulation of the physiological functioning, e.g. through self-soothing activities, becomes internalised during normal development.

Torture disturbs not only basic trust and the sense of safety, but also physiological regulation, as it generates hyperarousal beyond the normal range. Self-soothing activities are severely affected and may be impaired. It goes without saying that torture can

disturb even sound foundations of attachment in childhood. If the tortured individual has developmental deficits in self-regulation or in attachment, it is clear that the processes of restoring physiological arousal regulation and of regaining trust in other human beings will be more lengthy and difficult and in some cases may never be achieved. An enduring and dependable relationship with other human beings – the mental health care provider being one of them – is necessary in order to restore safety and to relearn regulation through self-soothing techniques, e.g. relaxation, visualisation.

7.2 Emotion

Despite coping efforts, emotions in torture survivors are intense and prolonged and lose their signal value for adaptation (Lazarus 1991).

Chronic anxiety, for example, means that the individual is preoccupied with controlling the emotion itself and thus turns his or her focus away from solving the problems that trigger the anxiety. Uncontrollable anxiety is connected with feelings of helplessness and a loss of control, both experienced intensely during captivity and torture.

Torture evokes anger and aggression in the "fight or flight" response, which cannot be expressed during captivity and in many instances in very few other places afterwards, unless the individual feels secure. The family is usually a secure base where repressed feelings can be expressed. However, outbursts of anger counteract the restoration of attachment and mutual trust.

The individual may regain a feeling of control and power in destructive aggression in the family, but it eventually leaves him or her in a vicious circle of guilt and self-hatred.

If current situations are reminiscent of the torture trauma, hostile destructiveness may be expressed in the maltreatment of family members or in self-destructive tendencies.

7.3 Self-Image and Body Image

Self-image and body image are negatively affected by torture. The helplessness and humiliation often trigger feelings of being weak and dirty, with a damaged and distorted body. The feeling of shame is at the core of the torture trauma. Guilt is felt for surviving or for acts of disloyalty during captivity and torture, i.e. confession, not being heroic. Defensive measures against shame, caused especially by sexual torture, are withdrawal and avoidance, isolation from others.

Shame and rage are interrelated in the same spiral. Shame evokes rage. Rage means being out of control and evokes shame. This spiral also contributes to violence in the family and elsewhere.

Chronic stress can lead to emotional exhaustion, resulting in depression and in a lack of energy, anhedonism and a general disengagement in the world and previous activities.

Prolonged helplessness and hopelessness can eventually lead to learned helplessness. Loss and a sense of failure lead individuals to blame themselves for what they have experienced.

7.4 Consciousness and Memory

The ability to alter one's own consciousness differs from person to person, but trauma increases an individual's ability to dissociate him- or herself from traumatic memories as a protective mechanism. However, the dissociated experiences have a tendency to return intrusively in memory flashbacks and nightmares. Moreover, dissociation increases detachment from the outer world. Dissociation may protect the individual against painful experiences, but it also constricts the emotional life of the individual, leaving him or her with poor symbolisation. In addition, dissociation interferes with cognitive processes and learning capacity and creates gaps in self-experience. Restoring contact with reality re-associates the fragments of visual images, memories and bodily sensations (Herman 1992).

Extreme stress may impair memory such that sounds, smells and images do not occur in sequence. Tortured individuals have too strong a memory in one sense, e.g. images are brought to mind too easily, but too weak a memory in another sense, as images are fragmented and can be experienced with feelings of unreality. The blurred memory of the past can affect the memory of current things (Allen 1995).

7.5 Self and Relationships

Herman (1992) points out that, in victims of severe trauma, all structures of the self, i.e. the image of the body, the internalised images of others and self, the values and ideals that give a sense of coherence, are invaded systematically and broken down. A victim of repeated and prolonged trauma may even lose the sense of self. Traumatic experiences lead to internal

conflicts and conflicts with other people, which render the self insecure and affect the capacity to act.

8 Psychological Assessment

The effects presented above have implications for assessment, and many initial barriers may emerge between clinician and patient. Traditional clinical methods of asking torture survivors to relate their trauma in their own words are frequently ineffective (Mollica and Caspi-Yavin 1992).

The survivor may not reveal all the symptoms or tell the whole story of torture. The effect of trauma on memory, possibly impaired memory caused by a head injury, denial and avoidance of painful memories, cultural norms about revealing painful experiences, fear of contaminating the clinician with the evil of torture and language barriers are all problems that the clinician may face during the assessment. Language barriers can be overcome through specially trained interpreters, who should be regular members of the medical team. Clinicians, especially inexperienced ones, may be overwhelmed by strong emotions when interviewing a torture victim about his or her experiences. They may feel emotional resistance in hearing the horrors of torture and concern about creating severe emotional distress or re-traumatisation in the patient. Another pitfall in both the assessment and treatment of tortured individuals is over-identification with the survivor's suffering and over-idealisation of his or her former activities. Supervision on these counter-transference reactions is necessary.

Anamnesis and history taking must show sensitivity and allow the survivor to control the amount of information given, since establishment of a trusting relationship has a high priority (Jacobsen and Smidt-Nielsen 1997).

A trusting relationship is enhanced if the assessment includes not only symptoms and history of torture but also the person's more important life experiences, personal values, former and current life situation, family situation and practical problems impeding his or her reintegration in society, be it the original one or a new host society.

Concerning the exact information on torture, the application of a checklist of traumatic experiences, including types of torture and symptoms, may ease communication during assessment and is to be recommended rather than open-ended interviews on these issues. The use of structured interviews and diagnostic instruments presents additional advantages for reassessment and research purposes.

Questionnaires commonly used to measure trauma symptoms include the Allodi trauma scale (Allodi 1985), the Mississippi Combat-Related PTSD (Keane et al. 1988), the Impact of Event Scale (Zilberg et al. 1982) and the Harvard Trauma Questionnaire (Mollica et al. 1991).

9 Treatment

Psychodynamic therapy and counselling, cognitive behavioural therapy and individual and group therapy are suitable for torture survivors (Basoglu 1992). There are as yet no clear research results on the effectiveness of different interventions. None of the above-mentioned methods has proved to be better than the others. The length of treatment varies; the insight therapy carried out at the RCT involves 20 to 80 sessions, while behaviour therapy involves ten to 20 sessions.

Most rehabilitation centres for torture survivors in countries where torture has been or is practised and in countries of resettlement base their work on a multidisciplinary principle with a broad spectrum of medical, psychiatric, psychological, physiotherapeutic and social care. A total of 126 centres and programmes are currently providing services for victims of torture in 54 countries (Network Coordination Division 1998). Most centres are run by non-governmental organisations funded by a range of sources. In most countries, the centres are dependent on international funds, local donations, the United Nations's Voluntary Fund for Torture Victims and money from the European Union or national governments. The scarcity of financial support often creates disruptions in the flow of money and in the continuity of treatment, and significant professional time is taken up by fund-raising activities. There is now increasing emphasis on community-based interventions and on developing mainstream health systems in order to address the needs of tortured individuals.

The supportive elements prevail in psychotherapy, especially during the initial phases. Survival and resettlement needs may initially dominate more than torture experiences or psychiatric symptoms. However, social support for a survivor with PTSD may not be of great use if the person is unable to profit from it due to psychological disturbances (Basoglu 1992). The therapist must be prepared for great fluctuations in psychological functioning depending on the phase of trauma exploration in therapy or stressors experienced in the victim's life as an exile in a strange culture with financial, employment, housing and educational problems (Somnier et al. 1992). Reconstructing and retelling traumatic experiences will always weaken defence

mechanisms and revive disturbing and often aggressive feelings towards the therapist and family members.

It is imperative for the therapist to find a balance between denial and the "conspiracy of silence" surrounding horrendous experiences and premature pressure on the patient to tell his or her story. It is important that survivors are allowed to tell their story at their own pace in order to avoid re-traumatisation. Torture victims are very likely to experience the therapist as an interrogating torturer (Tocilj-Šimunković and Arcel 1998). As bad psychological functioning impairs the survivor's whole quality of life and family life, some therapists suggest that the main objective of therapy is not total reconstruction of the trauma or symptom reduction, but rather increased functionality in achieving personal goals. The achievement of limited personal goals will create a good basis for further trauma reconstruction.

Cultural issues prevail when a therapist works with torture survivors who are refugees. They are often quite alien to psychological treatment and insist on the treatment of physical symptoms as the main objective of therapy; such patients need a thorough explanation of the nature of psychotherapy. Expression of emotion may be a social taboo in males from many cultures, as it is understood as a loss of control or "feminine" behaviour.

The core issues in any therapy independent of its theoretical orientation are as follows:

- Establishing a working alliance in a trusting relationship in order to restore faith in humankind and to re-establish attachment
- Recollection and cognitive reconstruction of traumatic experiences under the safe conditions of therapy
- Strengthening the individual's coping mechanisms by including the current life situation and its conflicts in therapy
- Attribution of meaning to the torture experience and helping the survivor to discard the "victim role"

The victim's family may be included in some phases of therapy. Muscular tension may be treated with physiotherapy and psychotherapy and may subsequently reach levels corresponding to those of a healthy working adult by the end of the treatment. During physiotherapy, the survivor is gradually made to understand the connection between his or her symptoms and the vulnerable points at which the torturers directed the torture.

Almost all torture survivors seeking treatment, i.e. both refugees and others, will need practical assistance along with medical and psychological treatment. Focusing on survivors' current life situation, family, personal values, on existential dilemmas created by their possible ideological disillusionment or the opposite and on the advantages and disadvantages of their role in their country's political situation is just as important for torture victims as the medical assessment and treatment.

Medication has been found to be effective in major depressions, obsessive–compulsive disorders, anxiety and psychotic symptoms. In a review article, Smith et al. (1998) reached the conclusion that tricyclic antidepressants and monoamine oxidase inhibitors produce modest improvements in positive symptoms of PTSD.

10 Prevention

In the medical work for the eradication of torture, the public health model with its distinction of three levels of prevention was the first to be developed and has been widely recognised. The primary focus aims at society and tries to prevent the practice of torture. In order to achieve this, many strategies may be used, including identification of agents of torture, the legal basis and the actions to be taken. Secondary prevention focuses on high-risk groups, e.g. medical and law-enforcement personnel, and may include arranging training activities for these groups. Tertiary prevention aims to provide rehabilitation at an individual level for those who have been exposed to human rights violations and for their families (Arcel et al. 1995; Arcel 1994, 1998). The prohibition of torture from a legal point of view is regarded as an imperative rule of international law, and specific international and national mechanisms have been devised to prevent torture. The emphasis here is on the state's obligation to ensure that the prohibition of torture becomes an integral part of the training of civilian and military law-enforcement personnel and medical personnel and others involved in the custody, treatment and interrogation of detainees. During medical examinations of victims by doctors from many countries connected with the International Rehabilitation Council for Torture Victims (IRCT)/Rehabilitation and Research Centre for Torture Victims (RCT) programme, it was particularly disturbing to discover the extent of participation in torture by medical doctors and other health care professionals who were present during the administration of torture, who determined the intensity and who decided when to continue or to stop (Vesti et al. 1998).

Doctors at risk are prison doctors who are often asked to help the torturers and forensic doctors who are tempted or directed to falsify death certificates and to minimise the extent of physical and psychological sequelae. Military doctors are put under pressure to conceal the atrocious activities of their colleagues (Rasmussen 1990; Eitinger and Weisaeth 1998; Pross 1988). International professional support networks can facilitate regulation of the professional ethical problems of doctors at risk and support these physicians in their roles as witnesses of conscience.

Seen in a developmental perspective, torture and organised violence is closely related to the political, structural and cultural conditions in a society. As a consequence, preventive interventions may be linked to a change in the underlying sociopolitical causes and to the creation of the necessary conditions for human rights and development at the level of society.

V. Folnegović-Šmalc

Psychiatric Problems Related to Violence and Rape

1 Introduction

For a long time, the focus of psychiatric interest in violence and rape has been on the personality of violators and/or rapists, and the discussion has been restricted mostly to forensic papers or textbooks. As for victims, the focus was on the victimizing role in the act of violence and therefore on the description of their mental condition prior to and during the act. Only recently have the consequences of violence and rape on the mental condition of victims and their environment come into the centre of attention (Burgess and Holstrom 1974). The description of the mental condition of victims and the corresponding diagnostic categories – severe stress (F43) and enduring personality change after catastrophic experience (F62.0) – were first introduced by the World Health Organization (WHO) in the International Classification of Diseases 10 (WHO 1992). Much attention in modern psychiatry is given to children and adolescents who have been victims of violence and/or rape, since they often suffer more severe and enduring consequences than adults. Provided that the intervention is adequate and timely, the development of severe and enduring consequences in children can often be successfully prevented (Kocijan-Hercigonja et al. 1996).

2 Epidemiology

Even though violence (and rape as a subcategory of violence) has been part of society since history began to be recorded, the incidence of violence seems to have increased over the past decades. Modern wars that rage not only on the front lines, but also behind the lines, the genocide that took place during the twentieth century (e.g. Jews in the Second World War, Bosnians and Croats in the recent war in the former Yugoslavia) and increased antisocial civilian behaviour may all have contributed to the increased incidence of violence.

During the recent war in Croatia, there were 650,000 refugees and displaced persons; 8646 civilians were wounded, of whom 11% were children and 25% women. The number and nature of traumatic events were studied in some refugee camps, and the results show that 40% of civilians were physically maltreated, 10% witnessed killing and 10% were raped or witnessed rape (Folnegović-Šmalc and Folnegović 1998). Children are often victims in modern wars. In the war in Croatia alone, 268 children were killed, 971 wounded and 900 lost both and 5497 one parent (Kocijan-Hercigonja et al. 1996).

In the United States, violence increased substantially from 1958 to 1968: homicide by 52%, rape by 71% and robbery by 143%. According to the Uniform Crime Reports, 1,932,274 violent crimes were committed and 109,002 individuals were raped in the United States in 1992 (Tardiff 1995).

Post-traumatic stress disorder (PTSD) was initially studied in Vietnam veterans. The prevalence of PTSD in Vietnam veterans up to 19 years after the war was 15% (Kulka et al. 1990), with an even higher rate in wounded veterans (Helzer et al. 1987).

Some very significant epidemiological data are presented in studies of monozygotic twins. Of the twins who had served in Vietnam, 16.8% had PTSD, while only 5% of the twins who had not served had PTSD (Goldberg et al. 1987). Trauma survivors' risk of PTSD may be related to positive heredity for PTSD (Watson et al. 1995). These data point to the need for further investigation of possible genetic factors in the development of mental consequences of trauma.

3 Factors Influencing the Development of Mental Consequences

Victims of violence experience severe psychotrauma that can lead to the development of serious mental problems. The consequences of violence for the victim depend on a number of factors, such as the nature of the violence and the way it is performed, the duration and number of psychotraumatic events, who the violence was performed by, the victimizing role of the victim, the victim's personality structure, mental condition and past diagnosis (Frank and Anderson 1987) and previous traumatic or other experience, the age, gender and educational level of the victim, the general medical, social and financial consequences of violence and their reversibility, the length of time since the violence has occurred, the support provided by the family and environment and primary prevention.

3.1 Nature of Violence and the Way It Is Performed

The nature of violence and the way it is performed generally reflects the personality structure and cultural and financial background of violators and their relationship towards the victim. Physical maltreatment is most common in poor and primitive environments. If the victim is a woman, and in some cases in men as well, rape often takes place. In better-off environments, violence is often performed in a more sophisticated way (e.g. conducting biological experiments).

Rape is a very common form of violence in which sexuality is in the service of non-sexual needs and wishes, used to express power, anger and domination. Sexuality can also be the basic motive for rape, but this is rarely the case. Rapists in these cases are usually mentally disturbed people, their victims are often children or the elderly and sexual act is often incestuous.

Rape can be public or without witnesses, and there can be one or more rapists. It can be combined with other forms of mental or physical maltreatment, or it may be the only form of abuse. Trauma can be collective or single. Mass public rape is commonly used in war situations to terrify the enemy and to achieve certain goals of war strategy, such as ethnic cleansing. In public rape, there can be two different groups of victims. Direct or active victims are those who have been raped, while indirect or passive victims are those who witnessed the rape or were threatened to be raped as well. There is a significant difference between the two groups from the gynaecological point of view, but there is often not much difference from the psychiatric point of view.

Raphael (1986) found higher rates of PTSD after collective traumatic situations than after single trauma. According to the results of a study of the connection between the development of PTSD and the nature of psychotraumatic events (Folnegović-Šmalc and Folnegović 1998), PTSD developed in more than 80% of individuals who had been publicly raped, wounded or witnessed killing (Fig. 1).

3.2
Duration and Number of Psychotraumatic Events

The severity of mental symptoms is considered to depend on the duration and number of times violence and/or rape has occurred, symptoms being more severe if the duration is longer. The results of our study (Folnegović-Šmalc and Folnegović 1998) show that PTSD develops significantly more often in people who have experienced four or more psychotraumatic events (Fig. 2). The therapeutic outcome is also more favourable for people who have experienced a smaller number of traumatic events.

3.3
Violator

Parents, children, other family members, acquaintances, strangers or enemies can all be violators. In the abuse of children, the most common violators are parents, and in the abuse of elderly, the most common violators are children or other family members. Violent acts towards the mentally ill or disabled people are often performed by hospital staff. In war situations, violent acts are most commonly performed by hostile army, but in modern wars, they are often performed by former neighbours or acquaintances who have chosen the opposite side in the war. Mental suffering is more intense and the number of symptoms increases if the victim knows the violators or rapists than in cases when the violators are strangers (Kozarić-Kovačić et al. 1995).

3.4
Victimizing Role of the Victim

Victimizing is very important for violence that takes place within family, especially for physical maltreatment. Mentally ill, alcoholics and people with personality disorders exert a victimizing influence more

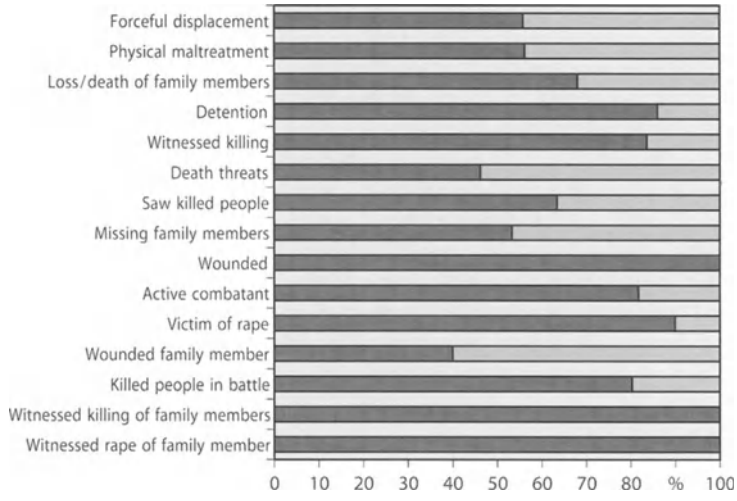

Fig. 1. Incidence of post-traumatic stress disorder (PTSD) in refugees with different traumatic events. *Shaded bars*, PTSD; *white bars*, no PTSD

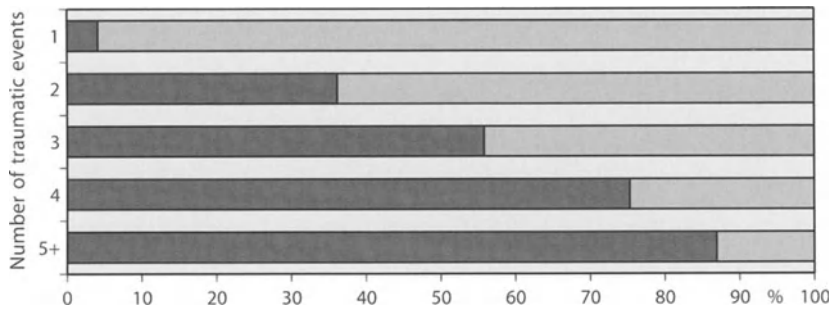

Fig. 2. Number of traumatic events in refugees with (*shaded bars*) and without (*white bars*) post-traumatic stress disorder (PTSD)

often. In war, however, there is no direct victimizing, unless opposite interests and attitudes are considered victimizing.

3.5
Victim's Personality Structure, Mental Condition and Previous Experience

In the description of acute stress reaction or PTSD (ICD-10), a traumatic event is described as one that "is likely to cause pervasive distress in almost anyone" (WHO 1992). Emphasizing that distress can be caused in *almost* anyone, this quotation indicates that the development of distress or PTSD is determined by the victim's personality structure and that individual vulnerability and coping capacity play a role in the occurrence and severity of acute stress reactions. Coping is defined as constantly changing cognitive and behavioural efforts in order to manage specific external and/or internal demands appraised as taxing or exceeding the resource of the person (Lazarus and Folkman 1984). It is well known that, in war for instance, many people have been exposed to similar traumatic experiences and yet not all of them have developed PTSD or other forms of mental decompensation. Furthermore, positive development in the form of defence mechanisms and maturity has been observed in poly-traumatized individuals who have spent months under traumatizing circumstances (Kozarić-Kovačić et al. 1998).

Earlier traumatic experience plays an important role in the way a person reacts to trauma (Breslau et al. 1991, 1997). People who have experienced severe psychotraumatic events earlier in life are more vulnerable when new trauma occurs. The recurrent traumatic event can be a precipitating factor for the development of serious mental decompensation, PTSD or even a psychotic condition. One of our patients is a good example: aged 63, married and retired; as a child during the Second World War he had to flee and leave home; his father was killed and his mother ran away to another country; he suffered severe mental and physical traumata; until 1991, he had never complained of or been treated for mental disorders. One evening during the war in 1991, he saw people on the news being forced to leave their homes in Vukovar. He became acutely psychotic and was admitted to hospital with mixed dissociative disorder (F44.7). After a few days of treatment, the psychotic symptoms withdrew and PTSD developed, the intrusive content being characterized by his early traumatic experience.

In addition to early traumatic experience, pre-existing psychiatric disorders, a family history of anxiety disorders and prolonged early separation from parents all contribute to the increased risk of mental decompensation after traumatic events (Breslau et al. 1997). The most common pre-existing psychiatric disorders are personality disorders. Alcoholism more commonly appears as a co-morbidity than as a pre-existing disorder. Co-morbidity depends partially on gender differences, depression being more prevalent in the female population and alcoholism being more prevalent in the male population (45%), followed by depression (37%), anxiety, personality disorders, opioid dependence and psychosis (Folnegović-Šmalc and Folnegović 1998). Out of veterans that had PTSD, 54% had co-morbidity, while 7% had developed enduring personality change after catastrophic experience during the 3 years after PTSD was diagnosed.

3.6
Age, Gender and Educational Level of the Victim

The victim's age is a very important factor in determining the kind and intensity of mental decompensation after violence and rape. The most vulnerable groups are children (Robinson et al. 1994; Shannon et al. 1994), adolescents and the elderly (Cheung 1994).

Most studies indicate a greater frequency of PTSD in the female population (Breslau et al. 1997; Davidson et al. 1991; Helzer et al. 1987), but some of them

indicate the same frequency for both genders (Folnegović-Šmalc and Folnegović 1998; Kozarić-Kovačić et al. 1998).

Low socio-economic status seems to be positively correlated to the development of mental difficulties after traumatic experience (Weisaeth 1996). Educational level, on the other hand, negatively correlates with the intensity and number of symptoms. The cognitive and emotional personality structure is reflected in the way a person interprets traumatic events. The level of education determines defence mechanisms and coping ability (Horowitz 1993; Myers et al. 1984) and influences cognitive levels of interpretation; it can therefore postpone or play a protective role in the development of severe mental consequences.

3.7
General Medical, Social and Financial Consequences of Violence

General medical, social or financial consequences of traumatic events can contribute to the development of mental symptoms. Taking rape in war as an example, mental symptoms and PTSD are likely to develop in victims. If general medical consequences such as infections or vaginal lesions occur, the likelihood of PTSD developing is greater. Furthermore, of those raped women who became pregnant and had a baby, almost 100% develop PTSD. They perceive the baby as "a foreign body in their womb". In this group, suicidal behaviour, psychotic symptoms and sexual disorders, most likely orgasmic disorders, dyspareunia and vaginismus, are also frequent (Kozarić-Kovačić et al. 1995).

3.8
Duration of Period After Violence Has Occurred

The length of time that has elapsed since violence had occurred is very important for an individual's assessment of the intensity of psychotrauma. The victim's assessment of the intensity of psychotrauma was studied in a group of refugees and displaced persons that had experienced the following traumatic events: exile, hunger (personal or other family members), loss of material goods, permanent life-threat and physical torture, permanent physical disability by torture (personal or other family members) or death of a family member. Immediately after arrival at the camp, i.e. within a few days of the traumatic experience, hunger was rated as the most intense traumatic experience. Two to three months later, the death of a family member was rated as the most intense traumatic experience by the same group (Folnegović-Šmalc and Folnegović 1998). These results indicate that, shortly after violence has occurred, existential problems and material losses are most significant for the individual, but as time passes, the individual experiences irreversible emotional consequences as most traumatic.

3.9
Support from Family and Environment

Psychosocial and material support, understanding from their family and environment and the ability to make autonomous decisions are significant for traumatized subjects immediately after the traumatic event has occurred. Providing help in dealing with feelings of shame and guilt and recognizing possible suicidal intentions are of extreme importance.

People that have been raped need support in organizing medical examinations, in knowing the truth about possible sexually transmitted diseases (STD) or pregnancy and, if they insist, in keeping the event secret. People who want to keep the traumatic event secret should not be included in group therapy. The family should be advised on how to provide maximum support, and the individual should return to family as soon as possible. An exception to this is when a husband cannot accept that his wife has been raped, in which case the return to the family can be postponed until they both reach a decision about their future life together.

It is important to remind caregivers and members of the family that, prior to their experience of assault, rape victims were no different from anyone else of their age and social background with respect to psychiatric symptoms or diagnoses and that, following rape, most victims experience a large number of serious psychiatric symptoms and may appropriately be considered for interventions directed at reducing the intensity of those symptoms. The interventions should include education about normative reactions to rape and about the falsehood of rape myths, exploration of the meaning of the assault to the victim, relaxation training and other anxiety-reduction techniques as well as guidance in decision-making regarding disclosure of the rape, prosecution of the assailant and possible changes in where the victim lives or other life-style changes (Frank and Anderson 1987).

3.10
Primary Prevention

Primary prevention of mental consequences of violence is focused on providing basic existential security

and support by family and environment, limiting exposure, providing education about the individual expectation of the person who has been traumatised – about the course, prognosis and consequences (e.g. pregnancy) – education of family members, providing general medical services, regulating sleep and debriefing. If co-morbid disorders occur, adequate therapy is needed.

4 Clinical Presentation

Mental response to stressful events reflects the complexity of psychotrauma, and various alternatives may predominate in the clinical presentation within this complex model. A variety of traumatic events can thus provoke various mental symptoms. Clinical experience confirms that the nature of symptoms is usually determined by the nature of the stressful event, while their intensity is determined by the pre-morbid personality structure, the intensity and duration of traumatic events and the attitude towards the victim in his or her environment.

Symptoms can meet the criteria for acute stress reaction, PTSD, other reactions to severe stress and reaction to severe stress, unspecified. Conditions that meet criteria for diagnostic categories included in sections other than "reaction to severe stress" can also develop. These include sleep disorders, eating disorders, alcoholism, other substance-related disorders, depression, anxiety and psychotic conditions. In describing PTSD, recent classifications of mental disorders have focused on symptoms in veterans or prisoners so that, despite their severity, symptoms in people who have been raped often have to be classified as other reaction to severe stress (ICD-10), which is a worse category in diagnostic terms. This indicates the need for further subclassification of the reaction to severe stress category.

People who have been raped often have following symptoms: changes in behavioural patterns, markedly diminished interest in life or significant activities, prolonged silences, social withdrawal, memory disturbances, depression, feeling guilty and anxious, feeling numb or detached, sleep disturbances or loss of appetite. Victims may experience an extremely wide range of emotions. The impact of the rape may be so severe that feelings of shock or disbelief are expressed. They can show different emotional styles: the expressed style, in which feelings of fear, anger and anxiety are shown through such behaviour as crying, sobbing, smiling, restlessness and tenseness; and the controlled style, in which feelings are masked or hidden and calm, composed or subdued affect is seen. Confused thinking, difficulty in making decisions, uncertainty and poor problem solving can also be observed. Victims can feel helpless and self-pitying, and the risk of suicidal behaviour and actual suicide is high. Aggression towards others and intrusive symptoms are rare. People who have been raped may have symptoms of sexual disorders such as orgasmic or sexual pain disorders that are rarely observed in other psychotraumatized individuals. Victims are often afraid of possible sexual contacts. Dysmenorrhoea and symptoms such as those accompanying pregnancy are frequent. Psychosomatic disorders and complaints about feeling tired, exhaustion, chest pain, headaches, nausea and vomiting, accompanied by excessive sweating, increased heart rate, elevated blood pressure and rapid breathing, are also more frequent in people who have been raped than in other psychotraumatized subjects.

5 Malingering and Negation

As emphasized in DSM-IV, when making a diagnosis of PTSD in people who have experienced some forms of physical violence, malingering must be "ruled out in those situations in which financial compensation, benefit eligibility or forensic determinations play a role" (American Psychiatric Association 1994). In contrast, in cases of rape, victims themselves often use negation and denial as defence mechanisms. Depending on the individual and cultural background, the raped person may feel guilty and the attitude towards him- or herself may be negative and rejective, even in cases when there was no victimizing influence on the part of the victim. Rape is therefore often not reported even when other forms of violence also took place. Special models of psychological, social and general medical assistance should be offered to victims in order to help them overcome these difficulties. Therapists should play an active role in discovering that the person has been raped, should offer maximum confidentiality and should provide the possibility of anonymous phone interventions and other general medical services.

6 Treatment

Debriefing, other forms of cognitive behavioural therapy and pharmacotherapy are most frequent in the treatment of PTSD (Davidson 1992). A specific approach is needed in the treatment of psychotrauma

after rape. In addition to the standard methods applied for PTSD, individual psychotherapy is recommended. In pharmacotherapy, the focus is on possible suicidal behaviour, depression and sleep disorders.

A victim of violence and/or rape should always be viewed as an individual, bearing in mind the complex and dynamic interaction of that person's past and present experience and the variety of biological, psychological and environmental influences. Mental consequences in victims of violence comprise a broad range of symptoms and intensity, whereas symptoms and defence mechanisms in victims of rape are more alike. Violence and rape affect not only the victims, but also their family, with the possibility of the development of severe mental disorders and even psychotic conditions in family members. In conclusion, violence and rape represent a serious psychiatric and public health issue, and the importance of primary prevention and timely psychiatric intervention must always be emphasized.

Psychiatry in Custody and in Prisons

Translator: E. Taub

1
Institutional Settings for Imprisonment

The commonest forms of imprisonment are on remand and under sentence following a criminal conviction; of more limited significance are detention by the police and the detention of individuals who are, or are suspected of being, illegal aliens. To be distinguished from these is detention in camps, particularly in concentration camps and as prisoners of war.

1.1
Rates of Detention

In the penal institutions of the Federal Republic of Germany, the total number of prisoners on the 31 December 1994 was 60,289. Of these, 39,291 were sentenced prisoners (of whom 1570 were women), 4265 prisoners in youth detention centres and 20,203 prisoners on remand. This gives an overall rate of detention of 73.9 per 100,000 inhabitants. Making international comparisons, there are countries with lower rates of detention, such as Sweden (50.6 per 100,000 inhabitants) or the Netherlands (50.7), but also countries with higher rates, such as England and Wales (89.9) or the USA (455) (Tomasevski 1992).

1.2
Conditions of Imprisonment

Internationally, there is great variation in the conditions under which prisoners are kept. Factors which can influence psychological state include nutritional deficits (which in niacin or vitamin B_{12} deficiency may even produce dementia), appalling hygienic conditions or maltreatment by prison staff (who may sometimes be acting out sadistic impulses). These factors should play no role in those countries which adhere to the *Standard Minimum Rules for the Treatment of Prisoners* of the United Nations or to the Council of Europe's (1987) guidelines, which to a large extent concur with those of the United Nations.

A question of significance not only for legal outcome concerns the extent of prisoners' integration into the subculture, e.g. the extent to which they have relationships with fellow prisoners which are oppressive and the role they play in the environment in which they live. The mentally ill are at increased risk of being subject to harassment (verbal threats, discrimination, physical violence) and exploitation by their fellow prisoners. Sexual abuse even extends to being raped by fellow prisoners.

Greater rates of contact and consultation with doctors are found than in the general population. The functions of this in everyday prison life are not only the provision of acute medical care, but also relief from isolation (e.g. through opportunities for contact in the waiting room/waiting cell) and the provision of treatments which at earlier stages were neglected or postponed (e.g. dental care).

1.3
Role of the Psychiatrist

The professional medical role of a psychiatrist and/or psychotherapist working in a prison has a conflict inherent in it. On the one hand, the doctor acts according to the requests and interests of his or her imprisoned patient and, following the Hippocratic oath, assigns the highest priority to the preservation and restoration of the patient's health, yet on the other hand he or she is an employee of that authority which, in carrying out the punishment required by the state, implements measures which may well damage the prisoner's health (Binswanger 1979). Unlike the surgeon or physician working in prison, who treats illnesses which have been imported from conditions of freedom or which happen to have occurred during imprisonment, the psychiatrist in prisons daily deals with large numbers of individuals with "prison reactions", which have arisen directly as a consequence of imprisonment. To a certain extent, the function of the psychiatric and psychotherapeutic treatment provided by the psychiatrist is to keep the prisoner fit for imprisonment, serving a pacifying and mollifying function (Mechler 1981). Prison psychiatrists find themselves in ethically questionable territory if they carry out psychopharmacological or other medical interventions for which there is no primary medical indication, in order to allow judicial proceedings and the penal system to run smoothly (Binswanger 1979).

Because particular stresses in imprisonment can lead to adjustment disorders, the psychiatrist is in a position to propose changes in conditions of imprisonment. These need not be confined to changes for a single individual (e.g. transfer to a protected place of imprisonment), but may also promote more general reforms in prison conditions, with the aim of creating a therapeutic atmosphere. Persisting stress from an atmosphere of violence and provocation can also lead to psychological disturbances among prison staff.

Acutely mentally ill individuals are not infrequently dealt with under conditions which seem inappropriate when compared with psychiatric treatment in the health system. Thus there are instances of mentally ill individuals being dealt with through disciplinary procedures and placed in isolation, even when they are

incapable of understanding the workings of the institutions or of following the rules (e.g. when they refuse to leave the cell when ordered to do so or violate rules about hygiene, e.g. by showering fully dressed; Hodgkins 1995). Other typical behaviours of psychiatrically disturbed prisoners include acts of self-harm, firesetting in their cells, neglect of personal hygiene and vandalising the contents of the cell (Adams 1986).

2 Selection Processes – Diversion

A psychiatrically disturbed individual who has been accused of a crime which may carry a custodial sentence passes through a series of filtering processes en route to a penal institution. In the course of these processes, indications may be identified for his or her removal from the criminal justice system (diversion) by, for example, transfer to a psychiatric facility. Whether the potential routes for diversion available in a particular country are used in practice depends on basic convictions about where a mentally disordered offender primarily belongs (Steadman et al. 1995).

2.1 Role of the Police

A key initial crossroads for the diversion process is represented by the actions of the police. In some circumstances, for an offender with conspicuous psychiatric morbidity (who may in fact be more readily identifiable as the perpetrator of a crime; Porporino and Motiuk 1995), the police may not even initiate criminal proceedings via a remanding judge, but may refer the offender to a psychiatric service. For the preliminary inquiry, decisive importance is assigned to the police report (Duff 1997).

If the police attribute no particular importance to an apparent psychiatric disorder, or if criminal prosecution is initiated in spite of this, the public prosecutor's office, as the authority responsible in Germany for criminal prosecution, may put aside the preliminary enquiry. This occurs if the accused is obviously not capable of taking responsibility for his or her criminal act and the severity of the offence committed does not suggest that he or she is generally dangerous. Internationally, there are variations between different legal systems in the definitions of responsibility under criminal law. These differences concern the capacity for being held responsible for criminal actions, fitness to plead and, in particular, the possibility of a judgement of "guilty but mentally ill". Even in Germany, the presence of a psychosis does not automatically mean that lack of responsibility for criminal actions is assumed (see Vol. 1, Part 2, Chap. 16; Konrad 1995).

2.2 Alternatives to Imprisonment

A significant question is whether there are alternatives to a custodial sentence within the criminal justice system: shortage of adequate care institutions, particularly long-term in-patient facilities, gaps in community systems of support and very narrowly formulated criteria for hospital detention under civil or public law may convey the impression of a gap in security, which in the absence of other social controls it may seem most appropriate to close using the criminal justice system (Edwards et al. 1994). Sometimes the criminal justice system is seen as operating as a facility capable of providing multiple services and, as such, as being the best place of treatment for the mentally ill (Dell et al. 1993), without account being taken of the extent to which treatments are really available in practice in particular local institutions.

However, even among those detained on remand for relatively long periods, psychiatric illnesses may not always be recognised (Teplin 1990). While staff responsible for admitting prisoners to custodial facilities generally only detect illnesses characterised by massively conspicuous behavioural abnormalities, the admission medical examination which is obligatory in some countries is not a fully reliable filter for detection of psychiatric illnesses, particularly depressive disorders, either.

2.3 Admission to a Psychiatric Hospital

Where the offence is more serious, German criminal law allows for provisional detention in a psychiatric hospital under the provisions of Art. 126a of the German code of criminal procedure (*Strafprozeßordnung*, StPO). If, in the course of remand in custody, it becomes apparent that the conditions are met for the final outcome to be a compulsory detention in a psychiatric hospital under Art. 63 of the penal code (*Strafgesetzbuch*, StGB), Art. 126a StPO may be applied to allow transfer from remand in custody. Both provisional detention under Art. 126a StPO and longer-term detention according to Art. 63 StGB generally involve admission to the official secure facilities (see Vol. 2, Chap. 17), which are obliged to accept these transfers on the orders of a judge.

In countries in which there is no legal obligation for treatment institutions within the health service to accept admissions on court orders, a psychiatrically ill individual may remain within the criminal justice system regardless of the severity of his or her disturbance. The major reasons for refusal to accept such individuals for treatment are that they appear excessively dangerous for the treatment facility (e.g. because of inadequate physical security conditions or lack of staff experience in forensic psychiatric practice), that suitability for treatment is limited (e.g. with "difficult" chronically psychotic patients) or that the indication for treatment is not sufficiently strong. Doctors' attempts to provide a route into the health system, e.g. by writing a report, may be associated with delays (time allowed for provision of reports, time for provision of a second opinion in contentious cases) and may thus even prolong the period of detention on remand (Robertson et al. 1994). The time between the issuing of the order for transfer to a psychiatric facility and the actual transfer taking place (e.g. when there is a shortage of beds) can also influence the prevalence of psychiatric disorders within penal institutions (Dell et al. 1993).

2.4
The Mentally Ill Remanded in Custody

When a mentally ill individual does end up remanded in custody, early diversion processes are important, above all because of the relatively high suicide risk. In addition to an as yet unrecognised mental disorder being overlooked (e.g. schizophrenia with predominantly negative symptoms), there is a possibility that a psychiatric disorder present at the time of the crime may have been in remission at the time of detention and may again become apparent only at a later point in time.

In some countries, such as Germany and England, there are legal provisions which allow a prisoner with a severe mental illness to be defined as unfit to plead and spared further remand or criminal proceedings. Some countries make use of the possibility of transferring mentally ill individuals in custody for (temporary) treatment of their illnesses in public hospitals, if specific provisions for this are not available within the criminal justice system (e.g. in specific forensic hospitals).

Because the presence of a psychiatric disorder may be equated with dangerousness, there may be delays compared with fellow prisoners in release with a caution (Teplin 1994) or in measures granting reduction of sentences, including early release on parole (Porporino and Motiuk 1995). This phenomenon also influences the prevalence of psychiatric disorders in custody. Finally, there may be tendencies for special conditions to be imposed when psychiatrically offenders are released on parole and for greater social surveillance to be put in place by the authorities, leading to a higher rate of recall following release on parole even where no new criminal offence has been committed (Porporino and Motiuk 1995).

3
Prevalence of Psychiatric Disorders

3.1
Methodological Problems in Empirical Studies

Empirical studies (e.g. Roesch 1996) have not confirmed the assertions which are periodically made that rates of psychiatric disorders among prisoners are increasing (e.g. Jemelka et al. 1989) and that this may be linked to deinstitutionalisation programmes. In view of the lack of clarity about diagnostic criteria which is not infrequently a characteristic of studies, and the use of selective samples and of unstandardised procedures for diagnosis, scepticism has been expressed regarding the conclusions of some of these studies. In cross-sectional studies, problems also arise from the variations in length of imprisonment prior to the survey, which can lead to confusions between illnesses present prior to imprisonment and those which have developed during imprisonment, as well as in comparisons between point and lifetime prevalence. In addition, the widespread tendency to associate psychiatric disturbance with dangerousness can encourage tendencies to conceal symptoms among prisoners who do not wish to jeopardise their chances of earlier release on parole (Smith 1987).

Variations in prevalence found in different studies may arise from the particular characteristics of the population examined as well as from the specific survey method. Thus generalisations across countries should be avoided and the prevalence figures arrived at should mainly be used for service planning (Roesch et al. 1995).

The summary presented in Table 1 only includes studies involving the examination after 1990 of a relatively large ($n > 100$) representative sample of a population of prisoners with standardised diagnostic instruments and a diagnosis which has been made on the basis of an international system of classification in which dependence syndromes have been included. Limitations arise above all from the generally limited willingness of remand prisoners to co-operate, from the reliability of the survey instruments used (e.g. Diagnostic Interview Schedule, DIS) in detecting per-

Table 1. Empirical studies on the prevalence of psychiatric disorders

Author	Country	Population	Subjects (*n*)	Survey instruments/ classification system	Diagnosis made (%)	Schizophrenia (%)[b]	Affective disorder (%)[c]	Personality disorder (%)	Alcohol dependence (%)	Drug dependence (%)

[a]Those held in "jails" are generally prisoners on remand and those serving short sentences (< 1 year).
[b]Paranoid psychoses are also included in the "schizophrenia" diagnostic group.
[c]For classification according to ICD-9 affective psychoses, and for classification according to DSM-III(-R) major depression and bipolar disturbance are included in the "affective disorder" column.

sonality disorders and from inter-rater reliability, which is not always adequately examined.

3.2 Drug and Alcohol Use

Despite the variations which result from particular local characteristics and from differing research methods, a generalisation which may be made is that once the diagnosis of antisocial personality disorder is excluded (for which frequency estimates vary greatly because of limited reliability), drug and alcohol dependence generally constitutes the most important diagnostic group. Where more than one diagnosis has been recorded for probands, dependence syndrome plays an important part as a co-morbid disorder (Anderson et al. 1996; Brooke et al. 1996). Overlaps have been described above all between the diagnoses of antisocial personality disturbance, alcoholism, drug dependence and major depression (Abram 1990). Indeed, the use of illegal substances together with behavioural abnormalities and lack of treatment can create the route into prison (Chiles et al. 1990). Co-morbidity requires specific treatment programmes which differ from models of treatment used for "pure" disorders (Teplin et al. 1996).

Table 1 suggests a higher prevalence of psychiatric disorders among remand prisoners than among those serving sentences. Evidence supporting this conclusion comes from the finding that a transfer on the grounds of a need for in-patient treatment was judged to be indicated among 9% of remand prisoners (Brooke et al. 1996) compared with 3% of those serving sentences (Gunn et al. 1991) in England and Wales.

To the extent to which comparisons have been undertaken with the general population, a greatly raised prevalence of psychiatric illness among prisoners has been found across countries and across diagnostic groups (Arboleda-Flórez 1994; Bland et al. 1990; Brooke et al. 1996; Hodgins and Côté 1990). Considering diagnoses individually, this is particularly marked for the dependence syndrome disorders.

3.3 Sex Differences

Higher rates of morbidity are found among female than among male prisoners (Anderson et al. 1996; Maden et al. 1994), suggesting that the filters in the selection processes outlined above operate differently. Thus one would expect a greater level of need for treatment in the female penal system, related to higher prevalence of psychiatric disturbances (Maden et al. 1994). In practice, female prisoners tend to be more willing to accept offers of treatment. This may also be related to a better therapeutic atmosphere among female prisoners. Further, women's experiences of stigma are not so severe when they enter (psycho-) therapeutic treatment. Empirical evidence has not yet been provided for the hypothesis that rates of early traumatic life experiences are higher among imprisoned women than among those not in prison (Jordan et al. 1996).

4 Specific Clinical Pictures in Prison

4.1 Addiction-Related Disorders

Dependence disorders are currently the most commonly occurring psychiatric disorders in prison in most European countries and in America (Edwards et al. 1994; Teplin et al. 1996). Taking a longitudinal perspective over the past few years, a shift can be observed from alcohol dependence towards dependence on opiate-type substances and multiple substance dependence (Anderson et al. 1996), with particular national patterns of consumption and the availability of psychotropic substances having an important impact.

4.1.1 Withdrawal Syndromes

Among those with dependence disorders, psychological and physical manifestations of dependence – which vary greatly within and between individuals – may be observed in the first few days after imprisonment. The severity of drug withdrawal syndromes following forced abstinence is often overestimated. Marked withdrawal syndromes occurring in German penal institutions are often treated with medication ("supported withdrawal", e.g. with methadone and/or diazepam in gradually diminishing doses). Prolonged withdrawal syndromes and, in particular, persisting depressive syndromes after the physical manifestations of withdrawal subside may require longer-term treatment with antidepressants, e.g. doxepin.

Sometimes people with drug dependence try to conceal their addiction after imprisonment. As well as reduced general and nutritional state, alertness should be aroused by fresh injection sites and by older, hardened and dark-coloured areas of veins (not only in the elbow region) which may indicate old injection sites.

Acute withdrawal symptoms can strengthen suicidal tendencies in prison (Bogue and Power 1995). Prac-

tices which are contraindicated are iatrogenic maintenance of addictive tendencies through excessively prolonged treatment with psychotropic drugs such as chlormethiazole, which were initially indicated by psychopathological symptoms, through the use of a broad range of indications for tranquilisers or through uncritical administration of analgesics in a way that promotes dependence. Analgesics are sometimes administered by nursing staff or even prison officers without medical staff first establishing that they are indicated.

4.1.2 Therapeutic Options

Prisoners with dependence disorders constitute a particularly difficult clientele from the point of view of amenability to treatment. In countries in which treatment can be offered as an alternative to imprisonment, the patients found in the penal institutions are above all those who have failed to proceed through this channel, with many of the failures already occurring at the start of treatment, e.g. when patients fail to enter the treatment facility or leave within a few days. Those prisoners with longer sentences for whom, despite their wish for treatment, conditions of imprisonment do not allow transfer to an external treatment facility suffer because of the treatment-hostile culture of the normal penal institution become involved in the subculture and can sometimes obtain addictive substances without much effort (Chiles et al. 1990).

4.1.3 Drug Consumption in Prison

Under prison conditions, it is generally not possible to guarantee absolute freedom from drugs. Alcohol can be manufactured from yeast, fruit and bread laid down in a warm place, e.g. by the central heating. Particularly in larger, more chaotic places of imprisonment, drugs enter by a variety of routes. These are generally cannabis and heroin, and more rarely cocaine or other drugs which change hands at higher prices than heroin. Purchase of drugs via other prisoners can bring with it an increasing involvement in subcultural activities and accumulation of debts, which can sometimes make the situation in prison unbearable for an individual prisoner.

Where the supply of substances is irregular, the possibility that withdrawal symptoms may develop may sometimes not be considered, e.g. following transfer into a particularly sheltered area. Flashbacks are a rarity in everyday prison life. When prisoners who have been identified by prison staff as having psychiatric morbidity are interviewed, particular care is required in differential diagnosis, as these disorders are often categorised as belonging to the range of substance-related disorders; an important danger is that the presence of a schizophrenic illness with "secondary" drug dependence may in particular be missed on superficial interview. Of critical importance are reliable urine tests, i.e. specimens obtained under observation, preventing the use of prepared urine specimens supplied by other prisoners which may have been kept warm by the heating.

4.2 Adjustment Disorders

"Prison is by its whole nature an unnatural milieu", according to Birnbaum (1931), "and in keeping with this the state of imprisonment is an unnatural condition in which to live." The clinical pictures to be classified as adjustment disorders would not have arisen without imprisonment as a psychosocial stress or, to be precise, a critical life event.

4.2.1 Different Forms of Experience

With the reduction in the range of external stimuli and impressions, the prisoner may sink into a state empty of thoughts and feelings, sometimes extending to complete apathy, or else may experience an intensification of the emotions associated with perceptions and an increase in imaginative activity, including daydreaming (Sieverts 1979). For those with narcissistic personality traits and disorders, fantasies can include the reversal of the previous failure and the anticipation of future successes in crime.

Different individuals also cope differently with feelings of profound desolation and inner needs. Fears of maltreatment are of considerable significance for those prisoners who have maltreated or abused children, have been informers to prison or judicial staff or who cannot pay debts (from drug purchase or gambling). Tendencies to regress may be expressed through an increasingly dilapidated physical state and weight gain.

4.2.2 Symptoms

Among the many forms of experience provoked by the prison situation, fluid transitions to symptomatic pictures which meet ICD-10 criteria for adjustment disorders sometimes occur. Symptoms observed vary greatly both between individuals and over time for a single individual, and they include despondency, withdrawal into isolated ruminations in the cell,

anxiety, stupor, agitation and hostility. It has been suggested that adjustment reactions vary according to the form of imprisonment (single or communal imprisonment), but as yet there is no scientific evidence to support the generalisations which have been made about the various factors which may be significant (e.g. variations in the level of isolation, including solitary confinement, differing sizes of rooms allowing retreat to different degrees, variations in daily routine and in characteristics of fellow prisoners).

4.2.3 Basis for Explanation

Attempts to explain these "prison reactions" emphasise the triggering effects of particular stresses, such as the issuing of an arrest warrant, interviews with the police, being confronted with the statements of accomplices or witnesses, being denied visits, episodes of isolation, appointments for review of remand in custody, delivery of the indictment, end of trial and judgement being pronounced. General factors associated with imprisonment should also be taken into account: loss of social status, limitation of freedom of movement, living space and sphere of action, isolation through removal from the usual social networks, change in patterns of communication and profound alteration in previous living habits. It is difficult to gauge precisely the effects of these factors on a particular individual and the reduction in coping resources which they bring about. Stresses can also result from the uncertainty about how severe a punishment to expect, contemplation of the criminal act and the experience of lack of understanding or contemptuous treatment from the prison staff.

Ways of reacting to these stresses and the evolution of adjustment disorders are widely regarded as being related to personality (e.g. Langelüdekke and Bresser 1976), in that personality influences the significance for the individual of imprisonment, vulnerability to stress and the tendency to get involved in stress-producing situations such as arguments with fellow prisoners (Hurley and Dunne 1991). However, as various authors have described (e.g. Schleusener 1976), there are difficulties in recording reliably transient psychological changes among prisoners, perhaps because the sensitivity of the instruments thus far used to measure them is limited (Rasch 1976). "Imprisonment shock", a transient stupor-like state of total resignation, tends above all to afflict younger and very active people; the third decade is a stage of life during which intolerance of imprisonment is great (Birnbaum 1931).

4.2.4 Course

Adjustment disorders are observed less frequently among sentenced prisoners (1.9%) than among those on remand (7.6%–18.5%) (Gunn et al. 1991; Hurley and Dunne 1991; Brooke et al. 1996). As length of imprisonment increases, symptoms diminish to a degree, with adaptation to life in prison becoming greater and roles within the subculture which stabilise self-esteem perhaps being adopted (Backett 1987). Thus the proportion of remand prisoners judged to be severely disturbed in a Swiss prison fell from 57% on the tenth day after imprisonment to 43% after 60 days in prison (Harding and Zimmermann 1989).

4.2.5 Classification of "Prison Reactions"

The classification of "prison reactions" is not uniform. Langelüddeke and Bresser (1976) distinguish between panic-dominated, paranoid, aggressive, querulant, depressive, suicidal and simulated prison reactions. From the perspectives of attempting to make more reliable psychiatric diagnoses and keeping practice embedded within the framework of clinical psychiatry, there are no advantages to using terminology which deviates from the international systems of classification.

Thus the condition known as "prison rage" (a state of explosive agitation in which cell contents are smashed up and acts of violence sometimes committed towards staff or fellow prisoners) should be classified as an adjustment disorder with predominant disturbance of conduct (ICD-10 F43.24). This is observed above all following longer periods of isolation in situations in which there has been an experience of rejection, such as recall from parole or separation from a partner (Mechler 1981).

Reactive psychoses, such as those manifested by foreigners in environments where they do not speak the language, can be classified as acute and transient psychotic disorders (ICD-10 F23). In terms of differential diagnosis, strong consideration should be given to disorders related to psychotropic substances (above all delirium or psychotic symptoms) as well as to schizophrenia or delusional disorders.

4.3 Prison Psychoses

4.3.1 True Psychoses Versus Prison Psychoses

While adjustment disorders predominate in out-patient clinical practice within the criminal justice system (see Vol. 1, Part 2, Chap. 17), psychoses are the most

frequently occurring disorders in the in-patient sphere (Konrad 1997). With reference to mental illnesses with psychotic symptoms, a substantial proportion of German psychiatrists maintain the distinction which originated in the last century between "true psychoses" and "prison psychoses". The disorders regarded as "true psychoses" generally fit into the category of schizophrenic illnesses, with psychopathology which may be coloured by prison conditions in aspects such as the contents of delusions, whereas "prison psychoses" are specific reactions to imprisonment (Langelüddeke and Bresser 1976; Mechler 1981). According to this model, it is assumed that "prison psychosis" is a product of individual vulnerability factors, such as an innate disposition to become psychotic (Birnbaum 1931) or particular sensitivity to prison conditions among impulsive and opportunistic offenders (Nitsche and Wilmanns 1911), together with factors related to current circumstances, such as the prevailing social climate of the time (Wilmanns 1924) or conditions in the penal system (Knigge 1932). Blurred boundaries are described between this state and dissociative phenomena and simulation (Wilmanns 1924; Mechler 1981).

The rarely observed Ganser syndrome is located on this continuum, in which the typical symptomatic picture involves talking past the point together with a qualitatively altered state of consciousness. This state, however, appears more frequently in situations where examinations are taking place than in everyday prison life. In this condition, the symptomatic picture is reported to be relatively stable during the generally short period for which it is manifest. The syndrome is more commonly observed among people with lower than average intelligence and histrionic personality traits (Bellino 1973).

Some authors conceptualise prison psychoses as intensifications of and developments from "prison reactions", from which they differ in their persistence and in the particular symptoms which develop. Langelüddeke and Bresser (1976) characterise subtypes, differentiating between pictures characterised by paranoia and sometimes hallucinations, based on a "delusion of innocence", primarily simulated states and extreme manifestations of poorly developed personalities, with blunting and loss of initiative. Apparently unprovoked attacks on prison officers are manifestations of these states with obvious practical significance and may lead to confinement in a place of special security or other disciplinary measures.

4.3.2 Differential Diagnosis

"Prison psychoses" have not entered international classification systems (ICD-10, DSM-IV) as a distinct clinical entity. Attempts to differentiate them diagnostically from the early manifestations of "true" psychoses, especially schizophrenic illnesses, for which imprisonment has to varying degrees been identified as an important trigger, make reference to the narrowness of the scope of paranoid beliefs in prison psychoses, with a tendency for delusions to be limited to the immediate environment but not to relate directly to fellow prisoners (Nitsche and Wilmanns 1911). Another differentiating factor which has been identified as crucial is the termination of prison psychotic phenomena with the interruption or ending of imprisonment, even though there may be "remnants" in the form of "now affect-free remains of delusions" or querulant or hypochondriac character traits (Birnbaum 1931).

4.3.3 Schizophrenic Illnesses

In comparison with other prisoners, prisoners with schizophrenic illnesses have a greater tendency to develop difficulties in obeying prison rules and in sustaining work roles within the institution. Because they more often behave in aggressive and violent ways, they are more often put under lock and key (Morgan et al. 1993). Occasionally, beliefs about being poisoned may be the basis for a refusal to eat, which is misinterpreted as a hunger strike. Even in countries where routine medical examinations are required, the presence of schizophrenic illnesses is not infrequently overlooked, especially when negative symptoms dominate the clinical picture (Anderson et al. 1996).

4.3.4 Depressive Illnesses

Depressive illnesses are sometimes missed in prison medical practice (Herrman et al. 1991). When a nonconformist prisoner presents with physical complaints without organic correlates, in clinical practice in the criminal justice system a diagnosis is too often made of simulation or of a psychosomatic disorder, without due consideration being given in differential diagnosis to the possibility of an affective illness. A depressive illness may also underlie apparently disruptive conduct in prison, e.g. when prisoners vandalise their cells (Maden et al. 1994).

Simulation of psychiatric disorder, e.g. through feigning of psychotic symptoms, is not frequent and can constitute a coping strategy aimed at improving conditions of imprisonment or obtaining prescribed medications for the prisoner's own use or for dealing.

4.4
Vexatious Complainers

Prisoners who are vexatious complainers generally begin with prolific writing activities, which are extremely time-consuming for the staff responsible for dealing with them. These activities may relate to judgements or decisions of the court felt to be unjust or to real or imagined neglect or discrimination during imprisonment.

Half of the complaints which need to be dealt with in a penal institution generally originate from just a few prisoners. For them this behaviour may not only be a kind of "occupational therapy", embarked on as a way of coping with loneliness and emptiness, but may also result from a subjectively experienced "cul-de-sac" in the course of imprisonment. The complaints often stop if an acceptable shared perspective and plans for the sentence can be arrived at with the prisoner before he or she becomes entirely alienated from the system.

5
Suicide and Suicide Attempts in Prison

5.1
Suicide Rate

In many places, suicide is the leading cause of death in prison (Tomasevski 1992). Published suicide rates range from 43 to 465 per 100,000 prisoners per annum (Liebling 1992). Based on the results of international suicide research, there is a consensus that the suicide rate in penal institutions is several times higher than for the general population (e.g. Cooke and Michie 1996; DuRand et al. 1995; Frühwald 1996). An explanation which has been advanced for this is that the most commonly used method – hanging, which is used by 85% of those committing suicide (e.g. Rieger 1971; Thole 1976) – is associated with a more limited chance of being saved than the methods frequently used in suicide attempts outside prison. Here it is also important to take into account the fact that the prison population is not a representative sample of the general population, but has overrepresented within it groups who are at especially high risk of suicide, above all those with addictions (Cooke and Michie 1996). More precise comparative studies, taking account of these selection factors, have not yet been published. There is a greater suicide risk during remand on custody than among sentenced prisoners, especially at the beginning of imprisonment. For example, the proportion of all suicides in prison which are recorded as having occurred during the first month of imprisonment has been reported as 42% (Thole 1976), 46% (Bogue and Power 1995) and even 73% (DuRand et al. 1995). This may be explained by the condition described as "imprisonment shock", i.e. by imprisonment as a stress factor (Harding and Zimmermann 1989), which varies greatly from individual to individual. Among those with dependence disorders, withdrawal symptoms have been identified as important stressors (Bogue and Power 1995). This period is also the one during which uncertainty about the future is greatest (Backett 1987). The population in prison on remand is characterised by a higher turnover, in particular a higher rate of new admissions than among sentenced prisoners, and there is also evidence for a higher prevalence of psychiatric disorders among those on remand (Bogue and Power 1995).

5.2
Risk Among Those Who Have Committed Homicide and Sexual Offences

A higher risk of suicide has been described among those guilty of homicide and of sexual offences (e.g. Thole 1976; Dooley 1990). This has been explained in terms of the long sentences anticipated by this population, the psychodynamic model of "internalisation of aggression" (e.g. Bogue and Power 1995) and the helplessness and hopelessness which may characterise long sentences. As yet it is an open question how far the process of stabilisation which has been described in longitudinal studies (e.g. Konrad 1994) among those serving long sentences might also be a sign of damage by imprisonment, reflecting sinking vitality and diminishing abilities to cope with life outside prison.

5.3
Risk Factors

Risk factors for suicidal behaviour, for which detection could be made more effective by the use of semi-structured interview instruments (Malone et al. 1995), are the following (e.g. Dooley 1990; Felthous 1994; Hurley 1989; Ivanoff et al. 1996):

- The presence of psychiatric disorders (above all schizophrenia, affective disorder, dependence syndrome), which has sometimes already led to inpatient psychiatric treatment
- Direct or indirect suicide threats
- Concrete suicidal ideation, in which exploratory discussion reveals thoughts about how in practice to prepare for and carry out the act

- Preparatory actions (e.g. setting aside a naked razor blade, preparatory cuts on the arm, collecting tablets)
- Previous suicide attempts
- Experience of loss, e.g. divorce
- Limited ability to cope with loss, frustrations, aggressions
- Accused of an aggressive or sexual offence

5.4 Characteristics of Suicides

On the basis of the current status of research knowledge, the predictive value of risk factors relating to history, such as the "broken home situation" (Rieger 1971) or suicide in the family or environment (Thole 1976), or of risk factors specific to imprisonment, such as confinement under particularly secure conditions, overcrowding and staff shortage (Felthous 1994), has not yet been adequately demonstrated. Here, the great variations between institutions in the characteristics of those who commit suicide must be taken into account; thus, in U.S. prisons, those involved are more often young, sober individuals accused of serious offences, compared with older intoxicated people with less serious offences in police custody (DuRand et al. 1995).

5.5 Suicide Prevention

Successful prediction of a behaviour such as suicide in prison, which is uncommon overall, remains difficult, above all because of lack of specificity of risk factors. The construction of a suicide profile, even when regional differences in the prison population are taken into account, is only of limited usefulness (Lester and Danto 1992). Beyond this, suicide prevention needs to involve caution in uncontrolled distribution of medication to those at risk of suicide, which creates the danger of collection and ingestion of a lethal dose.

5.6 Suicide Attempts

Not only the suicide rate, but also the rate of suicide attempts, among which the most frequently observed form is wrist cutting (Liebling 1992), is higher in prisons than in the general population (Ivanoff et al. 1996). In a sample of Canadian prisoners, previous suicide attempts were identified among 22.8%, compared with 7.1% of a comparable sample of the general population (Bland et al. 1990). In terms of history, prisoners who attempt suicide generally differ only slightly from comparison group probands, with more frequent experience of family violence and sexual abuse as the main area where a difference can be identified. A more important factor is the current prison situation, e.g. difficulties with fellow prisoners, lack of work or persisting sleep disturbances (Liebling 1995). A clear and reliable differentiation between "serious" and "not serious" suicide attempts cannot be made from either observation of manipulative behaviour or extent of planning and preparation or from the lethality of the methods used (Haycock 1989).

6 Deliberate Self-Harm

6.1 Sex Differences

Deliberate self-harm can be defined as a self-inflicted, direct physical injury which is not intended to be life-threatening (Herpertz and Saß 1994). The major self-harming behaviours reported in prison are injuries by cutting, self-poisoning and inflicting burns. The prevalence of patients manifesting such behaviour has been reported as 6.5% among male prisoners (Toch 1975), rising to 24% among prisoners with antisocial personality disorders (Virkkunen 1976). A history of self-harming behaviours can be obtained from 32% of female compared with 17% of male sentenced prisoners in England and Wales (Maden et al. 1994); this difference mainly reflects different frequencies of self-poisoning with tablets. Among female prisoners, it is rare for self-injurious behaviours to be reported as having taken place exclusively in the context of imprisonment; here, the previous history generally reveals self-harm outside the penal institution, pointing to the importance of individual vulnerability in explaining this phenomenon. During the period of imprisonment, the prevalence rate for both sexes is around 5%. In an Australian sample of female prisoners (Hurley and Dunne 1991), there was a history of at least one incident of self-harm among 22% of those interviewed, with self-harm having occurred exclusively before imprisonment in 11%.

6.2 Possible Explanations

Self-injurious behaviour is rarely a manifestation of a psychotic illness. In a study of U.S. prisoners, half of

the self-harmers gave a goal-directed motivation for their behaviour (Franklin 1988). Stressful experiences leading up to self-harm often involve real or imagined rejections or, less frequently, experiences of loss or of failure (Herpertz and Saß 1994). In borderline personality disorders, where acts of self-harm are common, such acts may serve as self-stimulation in the context of an experience of pain which is possibly abnormal, overcoming states of emptiness and boredom and interrupting unpleasant moods. They may also be a weapon, used to express anger against significant others (Frühwald 1996). Biological explanations emphasise the status of the opioid system, the dopaminergic and/or the serotinergic systems as substantial factors within a complex structure of causality involving life history, situational stresses and personality characteristics (Herpertz and Saß 1994).

6.3 Motives

Ideas from learning theory interpret deliberate self-harm as a dysfunctional form of problem solving (e.g. aimed at provoking attention or maintaining a relationship in which care is received) which can become established through positive and/or negative reinforcement. Self-harmers who report goal-directed motives more often give a history of such behaviour than those with suicidal intent (Franklin 1988). The psychodynamic approach of ego psychology emphasises the co-existing auto-aggressive, self-punishing tendencies and relieving, protecting and ego-stabilising functions (for a review, see Lester and Danto 1992).

In the range of motivations of those who harm themselves, there is a wide overlap with the intentions indicated by individuals who present having swallowed foreign bodies such as razor blades, batteries or cutlery; the spectrum extends from responses to command hallucinations experienced by people with schizophrenia to suicidal tendencies or goal-directed action aimed at achieving a transfer to a hospital situated outside the penal institution. Multiple episodes of swallowing foreign bodies are not uncommon (Karp et al. 1991). Compared with a control group, metal swallowers have a raised prevalence of schizophrenic illnesses, personality disorders and dependence disorders (Tacke et al. 1975).

One of the considerations which needs to be taken into account in prison practice is the secondary illness gain through the diagnostic and therapeutic measures resulting from presenting with symptoms. Benefits which prisoners may aim to achieve include alteration of prison conditions, sometimes extending to transfer outside the restrictive conditions of prison and even achieving an opportunity for escape.

7 Special Situations in Custody

7.1 Solitary Confinement

Solitary confinement in custodial institutions in most countries is a legally regulated exception to normal practice, which may, for example, be arranged in response to certain requirements regarding security. While isolation under experimental conditions over a 4-day period did not provoke any substantial psychopathological changes (Walters et al. 1969), it seems that with substantially longer periods, free-floating anxieties, increased reactivity to external stimuli and distortions of perception, disruptions of concentration, derealisation, pseudo-hallucinations and hallucinations in various sensory modalities (Rasch 1976; Grassian 1983) may manifest themselves. The picture will be shaped by a complex interaction between variables related to the individual (e.g. presence of a personality disorder, extent of positive symptoms among people with schizophrenia) and the type of isolation (above all degree of sensory deprivation, size of room). States of agitation and acts of self-harm may be observed as a result of this, and it can be assumed that the suicide risk is increased (Bernheim 1994). The development of an acute confusional state followed by partial amnesia and delusions of persecution, often accompanied by hallucinations of an anxious character, has also be described. The symptoms generally fade a few hours after the end of isolation (Grassian 1983). On the other hand, among schizophrenics who are susceptible to acute symptoms, a relapse of positive symptoms appears to occur (for a review, see Grassian and Friedman 1986).

7.2 Life Sentences

In very recent times, initiatives for abolishing lifelong sentences have re-ignited the debate about the possible damaging psychological consequences of longer sentences. It has been suggested that prisoners may become incompetent at living, may lose their will to carry on with life, decline physically and mentally and become deadened and that the likelihood of damaging consequences from imprisonment grows with increasing length of imprisonment. In the first decades of this century, it was suspected that there was a connection between lifelong imprisonment and psychiatric illnesses. However, the model of prison-related damage as having a uniform course with defined phases was soon abandoned.

7.2.1 Psychological Consequences

Taylor (1961) postulated a general psychopathological syndrome among long-term prisoners, characterised by apathy, flattening of affect and loss of initiative; a corresponding set of interpretations and causal pathways was proposed. Long-term imprisonment was seen as associated with monotony, loss of autonomy and loss of contact with the outside world (Walker 1983). Further psychopathological changes identified were early senility among older people, personality disorders, depression, states of nervous exhaustion and psychosomatic illnesses.

7.2.2 Moderating Variables

Variables proposed as moderating such prison damage have on the one hand been the prisoner's own characteristics, such as personality traits, age and state of health, but also attitude to the crime and the prison sentence, and on the other hand the nature of the prison environment, i.e. the atmosphere of the institution, basic living conditions (Walker 1983) and also remaining scope for action and behavioural characteristics of the prison officers.

7.2.3 Results of Empirical Studies

Discussions of possible connections between psychological disorders and longer prison sentences based on subjective understanding and personal experience have led to contradictory conclusions reported in the literature. In a study of self-reported damage from imprisonment, around half the subjects, individuals who had been released but were originally sentenced to life imprisonment, reported negative effects due to the prison sentence served (Peper and Kramer 1978).

The empirical studies of an English research group (Banister et al. 1973; Heskin et al. 1973) of a cross-sectional sample of 175 prisoners who had served different periods in prison did not detect any reduction of intellectual abilities. In their psychological study of personality, they found an increase in (predominantly intropunitive) hostility, a tendency to introversion and a reduction in self-esteem with increasing time in prison. In a follow-up study around 19 months later (Bolton et al. 1976), there were no indications of a general deterioration in psychological state, but rather an increase was observed in verbal intelligence, as well as a decrease in hostility, linked to an increase in emotional maturity. In a longitudinal study of 23 Austrian prisoners (Lapornik et al. 1996), no significant changes in intellectual capability were found, but there were indications of a reduction in concentration and attention capacities in the *Syndrom-Kurztest* (SKT; Short Syndrome Test), although without motivational effects being taken into consideration.

The results of the English research group were in essence confirmed by a cross-sectional study in Berlin (Rasch 1981). Rasch (1981) also pointed out that the subjective impression of a maturing process could not be evaluated, as the scores obtained for ego strength, emotional lability and immaturity for the group as a whole lay beyond the norm. He concluded by suggesting that enduring damage cannot be assumed necessarily to be the sequel to longer periods of imprisonment.

In a systematic longitudinal study, Zamble (1982) established that during the course of imprisonment, after an average of 7.1 years, the long-term prisoners he examined were increasingly occupied with work or other structured activities and their frequency of contact with "outside" had largely been maintained. As measured by psychometric testing, the level of emotional disturbance in the group as a whole fell, as did stress-related medical problems and the frequency of disciplinary measures. The conclusion drawn from this was that the likelihood of damaging consequences from imprisonment was low. Zamble (1982) suggests that the change in living environment at the beginning of the sentence causes substantial psychological complaints, but that the constancy of the prison atmosphere then leads to slow and gradual improvement.

7.2.4 Increasing Psychological Adaptability

There was also evidence of increasing psychological stabilisation in a more recent empirical study with a mean follow-up time of 9.5 years (Konrad 1994), based on the longitudinal observation of qualitative phenomena (the development of psychiatric diagnoses and physical illnesses) and results from psychological testing, e.g. results on the *Freiburger Persönlichkeitsinventar* (FPI; Freiburg Personality Inventory) and the 16-PF (*Persönlichkeitsfaktorentest*; Personality Factors Test). However, this should not be immediately equated with an absence of damage from prolonged imprisonment; it primarily simply indicates an increasing ability among the subjects to adapt psychologically to prison conditions as the years pass, internalising the reality of the prison environment.

The empirical findings could also be interpreted as reflecting the prisoner's constantly declining inner resistance against the situation of being imprisoned, with a corresponding reduction in psychological and physical indicators of stress. Thus it has been observed

that reactive aggressiveness as measured in psychological tests – which within the normal range functions as an indicator of intact capacity for self-assertion – moves significantly away from the normal range with increasing length of imprisonment. Subjects' tendency to give in increases, which can also be interpreted as an indicator of resignation. Such an interpretation suggests that parallels might be drawn with long-term hospitalisations, in which, with increasing periods of comprehensive care within a "total" institution, competence in living and the capacity to cope adequately with life outside the institution diminishes more and more. Understood in this way, damage due to imprisonment cannot therefore be evaluated using indicators which are measured exclusively during imprisonment.

Psychiatry and the Homeless

Translator: E. Taub

1 Introduction

Homelessness is context dependent; it changes over time and differs in different cultural areas. The diversity of terms used for it over the years itself demonstrates this fact. In pre-industrial Germany, the homeless were called *Vagierer*, *Kammesierer*, and *Hippenbuben* (all pejorative terms for migrant beggars and confidence-men); in the nineteenth century, they were known as *die verarmten Korrigenden* ("impoverished persons requiring correction") and were sent off to workhouses; in the early twentieth century, they were *Landstreicher und Vagabunden* ("tramps and vagabonds," Wilmanns 1906) or, in psychiatric circles, *die unsteten Psychopathen* ("vagrant psychopaths"); under Nazi rule, they became *die arbeitsscheuen Nichtsesshaften* ("work-avoiding persons without fixed residence"); and after the Second World War they became "the homeless medically ill" in English-speaking countries and *die Wohnungslosen* ("the dwelling-less") or *die Obdachlosen* ("the shelter-less") in the German-speaking countries. These changing expressions partly reflect a change in the population designated, and partly a change in society's attitude toward it.

In the early years of the twentieth century, German psychiatric research on the homeless achieved international prominence through the work of Karl Wilmanns, above all through his monograph *Zur Psychopathologie des Landstreichers* ("The Psychopathology of Tramps"), which appeared in 1906. Working in the tradition of Kraepelin, Wilmanns showed that a considerable percentage of the "tramps and vagabonds" then confined in workhouses and prisons were suffering from dementia praecox. Consequently, he advocated the humane accommodation and psychiatric treatment of mentally ill "tramps," publicly supported preventive education of children and adolescents at risk, and provisions to combat unemployment and alcoholism. Kurt Schneider's concept of psychopathy was also applied to research on the homeless (Schneider 1934).

In Nazi Germany, starting with the *Bettlerrazzia* ("Raid on Beggars") of September 1933, homeless persons with "pathological inferiorities" were confined to workhouses and concentration camps. Several thousand perished in concentration camps. Later applications for reparations were turned down on the ground that Sec. 1 of the the German Federal Compensation Law (*Bundesentschädigungsgesetz*, BEG) provided for reparations only for injustices committed out of motives of racial, political, or religious persecution.

Rising unemployment since the 1970s, increasing housing costs, and the policy of "deinstitutionalization" (which resulted in a considerable reduction in the number of beds for psychiatric patients) exacerbated the problem of homelessness in most Western industrial countries. After a latency period, there also ensued an intensification of research on the homeless, particularly in English-speaking countries.

In North America and Northern Europe in the 1980s and 1990s, social measures were introduced that removed homeless people from the streets by making living space available to them in shelters and boarding houses. These measures were effective on the whole, although the psychiatric and other medical care received by these formerly homeless persons is still largely inadequate. Legal measures were taken in the United States in the 1980s (McKinney Homeless Assistance Act). A further discussion of the historical development of homelessness is contained in Greifenhagen and Fichter (1996).

2 Epidemiology

In the last 20 years, a number of methodologically sound studies, involving representative population samples, were performed in North America, and later in Germany, to determine the prevalence of mental illness in the homeless. These studies required that the population of "homeless persons" be rigorously defined and that a representative sample of it be taken. Special research methods were needed, such as those applied successfully by Koegel et al. (1988) in Los Angeles and by Fichter et al. (1996) in Munich. Moreover, the development of operational psychiatric diagnosis (DSM-III, DSM-III-R, DSM-IV, ICD-10) and of standardized and structured interviews for the reliable assessment of psychiatric manifestations and the provision of diagnoses further increased the accuracy of psychiatric and epidemiologic studies of the homeless.

The instantaneous and lifetime prevalence of mental illness, including alcohol and drug abuse/dependency, among homeless populations in the 1980s and 1990s is now well documented (Jones et al. 1991; Fichter et al. 1996). Several American studies showed that the lifetime prevalence of severe mental illness (schizophrenia or typical affective illnesses) among the homeless was 15%–30%, and of alcohol and drug abuse/dependency 60%–70% (Fischer et al. 1986; Koegel et al. 1988; Robertson 1992).

Many epidemiological studies of mental illness in the homeless have shown that the homeless make far

less use of psychiatric and other medical services than the general population. That this group is medically underserved is even more evident if we consider that the prevalence of mental illness is much higher in the homeless than in the general population. One of the conclusions of the UCLA Homeless Health Study (part of the Rand Corporation's Course of Homelessness project carried out in the United States) was that homeless persons gave other matters that are important in everyday life and survival higher priority than their health: solving the recurrent daily problems of finding food, clothing, and shelter required so much effort that they had little opportunity to look after their health (Gelberg et al. 1997).

Research on homelessness and mental illness in the Federal Republic of Germany was reviewed by Rössler et al. (1994) and by Greifenhagen and Fichter (1996). Fichter et al. (1996, 1997) reported the results of the first epidemiological study of a representative sample of homeless men in Munich, the First Munich Homeless Project. In June and December 1988, in the first stage of this study on the prevalence of mental illnesses, 456 homeless men were briefly interviewed to provide a "preliminary sampling" in order to determine the population to be studied. A second stage resulted in the definitive selection of a sample of 172 homeless men, of whom 146 (85%) were studied with the aid of a standardized psychiatric interview based on the DSM-III criteria (Diagnostic Interview Schedule; DIS). These interviews took place in 1989/1990.

The homeless men were 26–60 years old, with an average age of 43 years. A large number of them either had never been married (55%) or were divorced (38%). Their level of education was below average (13% had not finished secondary school). They had first become homeless at an average age of 33.7 years (standard deviation, 10.4 years); the duration of homelessness, according to their responses in interviews, was 9 years on average (standard deviation, 8.1 years). Recurrent homelessness was not uncommon, and most of these homeless men had no regular work. A total of 89.7% had an annual income of less than 20,000 marks (approximately $12,500), and 67.8% had an annual income of less than 10,000 marks (approximately $6,250).

These homeless men were found to be relatively sedentary; 79% had lived exclusively in Munich during the 12 months before the interview, 12.3% in Munich and one other city, and the rest in three or more cities. Their preferred sleeping place in the 4 weeks before the interview was outdoors in 70.5%, in a homeless shelter or boarding house in 19.9%, with acquaintances or relatives in 18.5%, and in unfinished or demolished buildings in 14% (multiple listing was allowed). In the time since the study was performed, these numbers have likely shifted to a large extent in the direction of residential homes, shelters, and boarding houses.

The homeless men themselves stated that they were homeless because of financial problems (65.1%), unemployment or loss of employment (49.3%), divorce (8.2%), or other family problems (11.0%). Mental problems were said to be a reason for homelessness by 17.1%, alcohol problems by 37.0%, drug problems by 2.7%, and general medical problems by 12.3% (listing of multiple reasons was allowed).

Life on the street has its dangers: 40.4% of the homeless men surveyed had been victims of physical violence leading to injury on at least one occasion; 33.6% had been robbed, 28.8% had been victims of theft, and 9.6% had been victims of sexual harassment or sexual abuse. The homeless men interviewed had relatively frequent contact with the police: 78.1% had been arrested at least once, usually for smaller offenses such as riding the subway without a ticket or petty theft, while 18.5% of the homeless men had been convicted of robbery, battery, or another crime. Karl Wilmanns already noted at the beginning of the twentieth century that mentally ill homeless persons were relatively frequently arrested and imprisoned, and it was only late in the course of illness that they entered psychiatric treatment.

Table 1 contains a summary of the more important findings obtained in Munich in 1989 (Fichter et al. 1996). A total of 138 out of 146 homeless men studied (94.5%) had an axis I diagnosis of a mental illness according to DIS/DSM-III. The most common diagnostic categories were substance abuse, affective diseases, anxiety disorders, and schizophrenia. The prevalence rates were much higher than in reference samples of the general population. There was also a relatively high psychiatric multimorbidity; 53.4% had two or more lifetime psychiatric diagnoses. Only 27.6% of the homeless men had ever been treated in a psychiatric inpatient unit, 11% had been in an alcoholic rehabilitation clinic, and 2.8% in a drug rehabilitation clinic.

The same group that had conducted the First Munich Homeless Project described above carried out a further, comprehensive public health study in Bavaria, in which 262 homeless men were studied at the time of an initial interview, and again 3 years later, with respect to the prevalence of mental (and serious physical) illness. In the same period of time, the effect of an intervention (assignment of fixed, permanent housing) on the further course of homelessness and health was studied in a separate group of subjects. This Public Health Homeless Project arrived at essentially the same conclusions as the First Munich Homeless Project (Fichter and Quadflieg 1999). Reviews on the

Table 1. Lifetime prevalence of mental illness according to the DIS/DSM-III criteria among 146 homeless men in Munich in 1989 (after Fichter et al. 1996)

	Homeless men in Munich (%)	Representative population sample in Los Angeles (%)[a]
Schizophrenia	12.4	0.5
Affective illness	41.8	8.8
Anxiety disorder	22.6	8.9
Cognitive impairment	8.9	NR
Alcohol abuse/ dependency	91.1	23.9
Drug abuse/ dependency	17.8	13.9
Any DIS/DSM-III axis I diagnosis	94.5	NR
No psychiatric diagnosis	5.5	NR
Only one DIS/DSM-III axis I diagnosis	41.1	NR
Two DIS/DSM-III axis I diagnoses	29.4	NR
Three DIS/DSM-III axis I diagnoses	18.5	NR
Four or more DIS/ DSM-III axis I diagnoses	5.5	NR

DIS, Diagnostic Interview Schedule; NR, not reported.
[a]Epidemiological Catchment Area (ECA) Study of 3055 men from Koegel et al. (1988).

prevalence of mental illness in the homeless may be found in Robertson and Greenblatt (1992), Schutt and Garrett (1992), Scott (1993), Rössler et al. (1994), Kuhlman (1994) and Bhugra (1996).

As for the frequency of mental illness in homeless women, there is a difference between women caring for one or more children (prevalence less than among homeless men) and women not caring for children (in this study, prevalence higher than among homeless men). The prevalence figures among homeless women vary from study to study because of differences in the sample populations (Merves 1992; Zima et al. 1996).

3 Possible Causative Factors and Course

A number of potential causative factors for the generation and perpetuation of homelessness have been discussed in the literature. Table 2 classifies these possible causative factors according to the level of social organization at which they are observed.

On the broad *cultural level,* discrimination against minorities and the basic social attitude toward marginal groups may play a role. On the *institutional level,* unemployment, an inadequate supply of housing, psychiatric deinstitutionalization without the provision of other measures by the community, and inadequate psychiatric and other medical services for the homeless may all contribute further. The services offered may be poorly integrated, not suitable to the needs of the recipients, or poorly accessible (*organizational level*). Inadequate social support, e.g. from family and friends, may exacerbate the problem (*group level*).

Finally, the *individual* may exhibit traits that elevate the risk of homelessness, such as the presence of mental illness, childhood traumas (Herman et al. 1997), deracination through emigration (Silove et al. 1997), unemployment (Fergusson et al. 1997), or

Table 2. Possible causative factors for homelessness (modified from Morse 1992)

Level of observation or causative factor	Can produce or maintain homelessness (example)
Cultural level	Discrimination against minorities, indifference to marginal groups
Institutional level	Unemployment, inadequate supply of housing, curtailment of financial support, policy of psychiatric deinstitutionalization with deficient establishment of corresponding measures in the community, lack of psychiatric and other medical services for the homeless
Local community	Unilateral local political measures
Organizational level	Inadequate organization and coordination of services offered, poor accessibility, mismatched to needs
Group	Inadequate social support to the individual
Individual	Illnesses, handicaps, personal preferences, inadequate adaptation to new (e.g. occupational) requirements

alcoholism (Koegel and Burnam 1988; Fichter et al. 1997; Welte and Barnes 1992; Podschus and Dufue 1995). Bremner et al. (1996) found a relationship between a low initial intelligence quotient and later homelessness; there was an even closer relationship between a decline in the intelligence quotient over time and homelessness, which may be explained by the presence of other risk factors (mental illness, schizophrenia, or substance abuse).

Very little is known about the course of homelessness and the course of mental illnesses in the homeless. Studies of these questions can also reveal factors that perpetuate illness (Koegel and Burnam 1991; Craig et al. 1996).

4 Intervention and Prevention

The conceptual scheme of causative factors for homelessness on several levels of observation, as illustrated in Table 2, suggests a similar multilevel approach to the classification of interventional measures. On each level of observation, there may be a corresponding intervention. Factors on the cultural, national, or institutional level, such as discrimination against minorities, a high rate of unemployment, or an inadequate supply of housing, cannot be effectively counteracted on the individual level. The same holds for the policy of psychiatric deinstitutionalization.

In view of the fact that, in the 1980s and 1990s, a very large part of the homeless in the United States and Northern Europe either were suffering from mental illness or had a history of mental illness, often with lasting sequelae, we as psychiatrists are obliged to do our best to improve the lot of the homeless mentally ill. This can, and should, be done simultaneously on each of the levels listed in Table 2. We can do the following (Levine and Rog 1990; Katz et al. 1992; Breakey 1997):

1. Provide help to individuals
2. Contribute to better coordination of the existing provisions for the homeless and their better adaptation to current needs
3. On the institutional level, influence the development of collateral provisions, and the establishment of provisions with a sufficiently low threshold to reach the affected persons

So far, there has been much talk and little action in this area, and scientific evaluations are sparse. There have been a few empirical evaluations in recent years. Lipton et al. (1988) studied 49 severely mentally ill homeless persons in the emergency room of a hospital in New York. The subjects were assigned either to a control group ("routine discharge planning") or to an intervention group receiving "individualized case management, coordination of public assistance or social security benefits, medication monitoring, money management, meals, activity therapy, and, when appropriate, referrals to psychosocial and rehabilitation programs" (Lipton et al. 1988, p. 41). Over the ensuing year, the patients in the intervention group spent fewer nights in the hospital and reported greater satisfaction with their life situation.

Building further on these results, Morse et al. (1992) compared several different conditions of treatment ("traditional outpatient mental health treatment vs. daytime drop-in centers offering food, recreational facilities and referrals vs. a continuous treatment team that provided therapeutic services to help clients to cope with personal problems, link with psychiatric and other services and learn community living skills"). Patients in the "continuous treatment" group were homeless for fewer days, made more use of the opportunities offered to them, and were more satisfied with what they received.

Cauce et al. (1994) applied a similar study protocol in a group of 300 adolescents with comparable results. Studies on the reduction of alcohol or drug dependency were reviewed by Mercier et al. (1992). The results were rather disappointing with regard to abstinence, but significant effects were found with regard to social adaptation, arrests, convictions, stability of living situation, and access to medical services.

Susser et al. (1997) studied 69 men who were transferred from a homeless shelter to an apartment in the community or city. Half of the subjects were randomized to standard care and the other half to an intervention group with additional care for 9 months ("critical time intervention"). The results indicated that additional care lowers the recidivism rate for homelessness. Toro et al. (1997) evaluated the course of 200 homeless persons randomized either to a control group or to a group receiving "intensive case management intervention." Follow-up at 6, 12, and 18 months revealed positive effects on the severity of psychopathology, harmful life events, and the quality of the home environment.

5 Overview

Many efforts have been made in the past decade to take the homeless off the streets and put a roof over their heads. The mentally ill homeless, however, cannot be made well by a roof over their head alone. The mentally ill homeless (and former homeless), in whatever country they may be, need help with their personal affairs (e.g. social contact, financial, occupa-

tional) and, above all, competent psychiatric treatment. Some of the illnesses affecting the homeless are inherently accompanied by limited insight into the illness and limited motivation to undergo treatment (alcohol and drug dependency, schizophrenia, manic phases). It is thus necessary to organize and coordinate the provision of care for the homeless so that it may also reach those who do not seek help for themselves, especially in situations where bureaucratic or other impediments make it even less accessible.

Low-threshold care provisions must be brought actively to the affected individuals ("outreach"). Because the services available today are highly fragmented, what is needed is care of the affected individuals in a manner corresponding to their needs, initiatives by individual organizations and facilities, accompanying evaluation, and continuous improvement and adaptation to the changing needs of the homeless population.

A.J. Holland

Mental Retardation: A Psychiatric Perspective

My thanks go to Robbie Patterson for considerable administrative and secretarial support and to colleagues in the community teams for adults with learning disability, Lifespan NHS Trust, and colleagues at the University of Cambridge for help and advice.

1 Introduction

1.1 Historical Perspectives

This past century has seen dramatic changes in almost every aspect of the lives of people with mental retardation. Among the most striking are the attitudes of society and the changing philosophy away from segregation towards integration. Equally as striking have been those advances in fields such as cytogenetics, molecular genetics and teratology that have enabled some of the causes of mental retardation to be identified. These two examples, taken from the diverse fields of the social and biological, vividly illustrate how significant this change has been. In the early 1900s, the eugenics movement was a powerful force and genetic theories were used to justify what are now seen as harsh and inhumane attitudes. Equally, biological knowledge was in its infancy. Inborn errors of metabolism were only just beginning to be investigated, and the human chromosome complement was a long way off being described. In the later part of this century, increasing understanding of the process of early human development at both the biological and psychological levels led to studies of whether mental retardation was a result of "delayed" and/or "deviant" development (Hodapp et al. 1990). Research in the behavioural sciences has centred on trying to understand more about the characteristics and aetiology of specific disabilities such as autism and the factors which contribute to the occurrence of behavioural and psychiatric disorders. These have included epidemiological studies such as those of Rutter et al. (1970) and Birch et al. (1970), which demonstrated the high rates of such disorders in children and adults with mental retardation. Since then, an extensive and primarily psychological literature on causation of behaviour disorders has also developed. The challenge now is to attempt to integrate developmental and biobehavioural models.

1.2 Terminology

The use of terms such as "mental retardation" cannot fully convey the complexity of abilities and disabilities present in any given individual but, as has been seen historically, can instead easily become a term of abuse and can be used to discriminate against the person concerned. The issues are well illustrated by the fact that the terminology varies across countries and changes over time. In its classification of mental disorders (ICD-10), the World Health Organization (1992) uses the term "mental retardation" as it is still used in the United States (American Psychiatric Association 1994). In the United Kingdom, terms such as "idiot", "imbecile" and "feeble-minded" were used in legislation in the early 1900s, followed by "mental sub-normality", "mental handicap" and now "learning disability". In Australia, and increasingly in the United States, the term "developmental disability" is used. Labels are necessary to enable resources to be directed to those people with special needs, but they should not offend and they should reliably inform. In this chapter, the term "mental retardation" has been chosen primarily because it is still the most widely used. Because labels in this area all too easily become pejorative, it is essential that they are used with respect and with the aim of helping the person concerned rather than in a manner which results in segregation and denial of rights.

1.3 Human Development

Understanding how specific abilities and disabilities arise and identifying the nature of the interventions that are needed requires an appropriate conceptual framework. In the case of mental retardation, this particularly requires a developmental perspective and recognition of how the importance of biological and environmental factors changes over time (Clarke and Clarke 1984). Normal human development, from conception to adult life, follows a path which is largely predictable. Prenatal development is characterised by the systematic differentiation of organ systems and parts of the body, resulting in a viable fetus at the time of birth. In childhood, growth and physical development continues and the reaching of developmental milestones such as smiling, sitting, standing, walking and early language development becomes apparent. More advanced and uniquely human abilities are also acquired, such as literacy and numeracy, the ability to engage in symbolic play and understanding and communicating complex ideas and feelings through an increasingly sophisticated language. This process of cognitive development starts prenatally (for a review, see Karmiloff-Smith 1995) and is dependent on the regulation of the expression of particular genes in specific organ systems over time. The modulation of gene expression by intra- and extracellular environmental factors occurs within the context of a social environment which meets both the nutritional and emotional needs of the individual (for an historical perspective on "psychobiological development", see Gottlieb 1996).

There is variation in the precise timing of these developmental milestones because of inherent differ-

ences between individuals and their environments. At birth or in the neonatal period, a child may be identified as having a syndrome commonly associated with mental retardation and/or the presence of developmental delay, with significant intellectual impairment and learning disabilities becoming apparent in early life (see Table 1 for examples and below for further discussion). In this context, the role of paediatricians and clinical geneticists is to determine the likely cause of the developmental delay, advise whether specific treatments are indicated and, if requested by the family, to give advice as to the likely outcome of any future pregnancies. At this early stage, establishing the cause of the developmental delay is also important. It may help the parents adjust to having a child who may have a specific genetic or environmentally determined disorder, and it may help in determining whether other problems, e.g. sensory or physical impairments, are likely to occur in the future.

There are also rare situations where the presence of developmental delay and subsequent mental retardation is not immediately apparent, but early identification of the presence of a specific disorder and the starting of treatment are important. This is particularly so for congenital hypothyroidism and the rare inborn error of metabolism phenylketonuria. The former is treated with thyroid replacement and the latter with the use, until adult life, of a diet low in the amino acid phenylalanine. Screening for both these disorders shortly after birth is routine in many countries, as prompt treatment prevents the development of what would otherwise be significant intellectual impairment and mental retardation.

2 Definitions

2.1 Diagnostic Criteria

At each stage in the progression of development, the extent to which the child or adult has attained those abilities expected for that chronological age can be assessed and the presence or absence of any impairments or disabilities judged. When the process of development falls significantly below what is expected in terms of intellectual ability and the acquisition of particular skills, the term "mental retardation" may apply. This term therefore implies the presence of a disorder of development which has affected the ability to acquire social and living skills (adaptive behaviours) in association with significant impairment of intelli-

Table 1. Examples of syndromes commonly associated with varying degrees of mental retardation either due to a gene mutation or the presence of a chromosome abnormality

Syndrome	Genotype	Phenotype
Angelman syndrome	Deletion chromosome 15q11–13, maternal chromosome	Abnormal gait, characteristic facial appearance, excessive laughing
Down syndrome	Trisomy 21	Characteristic facial appearance, flattened occiput, short stature, shortened and curved little finger
Fragile X syndrome	CGG repeats FMR-1, gene Xq27.3	Long face, prominent ears, large testes post-puberty, speech abnormalities, gaze avoidance, females can be mildly affected
Lesch-Nyhan syndrome	HPRT gene mutation, Xq26–27.3	Severe self-injurious behaviour, choreoathetosis, motor delay, dysarthric speech
Prader-Willi syndrome	Deletion chromosome 15q11–13, paternal chromosome	Neonatal hypotonia, delayed sexual development, short stature, characteristic facial appearance, over-eating leading to obesity
Rett syndrome	Possibly X-linked dominant	Females only affected, regression in development 1–2 years of age, repetitive movements hands and body, abnormal breathing
Tuberous sclerosis	Mutations chromosome 9q34 and 16p13	White and shagreen skin patches, facial rash (adenoma sebaceum), hamartomas, renal lesions
Williams syndrome	Deletion elastin gene chromosome 7q11.23	Characteristic facial appearance, aortic and/or pulmonary heart valve stenoses, hypercalcaemia

There are several hundred syndromes resulting in significant mental retardation, and readers are advised to consult genetic and paediatric texts for a complete description of the phenotype of the above syndromes and for a full list of syndromes. These have been chosen either because they are relatively common or because they illustrate a specific genetic/chromosomal abnormality.

gence. The latter is usually taken to be a score on an established intelligence quotient (IQ) test greater than two standard deviations below the mean. For those tests with means of 100 and standard deviations of 15 points, this is a score of less than 70. A summary of the DSM-IV criteria for mental retardation is given in Appendix A. As can be seen, the presence of a significant intellectual impairment in itself is insufficient to determine the presence or absence of mental retardation, and additional evidence of a functional disability is required. Although the benefits and pitfalls in the measurement of intellectual capacity (IQ) have been debated, it does serve as an objective, standardised and reliable measure in assessing an individual's ability to perform cognitive tasks which, in turn, are likely to relate to their ability to solve everyday problems. The IQ therefore remains an important guide to the severity of mental retardation. Measurement of "adaptive behaviour" and general functioning has been more problematical, but the use of assessment instruments that are well standardised has been a considerable advance. Examples of these include the revised Vineland (Sparrow et al. 1984) and the revised Adaptive Behaviour Scales (Nihira et al. 1993) of the American Association for Mental Retardation (AAMR). These informant-based schedules are divided into different domains (e.g. socialisation), giving an overall comprehensive picture of an individual's strengths and weaknesses.

The term "mental retardation" refers to a highly heterogeneous group of people who have in common evidence of developmental delay that affects their ability to learn. However, individuals differ widely in the extent of their disabilities, the presence or absence of other impairments and disabilities (e.g. physical and sensory) and in the cause and exact characteristics of their impairments and disabilities. Like the rest of the general population, they also vary in personality and life experience. No one term can adequately describe this group of people with such varied and complex needs, and for this reason a more hierarchical definition has been adopted by the World Health Organization.

2.2 Impairments, Disabilities and Handicaps

The World Health Organization (1980) has proposed a classification scheme which helps to overcome some of these difficulties and, most importantly, also helps to guide appropriate intervention. The definitions of the above terms, and how they link together, are given in Appendix B and Fig. 1. In this scheme, mental retardation can be understood on a number of different levels. At the level of "impairment" (intellectual impairment), the organ system involved is primarily the brain. It is impairment in this organ system for genetic, chromosomal or environmental reasons (e.g. as listed in Table 1) which has primarily affected the acquisition of developmentally determined skills and the process of learning. The "disability" (learning disability) which follows is that of the ability to learn and acquire those skills which come with development and are necessary for independent life. The extent of the disability may vary, e.g. from profound delay in the acquisition of language, motor and self-help skills on the one hand to more subtle difficulties in the acquisition of skills such as numeracy and literacy, this only becoming apparent when the child starts school. As is discussed later in the chapter, the level of disability may relate to the degree of brain impairment but may be influenced by the extent of interventions and additional support available. The intervention at this level is one of special education and additional help with physical and other disabilities. In the United Kingdom, this involves the process of "statementing", which identifies the special educational needs of the child and entitles them to nursery education from the age of 3 and full-time education from the age of 5 until they are 19. The "handicap" (mental handicap) experienced by the person is a measure of the extent to which the person is disadvantaged as a result of their disabilities. Importantly, this is not something which is necessarily fixed by the level of the disability, but is seen as an interaction between the disabilities on the one hand and the extent of support and intervention on the other. For example, a person who has not acquired the ability to appreciate danger and therefore cannot be out by him-/herself will have a very restricted quality of life unless family and care staff are available to go with the person to shops, on buses etc. The level of handicap can therefore vary significantly depending on the level of support and attitude of carers supporting the person concerned. The better the level of support available to the individual, the less the likely disadvantage and handicap experienced by the person him- or herself.

This system of conceptualising mental retardation helps to overcome the problems of stigma which are

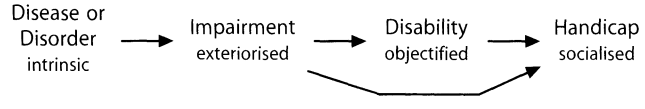

Fig. 1. Link between impairments, disabilities and handicaps

associated with more commonly used labels and provides the mechanism whereby the needs of any particular person and his or her family can be considered. These include tasks as varied as the identification of the extent and the cause of the impairment as well as intervention at the educational and social levels.

3 Epidemiology

3.1 Prevalence Rates

The above definitions help to illustrate how difficult it is to obtain accurate estimates of the number of people considered to have mental retardation. Firstly, definitions vary and there is no obvious dividing line between what is mental retardation and what is not. Secondly, prevalence rates are highly dependent on whether a true population sample is identified or whether an "administrative sample" (i.e. those known to mental retardation services) are used. Thirdly, rates are very age dependent in that those with profound mental retardation have an increased mortality rate and many with mild mental retardation leave services once they finish school. Finally, there are likely to be cultural differences depending on the educational system and expectations in any particular society or socio-economic group. Figures should therefore be considered with caution.

The World Health Organization's system of impairments, disabilities and handicaps used to conceptualise the complex disabilities referred to as mental retardation can be refined and operationalised so that, for example, for epidemiological purposes more accurate estimates of the extent of such disabilities in any community can be obtained. The appropriate use of IQ scores can be used to obtain some measure of the proportion of the population who have a significant intellectual impairment and are therefore at risk for learning disability and for being disadvantaged or "handicapped" as a result. Intellectual performance measured by such tests has been shown to have an almost normal distribution in populations with a skew to the left due to the presence of biologically determined disorders affecting brain development. Approximately 2%–2.5% of a population fall greater than two standard deviations below the mean of 100 (IQ < 70). Of those with IQs below 70, approximately 80% have mild mental retardation (more accurately, mild intellectual impairment), 12% moderate, 7% severe and less than 1% profound.

Although there were variations in early prevalence studies due to the use of different definitions, there is general agreement from a number of studies that the prevalence rate for severe mental retardation is 0.3%–0.4% (for a review, see Fryers 1991). These estimates are obtained primarily from administrative samples, but given the level of need of the individuals in the studies, it is likely that the majority had been identified. The estimates can therefore be seen as reliable. When it comes to aetiology, the distinction between those with IQs between 50 and 70 (mild) and those with IQs less than 50 (moderate to severe) becomes important (see also the epidemiological studies by Rutter et al. 1970; Birch et al. 1970).

3.2 Learning Difficulties

The percentage of children defined as having learning difficulties within a population is greater than those with an intellectual impairment. In the United Kingdom, the Warnock Committee estimated that about 20% of children are likely to have learning difficulties at some point requiring special educational help. The reasons for their special educational needs can be as diverse as severe mental retardation, the presence of a chronic physically disabling condition, emotional and behavioural problems and specific learning difficulties. Given these diverse reasons, the severity and extent of "learning disabilities" are not easy to define and may well depend on a variety of factors including, for example, the school system, the extent of social disadvantage and definitions of specific and generalised learning disabilities. While some children will have been identified prior to starting school as having profound developmental delay affecting their intellectual and learning abilities, others will only be identified as having "learning difficulties" after starting school. Similarly, for some the severity of the learning disability is such that it will have a profound effect on their future lives, whereas with others it may not seriously affect future prospects.

3.3 Lifespan Differences

There are also changes over the lifespan from conception, through childhood, adult life and old age. At conception, many chromosome disorders which would otherwise have resulted in a child with severe developmental delay and profound mental retardation result in a spontaneous miscarriage. At birth, it has been estimated that approximately 1% of children have a chromosome anomaly which, depending on what form it takes, may result in the presence of mental retarda-

tion (Jacobs 1990). However, developments in prenatal screening programmes for Down syndrome and inherited disorders allowing parents, depending on national laws, to decide whether or not to have a termination of pregnancy may affect these rates. Children with profound mental retardation, some with progressive metabolic disorders, have a reduced life expectancy, and in others there may be high rates of congenital disorders resulting in an increased mortality rate. At the milder end of the spectrum, the presence of intellectual impairment and learning difficulties may not be suspected or confirmed until the child starts school and is found to be behind other children in their learning ability. Some of course will have specific learning difficulties, such as dyslexia, rather than more general learning difficulties. Rates may remain relatively stable during statutory school years, but as children with past special needs leave full-time education they may no longer be considered in need of special education or other specialist services and may therefore no longer appear in prevalence figures. Examples of how age-specific prevalence rates of severe mental retardation vary are given by Fryers (1991). In childhood, they are estimated at between 3 to 5 per thousand of the population, dropping to 2.5 or less after 45 years of age.

4 Aetiology

The factors which contribute to the ultimate level of an individual's disability and their relationship to each other are likely to be complex. The starting point is the World Health Organization's system of classification. In the case of some individuals, the impact of, for example, an inherited disorder on brain development may have been so profound that it has a very powerful effect on the ultimate level of that person's disability. In other cases, the level of impairment may have a less profound effect and educational and social factors and life opportunities may be the significant influence.

4.1 Sub-cultural and Organic Division

The same arguments that apply to studies of the epidemiology of mental retardation can also apply to studies of aetiology. For example, the proportion of people considered to have a genetic, chromosomal or environmental cause of mental retardation will critically depend on how the base rate of people with mental retardation is defined. If it is those people known to services, then there will be a bias towards those with biologically determined and more severe mental retardation who are identified at birth or shortly afterwards, whereas a true population sample ascertained on the basis of IQ or special educational needs will include a much more diverse population.

Historically, there has been a division between those with an obvious biological reason for their mental retardation and those without such an obvious cause, generally resulting in milder disabilities. These groups have been referred to as having organic and sub-cultural mental retardation, respectively. In the case of the former, the mental retardation is due to a single major effect. It is this group which predominately accounts for the deviation of the normal distribution of IQ to the left, whereas the latter (sub-cultural group) has been considered to be the extreme left side of the normal curve and part of a continuous variable, the aetiological factors being familial (both polygenic and environmental). Table 2 summarises the main differences between these two groups (see also Scott 1994).

However, this distinction between mild/familial and severe/biological is less robust than previously supposed for the following reasons. Firstly, new biologically determined causes of mild mental retardation (e.g. female carriers of the fragile X syndrome) have been described. Secondly, it is recognised that people with specific syndromes (e.g. Down syndrome) usually have a distribution of abilities and some will have only mild intellectual impairments. Thirdly, even in clearly genetically or chromosomally determined disorders,

Table 2. Differences between biologically determined and sub-cultural mental retardation

Biological	Sub-cultural
Moderate/severe impairment	Mild or borderline impairment
Significant impairments in adaptive functioning	Minor or no impairment in adaptive functioning
Frequent evidence of CNS abnormalities	Evidence of CNS abnormalities uncommon
Family members usually of normal intelligence	Intellectual abilities mildly impaired in family members
Dysmorphic characteristics common	Dysmorphic characteristics unusual
Other impairments and disabilities common	Other impairments and disabilities unusual
Equal distribution across families of different socio-economic status	More common in families of lower socio-economic status
Social adversity unusual	Social adversity more common

there are other factors which have an influence on the ultimate cognitive profile of that person and there is not necessarily a direct relationship between, for example, the genetic mutation on the one hand and the level of disability on the other. Furthermore, such relatively crude methods fail to take into account the distinction between the levels of impairment, disabilities and handicaps which, as has already been argued, may be influenced by different factors at any one time as well as over time.

4.2 Genetic and Chromosomal Causes of Impairment

Biologically determined aetiological factors which have a significant effect on brain development and thus on intellectual development are clearly important. These biologically determined causes of impaired brain development can be divided into the following:

1. Those due to the loss or addition of whole or parts of specific chromosomes (autosomes and sex chromosomes) or the rearrangement of chromosomes
2. Those due to the effects of a single gene mutation which either has a direct effect on brain development or indirectly affects brain development through the accumulation of metabolites
3. Those due to the effects of pre-, peri- or postnatal trauma

The disorders of chromosome numbers (mainly Down syndrome) and other chromosomal anomalies account for approximately 30% of all causes of significant mental retardation. Over 500 single gene disorders associated with mental retardation have been described, but as a group they only account for a few per cent of cases (Wahlstrom 1990). Although a large number of syndromes associated with mental retardation have been described, there remains a significant number in which the genetic or chromosomal basis for the syndrome has not been identified or in which neither a cause or syndromal cluster of signs has been established. However, increasing numbers of single gene disorders, different mutations in the same gene, different genetic mechanisms and previously unrecognised sub-microscopic chromosomal deletions are now being described which are associated with mental retardation (e.g. see Flint et al. 1995).

It is beyond the scope of this chapter to cover in detail all the different causes of mental retardation. A few particularly important syndromes are discussed below and some listed in Table 1, either because they are numerically important or because they illustrate psychiatric or genetic points. For further details about chromosomal disorders, see Bolton and Holland (1994). The role of genetic factors in the causation of mental retardation has been reviewed by Simonoff et al. (1996).

4.2.1 Down Syndrome

The single most important disorder almost invariably associated with mental retardation is Down syndrome. In approximately 95% of patients, this is due to the inheritance of three rather than two copies of chromosome 21 (trisomy 21) in all somatic cells as a result of chromosomal non-dysjunction during meiosis. In the other few per cent, it is either due to the presence of an unbalanced chromosomal translocation or to the presence of mosaicism. In the former, there is a rearrangement of two pairs of chromosomes including 21, and in the latter only a proportion of the cells have trisomy 21 due to the occurrence of non-dysjunction of chromosome 21 in a somatic cell rather than a gamete. Maternal age is well established as the most significant factor contributing to the likelihood of non-dysjunction occurring in the female gamete: The probability of having a child with Down syndrome increases from approximately 1:2000 in early adult life to 1:45 when maternal age at conception is in the 40's (for a review on Down syndrome, see Berg 1993). From a psychiatric perspective, the relationship between Down syndrome and the high risk for Alzheimer disease has become increasingly important because of the considerably improved life expectancy experienced by people with Down syndrome. It is clear that increased cerebral amyloid disposition occurs from early in life, and by their 30s the majority of people with Down syndrome will have Alzheimer-like plaques and tangles in their brains. Rates of Alzheimer disease are, however, less than the neuropathological findings would predict. Although studies vary, Alzheimer disease affects a few per cent of people with Down syndrome in their 30s, increasing to approximately 40% in their 50s. Although the reasons for this early onset of Alzheimer disease in people with Down syndrome is not known for certain, the gene for the amyloid precursor protein (APP) has been shown to be located on chromosome 21 and a reasonable hypothesis is that excessive amyloid production is an important factor. The differential diagnosis of apparent cognitive and functional decline in later life includes not only Alzheimer disease but also hypothyroidism, the effects of sensory impairments and depression (for a review, see Holland and Oliver 1995; see also Sect. 6.3).

4.2.2 Prader-Willi and Angelman Syndromes

As the techniques available for the study of chromosomes have improved and with the development of

new chromosome banding techniques followed by the ability to mark specific DNA sequences using fluorescent in situ hybridisation (FISH), an increasing number of chromosomal deletions have been identified. In the case of two syndromes (Prader-Willi and Angelman syndromes), this has led to the discovery of the importance of gender-specific genomic imprinting in the causation of different phenotypes. In the case of both syndromes, the majority of affected individuals have a deletion on chromosome 15 (15q11-13). In the case of Prader-Willi syndrome, this is on the chromosome 15 of paternal origin and, in Angelman syndrome, of maternal origin. Particular genes on the other chromosome 15, at the same site as the deletion, are differentially imprinted according to the gender of the parent of origin. Thus both copies of different genes in the two syndromes are lost through deletion and because they are normally switched off by being imprinted. The effects of gender-specific genomic imprinting also explains the cause of those cases of Prader-Willi and Angelman syndrome not associated with a chromosome 15 deletion. In the majority of these cases, both copies of chromosome 15 are from one parent and hence both copies of specific genes (depending on the gender of the parent of origin) are imprinted and therefore not expressed. In the case of Prader-Willi syndrome, the problems of over-eating and severe obesity together with an apparently increased propensity to severe temper tantrums has been of psychiatric interest (see Sect. 6.3).

4.2.3 Fragile X Syndrome

More recently, the fragile X syndrome has been recognised as an important cause of mental retardation since the characteristic fragile site on the X chromosome (Xq27.3) was described by Lubs in 1969 after culturing the chromosomes of an affected individual in a medium low in folic acid. The genetic basis of this X-linked disorder is the presence of a triplet repeat sequence (CGG) in the FMR-1 gene. The normal repeat sequence is less than 50, but pre-symptomatic carriers have between 50 and 200 repeat sequences and mildly affected female carriers and affected males have 200 or more. Males are more severely affected and have moderate to severe mental retardation, a characteristic litanic and cluttered form of speech, gaze avoidance and other social impairments, minor dysmorphic facial characteristics (e.g. large ears, long narrow face) and, post-pubertally, large testes. Increased rates of autism have been reported, but this is disputed and these findings may be due to the gaze avoidance and other social impairments present. Approximately 1 in 2500 males in Caucasian populations are affected (for a review, see De Vries et al. 1994).

4.3 Environmental Causes of Impairment

The occurrence of environmentally determined causes of mental retardation may well depend on economic and socio-cultural factors as well as health policies. In the developing world, serious perinatal problems, severe malnutrition and chronic infections are likely to be more significant factors than chromosomal disorders as causes of impaired early development and sub-optimal functioning in later life. In the developed world, it is estimated that approximately 20%–30% of significant mental retardation may be caused by environmentally determined factors, the majority of which are due to perinatal injury, particularly in very low birth weight babies. Improvements in neonatal care are resulting in greater survival, and particularly for those with birth weights below 1500 g there is an increasing risk of future physical and/or intellectual impairment as a consequence of periventricular haemorrhage (for details, see Reynolds 1996). Congenital viral infections such as cytomegalovirus and toxoplasmosis remain important potential causes. Rubella, as a cause of severe fetal abnormalities, has been largely eliminated in many countries through immunisation campaigns. Excessive maternal alcohol abuse leading to the fetal alcohol syndrome (see Porter et al. 1984) and, more recently, maternal human immunodeficiency virus (HIV) infection can both lead to babies with significant impairment of brain development and therefore of intellectual ability. While specific environmentally determined biological factors may give rise to significant mental retardation, others may have a less obvious effect, reducing the potential of the people concerned. Examples include poor maternal and child nutrition and the effects of lead. From a worldwide perspective, these examples are likely to be of great importance.

4.4 Polygenic Effects

The effects of these organically determined factors on intellectual development is usually such that developmental delay and the other features of mental retardation are apparent in early life and place limitations on ultimate levels of attainment. In the case of those with mild levels of intellectual impairment and with no obvious organically determined disorder, the picture is more complex. Studies of the influences on intellectual ability (IQ) have demonstrated that, within those populations studied, genetic influences are significant and are likely to be polygenic. However, the somewhat artificial dichotomy between "nature" and "nurture"

has increasingly been seen to be unhelpful. Interactive and more complex models of the relative roles and relationships between what is inherited and what is in the environment are being developed (for a review, see Simonoff et al. 1996). In this review, the role of shared and non-shared environmental influences and the numerous complexities which have to be considered at both the genetic and environmental level are discussed. Plomin and Daniels (1987) have also extensively reviewed this field, specifically with regards to personality and intelligence, and have concluded that individual (non-shared) environmental effects are more significant than shared environmental effects. For example, individuals may respond to similar environmental influences differently and age and gender may modify the response.

As genetic and biological mechanisms are identified and more complex models of understanding are developed, then some key questions about intervention can begin to be addressed. These include the following issues:

1. How to identify the mechanism whereby a specific single gene or chromosome disorder gives rise to impaired brain development and intellectual impairment and what contributes to individual variation within syndromes. In the case of phenylketonuria understanding the genetic defect and its consequences has led to a preventative strategy, but the same may be true for disorders such as Down syndrome.
2. Whether early intervention modifies the future severity of any disability and the extent to which this is the case regardless of the cause or severity of the impairment. This is a complex issue. Past research has suggested only limited effects (Zigler and Berman 1983). However, more complex models that take into account both biological and environmental factors may show differences.
3. How the extent of a given impairment, disability and resultant disadvantage can be minimised. As has already briefly been discussed, this not only includes the role of intervention in childhood but also the availability of resources and support to those with mental retardation in later life.

In psychiatric practice, it is necessary to try to integrate knowledge from this whole range of scientific study, including the causes of and nature of the mental retardation, the additional mental health or physical problems, together with dynamic and family factors that may contribute to the level and extent of any person's disability as well as to his or her general well-being and quality of life. Particularly for those with mild mental retardation, cycles of disadvantage can be seen which include the effects of poor parenting, a failure to engage in education, poor nutrition, lack of opportunities and the presence of abuse and a neglectful environment.

5 Changing Needs

The definitions of mental retardation now used and particularly the refinement of classification, such as that of the World Health Organization, provide the basis whereby the general and more specific needs of both children and adults with mental retardation can be considered. The needs of people with mental retardation and the needs of their families and other carers change over time. At birth and in early childhood, the focus may be on the identification of the cause of the developmental delay and the treatment of other congenital problems which may be present. In developing countries, the prevention of malnutrition and infections would be the priority. Later, the need is to provide help to the child and their families and to maximise the development of skills through specialist educational support. In adult life, the availability of appropriate support networks and supported employment opportunities may be the priority. At each of these stages, it is necessary to be able to characterise the extent and nature of the person's abilities and disability, and in this context it is important to be clear about definitions and to use any labels which might be applied in a positive manner.

Traditionally, distinctions have been drawn between what are predominately social care needs and what are health needs. Although this can be useful, this distinction can be somewhat artificial. Both physical and mental health can be influenced by the quality of the social care environment and, similarly, the state of a person's mental health and the extent to which he or she presents with problematic behaviour can influence the quality of the social care environment. High rates of problem behaviours reported in institutional settings are not simply consequent upon the quality of the environment, but also relate to the fact that it was the presence of problem behaviour in the first place which resulted in admission to an institutional setting.

5.1 Special Needs

The general and mental health needs of people with mental retardation require special consideration for a number of reasons. Firstly, as described below, there are much higher rates of associated physical and sensory impairments, psychiatric and behavioural dif-

ficulties and other illnesses. Secondly, particularly for those with more severe disabilities, there may be the presence of many health problems and therefore the need for often complex and multiple interventions. Thirdly, given the limited intellectual and language development, which is a central feature of mental retardation, the recognition and diagnosis of specific illnesses can be problematic. A person may not be able to describe or easily localise pain or report other symptoms; thus physical illnesses go unnoticed until they become severe. Finally, while children have the support of their parents in seeking medical help, if unwell, adults with mental retardation may not be able to take the initiative in seeking help and may find accessing primary and secondary health services very difficult. Similarly, routine health screening procedures such as breast examination and cervical smears in women may not happen. In these circumstances, carers have the responsibility to be aware of possible health problems and to help the person access health services as and when required. Community surveys investigating the physical health of people with mental retardation have reported significant rates of undetected illness.

5.2 General Health Needs

The starting point in considering the general health needs of children and adults with mental retardation is that they have the same needs as those without such disabilities but in addition may have additional needs for the reasons given above. Many of the biologically determined causes of mental retardation are also associated with the presence of additional impairments and resultant disabilities. These include high rates of physical and sensory impairments and disabilities as well as additional illnesses, such as epilepsy. In some cases, very specific risks are associated with particular causes of mental retardation. For example, people with Down syndrome are at risk for congenital heart disease or, in later life, sensory impairments, thyroid disorders and Alzheimer disease with age-specific prevalence rates for these disorders increasing from a few per cent in those in middle age to up to 50% in those aged 50 years and over (see Berg et al. 1993).

For the same reasons as given earlier, accurate estimates of the prevalence of these additional impairments is problematic. Not only are the studies primarily on administrative samples, but they also include different age-groups and different service settings. Prevalence rates of physical impairments and disabilities, sensory impairments and epilepsy all increase with the degree of mental retardation. In the case of epilepsy, prevalence rates rise to 50% in those with profound disabilities (for a review, see Bird 1997) and may also include different types of seizures which are difficult to control, resulting in the use of more than one anti-convulsant.

5.3 Mental Health Needs

There is convincing evidence that people with mental retardation have higher rates of mental health problems than the general population. However, such epidemiological studies face similar difficulties as have been described earlier. These include the problems associated with the definition of "mental retardation" and the difficulty of diagnosis of specific mental disorders in those with impaired language development. Inevitably, diagnostic criteria have to be modified. However, if they are too loose, they are no longer valid, and if too strict, they underestimate the true prevalence of mental disorder in this population.

There is no readily accepted definition of "mental health" other than the rather unsatisfactory one of "the absence of mental disorder". However, what is meant by the term "mental disorder" has over many years become more refined through the development of diagnostic criteria such as defined in the International Classification of Mental and Behavioural Disorders (ICD-10; World Health Organization 1992) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; American Psychiatric Association 1994). The range of mental disorders as defined in the above classification systems are found affecting people with mental retardation as well. As with the general population, appropriate diagnosis is essential, as it is the diagnosis and associated formulation that primarily determines treatment. As is well recognised, the range of mental disorders includes those due primarily to identified organic factors (e.g. delirium and dementia), the functional psychoses (e.g. schizophrenia), affective disorders (e.g. depression, manic depressive psychosis), neurotic disorders (e.g. obsessive compulsive disorders, phobias) and personality, behavioural and developmental disorders. In some cases, the diagnostic process is less helpful in informing treatment and is in danger of having a negative influence on outcome (e.g. in the case of personality or behavioural disorders). The diagnosis of a "behavioural disorder" assumes the exclusion of an underlying organic disorder or mental illness which might be directly causing the behaviour, and clearly in these circumstances a more sophisticated psychological analysis is required.

The Isle of Wight study of children (Rutter et al. 1970), the Aberdeen studies (Birch et al. 1970) and a number of other studies have reported population prevalence rates of psychiatric disorder of between 25% and 40%. This includes the full range of disorders.

The differences across studies reflect differences in methodology, specifically the diagnostic criteria used and the nature of the population studied. Prevalence rates of psychiatric disorder in general increase with the severity of the intellectual impairment from 20% in those with mild impairment to 45% in those with severe intellectual impairments. Similarly, rates of "pure" behaviour problems increase with the severity of impairment from a few per cent to between 20% and 30%, respectively (Kushlick and Blunden 1974; Richardson and Koller 1985).

The development of better diagnostic instruments such as the PAS-ADD schedules (Moss et al. 1996) now enable more accurate studies to be undertaken. Early studies using the instrument in a population of people with mental retardation over the age of 50 found rates of psychiatric disorder of 12% and of dementia of 12% (Moss et al. 1993; Patel et al. 1993). Cooper (1997) developed her own semi-structured informant interview and in a study of older people with mental retardation in a defined area compared prevalence rates of psychiatric disorder with that in a control group of people with mental retardation identified from the local register. Rates of psychiatric disorder were generally higher in the older group (68.7% vs. 47.9%). In both cases, behaviour disorders made up the single most prevalent group. Rates of past affective disorder were significant in the older and control groups (22.4% and 11%, respectively). The difference in these "lifetime prevalence" rates may simply reflect the difference in age in the two groups. The prevalence rate of dementia in the older group reached 21.6%. This study paid close attention to issues of diagnosis using ICD-10 criteria with the addition of a category of behaviour disorder. However, the population studied was an administrative sample and therefore may have had an over-representation of people with mental retardation and additional problems, as they are more likely to be known to services.

The recognition that a person with mental retardation may also be suffering from a severe psychiatric illness is particularly important because of the treatment implications. Prevalence rates of schizophrenia, in particular, have been reported to be three times greater in people with mild intellectual impairments compared to the general population (lifetime prevalence of 0.03 vs. 0.01). Initially, early-onset schizophrenia was considered to be a cause of significant mental retardation and the term "pfropfschizophrenia" was used. The presentation of schizophrenia in people with mild intellectual impairments is not significantly different from those without such an impairment.

Consideration of the mental health needs of people with mental retardation therefore should include creating the right social care environment to minimise the risk of abuse and to maximise opportunities, ensuring that mental health problems are detected and that appropriate assessment is available, leading to the necessary treatment and management strategies. These are outlined in more detail below.

6
Assessment and Treatment of Psychiatric and Behaviour Disorders

In the field of mental retardation, there are a profusion of different terms (e.g. psychiatric disorder, challenging behaviour, behaviour disorder) and a variety of perspectives from different disciplines. Most of these terms, such as "challenging behaviour", do not imply any understanding as to aetiology but are simply shorthand descriptive terms. The use of the word "behaviour" in such terms does not mean the approach is necessarily a behavioural one, just as calling something a "psychiatric disorder" does not mean that a psychiatric approach is necessarily the correct one or the only one needed.

People with more severe mental retardation have abnormalities in brain development resulting in impairments in skills and language development and increasing their vulnerability to psychiatric and emotional difficulties. For people with mild mental retardation, impaired brain development may be less severe but factors such as social disadvantage may help to account for the presence of psychiatric and emotional disorders. Furthermore, marked differences, particularly in the level of language development, give rise to considerable variations in the way in which individuals with mental retardation are able to describe their thoughts and feelings and therefore the way in which emotional distress and/or major psychiatric illness presents. Given the extreme diversity of people with mental retardation, it follows that the factors that should be considered with regards to mental health will be very varied across the range of disability.

6.1
Challenging Behaviour and Psychiatric Disorder

The high rates of these problems, together with the impact they can have on the lives of children and adults with mental retardation and their families, means that they account for many of the referrals to specialist community teams. The task of services is to undertake appropriate assessments in order to try and understand the reasons for the index problem and how it can most effectively be treated and managed.

Given the heterogeneous nature of this group of people defined as having mental retardation, it is not possible to make general statements about the presentation of psychiatric disorder and its treatment which are readily applicable to all those with mental retardation. The extent of impairment and, in particular, the level of language development will be crucial in determining how disorders such as depression might present. A psychiatric perspective is but one approach to understanding problem behaviour and is primarily a diagnostic one. It is also clear that psychological theories about learning and how behaviour can be shaped and reinforced over time are particularly important when it comes to understanding the reasons for problematic behaviour and when developing appropriate management strategies. The presence of problem behaviour therefore necessitates that multidisciplinary assessments take place, the facts contributing to the behaviour be identified and appropriate interventions initiated.

6.2 Psychiatric Assessment

The role of the psychiatrist when asked to see a person with mental retardation is essentially twofold. Firstly, through a detailed history taking (often from an informant, particularly if the person has limited language), mental state and physical examination together with necessary investigations to establish whether an additional mental disorder (over and above mental retardation) or physical illness is present, which might account for the index problem. The key issue is whether there has been a change in the person's behaviour, general well-being or intellectual or functional abilities. If so, this requires an explanation. The differential diagnosis will depend upon the clinical features but may include the development of a physical illness, the onset of a psychiatric illness such as depression, the impact of some life change or the development of some organic psychiatric disorder such as dementia. The diagnosis will depend upon the nature of the change, associated features (e.g. features of depression, the presence or absence of abnormal mental experiences, cognitive changes) in the context of a comprehensive picture over time of the person's life and any significant events. Additional information maybe required from a carer, specifically about whether a person's mental state appears to have changed, the person's apparent mood, their sleep and appetite pattern and whether he or she has lost interest in things or may be hallucinating. Secondly, a psychiatric assessment will also include a detailed developmental and family history, the purpose of which is to establish the cause, nature and extent of mental retardation and to address the questions as to whether the nature and cause of the mental retardation might contribute to or account for the index problem. For example, observed behaviour difficulties in a person with a developmental history diagnostic of autism may significantly help in the understanding of his or her behaviour. Changes in routine and excessive demands may be particularly difficult for people who are autistic and result in behaviour problems. Treatment in this case may involve helping carers understand the nature of autism and encouraging them to develop appropriate management strategies and, as far as is possible, a routine and predictable environment.

6.3 Behavioural Phenotypes

Knowing the cause of the mental retardation may also be important, as particular genetic or chromosomally determined disorders may be associated with specific psychiatric disorders or problem behaviours. For example, the behaviour of older people with Down syndrome may change because they develop hypothyroidism or Alzheimer's disease. Other examples of close links between specific syndromes and particular psychiatric or behaviour problems include the link between Prader-Willi syndrome and excessive eating leading to severe obesity, Lesch-Nyhan syndrome and self-injurious behaviour and Williams syndrome and a specific pattern of language development. These associations have been referred to as the "behavioural phenotype" of the specific genetic or chromosomally determined disorder (see O'Brien and Yule 1995). These associations are important, partly because they alert people to the potential for specific difficulties but also because of possible treatment implications.

6.4 Treatment

Changes in behaviour, general well-being and/or social and living skills in people with mental retardation should always lead to a more detailed assessment to address the question of the cause or causes of this apparent change. This invariably requires different approaches from different disciplines. All too easily it is assumed that such behaviour is simply due to the person's mental retardation and that nothing can be done about it. Treatment is based on both diagnosis and a holistic picture of the person and their circumstances. The range of treatments commonly used in psychiatry may well be applicable, taking into account how the person's impairments and disability may make a difference. In addition, particular attention

should also be paid to the environment within which the person lives. For example, it has become increasingly clear that significant amounts of physical and sexual abuse go unreported and undetected. The quality of the environment and the nature of the support available certainly influences the likelihood of problem behaviour or depression.

Given the fact that epilepsy is particularly common in people with mental retardation, the possibility should be considered that pre-, peri- or post-ictal states as well as the fit itself may contribute to problem behaviour. More effective treatment of the fits should then resolve the behaviour difficulties. The excessive use of and/or the use of inappropriate anti-convulsants (e.g. phenobarbitone) can contribute to further impairment of cognitive function or an altered mood state. A detailed clinical assessment and investigation of temporal relationships between seizures and behaviour, together with appropriate investigations (e.g. EEG, brain scan) should enable any link to be established (for a review, see Bird 1997).

Psychiatric illness is likely to require treatment with the appropriate neuroleptic, anti-depressant or mood-stabilising medication. However, there is a long and dubious history of using tranquillising medication to "control behaviour". The use of medication should be firmly guided by diagnosis and be used in the knowledge that it has been shown to be useful in treating that particular disorder (e.g. increasing aggression in the context of a depressive illness can be effectively treated with anti-depressant medication, as can a psychotic illness with neuroleptic medication). Medication acting on the central nervous system should be used with caution, as the response to such medication in those with a pre-existing disorder of brain development may be atypical. The risk of side effects from neuroleptic medication may be increased. As a general rule, doses of such medication should be low and increased with care together with regular monitoring of outcome.

In addition to cognitive and behavioural psychological interventions, interpretative psychotherapy and family therapy has been used, e.g. following bereavement or when family dynamics are thought to be playing a crucial part in the maintenance of the index problem. Given the additional problems that such therapies might encounter, because of the presence of impaired language development, music and art have been used as ways of helping people with limited or very limited verbal skills explore their emotions. It is clear that people with mental retardation can suffer major psychological traumas as a result of abuse or major life events. Music and art therapies may well provide ways of helping the individual resolve these issues or recovering from post-traumatic stress. Furthermore, the ability to make ones needs known and to understand and be able to communicate with others is a skill we take for granted, but when it is impaired, improving communication or developing new methods of communication (e.g. Makaton signing) may be a key factors in improving behaviour, enhancing skills and improving the person's quality of life. Speech and language therapy assessment and intervention are very important for this reason.

6.5
Functional Approaches

In addition to a diagnostic formulation, it is also important not only to consider what might be the causes of the particular change in behaviour or mental state, but to ask whether factors in the environment or in the type of care might be maintaining the problem. This can be particularly relevant where a behaviour appears to have a "function".

Psychological research and clinical practice has increasingly focused on the role that particular behaviours might have in enabling a person to have some control over their environment. Behaviour (e.g. aggression or self-injury) is seen to have a function (e.g. removing a particular demand or receiving social interaction). The task of psychological assessment is to identify the patterns of reinforcement and the environmental settings within which such behaviour is most likely to occur. This understanding then leads to management and/or environmental changes of a positive kind which in turn result in changes in the pattern of behaviour. The use of functional analysis and appropriate models of behavioural modification are now common place and can be highly effective (for a review, see Emerson 1995).

7
Social Care Needs and Normalisation

The shift away from institutional care towards a more focused, needs-led approach together with the changes brought about by the concepts of normalisation, first developed in Scandinavia (Bank-Mikkelsen 1969; Nirje 1973) and later in the United States with the concept of "social role valourization" (Wolfsenberger 1983), have been striking. These changes have led to a strong emphasis being placed on the rights of people with mental retardation to be integrated into mainstream society, to have the opportunities to establish and maintain friendships, the right to choose in matters of everyday life, the chance to develop competence through meaningful activity and the right to be

respected (O'Brien 1987). In the United Kingdom, the Government consultative paper *Better Services for the Mentally Handicapped* (Department of Health and Social Security 1971) was the starting point for major strategic change in the provision of care for people with mental retardation. These changes came about following major scandals concerning the quality of care and observed abuse in specific long-stay hospitals. Not only was there no theoretical basis for such institutions, other than those put forward by the eugenics movement, but the environments created did not foster development and easily became places of abuse. The process of closing large institutions and developing smaller, community-based homes continues to this day. Although there remains some debate about the role of what have come to be called "care villages", the basic principles of community care are accepted and not challenged.

As with health care needs, children and adults with mental retardation have similar basic social care needs as the rest of the population. These include a caring and supportive environment during childhood with appropriate emotional and physical support and opportunities to learn and develop skills necessary for independence in later life. In childhood, the focus has been on the development of special education either within mainstream schools or separately in special needs schools. The need for education is likely to continue into adult life and to include college courses providing further social and living skills training and literacy and numeracy teaching.

7.1 Needs Assessment

In the United Kingdom, there is now a statutory responsibility upon education authorities to provide special education and upon local social services departments to undertake needs-led assessments for all those with special needs. Such assessments should take place at key transitions in life (e.g. leaving full-time education and moving to adult services). The focus of this approach is to recognise the diversity of need both in individuals over time and across the group of people with mental retardation as a whole. While educational support during childhood has been excellent in many countries, the provision of day services for adults with mental retardation has been varied. A significant change has been the increasing development of supported employment schemes, whereby people with mental retardation can be helped to work in a variety of settings through the use of "job coaches". As with residential services, a variety of support is likely to be needed, the purpose of which is to provide meaningful occupation, the opportunity to develop further living and social skills and to have an acceptable quality of life.

7.2 Family and Paid Carers

With the closure of institutions and with the focus very much on "care in the community", the needs of both family carers (usually mothers) and of paid carers has received increasing attention. The stress involved in caring for a person with a significant mental retardation is well recognised. Levels of carer stress predominately relate to the presence or absence of additional behaviour problems rather than to the extent of disability. A good informal and formal support network, the availability of respite care and sharing the caring role seem to be key factors in minimising stress and the risk of neglect and/or abuse which can result. Recently introduced legislation in the United Kingdom now require social service agencies to specifically consider the needs of family carers.

7.3 Support Groups

The extent of support available to people with mental retardation and their carers varies considerably within and between countries. In addition to statutory health and social service agencies, there are an increasing number of specific syndrome support groups. These are a major source of information and advice. In many countries, organisations exists for even the rarest of syndromes or there are umbrella organisations which cover a range of syndromes.

7.4 Ethical and Legal Considerations

People with mental retardation may have special needs; they may be vulnerable to abuse and exploitation and may have considerable difficulties in making their needs known and being able to take significant decisions which affect their lives. For this reason, some of the potential legal and ethical issues which may arise regarding both social and health related issues should be considered.

In the case of children, parents or guardians have the responsibility for the care of those in their family whether they have a disability or not. The legal framework of most countries clearly places responsibility for the care of children and their protection from exploitation or abuse with the family. Parents have the legal right to take decisions on behalf of the child, where

possible taking his or her views into consideration. In adult life, the situation can be more complex, both ethically and in law. Tension exists between the right of an adult to self-determination and the need for the care and protection of people who may not be able to fully care for them. For example, in the United Kingdom, the absolute right of an adult to make the decision to accept or reject medical advice has been established through case law, providing that he or she is not incompetent to make that decision due to the presence of mental disability (e.g. due to mental illness, dementia, head injury). As far as medical treatment is concerned, for those adults who are considered incapable of making a decision, a doctor has a duty, under Common Law, to act in the best interest of the person concerned.

More generally, decisions are made everyday on behalf of people with significant mental retardation. Families and paid carers may involve him or her in that decision to the extent possible. However, under particular circumstances there is clearly a duty of care and there has to be the right balance between autonomy and risk. Examples of this include the decision as to whether a person with mental retardation can go out by themselves. Making such a decision would include an assessment of the skills of the person concerned and whether further help would allow the person to develop greater independence skills, an assessment of how any risk might be reduced and the views of the person him- or herself.

The over-paternalistic approaches which were commonplace are in danger of being replaced by an excessive wish to allow people with disability to make "choices" even when it is evident that they may not have the ability to make them. In some countries (e.g. Australia), guardianship laws have been enacted to provide a mechanism whereby a person has the right to make decisions on behalf of someone who lacks the capacity to make that decision for themselves. While such a legal framework has its benefits, it is also open to abuse and can become too restrictive. There is no easy solution to this issue. This tension has to be recognised and made explicit, and there is a need to balance the right to self-determination against the need to protect potentially vulnerable people.

8 Conclusions

This chapter has considered certain key themes. In summary, these are as follows:

- The history of the care of and attitudes towards people with mental retardation is not an honourable one. There have, however, been significant changes, and it is essential that people with mental retardation are considered with respect; when this label is applied, it must be for the benefit of those concerned.
- The term "mental retardation" refers to a highly heterogeneous group of people who have in common a history of early developmental delay, together with a significant intellectual impairment and impairment in social functioning, but differ in the extent and nature of their disabilities.
- The needs of both children and adults with mental retardation are often multiple and complex and change across the life span. Different disciplines and services will be involved, and the identification of needs can be aided by considering separately the reasons for and levels of impairments, disabilities and handicaps.
- People with mental retardation have high rates of behaviour and psychiatric disorder compared to the general population. Impaired language development can make the diagnosis of an additional mental disorder more difficult, but if changes in behaviour, mental state or well-being are observed or there is evidence of a loss of abilities, an assessment is essential. Multi-disciplinary assessments are often indicated. The role of the psychiatrist is to provide a psychiatric perspective to an understanding of the index problem. This includes the identification of additional medical or psychiatric disorders. Identifying the exact cause of the mental retardation can also be important.
- Detailed assessments provide the guide for intervention and specific treatment. Treatment and management strategies may include the full range of psychiatric, psychological and other psychotherapeutic interventions. Physical illness can become manifest as a change in behaviour and, particularly in those with limited language, should always be considered.
- People with mental retardation may have particular difficulties in making their needs known and because of their impairments and disabilities may be vulnerable to abuse and exploitation. Particularly in the case of adults, there can be a difficult balance between the rights of individuals to determine their own lives and the need for care and protection from risk.

Appendix A: Summary of the Diagnostic Criteria for Mental Retardation (DSM-IV)

A. Significant sub-average general intelligence
B. Significant limitations in adaptive functioning in at least two of the following:

- Communication
- Self-care
- Home living
- Social/interpersonal skills
- Use of community resources
- Self-direction
- Functional academic skills
- Work
- Leisure
- Health
- Safety

C. Onset before 18 years of age

Note

Significant sub-average intellectual functioning is defined as an IQ of about 70 or below. The choice of testing instrument should take into account the individual's socio-economic background, native language and other associated handicaps.

Adaptive functioning refers to how effectively individuals cope with common life demands and how well they meet the standards of personal independence expected of someone in their particular age-group, socio-cultural background and community setting. Adaptive behaviour may be influenced by individual and/or environmental factors, including the presence or absence of additional mental or physical disorders. Information on adaptive behaviour should be gathered from one or more independent sources.

The degree of severity of mental retardation may be specified on the basis of intellectual impairment taking into account other aspects of functioning.

Mental retardation may be classified as follows:

- Mild mental retardation:
  IQ level of 50–55 to approximately 70
- Moderate mental retardation:
  IQ level of 35–40 to 50–55
- Severe mental retardation:
  IQ level of 20–25 to 35–40
- Profound mental retardation:
  IQ level below 20 or 25

Appendix B: Impairments, Disabilities and Handicaps

Impairment

- Any loss or abnormality of psychological, physiological or anatomical structure or function
- Represents deviation from some norm in the individual's biomedical status
- Characterised by losses or abnormalities that may be temporary or permanent
- Includes the existence or occurrence of an anomaly, defect or loss in a limb, organ, tissue or other structure of the body or a defect in a functional system or mechanism of the body, including the systems of mental functioning
- Not contingent upon aetiology

Disability

- Any restriction or lack (resulting from impairment) of ability to perform an activity in the manner or within the range considered normal for a human being
- Concerned with compound or integrated activities expected of the person or of the body as a whole, such as represented by tasks, skills and behaviours
- Excesses or deficiencies of customarily expected activities and behaviour, which may be temporary or permanent, reversible or irreversible and progressive or regressive
- Process through which a functional limitation expresses itself as a reality in everyday life

Handicap

- A disadvantage for a given individual, resulting from an impairment or disability that limits or prevents the fulfilment of a role that is normal for that individual
- Places some value upon this departure from a structural, functional or performance norm by the individual or his or her peers in the context of their culture
- Relative to other people and represents discordance between the individual's performance or status and the expectations of his or her social/cultural group
- A social phenomenon, representing the social and environmental consequences for the individual stemming from their impairment and disability

Psychiatry and Somatic Disorders

CHAPTER

1

H. Förstl, A. Jablensky

Organic Origin of Mental Disorders: An Introduction

If we had complete understanding in any one of the three areas of mental illness, namely, pathological anatomy, etiology or symptomatology, then not only from each of them could an integrated and thoroughgoing classification of psychoses be found, but each of them would also – a requirement that is the foundation of our scientific research in general – substantially coincide with the other two. Illnesses having the same causes would also always present the same symptoms and have the same autopsy results. From this basic idea it follows that the clinical grouping of mental disorders will be based *at the same time* on all three aids to classification, and they must still fall into line with experiences gained from the course, the outcome, and, indeed, the treatment.

Kraepelin (1899)

Translator: S. Henn

1 Introduction

One hundred years after Kraepelin's statement, the hope for an exhaustive knowledge of the structural, molecular biological, and clinical features of mental disorders has not yet been fulfilled. It appears doubtful whether sufficient knowledge of the individual levels of observation can ever be obtained and whether a satisfactory congruence between morphology, biochemistry, and symptomatology can actually be achieved. The scientific realism of Kraepelin, i.e., the assumption of a real and concrete substratum of terminologies and theories, independent of the observer, still does not appear to be supported firmly enough in psychiatry. The classification of mental illnesses according to ICD-10 and DSM-IV is still based mainly on clinical symptomatology (APA 1994; WHO 1991). Results of additional technical investigations are referred to first in order to prove or exclude "organic" factors and, thereby, to make a clinically suspected diagnosis more or less probable. Earlier difficulties and achievements in diagnosing organically caused mental disorders seem today only a little more understandable in view of the way in which it is taken for granted that modern investigative techniques can give information about some central nervous system (CNS) functional disorders. The results so gathered, however, are then additionally used for diagnostic arrangement into classification systems, whose hypothetical character becomes particularly clear in the revision phases and is even more obvious in psychiatry than in other medical specialities. In this chapter, several lines of development will be outlined which have led to our currently used nosology and understanding of organic causes of mental disorders.

2 From Classical Antiquity to the Nineteenth Century

2.1 Early Clinical Observations

In classical antiquity, mental disorders were regarded as direct consequences and, thereby, as signs of somatic diseases. As a result, there was no separation between organic and functional disorders and no differentiation of independent mental illnesses. In the Hippocratic corpus, there is talk for the first time of "phrenitis," a condition of confusion and sensory excitement. Celsus (25 B.C. to 50 A.D.) drew up an extensive psychiatric nosology, which, in addition to mania, melancholy, and hysteria, also cited lethargy (with fever, somnolence, and unfavorable prognosis) as well as phrenitis. Phrenitis was characterized by its acute appearance and fever. The recommended acute treatment was directed at the fever. Transition to a condition of a continuous cognitive deficit, a "dementia continua," was possible. As causes of phrenitis, Aretaeus (50–130) cited fever, alcohol, and other intoxications, e.g., with the anticholinergic scopolamine. Galen (129–199) localized the starting point of such disorders in the brain.

Until the time of the Enlightenment, variations on the classical concepts remained in use, although the meanings of the concepts were subjected to numerous changes. Kendall (1978) compared the early Hippocratic school with its empirical-biographical base to the theoretical base of Platonic universal teachings, which attempted to discover reality in universally valid ideas. Stimulated by Sydenham's suggestion to introduce a system into medicine after the model of Linnaeus' *Systema Naturae*, the theoretical-platonic base gained the upper hand until the eighteenth century. The lack of clinical experience on the part of many authors was a recognizable deficiency of their theoretically striking extensions of psychiatric classification systems.

Organically caused disorders were assigned to different forms of mania, melancholy, or madness according to their symptomatology. William Cullen (1777) differentiated the group of "neuroses" or nervous diseases as disorders of perception and movement without fever and without focal signs. Within neuroses, he differentiated "comata" (apoplexy and paralysis), "adynamiae" (syncopes, hypochondria), "spasmi" (e.g., convulsions, chorea, hysteria, hydrophobia), and "vesaniae" as disorders of intellectual achievements. In addition to congenital, acquired, and senile forms of "amentia," mania and melancholy were also included. Alexander Crichton's (1798) fine differentiation of amentia into six subforms has more characteristics of an elaborated psychopathological system than a nosological system (exhaustion, memory disorders, perception disorders, association disorders, and impaired abilities in judgment and execution).

2.2 Clinical-Anatomical Model

With few exceptions, nosology was based into the nineteenth century on cross-sectional observation of clinical disorders. In the seventeenth century, Thomas Willis (1672) had attempted to connect brain changes to mental disorders, but with little success. The dictum "mental diseases are brain diseases," which has frequently been ascribed to Griesinger (1845), comes from him. Giovanni Battista Morgagni (1761) proved

that many of the brain changes in mental illness which were described earlier represented chance findings which had nothing to do with clinical symptomatology. His studies on the pathological anatomy of internal diseases acquired great importance. Similar insights into neuropsychiatry still took time. The "organology" or "phrenology" of Franz Josef Gall and his followers proved to be both a stimulus and a strain for the serious investigation of clinical-neuropathological connections. They claimed to be able to read many talents and character features from the skull surface (cranioscopic psychodiagnosis), using these methods, however, in a more restrained fashion in assessing mental disorders (Spurzheim 1833). Only the description of the speech center by Broca (1861) and Wernicke (1874) created some confidence that certain clinical deficits could be connected with defined and recognizable cerebral changes. New knowledge in psychopathology could not keep pace with the swift and steady growth of knowledge in the pathoanatomical bases of neuropsychological deficits, i.e., aphasias, apraxias, and agnosias (Liepman 1905; Pick 1898; Wilbrand 1892). Following the description of important clinical syndromes at the beginning of the century and then a stagnant phase, the clinical-anatomical investigative approach likewise led to important successes in organic psychoses.

Thomas Sutton (1813) noticed that a subgroup of phrenitis patients, primarily alcoholic patients, showed special clinical features: onset of illness without high fever but with visual hallucinations, awkward movements (floccilegium), and occasional stereotypic executions of occupational actions (occupational delirium). In contrast to other forms of phrenitis, no improvement occurred with bloodletting, but only following administration of opium. He called this condition "delirium tremens." Pearson (1813) and Armstrong (1824) described similar conditions at almost the same time(an older description with the name "Kardiakos" comes from the Talmud; Hankoff 1972).

It took more than 50 years before Gayet (1875) and Wernicke (1881) – again almost at the same time – described characteristic anatomical consequences of alcohol abuse. Two of the three patients in whom Wernicke proved a superior hemorrhagic polioencephalitis were alcoholics and were admitted in delirium tremens. In a series of studies, Korsakow published additional clinical findings on the consequences of alcoholism. Among other things he described in them was the combination of anmestic syndrome and polyneuropathy (1887).

Progressive paralysis was a central theme of medical research in the nineteenth century, with significance reaching far beyond the study of syphilis. Bayle (1822) and Calmeil (1826) proved connections between progressive cognitive deficits, paralysis, and meningeal inflammation. This discovery is viewed today as the first description of a particular neuropsychiatric illness. Newly developed technology in the second half of the century made possible for the first time the implementation of reproducible histological and bacteriological investigations. The transmission of syphilis, its histological characteristics, and the demonstration of spirochetes in effluvia, of antibodies in cerebrospinal fluid, and, finally, of spirochetes in the brain together built up a chain of evidence which slowly led to greater precision in the concept of disease and also contributed to the description of some other, more important illnesses in modern psychiatry.

In 1894, Binswanger still expressed the view that the paralytic process of the illness "is undisputedly the consequence of a functional over-exertion of the CNS and, primarily, the cerebral cortex." In contrast to this, Alzheimer presumed "that in 70% of cases a connection with syphilis is certain or probable" (cited by Kraepelin 1899). Until discovery of the spirochetes and development of the Wassermann test, Kraepelin himself diagnosed one third of his patients as having a progressive paralysis, after which the rate sank to 5% (Hunter 1973).

The study of progressive paralysis led to a greater precision in the concept of dementia, albeit with a one-sided emphasis on "cognitive paradigms" (Berrios 1990). The term "dementia" or "amentia" was, as mentioned, in use since classical antiquity to denote a group of mental illnesses with disorders of intellectual abilities, but also of perception, affect, and intentionality. It included acute and chronic, primary and secondary, and congenital and senile forms. Cognitive deficits, above all of memory, were increasingly emphasized as the main feature of dementia. In addition, around 1900, the concept usually implied secondary appearance and irreversibility. Thus the number of subsumed illnesses was reduced and it became easier, within this less heterogeneous group, to track down anatomical and etiological bases of individual forms of dementia.

The effort to obtain a differential diagnosis of progressive paralysis contributed considerably to the characterization of other dementias with degenerative and vascular causes. That strokes could lead to grave cognitive deficits was known (Durand-Fardel 1843), and the term "apoplectic dementia" had already been created (Ball and Chambard 1881). Marce (1863) had established that a large part of senile dementia was not caused by progressive paralysis, but by vascular changes in the brain. Binswanger (1894) described clinical and macropathological features of a subcortical vascular encephalopathy.

Alzheimer (1895) differentiated in several studies a series of distinct vascular brain diseases with characteristic clinical features, among others a multi-infarct syndrome.

In earlier reviews and in his *Habilitationsschrift*[1] on progressive paralysis, Alzheimer mentioned forms of dementia with gland- or plaque-like interstitial depositions in the cerebral cortex. These had been described by Redlich (1898), among others, as miliary sclerosis of the cerebral cortex. The description of an individual patient (Alzheimer 1906) who became ill in late middle-age with a dementia having a particularly severe course and in whose cortex, in addition to plaques, a large number of previously unknown, intraneuronal fibrillary structures were found made Alzheimer's disease history, as the *casus primus*, the disease of the century, something which is probably not only owed to the scientific achievement of Alzheimer, but also to the influence of Kraepelin, who coined the eponym. Within 5 years, reports of more than ten patients with this form of dementia were published (Fuller 1912). Fischer (1907) had also demonstrated great numbers of plaques in senile dementia, and Simchowicz (1911) proposed quantitative neuropathological criteria with which to differentiate otherwise normal aging changes. Since then, the term Alzheimer's disease has also been broadened to include senile dementias with corresponding clinical and pathological features. In the same period, histological substrates of focal brain atrophy (Alzheimer 1911) and of tremor paralysis in Parkinson's disease (Lewy 1912) were described in Alzheimer's laboratory.

Alzheimer's large project to write a "pathological anatomy of mental diseases" remained unfinished. The *Anatomy of Psychoses*, edited by Spielmeyer (1930), contained extensive chapters on the pathology of neurological diseases, such as epilepsy, encephalitis, extrapyramidal motor illnesses, and consequences of intoxication and of CNS arteriosclerosis and degenerative dementias. The section on dementia praecox is short; depressive illnesses were not treated. Earlier attempts to present the whole of psychiatry as a science of diseases of the forebrain (Meynert 1884) or as an extension of the study of aphasia (Wernicke 1906) did not gain acceptance and were dismissed as "brain mythology."

3 Psychiatric Taxonomy in the Twentieth Century

3.1 Differentiation of Organically Caused Mental Disorders

As clinical observations and early successes in explaining their neuropathological bases and, sometimes, their etiology increased, new nosological concepts developed whose contours are also recognizable in present ICD-10 and DSM-IV classifications. Against the confusing background of seemingly innumerable putative causes (from infectious brain diseases and degenerative processes to nutritional-toxic influences and psychological trauma), it became possible to map clinical illnesses with some heuristic power at the turn of the century. As is also the case for many other models, psychiatric constructs developed in antithetical pairs (e.g., exogenous vs. endogenous, process vs. reaction, psychosis vs. neurosis). The influential and threefold division of mental disorders proposed by Kraepelin represents a form of these dichotomies. He compared the "organic" mental disorders, i.e., those associated with external causes and brain diseases, to functional psychoses (dementia praecox and manic depression) and to nonpsychotic mental disorders (neuroses and psychopathy), respectively. It quickly became clear that this simple schema did not permit an unambiguous and reliable classification of all mental disorders.

Contrary to the view expressed by Kraepelin, a specific psychopathological syndrome could not be attributed to each noxious substance, and it turned out that various systemic and brain diseases cause only quite a limited repertory of mental disorders. Whereas knowledge of neuropsychology could be further expanded and differentiated – not least by traumatizing war experiences – (e.g., Gelb and Goldstein 1920; Poppelreuther 1923), it constantly became clearer that unambiguous and integrated brain changes could not be understood using conventional postmortem neuropathological methods for a large number of mental disorders. This is the case both for progressive illnesses and for a series of clinical disorders with less pronounced deficits. A large number of clinical-phenomenological classifications were proposed for these mental reactions, but only a few are still in use today.

For Bonhoeffer (1908, 1910), dimming of consciousness was the main symptom of "acute exogenous type of reaction," i.e., those "types of mental damage" restricted to the large number of possible physical disorders. He differentiated the following: delirium; hallucinations with less pronounced loss of awareness and paranoid delusions; sudden motor and affective excitement with disorientation and failures in judgment (epileptiform type but without epileptic episodes); symptomatic stupor (from 1910: semi-conscious state) with slowing down, loss of awareness, loss of interest, impeded comprehension and reaction, and mild euphoria; finally, amentia with fluctuating consciousness disorders, incoherence, flight of ideas, mild ability to be diverted, and hallucinations. Only delirium and hallucinations still have comprehensible clinical significance today. It may be assumed that the others were possibly phenomena typical of the time.

[1]Translator's note: a postdoctoral thesis required to qualify as a university professor.

E. Bleuler (1916) differentiated between two types of "psychosyndrome" according to the damage observed, acute or chronic: the "diffuse brain psychosyndrome," largely synonymous with amnestic syndrome (Korsakow 1887; Moll 1915) and consisting of a loss of cognitive performance possibly accompanied by movement and perception disorders, and the "localized brain psychosyndrome," in which after focal or multifocal brain lesions, in spite of various locations of damage, a similar clinical picture appears with changes in drive and mood. Later, M. Bleuler (1954) added an "endocrine psychosyndrome," one that – with a variety of endocrine causes – can cause changes in social behavior, sleep, sexuality, movement, and sensitivity to warmth and cold, hunger and thirst.

The description by von Baeyer (1947) of "organic personality disorders" with lack of drive, cumbersomeness, affective disorder, over-familiar behavior, weakness, and increase or change in preexistent personality features is similar to E. Bleuler's definition of localized brain psychosyndrome.

A growing number of clinical observations showed that organic brain disorders could also be manifested similarly to schizophrenic illnesses or personality disorders. In a comprehensive literature review of 782 original articles, Davison and Bagley (1969) proved many systemic and brain illnesses to be the cause of a schizophreniform psychosis. On the basis of their symptomatology, organic and endogenous schizophrenia could not be reliably differentiated. It was clear that, in general, neither a noxious substance nor a lesion leads inevitably to a particular mental disorder, nor, on the contrary, does a particular psychopathological picture refer to a certain organic cause.

Kurt Schneider (1948) treated this diagnostic uncertainty with very restrictive criteria for the diagnosis of physically based psychoses: important physical finding, unambiguous connection, no indication of an alternative cause (e.g., through a familial genetic burden), favorable influence after improvement of the organic illness.

Lipowski (1975) advocated a broader concept, differentiating three kinds of mental disorders resulting from a systemic or brain illness:

- Disorders of organic origin in the narrower sense, with a variety of psychopathological disorders which are a direct consequence of diffuse or focal CNS damage or of a metabolic disorder
- Reactive disorders, i.e., psychoses, neuroses, personality or behavior disorders, which are a faulty adaptation to strains arising from mental illness and their psychological and social consequences
- Deviant behaviors with self-destructive refusal of compliance, denial of illness, or excessive dependency

At the same time, he emphasized the significance of cognitive disorders for the proof of organic causes, although a uniform and severe impairment of all cognitive abilities can only be found with extensive CNS changes. Disorders of organic origin can be classified in three ways by observing cognitive deficits: (1) according to the extent (global vs. selective, e.g., dementia and delirium vs. other disorders), (2) according to manifestation (severe vs. discrete, e.g., dementia and delirium vs. functionally evident disorders), and (3) according to the course (chronic vs. transient, e.g., dementia vs. delirium). Lipowski emphasized that the development of organically caused mental disorders is not only dependent upon the severity of the damage, but also upon dispositional and environmental factors. Kraepelin (1920) also came to share this view toward the end of his scientific career, when he moved away from his influential nosology and also from the concept of specificity of noxious substances.

3.2 Is the Concept of Organic Mental Illness Obsolete?

Attempts to dispense perhaps completely with the handy term "organic" – as proposed in DSM-IV – can prove difficult to enforce. The organic versus functional dichotomy continues to be useful in clinical practice and understanding, although it can scarcely be supported on theoretical grounds. Both of the currently most important classification systems, ICD-10 and DSM-IV, are similar in many important respects, but treat the problem of organicity differently. In DSM-IV (APA 1994), the concept of organic mental illness was abandoned, based on the consideration that this term implies the lack of a biological basis for nonorganic mental disorders. Those illnesses which were previously called organic now appear in sections on delirium, dementia and other cognitive disorders, psychological with medical illnesses, and drug-induced illnesses. The multiaxial structure of DSM fundamentally requires that every systemic or brain disease in which a causal relationship to a psychiatric symptomatology is assumed is recorded as comorbidity (axis III). This empirical base has an advantage, since it allows a theoretically unencumbered, unbiased collection of clinical data. Whether this is practical and leads to the accumulation of usable information remains to be shown.

In contrast to this, a more conservative approach was chosen in ICD-10 (WHO 1991), in which the classes of organic mental disorders were retained, although their boundaries were extended to include two groups of disorders, namely, a syndrome in which necessary and determining features are deficits

of cognitive functions or consciousness (i.e., the Bonhoeffer-Bleuler types of reaction and organic psychosyndrome), and a syndrome in which hallucinations, delusion, and disorders of affect, personality, and behavior are uppermost. In addition, ICD-10 differentiates between primarily organic psychosyndromes on the basis of specific brain diseases and secondary, symptomatic mental disorders caused by extracerebral illnesses.

The principle difference between DSM-IV and ICD-10 is concerned less with diagnosis and classification of diseases exhibiting cognitive deficits and disorders in consciousness than with the assessment of the gray zone of endogenous forms of mental and affective syndromes which are associated with functional disorders of the brain having variable genesis and severity. A schizophreniform illness with a somatic disease (e.g., epilepsy) according to ICD-10 could be coded in DSM-IV in several different ways: as schizophrenia on axis I (meeting the symptom and time criteria) with epilepsy (comorbidity on axis III), as a schizophreniform illness (if the diagnostic criteria of schizophrenia are not fulfilled) or as a psychotic illness with a somatic disorder, whereby the epilepsy would again then be encoded on axis III.

Research into "nonorganic" disorders in the last few decades has produced a series of organic correlates. In the case of schizophrenia, these results extend from ventricular enlargement and reduced hippocampal volumes to disordered neurons in the prefrontal cortex. In the case of delusional psychoses at higher ages, frequent neurodegenerative changes were found. In affective, anxiety, and compulsive disorders, as well as in personality disorders and many others, the significance of concrete organic factors becoming increasingly clear. It can be assumed that this research will lead to a fundamental contribution toward an integrated understanding of the interplay of psychological stressors and neurobiological factors.

With the increased sensitivity of neuroradiological and neurophysiological methods of investigation, the boundaries between "organic" and "functional" mental disorders are becoming blurred. At the same time, a revolution with a series of genetically determined diseases is indicated, which will shake conventional clinical nosologies and, at least in some areas, will make them obsolete, as diagnosis and intervention become possible even before symptoms are manifest. Similarly, the collection and classification of clinical and morphological data for these diseases will perhaps lose importance, as is presently the case for Kraepelin's symptomatology and pathology of neurosyphilis, which lost importance after the elucidation of its etiology.

Clinical Assessment of the Dementias

Translator: E. Taub

1 Definition

The term "dementia" denotes an etiologically nonspecific and semiologically heterogeneous constellation of psychopathological manifestations. Dementia is primarily characterized by an acquired, persistent or progressive impairment of memory and cognition, occurring in the absence of a disturbance of consciousness and resulting in a limitation of the patient's ability to carry out his or her daily activities. The cognitive changes are associated with changes of affect control and social behavior.

This syndrome may be produced by many neurological and systemic diseases that affect different parts of the brain and have varying temporal courses. Just as the etiology of dementia is extremely heterogeneous, so, too, are its clinical manifestations. Cerebral damage primarily affecting frontal areas is typically associated with personality changes, loss of initiative, and paucity of language. Damage of the temporal and parietal lobes, in contrast, primarily produces disturbances of memory and orientation.

The recognition of the presence of dementia and the establishment of its underlying cause are fundamentally different components of the diagnostic process. Many organic brain disorders are indeed associated with an impairment of memory and other cognitive functions, but have the clinical manifestations not of a dementia syndrome, but rather of an "organic personality change" (as in some frontal lobe processes) or of a "mild cognitive dysfunction" (as in many cerebrovascular diseases; see Chap. 8, this volume, Part 2). In other cases, when the patient's intellectual baseline is high, a decline in cognitive ability may lead the clinician to suspect a dementing illness even though the diagnostic criteria for a dementia syndrome or other organic psychosyndrome are not (yet) fulfilled. These cases may be designated as "subdiagnostic" dementia (Helmchen et al. 1996). On the other hand, there are rare cases of patients with an unusually low intellectual baseline who may cross the diagnostic threshold for the dementia syndrome merely because of an additional, age-related cognitive decline, even though no brain illness is present.

2 Diagnostic Criteria

The diagnostic criteria for dementia have undergone several changes since the last edition of this textbook. With the introduction of DSM-III, operational diagnosis became standard for all psychiatric diseases, including the dementing diseases. DSM-III was rightly criticized, however, for inadequately defining the aspects of cognitive impairment that are most typical of dementia, and for failing to provide a satisfactory solution to the problem of making a categorical decision about the presence or absence of disease manifestations on the basis of dimensional functional impairments (Jorm and Henderson 1985). These deficiencies have been largely or completely remedied in the current psychiatric classification systems, ICD-10 and DSM-IV, both of which specify the diagnostically relevant features of dementia and indicate which diagnostic studies are appropriate. The global character of cognitive impairment is no longer emphasized, but the mere demonstration of an impairment of memory does not suffice for the diagnosis of dementia in either system. The patient's cognitive deficits must lead to a decline in his or her level of performance and must not be due to a disturbance of consciousness or to delirium.

Despite these common features, the two classification systems differ in several important ways. In ICD-10 (Appendix A), the typically chronic or progressive nature of the dementia syndrome is stressed, and the clinical manifestations are required to be of at least 6 months' duration, so that other, reversible conditions will not be misdiagnosed as dementia. This inclusion of prognostic data in the definition of dementia accords with the European tradition.

DSM-IV (Appendix B), in contrast, contains no such restriction; the course of dementia may be progressive, remitting, or stationary, depending on its underlying cause. The two systems also differ markedly in the type and number of required and supplementary defining features and in the algorithms specifying how these must be combined. For example, ICD-10 attaches far less diagnostic importance to aphasia, apraxia, and agnosia than DSM-IV. On the other hand, ICD-10 requires impairment not only of memory, but also of executive function as an obligatory prerequisite for the diagnosis of a dementia syndrome, and it further requires an impairment of emotional control, initiative, or social behavior.

The distinction between dementia and milder degrees of cognitive impairment not associated with comparably widespread psychopathological manifestations is drawn in both systems by the use of a threshold level of psychosocial functioning. The definition of dementia is thus made to depend on its effects on the patient's social relationships and ability to cope with the activities of daily living. According to ICD-10, mild dementia may be diagnosed as soon as memory impairment or other cognitive deficits impede the patient's activities of daily living, so that complicated everyday tasks and leisure activities can no longer be performed. According to DSM-IV, however,

dementia may be diagnosed only if each of the demonstrated cognitive deficits significantly limits the patient's social or occupational activities and causes a clear deterioration of his or her performance.

With regard to their clinical utility, both classification systems, despite their differences, serve adequately to facilitate the recognition of the dementia syndrome and to increase the reliability of its diagnosis. Unfortunately, however, it is still difficult to determine in many cases whether a mild cognitive impairment meets the rather vaguely defined threshold criterion for the diagnosis of dementia, especially because the social consequences of dementia in the individual case largely depend on the patient's life circumstances at the time, as well as on his or her level of education and ability to compensate for the deficits.

Moreover, the features said to be characteristic of dementia are not equally so for all dementing diseases and all stages in the progression of dementia. Memory impairment is mild or lacking in several types of cerebrovascular disease and lobar atrophy. The occurrence of episodes of delirium, said to rule out the presence of a dementia syndrome, is actually characteristic of Lewy body dementia. It thus makes sense that DSM-IV not only rejects the conventional distinction between organic and functional mental illness, but also avoids providing a unified, disease-independent definition of dementia. DSM-IV lists the psychopathological features constituting dementia primarily in the context of etiologically specified disease processes. This decision to avoid defining unified, overarching organic psychosyndromes can be understood as an attempt to establish a closer correspondence between individual organic brain diseases and their characteristic psychiatric manifestations and physical findings. This tendency has the further consequence that progressive diseases of the central nervous system leading to dementia can often be diagnosed at an early stage, when the psychopathological and social defining features of the dementia syndrome are still absent. The diagnosis of a dementing disease is thus no longer coupled to the ascertainment of a disease-independent dementia syndrome. This trend is likely to continue as diagnostic tests become ever more refined and to result in the increasing availability of early therapeutic and even preventive interventions.

3 Differential Diagnosis of the Dementia Syndrome

Unlike dementia, which usually takes a chronic progressive course, *delirium* is an organically caused brain disorder of abrupt onset and limited duration, characterized by clouding of consciousness, reduced ability to maintain, focus, and shift attention, marked fluctuation of clinical findings, and cognitive and perceptual impairment, as well as severe impairments of psychomotor function and of the sleep–wake cycle.

The commoner causes of delirium are acute somatic illnesses and disorders, drug intoxications, and withdrawal phenomena. Delirium generally lasts no more than a few days or weeks. Delirium may be superimposed on preexisting dementia. In such cases, its cause must be sought in concurrent illnesses or substance-related problems.

The *amnestic syndrome* consists of an isolated impairment of memory and is thus generally easily distinguished from dementia, in which several areas of cognitive functioning are simultaneously impaired. Detailed neuropsychological study of amnestic patients may disclose impairment of visuospatial processing or other subtle cognitive deficits that would otherwise escape notice. Loss of motivation and behavioral abnormalities, normally seen in frontal brain damage, are found in the Wernicke-Korsakoff syndrome.

Dementia is characterized by the loss of previously present cognitive abilities. If an adequate history is not available, dementia may be difficult to distinguish from *mental retardation* (either congenital or acquired early in life), from *inadequate education*, or from severe *personality disorders*, especially when the latter result in lifelong impairment of social adaptation.

Elderly individuals may have purely *age-related cognitive changes*. Cognitive ability declines with advancing age to a highly variable extent (Reischies 1997). The areas of performance that are most affected are speed, memory, and visuospatial ability (Crook et al. 1986). The cognitive changes of normal aging differ from those seen in dementia in that they are milder, progress much more slowly, and rarely affect everyday activities (Helmchen et al. 1997). Nonetheless, it may be quite difficult to distinguish age-related cognitive changes from dementing illness in very old patients of low primary intelligence.

Dementia must also be distinguished from organic psychosyndromes that are clearly too severe to represent a purely age-related cognitive decline, but nevertheless not severe enough to meet the diagnostic criteria for dementia, delirium, or amnesia – the latter primarily because they do not affect everyday life significantly enough to rise above the psychosocial threshold criterion for dementia. Such cognitive impairments come under the headings of *mild cognitive disorder* (ICD-10), *cognitive disorder, not otherwise specified* (DSM-IV), or *mild neurocognitive disorder* (DSM-IV Research Criteria). A prerequisite for the provision of any of these diagnoses is the objective demonstration of a neurological, medical, or substance-induced disease state underlying the

psychopathological signs and symptoms. A mild cognitive abnormality lacking any identifiable cause cannot be assigned a diagnosis under either of the current classification systems. Cases of this type are common and occupy a still inadequately defined intermediate zone between normal cognitive aging and dementia. Various terms have been proposed for such cases (see Chap. 10, this volume).

It is currently considered certain that some of these cases represent a stage of Alzheimer's disease preceding the onset of overt dementia, and that mild cognitive disorder will progress to dementia within 1 year in approximately 15% of patients (Petersen 1995; Grundman et al. 1996; Petersen et al. 1997). An intensive research effort is currently being devoted to the problem of identifying neurodegenerative diseases in the pre-dementia stage with the aid of markers in the blood or cerebrospinal fluid or of sensitive imaging techniques (Kurz et al. 1998). Such patients are an important target group for future therapeutic techniques intended to prevent dementia.

Several longitudinal studies have shown that dementia is misdiagnosed as depression in more than one quarter of all patients and, conversely, that depression is often misdiagnosed as dementia. Misdiagnoses of the latter type are due to the frequent occurrence of memory impairment, lack of concentration, and cognitive difficulties in depression. This combination of cognitive and affective disturbances has been designated as "pseudodementia" (Kiloh 1961) or, alternatively, as the "dementia syndrome of depression" (Folstein et al. 1978). In most such patients, however, the cognitive impairment is not severe enough to merit the diagnosis of dementia, and its pattern is often atypical for the dementia syndrome. In particular, patients with "depressive pseudodementia" do not have aphasia, agnosia, or apraxia, disturbances of orientation, or impairment of their everyday activities because of their cognitive disturbance (Des Rosiers et al. 1995). Further features distinguishing such patients from those with organic cognitive disturbances include the previous occurrence of depressive episodes, a family history of affective disorders, and a discordance between the subjective perception of severe intellectual deficits and the relatively mild objective findings (Stoppe and Staedt 1994).

A close and consistent correlation between the degree of cognitive impairment and the severity of depression cannot be demonstrated. Moreover, even when there is marked clinical improvement with respect to the affective manifestations, cognitive performance typically recovers only in part (Alexopoulos et al. 1993). The degree of reversibility of cognitive disturbances in depression has likely been overestimated. When deficits of memory and intellect persist, a combination of dementia and depression should be suspected.

4 Clinical Assessment

A comprehensive mental status examination and physical examination must be performed to confirm or exclude the diagnosis of dementia in every patient in whom it is suspected. The examination begins with careful questioning of the patient and of a reliable informant. A history obtained from an informant other than the patient is the most important set of data for the diagnosis of dementia. The history includes information on when, how, and in what circumstances the illness first became manifest, its subsequent course, its effect on the ability to carry out activities of daily living, behavioral changes, previous illnesses, medication use, alcohol consumption, and the possible occurrence of similar illnesses in the patient's family. The history also includes information concerning the patient's primary personality, level of education, life history, and social situation. After the history has been taken, a detailed psychiatric examination is performed, which must include a test of cognitive functions.

History-taking and psychiatric examination serve the purpose of translating the grammar of the operationally defined classification criteria into a series of interview questions, through which information is obtained about the defining features of the dementia syndrome and of other disorders that must be differentiated from it, and which take account of the patient's intellectual capacity. If the examination yields sufficient evidence favoring a diagnosis of dementia, the severity of dementia should be gauged with a test of cognitive performance, such as the Mini-Mental Status Test (MMST). If the diagnosis is difficult to confirm, the use of additional standardized assessment techniques or neuropsychological testing for cognitive deficits should be considered. In some cases, a diagnosis of dementia cannot be made in a single examination and requires observation of the patient's behavior and clinical course over a longer period; this is especially true when a reliable informant is lacking, when there is concurrent delirium, and when subtle personality changes need to be evaluated.

The remaining steps of the evaluation are intended to establish the cause of the dementia syndrome. First, a detailed physical examination is performed, with special attention to the neurological examination. A series of baseline laboratory tests provides an overview of the functional state of the major organ systems and serves to identify possible causes of dementia as well as other, potentially treatable somatic illnesses. Beyond

these basic diagnostic techniques, further, possibly invasive procedures may be indicated if the initial investigation leads to the suspicion of particular underlying diagnoses. Further laboratory testing is sometimes necessary. A lumbar puncture is indicated in atypical, rapidly progressive forms of dementia or when an inflammatory process affecting the central nervous system is suspected.

The elements of the psychiatric examination can be summarized as follows:

1. History-taking from the patient
2. Questioning of a close relative
3. Determination of family history
4. Determination of psychiatric findings
5. Clinical dementia test to determine the severity of cognitive impairment
6. Physical examination, with particular attention to the neurological examination
7. Baseline laboratory tests: blood profile, erythrocyte sedimentation rate, urinalysis, electrolytes, hepatic enzymes, protein electrophoresis, thyroid-stimulating hormone (TSH), vitamin B_{12} and folic acid, *Treponema pallidum* hemagglutination assay (TPHA)
8. Electroencephalography (EEG)
9. Computed tomography (CT)/magnetic resonance imaging (MRI)

The evaluation of the patient does not end with the confirmation of the presence of dementia and the determination of its etiology. The *nomothetic diagnosis*, by which the patient's abnormal state is abstracted and categorized as conforming to a particular element of a disease classification system, must be complemented by *idiographic diagnosis*, i.e., the consideration of a large number of factors that are of diagnostic, prognostic, and therapeutic importance to the individual patient. One such factor is the possible presence of concurrent noncognitive disorders (Burns et al. 1990), which are often more responsive to symptomatic and palliative treatment than the cognitive deficits and the limitation of everyday activities. The assessment also includes the identification of retained abilities that may aid in rehabilitation and the detection of secondary factors, such as physical illnesses and handicaps or sensory deficits, as well as evaluation of the patient's present and future needs for social and nursing support or for assistance with legal and financial matters.

In many cases, a position must be taken regarding the patient's competence to provide informed consent to diagnostic and therapeutic measures. The ethical principles and legal criteria that apply in this area, and their practical implementation in methods of psychiatric assessment, have long been a subject of intense discussion in the biomedical community in all Western countries (Helmchen and Lauter 1995; Koch et al. 1996).

The various aspects of idiographic assessment can be briefly summarized as follows:

1. Psychiatric aspects:
   a) Particular manifestations of psychopathology (e.g., depression, hallucinations, delusions, sleep disturbance)
   b) Behavioral abnormalities (e.g., disorientation, danger of running away)
   c) Degree of independence and need for nursing care
2. Somatic aspects:
   a) Other somatic illnesses
   b) Sensory deficits (visual or auditory impairment)
   c) Motor deficits (gait impairment, danger of falling)
3. Social aspects:
   a) Living situation (alone, with family, in institution)
   b) Presence of other person(s) with a relationship to the patient
   c) Quality of relationship
   d) Burden on other person(s)
4. Personal aspects:
   a) Life history
   b) Personal values
   c) Awareness of illness and suffering
   d) Retained abilities
5. Legal aspects:
   a) Competence to give informed consent
   b) Need for legal guardianship
6. Prognostic aspects:
   Stage of progression of the dementing process

The goals of this type of assessment are the education and counseling of the patient and his or her family, the provision of social assistance, and the initiation of measures for treatment and rehabilitation.

5 Subjective Aspects

Statements made by demented patients reveal that they are aware of their cognitive impairment not only at the inception of the dementing process, but also in its advanced stages. Many aspects of these patients' behavior are not direct consequences of the underlying changes in the brain, but can rather be understood as natural reactions to, and attempts to cope with, the perceived loss of functional ability (Kurz et al. 1988; Haupt and Kurz 1990).

Family members are less disturbed by the patient's cognitive impairment itself than by the resulting difficulty of communication, progressive loss of

initiative, and changes in personality and behavior, including anxiety, aggression, sleep disturbances, agitation, and delusions. Particularly disturbing to family members is their often protracted uncertainty over whether the observed changes in the patient are merely aspects of his or her personality or expressions of an underlying disease. The patient's relatives are often poorly informed about the nature, manifestations, and course of dementing illnesses. They suffer from the increasing limitation of their own life possibilities and from often continuous tension, as well as role conflicts and guilt feelings. These stresses, in turn, may lead to the psychoreactive generation or exacerbation of health problems (Morris 1988). Awareness of the subjective aspects of dementia on the part of the physician is an indispensable element of the clinical evaluation and is a prerequisite for sympathetic interaction with patients and their families and for the alleviation of their suffering.

6 Standardized Techniques of Assessment

Psychiatric history-taking and examination are generally carried out in the form of a free interview. The free interview has the advantage that an experienced clinician can adjust the questions asked to the particular cognitive abilities of the patient under examination, or of his or her accompanying family members, and thus maintain a relaxed, conversational atmosphere that helps the evaluation attain its goal. Nonetheless, the data obtainable by this technique necessarily suffer, to some extent, from a certain informational and observational inadequacy and cannot be expressed in quantitative form. The use of standardized instruments of assessment can counteract these deficiencies. Such instruments, including clinical psychometric tests, structured interviews, and specific neuropsychological tests for the assessment of cognitive disorders, are discussed in the following section.

6.1 Psychometric Tests

Some of the typical features of dementia, such as memory impairment, are also found in normal elderly individuals and are distinguished as pathological only by their severity. Diagnostic assessment, to be useful, must therefore not just categorize these deficits, but also rate their severity. The degree of cognitive and psychosocial impairment is assessed by means of brief tests or rating scales that measure the severity of performance impairments, behavioral disturbances, and handicaps. They incorporate cutoff values that demarcate the different grades of severity of the deficits under study or serve as a threshold beyond which the diagnosis of dementia is probable. Such instruments can thus contribute to the evaluation of dementia. It should be remembered, however, that they only inform us about the behavior or cognitive performance of a subject at the time of examination and do not indicate what factors may be responsible for the deficits and abnormalities they reveal. Poor performance on a cognitive test may be due to dementia, but may also be the product of many other factors, including advanced age, poor attention, lack of motivation, depression, or physical illness. Clinical diagnosis, therefore, does not always accord with the results of psychometric tests (O'Connor et al. 1991).

From the methodological viewpoint, psychometric tests may be classified as objective tests of performance, self-assessment tests, and tests involving assessment by other individuals; they may, alternatively, be classified according to the source of the data (e.g., patient, examiner, family member). In Table 1, tests are classified according to the specific features that they test.

Several instruments are designed exclusively for the quantification of cognitive impairment. Other psychometric tests deal with the behavioral abnormalities and depressive symptoms of demented patients. Some tests serve to assess competence in the activities of daily living and provide a measure of retained independence and of the degree of need for social or nursing assistance. Some standardized instruments include batteries of performance tests and rating scales and are used for the simultaneous assessment of cognitive and noncognitive disturbances. There are yet other rating scales for the severity and stage of progression of individual dementing illnesses. A last group of instruments is used to assess changes in the patient's condition, particularly in the evaluation of therapeutic approaches.

6.2 Structured Interviews

Free questioning and assessment on the basis of the examiner's experience are not sufficiently reliable or valid for use in the evaluation of mild cognitive disturbances, particularly in field studies on large population samples, which generally employ multiple examiners.

Semistandardized, structured interview techniques are preferable for use in such situations. The questions have a prescribed form and structure, and the encoding and processing of the responses are standardized,

Table 1. Commonly used psychometric tests in dementia

Feature tested	Test	Reference
Cognitive impairment	Mini-Mental Status Test (MMST)	Folstein et al. (1975)
	Syndrom-Kurz-Test (SKT)	Erzigkeit (1983)
	Brief Cognitive Rating Scale (BCRS)	Reisberg et al. (1983)
	Mattis Dementia Rating Scale (DRS)	Mattis (1976)
	Hierarchic Dementia Scale (HDS)	
	Clock test	Ploenes et al. (1994)
Behavioral abnormalities	Behavioral Pathology in Alzheimer's Disease (BEHAVE-AD)	Reisberg et al. (1987)
	Cohen-Mansfield Agitation Inventory (CMAI)	Cohen-Mansfield and Billig (1986)
	Behavior Rating Scale for Dementia of the Consortium to Establish a Registry for AD (CERAD-BRSD)	Tariot et al. (1995)
	Neuropsychiatric Inventory (NPI)	Cummings (1996)
Depressive symptoms	Geriatric Depression Scale (GDS)	Yesavage et al. (1983)
	Dementia Mood Assessment Scale (DoMAS)	Sunderland et al. (1988)
Competence and functional abilities	Instrumental Activities of Daily Living (IADL) Scale	Lawton et al. (1969)
	Functional Assessment Staging (FAST)	Reisberg (1988)
	Progressive Deterioration Scale (PDS)	DeJong et al. (1989)
	Interview for Deterioration in Daily Living Activities in Dementia (IDDD)	Teunisse (1995)
	Disability Assessment for Dementia (DAD)	Gauthier et al. (1993)
Combined assessment of cognitive and noncognitive functions	Nürnberger Alters-Inventar (NAI)	Oswald and Fleischmann (1995)
	Alzheimer's Disease Assessment Scale (ADAS)	Mohs and Cohen (1988)
	Clinical Assessment Geriatric Scale (SCAG)	Shader et al. (1974)
Severity and stage of progression of dementia	Global Deterioration Scale (GDS)	Reisberg et al. (1982)
	Clinical Dementia Rating (CDR)	Hughes et al. (1982)
Changes in condition over the course of treatment	Clinician's Global Impression of Change (CGIC)	Guy (1976)
	Clinician's Interview-Based Impression of Change (CIBIC, CIBIC plus)	Schneider et al. (1997)
	Alzheimer's Disease Cooperative Study Clinician's Global Impression of Change (ADCS-CGIC)	Schneider and Olin (1997)

but the examiner still has considerable freedom to adapt the line of questioning to the situation of the particular individual being interviewed.

Some of these instruments have proved their value primarily in the evaluation of dementing and depressive illnesses in advanced age; these include the Initial Subject Protocol (ISP; Berg et al. 1982), the Cambridge Mental Disorders of the Elderly Examination (CAMDEX; Roth et al. 1986), the Geriatric Mental State Schedule (GMS; Copeland et al. 1976, 1986, 1988), the Comprehensive Assessment and Referral Evaluation (CARE; Gurland et al. 1977), the Canberra Interview for the Elderly (CIE; Henderson 1992), and, in German, the *Strukturierte Interview zur Diagnose von Demenzen vom Alzheimer Typ, der Multiinfarkt- (oder vaskulären) Demenz und Demenzen anderer Ätiologie* (SIDAM: Zaudig et al. 1991; Zaudig 1996). Zaudig (1995) has provided a detailed overview of these instruments.

The instruments named here also take account of information supplied by the patient's family, obtained in part through interviews with additional informants, and contain a number of internationally used rating scales. Diagnostic evaluation can thus proceed according to a preset algorithm, which has been tailored to the psychiatric classification systems currently in use.

6.3 Neuropsychological Tests

Neuropsychological tests are useful primarily for the early recognition of organic brain illnesses and the detailed study of their course. They are also used for the assessment of specific impairments of cognitive function, for the purpose either of providing a guide

for rehabilitation, or of precisely localizing the patient's clinical findings to structural or functional brain damage at a specific site. There are neuropsychological tests of different aspects of memory, linguistic and visuospatial ability, and cognitive executive and control functions, including certain aspects of attention, thinking, and problem-solving behavior. The test results can be compared with normal values for the patient's age, sex, and level of education. A simple and easily applied technique for neuropsychological assessment was developed by the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) (Welsh et al. 1994). The CERAD battery tests the patient's performance on verbal and nonverbal learning and memory tasks, naming, verbal fluency, and visual construction. It includes the MMST.

7 Screening Tests

Many dementing illnesses are not diagnosed until late in their course. Mild dementia is often overlooked, not only by physicians, but even by family members, especially those of very old patients (Ross et al. 1997). The question thus arises of whether elderly persons at especially high risk for dementia should undergo screening, as is done for other medical problems in this age-group. An ideal screening test would detect probable cases rapidly and efficiently, but would not necessarily have to provide a definitive diagnosis. The currently available tests are low in specificity, so that screening would have to be followed by a detailed psychiatric examination in many cases.

The Seven-Minute Screen (Solomon et al. 1998) is a new screening technique of this type that might find widespread application in general practice. It consists of four simple tests that may be conducted by auxiliary medical personnel, require no specialized knowledge for their diagnostic interpretation, and take a total of less than 8 min to apply on average. This screening procedure is very highly specific and sensitive for the differentiation of cognitively intact elderly persons from patients with mild Alzheimer's disease. It remains to be seen how well this procedure will perform under the conditions of general medical practice. The question of whether screening for dementia is ethically justified or medically defensible, in view of the possibly unnecessary worry it would cause elderly patients (Cooper and Bickel 1984; Henderson 1994), can now be answered more positively than a few years ago, in view of the better therapeutic options now available.

8 Comorbidity

An increased frequency of depressive disorders has been found repeatedly in cohorts of demented patients (Lammi et al. 1989; Henderson 1990; Reifler et al. 1982).

Field studies on community samples, however, have not demonstrated any correlation between categorically diagnosed dementia and depression. With the aid of dimensional evaluative techniques, it was revealed that depressive symptoms are more frequent with increasing cognitive impairment, but severe performance impairments due to dementia are somewhat negatively correlated with the presence of depressive symptoms (Helmchen et al. 1993). It must be borne in mind that severely demented subjects often cannot be included in field studies, and their responses often cannot be evaluated. Informant interviews, too, have only limited ability to establish the presence of depressive symptoms in demented patients, because relatives generally rate the severity of depression more highly than the patients themselves, particularly when dementia has reached an advanced stage (Karrer 1995). The validity of a diagnosis of depression in the presence of dementing disease is further called into question by the fact that several characteristic features of depression, including loss of initiative, slowing, social withdrawal, sleep disturbance, and vegetative symptoms, may also be the result of cognitive impairment, and their inclusion in a diagnostic scheme for depression may artificially exaggerate the correlation between dementia and depression.

Demented patients are more likely than individuals of the same age who are not mentally ill to suffer from multiple organic illnesses and physical handicaps. Somatic comorbidity contributes to the generation of depressive symptoms, some of which may be of purely somatic origin. The physician must bear this diagnostic ambiguity in mind when deciding whether treatment with antidepressants is indicated.

9 Ethical Problems in Research

The necessary improvements in the area of early diagnosis will only come about through a steady increase in scientific knowledge. This, in turn, depends on the voluntary participation of patients in epidemiological and clinical research studies that will yield a better understanding of the causes of dementia and of

potential early recognition of disease-specific traits. Severely demented patients, however, are not competent to give their informed consent to such studies. According to German law, individuals not competent to give informed consent may be included in a research project only when they are expected to derive an immediate benefit from it. This may be the case for therapeutic trials, but not for epidemiologic, pathogenetic, or diagnostic studies. It may be asked whether nontherapeutic research on incompetent patients ought to be legally permitted in some cases, e.g., in exceptionally promising scientific projects involving no particular hardship or risk to the patient, when the scientific question cannot be answered by studying competent patients, and when provisions are made for the patient's protection. This problem has recently come under discussion in Germany (Helmchen and Lauter 1995) and was extensively dealt with in the European Council's hearings on the Human Rights Convention in Biomedicine; it has also received much critical attention in the public at large (see Chap. 18, Vol. 1, Part 2).

Appendix A. Diagnostic Criteria for Dementia According to ICD-10

1. A decline in memory, which is most evident in the learning of new information. The decline should be objectively verified by obtaining a reliable history from an informant, supplemented, if possible, by neuropsychological tests or quantified cognitive assessments.
2. A decline in other cognitive abilities characterized by deterioration of judgment and thinking, such as planning and organizing, and in the general processing of information. Evidence for this should be obtained when possible from interviewing an informant, supplemented, if possible, by neuropsychological tests or quantified objective assessments. Deterioration from a previously higher level of performance should be established.
3. The disturbances described in 1 or 2, above, must be severe enough to adversely affect the patient's activities of daily living.
4. Absence of clouding of consciousness.
5. A decline in emotional control or motivation, or a change in social behavior, manifest as at least one of the following:
   a) emotional lability,
   b) irritability,
   c) apathy,
   d) coarsening of social behavior.

All five criteria must be fulfilled. For a confident clinical diagnosis, the abnormalities listed in 1 and 2 should have been present for at least 6 months; if the period since the manifest onset is shorter, the diagnosis can only be tentative.

Appendix B. Common Symptom Presentation in Disorders Listed in the "Dementia" Section of DSM-IV

A. Development of multiple cognitive deficits, which are manifest as

1. memory impairment,
2. at least one of the following four disturbances:
   a) aphasia (deterioration of language function)
   b) apraxia (impaired ability to execute motor activities despite intact motor abilities, sensory function, and comprehension of the required task)
   c) agnosia (failure to recognize or identify objects despite intact sensory function)
   d) disturbances in executive functioning (impaired ability to think abstractly and to plan, initiate, sequence, monitor, and stop complex behavior).

B. The items in both Criterion A1 and Criterion A2 must be severe enough to cause significant impairment in social or occupational functioning and must represent a decline from a previous level of functioning.

C. Dementia is not diagnosed if these symptoms occur exclusively during the course of a delirium. However, a delirium may be superimposed on a preexisting dementia, in which case both diagnoses should be given.

H. Bickel

Descriptive Epidemiology of Dementias

Translator: S. Henn

1 Introduction

The number of older individuals and their proportion they account for of the total population has risen steeply in industrial countries over the course of the twentieth century. In Germany, for example, the number of people over 65 increased fourfold to more than 12 million and is still increasing; at the same time, the number of those over 80 years of age increased tenfold (Statistisches Bundesamt 1985, 1994). In the wake of these demographic changes, the dementias have become a serious problem for the health care system.

Descriptive epidemiology endeavors to ascertain the distribution of dementias in the population and to provide information about time-related changes in frequency of the illness, locally varying distributions, and associations with personal characteristics such as age and gender. Routine statistics are of little value. Since the majority of patients do not seek help from specialists, the treatment statistics of psychiatric institutions or data from psychiatric case registers reflect only a portion of the morbidity present in the population. Statistics related to causes of death are also unproductive, since they likewise record only a fraction of the cases of illness. Epidemiology is therefore dependent upon field studies with random sampling of representative populations for a description of the actual spread of dementias.

Illness frequency in this study will be expressed in the form of variously defined measures of prevalence and incidence. Prevalence, which can be relatively easily estimated from cross-sectional studies, gives the portion of the population which suffers from dementia at a particular time, while incidence, which requires a more expansive and time-consuming longitudinal study, estimates the frequency of new illnesses within a particular period. The two values are relevant for different kinds of problems. Prevalence is above all important for the purposes of planning care, since it records the existence of the illness and can give clues to the existing need among the patients for medical and social services. Prevalence does not, however, allow compelling conclusions to be made regarding the distribution of risks for the illness, as prevalence depends both on the incidence and on the duration of illness, without it being possible to show in the cross-section studies which of these influencing factors is responsible for the prevalence difference. On the other hand, incidence, which is independent of duration of illness, can give information about etiologically important differences in risk between populations or within a single population.

2 Prevalence

Results relating to the prevalence of dementias in the elderly population are available from numerous field studies carried out in different parts of the world. Reported total rates for those over 65 years of age show considerable scatter, although the majority of studies show rates varying between 4% and 8%. Provided that the estimates refer to moderate and severe dementias, none of the newer studies exceeds a value of 8%, while the inclusion of milder dementias brings the values to 10% and more.

The comparability of single studies is greatly limited, however, by methodological differences, not least different age distributions in the populations studied. Some authors have therefore attempted to derive more stable estimates from meta-analyses of age-specific prevalence rates. The results are presented in Fig. 1 together with those from the most extensive European study to date (Ott et al. 1995).

Jorm et al. (1987) took into account all the studies which have been published between 1945 and 1985, while the so-called EURODEM Study (Hofman et al. 1991) was restricted to European studies with comparable sample definitions and case criteria. The analysis by Ritchie and Kildea (1995) was based on studies in which the criteria of DSM-III were applied. In spite of these differences in the selections made in the studies, the results show good agreement with one another. A sizable increase in prevalence is found with increasing age. The rates rise more than 20-fold from below 2% among those aged 65–69 years of age to more than 30% in those over 90.

Jorm et al. (1987) concluded from their statistical analysis that the prevalence rises exponentially, with a doubling of the rate in constant age intervals for each 5.1 years. This model of an exponential increase in the age range from 65 to 85 years is in accord with newer data and is congruent with results from both German (Häfner and Löffler 1991) and European (Hofman et al. 1991) studies. However, it is not appropriate to extrapolate to the oldest group, as above 90 years this model very quickly leads to excessive values and predicts a prevalence rate of 100% at 98.5 years of age.

It can be gathered from recently completed studies that prevalence increases markedly from the 85- to 89-year-old age-group to the over-90 group (Ebly et al. 1994; Wernicke and Reichies 1994; Fichter et al. 1995; Helmchen et al. 1996). However, whether a further increase occurs after 90 years or whether the rate approaches an asymptote is controversial. The limited data for the group over 95 leads us to suppose

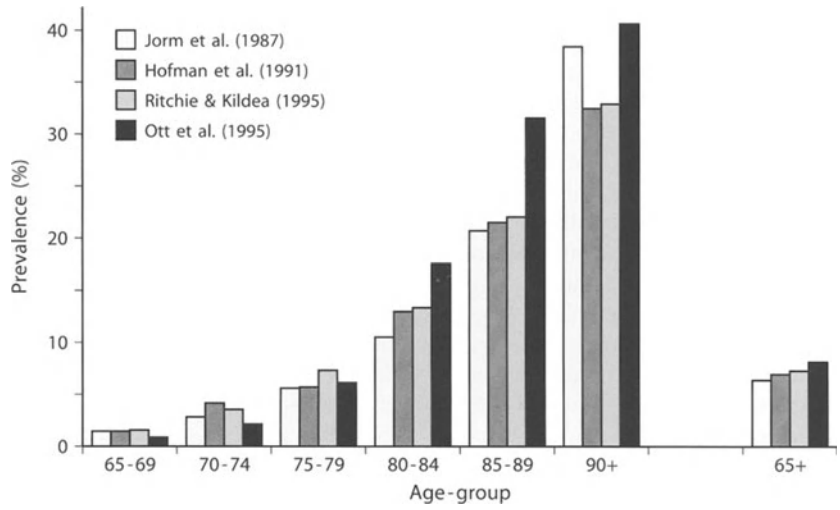

Fig. 1. Age-specific prevalence of dementia. *Asterisk*, standardized overall prevalence rates by age-group for those over 65 in the German population in 1992

a prevalence in the range of 28%–35% for moderate to severe dementias and between 40% to almost 60% for mild to severe dementias. Sobel et al. (1995) reached similar conclusions in the largest study to date on those over 100. In a country-wide study of all inhabitants of Finland who were 100 or older, they determined that 33% suffered from severe dementias and altogether 55.9% at most had mild to severe forms of the illness. These results are compatible with the conclusions from the meta-analysis by Ritchie and Kildea (1995), according to which prevalence grows exponentially over a wide age range, but the increase flattens out over 80 years and no additional increase worth mentioning can be observed over 95 years.

The information about gender-related differences in age-corrected prevalence rates is inconsistent. For the most part, no significant differences were found. However, in the EURODEM Study, men under 75 showed higher rates than women, and those above 75 showed lower rates.

If the age-specific rates are transferred to the present population in Germany (Statistisches Bundesamt 1994), a total prevalence of between 6.4% and 8.1% for those over 65 years is calculated. However, it has to be taken into account that the estimates include milder forms of dementias to a varying extent. The largest proportion of cases in absolute numbers can be expected with the given age configuration among the 80- to 89-year-olds (50%–60%), with proportions of between 25% and 35% among the 65- to 79-year-olds and from 12% to 16% among those over 90 years. In accordance with their overrepresentation in the elderly population, more than 70% of dementias should be found among women.

2.1 Presenile Dementias

Owing to the rarity of dementia among younger people, field studies are usually confined to the older population. For this reason, relatively little is known about the frequency of presenile illnesses. The EURODEM Study estimates prevalence in the 30- to 59-year-old age-group at 0.1%. Similar results are reported from studies based on case registers. The underestimation of the rates is probably low, since early cases of the illness, in contrast to the senile dementias, generally lead to the use of specialist care. Kokmen et al. (1989) report rates of 40–86 per 100,000 individuals in those aged between 45 and 59 years. Mölsä et al. (1982) found rates of 51 per 100,000 among those who are 45–54 years and rates of 144 per 100,000 among those 55–64 years old. According to these results, a prevalence of less than 0.1% to a maximum of 0.2% between the ages of 40 and 64 years can be concluded. People with dementia who are less than 65 years old should therefore comprise no more than 5% of the total number of the patients in western countries, where a high proportion of the population is older.

Newens et al. (1993), in a survey of results on the prevalence of presenile Alzheimer's dementia, report rates of between 18 and 47 cases per 100,000 individuals. In their own, very careful study in North England, they found rates of presenile forms of Alzheimer's dementia which continually rise with age, rising from 2.4 per 100,000 (45–49 years) to 11.8 (50–54 years), 35.6 (55–59 years), and 87.3 (60–64 years). The rates among men and women do not differ from one another.

2.2
Relative Frequency of Forms of Dementia

A rough classification of the illnesses is made in field studies separating an Alzheimer type of dementia, vascular dementia, and other forms of dementia. Little is known about the validity of this assignment, which is largely based on anamnestic information. Without additional technical diagnostic methods, which are of course planned in newer investigations but are often tolerated by only a minority of patients, the certainty of the diagnosis is probably very limited. Moreover, it is increasingly more likely that other brain illnesses, which can be hidden among Alzheimer-like dementias, such as frontal-lobe degeneration or dementia with Lewy bodies, are more frequent than previously assumed.

With these restrictions, Alzheimer's dementia is by far the most common form of dementia according to almost all field studies in Europe and North America. It accounts for between 50% and more than 80% of current cases. The large studies compiled from Canada (Canadian Study of Health and Aging Working Group 1994) and Rotterdam (Ott et al. 1995) conclude that 64% and 72%, respectively, of the illnesses originate from Alzheimer's dementia, followed by vascular dementia, accounting for 19% or 16%, respectively. The remainder of the illnesses, at most 5%–15%, in addition to cases of unknown origin, include a majority of specific forms of dementia, in which the majority are dementias connected to Parkinson's disease or to alcoholism.

To the extent that gender differences are taken into account, a higher portion of Alzheimer's dementia is found among women and a higher portion of vascular dementia among men, as the EURODEM Study showed (Fig. 2). The steep age-related increase in the prevalence rates appears to be caused primarily by Alzheimer dementia. Admittedly, vascular dementias and other forms of dementia are as frequent as Alzheimer dementia below 80 years of age. However, they increase to a lesser extent with increasing age. In contrast, the prevalence of Alzheimer's dementia rises very sharply from one age range to another, so that according to many studies it is responsible for nearly four fifths of dementia among the oldest elderly.

Results from Japan and China differ clearly from the pattern of distribution found in western countries. In these countries, which have a similarly high prevalence of dementias as Europe and North America, the vascular dementias are thought to be far more common than Alzheimer's disease. However, more recent Japanese studies indicate that the geographical difference is smaller than was suspected a few years ago (Ogura et al. 1995; Yoshitake et al. 1995). In addition, a study carried out in Shanghai justifies the assumption that the different results are based in part at least upon different diagnostic criteria (Zhang et al. 1990). Earlier reports, according to which Alzheimer's disease is not found in some African populations (Osuntokun et al. 1991), were unable to be confirmed by a study carried out with standardized methods in Ibadan, Nigeria, and Indianapolis (USA). Admittedly, a significantly higher prevalence rate of Alzheimer's dementia was found among the African-Americans than in the Nigerian sample, although at present it is unknown whether there is a different risk of illness in the two populations, which show a similar ethnic origin, or whether the prevalence differences are due to the different length of survival time of patients in Africa and in the United States (Hendrie et al. 1995).

3
Incidence

Although incidence has a far greater significance for the distribution of the risk of illness than does prevalence, which is dependent upon duration of illness, to date only a small number of prospective field studies have been carried out. According to the

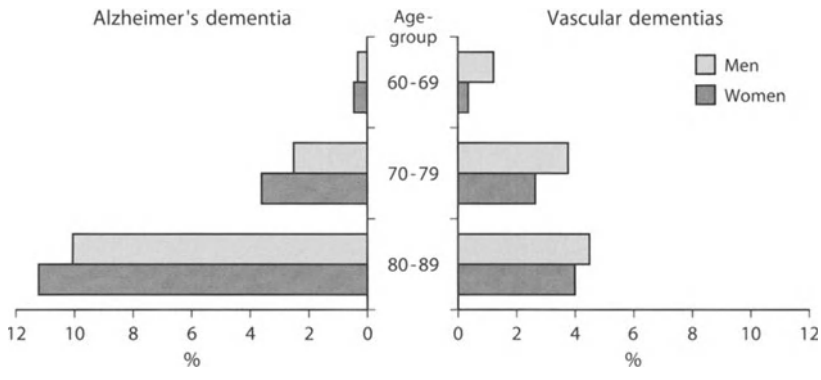

Fig. 2. Age- and gender-specific prevalence of Alzheimer's dementia and vascular dementias according to the results of the EURODEM Study (Rocca et al. 1991a,b)

Table 1. Age-specific incidence of dementia according to results of prospective field studies

Clarke et al. (1996)	Nottingham, UK	1042	65–69: 7.2 70–74: 13.2 75–79: 16.3 80–84: 34.6 85+: 21.7	65+: 15.8

results cited in Table 1, within 1 year, 1%–2% of people over 65 develop a dementia illness. Admittedly, no meta-analysis of age-specific incidence rates was carried out, but a steep, almost exponentially increased risk of new illness with increasing age is indicated. On average, the 12 investigations show that the number of new illnesses each year rises from 3 per 1000 individuals (65–69 years) to 7 per 1000 (70–74 years), 17 per 1000 (75–79 years), 33 per 1000 (80–84 years), up to about 50 per 1000 (>85 years).

Men and women are affected approximately equally; the gender-related differences in risk of illness are slight and inconsistent. As with existing cases, Alzheimer's dementia also prevails among the new illnesses, accounting for 42% in the Japanese study and between 55% and 75% in studies from western countries. The sizeable increase with age for incidence rates seems to be caused primarily by the steep rise in Alzheimer's dementia, which in the investigation by Letenneur et al. (1994), for example, was responsible for only one third of the first illnesses occurring in those aged 65–74 years, but for two thirds in those aged 75–84 years and for 96% of new cases in people over 85 years of age.

It is still a matter of speculation whether the increase in the incidence rates continues in the highest age-group, whether a plateau is reached, or even whether the rates reverse among the long-lived. This question is difficult to answer, since the estimated values show very broad confidence intervals due to the low numbers of people in the high age-groups. However, none of the studies support a reduction in the risk of disease at an age of more than 85–90 years. Rather, the indications are increasing that the incidence among the very elderly is very much higher than was previously assumed. While the studies showed in Table 1 report rates which deviate sizably from one another among the high age-groups, the investigations which have dealt with the very elderly show similarly high values. Thus Gussekloo et al. (1995), in the Netherlands, determined a 1-year incidence rate of 6.9% for those over 85 years of age; in Sweden, Aevarsson and Skoog (1996) established a rate of 9% for the same age-group; and Johansson and Zarit (1995) found rates of 9.9% and 7.7% in two surveys with 84- to 90-year-olds. Studies from Munich and Mannheim came to identical conclusions. According to varying diagnostic criteria, Fichter et al. (1996) estimated the yearly rate of new illness among those over 85 years of age at 7.2%–14.4%. Bickel (1996) calculated a rate of 7.5% for 85- to 89-year-olds and a rate of 11% for those over 90 years.

3.1 Presenile Dementias

In middle age, the risk of illness is slight, as expected for all forms of dementia. Mölsä et al. (1982) report a yearly rate of 10.2 new illnesses per 100,000 individuals in the age-group from 45 to 54 years and a rate of 27 per 100,000 in those aged 55–64 years. In the study by Kokmen et al. (1993), which looks at 5-year intervals from 1960 to 1984, the corresponding rates amount to an average of 10.7 and 46.9 first illnesses per 100,000 individuals.

The incidence of presenile Alzheimer's dementia is 6.4 or 2.6 cases per 100,000 in the 45- to 54-year-old age-group and 16.5 or 24.7 cases in the 55- to 64-year-old age-group in the two studies, respectively. Newens et al. (1993) report a rate of 3.4 per 100,000 between 40 and 60 years of age, with a continuous increase with age from 0 (40–44 years) to 0.9 (45–49 years), 4.9 (50–54 years), 8.1 (55–59 years), and 14.5 per 100,000 (60–64 years). Discontinuities among the age-specific incidence, which could be a clue to varying disease processes in presenile and senile forms of Alzheimer's dementia, were not observed in the present investigations.

3.2 Geographical and Time-Dependent Risk Differences

Geographical differences in the incidence of dementias can hardly be assessed in the absence of comparable data. Transnational studies with standardized methods, which could provide information about risk differences, have only recently been initiated. Without exception, presently available incidence data come from industrialized countries. They scatter just as widely within individual countries as between countries and provide no basis for the assumption that marked differences exist between European countries and countries with populations of predominantly European ancestry.

Convincing evidence for changes with regard to time is also lacking. Of course, the number of dementia patients has certainly increased in recent decades, but this increase can be explained by higher life expectancy and the sharp increase in the number of older people. The two single epidemiological studies which have been concerned with time-related differences in incidence come to opposite conclusions. In the Lundby study, in which a small region in southern Sweden was studied by the same research group over a period of 25 years, a lower, although not significantly decreased, incidence was found in the period from 1957 to 1972 than in the preceding period from 1947 to 1957 (Hagnell et al. 1981). If a downward trend did actually exist, it does not appear to have continued in subsequent years, for recent data from other studies do not point to an incidence that is still decreasing. On the contrary, Kokmen et al. (1993) in Rochester (USA) established a significant increase in the incidence rates in their register study spanning the years 1965–1984. However, this increase was only observed in those aged over 85 years, while the rates remained constant for the younger age-groups. Since the Rochester study is based upon cases which were known to the medical facilities, it remains doubtful whether there is a real increase or only an

apparent one caused by increasing use of medical assistance.

3.3 Life-Span Risk

A question that has received little attention despite its great relevance is that of the risk to the individual of becoming ill with a dementia over the course of his or her lifetime. This question has both a practical and a theoretical aspect. Practically significant is the question of the likelihood that a dementia will actually appear over the course of one's life, i.e., how high the individual risk is based on current life expectancies, or the size of the portion of the population which develops dementia. Theoretically significant is the question of the likelihood that a dementia will appear at a given age if death does not occur prematurely. In other words, will everyone become ill with dementia if he or she lives to becomes old enough, or is only a portion of the population predisposed?

Only a small amount of data is available relating to both questions. In a U.S. retrospective study of a representative random sample of deaths of people aged over 65, based upon information from surviving relatives, it was determined that 10%–15% of those who died aged between 65 and 72 years, 18%–25% of those who died aged between 75 and 84 years, and 32%–40% of those who were over 85 years of age at death had suffered severe cognitive impairments in their last year of life (Lentzner et al. 1992). A similarly designed study in Mannheim, which did not only ascertain cognitive disorders, but also used case criteria for dementia illnesses, came to comparable conclusions (Bickel 1996). According to this study, the number of dementia patients among the deceased rose from 4.5% in those who died between 65 and 69 years to 10% (70–74 years), 25% (75–79 years), 36% (80–84 years), and nearly 50% (>85 years). Altogether, about 30% of all deceased older individuals had suffered from a moderate to severe dementia during their lifetime. If age-specific prevalence rates and the higher rate of mortality of dementia patients are taken into consideration, this result appears plausible, indicating that nearly one third of those who now live beyond 65 years will become ill with dementia in the further course of aging.

Whereas the proportion of those affected among the deceased is in principle accessible to direct observation, the likelihood of becoming ill with dementia at a particular age can only be estimated indirectly from the age-specific incidence rates. The assumption must then be made that those who die before having reached the age of interest without having developed the illness would in the further course of aging have had the same risk as survivors from whom the incidence rates were derived. From this assumption, statements can be made about what portion of the population would become ill with dementia by a particular age if all were to survive until this age or until the onset of dementia, depending upon which occurs first.

The most sophisticated calculations of age-related risk of morbidity come from the Lundby study (Hagnell et al. 1981). According to the results, in the study period from 1947 to 1957, the cumulative risk for a moderate to severe dementia by age 89 amounted to 53.6% for men and 58.4% for women. In the study period from 1957 to 1972, the cumulative risk for both genders by age 89 was estimated to be 40%. Divided according to the two most important diagnostic groups, there turned out to be a risk for all grades of severity of Alzheimer's dementia of 25.5% for men and 31.9% for women and a risk for vascular dementia of 29.8% and 25.1%, respectively (Hagnell et al. 1992).

However, the Lundby data omit the very elderly. A retrospective study carried out in Mannheim (Bickel 1996) permits estimates for this age-group to be made, according to which the risk amounts to only 2% by age 70, rising to 6% by age 75, 12% by age 80, and 36% by age 85. At 89 years of age, the cumulative risk is in agreement with the Lundby study (50%), whereby the risk for Alzheimer's dementia is 28% and the risk for a vascular dementia is 22%. However, the probability of illness already reaches a value of 75% by 95 years of age and almost 90% by 100. It cannot be concluded from this steep increase that age-independent disease processes are responsible for the origin of dementias, but it seems a likely supposition that almost everyone will develop dementia if he or she reaches a very advanced age.

In contrast to this, the cumulative risk up to age 65 appears to be very low. If an estimation is based on the published incidence rates, the risk of becoming ill with presenile dementia should lie at clearly less than 1% for all forms taken together and at less than 0.3% for an Alzheimer's dementia.

4 Duration of Illness and Mortality

Epidemiological and clinical studies agree in showing that the remaining life expectancy of dementia patients is considerably reduced. Van Dijk et al. (1991) examined 90 publications on the mortality of patients with dementia and calculated an average 2-year death rate of 25% (range, 5%–35%) for outpatients, 50% (range, 35%–70%) following admission to a nursing home, and

60% (range, 40%–71%) following admission for treatment as a psychiatric inpatient. In a recent population-based longitudinal study carried out in Mannheim on prevalent cases averaging more than 80 years of age, the 2-year mortality rate was 25% for mild dementia, 45% for moderate dementia, and 55% for severe dementia (Cooper et al. 1996).

The total duration of illness is difficult to determine because of the usually insidious onset of dementia disorders. In some studies supported by information from relatives concerning time of appearance of the first symptoms, average survival times of 4.7–8.1 years for Alzheimer's dementia and 5.2–6.7 years for vascular dementias were found. The duration becomes shorter with increasing age at onset of illness, although all age-groups exhibit large differences among individuals in the remaining life expectancy. If the first symptoms appeared prior to 65 years of age, the duration of illness amounted to an average of 8–10 years. If they began between the ages of 65 and 80, the duration of illness was 5–8 years, and if they began at an age of more than 80, it was 3–5 years. Since at higher ages the general state of health is worse and associated illnesses accumulate, the decreasing survival rates permit no conclusion about a more rapid progression of dementia among the elderly.

If the length of survival is assessed in relation to other time frames more significant for care systems, such as the time of diagnosis or of an inpatient admission to a home or hospital, 6 years is found for illnesses beginning before 65 years of age and about 3 years for those developing later.

Compared with the mortality in the age-matched general population or, more precisely, in age-matched control groups of individuals without dementia, the mortality risk for patients with dementia is two- to fivefold higher. Although the survival time for illnesses arising early is longer than for those developing late, the discrepancy with the usual life expectancy is very high. This is the case above all for younger patients, since dementias developing in the very elderly reduce the remaining life expectancy to a lesser extent, as life expectancy is already short at this age. Nevertheless, a two- to threefold increased risk of mortality was found even with dementia patients over 85 (Aronson et al. 1991; Johannsson and Zarit 1995). In demented patients between 65 and 75, however, relative risks greater than fivefold were reported. The field study by Katzman et al. (1994) found a relative mortality risk of 5.4 for Alzheimer's dementia and 7.2 for other forms of dementia.

Factors associated with survival time include age, gender, and, in particular, severity of dementia. By controlling for other variables, Heyman et al. (1996), in an extensive sample of Alzheimer outpatients, found a 47% higher mortality risk with an increase in age of 5 years, twice the risk for men, and an increased risk of 36% for each additional level of severity when graded on a scale of four levels. The shorter duration of illness for men could explain the previously reported tendency toward higher prevalence rates among women. On the other hand, the decreased length of survival with increasing aging leads us to suppose that the increased prevalence seen in the elderly is not due to the accumulation of long-lasting illnesses, in particular, but that this increase in prevalence is actually lessened by decreasing survival time and that the figures reflect an even steeper increase of incidence.

The life expectancy of patients with dementia has risen in recent decades, but whether this will lead to increasing prevalence rates is still debatable, although there is some circumstantial evidence for such a trend. In several cohorts of hospital inpatients treated in the years 1957–1987, Wood et al. (1991) confirmed an increase in survival of 11.7 months for women and 7.4 months for men, an increase which could not be explained either by age differences or by differences in severity of impairments. Beard et al. (1994), on the basis of a population-based case register for the period between 1960 and 1984, found an 18% decline in the death rate for Alzheimer's patients at the end of each decade. The reasons for longer survival should more likely be sought in the improved treatment of concurrent illnesses rather than in changes in the natural course of the illness.

5
Dementias and Care Needs

5.1
Increasing Need for Care

During the course of dementias, the progressive amnestic and cognitive losses inevitably lead to a great need for help and care. In mild dementia, coping with difficult demands is no longer possible, but the affected individuals are not yet constantly dependent upon others. However, with moderate dementia, provided that memory loss, apraxia, loss of motivation, and disorientation have not yet led to complete dependency, supervision and instruction at least are necessary. Finally, in severe dementia, in which the patient is frequently bedridden, severe behavior disorders and bladder and stool incontinence appear, permanent help is necessary with even the simplest daily tasks. Cooper et al. (1992) confirmed this in a field study, in which 85.3% of moderately to severely demented patients over 65 and 16.7% of mildly demented patients were judged to need permanent care.

5.2 Comparison with Other Illnesses

The relative significance of dementias for the care needs of the elderly in comparison with other illnesses is difficult to estimate in view of the small number of representative studies that take dementias into account appropriately and in view of differences in definition and registration of the need for care. However, it is becoming increasingly clear that a large proportion of those needing care, especially those with the highest care needs, are dementia patients. Cooper et al. (1992), in a study of older general practice patients, established that 67.1% of those needing care suffered from severe dementia and a further 12.8% from mild dementia; only 20.1% of those needing a considerable amount of care were free of serious cognitive disorders. Harrison et al. (1990) reported a 63% prevalence of dementia in an extensive random sample of older people who were being cared for in inpatient institutions or outpatient services. When they differentiated this group according to the severity of dependence upon help from others, the portion of demented individuals rose from 44.5% at the lowest care level to more than 90% at the two highest care levels.

5.3 Dementia Patients in Old-Age and Nursing Homes

The significance of dementias for loss of independence and need for care in old age is supported by studies on residents in nursing homes. As can be seen in Fig. 3, a large proportion of the places in resident old-age facilities are occupied by dementia patients. In old-age homes, the prevalence rates fluctuate between 17% and 36%. In nursing homes, the proportion of demented patients rises to values between 51% and 72%. In addition, close correlations can be seen in all facilities between the individual amount of care required and the severity of the dementia. The greater the helplessness is and the more care services that have to be provided, the more frequently the patient is suffering from a severe grade of dementia (Nygaard et al. 1987). Thus, according to a study in Mannheim, the proportion of nursing home residents who are dementia patients, which at 65% is already high, increases to 80% among those residents requiring intensive care (Bickel 1996). Physical illnesses seem to play an ever smaller role in comparison with the mental handicaps as increased intensity of care is needed.

In many countries, half of all dementia patients are already being cared for in resident care facilities. Where large numbers of places are available, as in Scandinavian countries, the proportion increases to 55%–75% (Fratiglioni et al. 1994: Juva et al. 1993), while in other countries it is at most between 40% and 50% (Robertson et al. 1989; O'Connor et al. 1989). However, there is not much data about the situation in Germany. The ratios determined by Cooper (1984) at the beginning of the 1980s are frequently still assumed to be valid, according to which only 20.9% of dementia patients are cared for in resident old-age homes and nearly 80% are cared for by relatives. However, more recent results lead us to suppose that in Germany, too, about 40% of older people suffering from moderate to severe dementia are now cared for in nursing

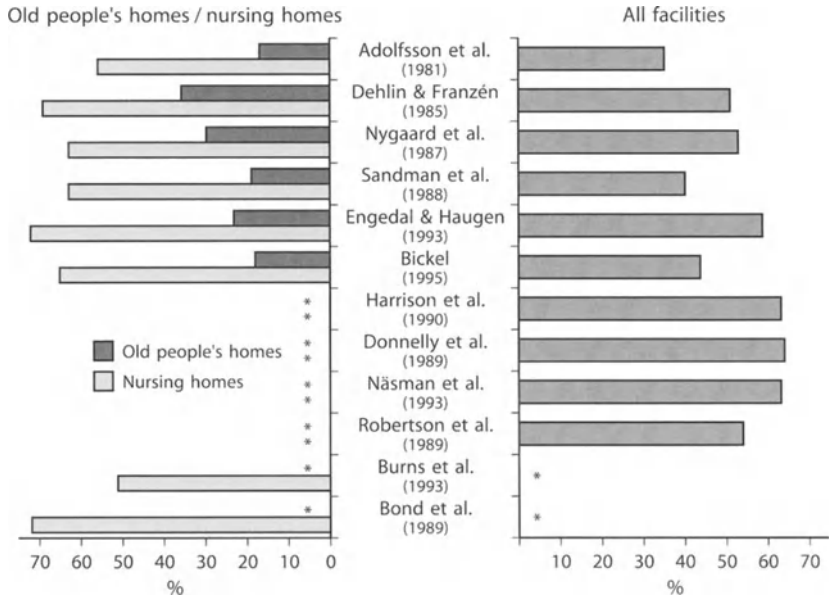

Fig. 3. Prevalence of dementias among residents of inpatient old-age facilities. *Asterisks*, no details given

homes and only 60% in their own home environment (Bickel 1995).

Dementia patients have obviously become the main reason for using nursing homes. In the United States, a dementia illness has been established in two thirds of new admissions (Rovner et al. 1990). In Mannheim, according to information from relatives, 50% of those entering nursing home are admitted because of dementia (Bickel 1995). Sooner or later, most patients are dependent upon residential long-term care. Each year, more than 20% of dementia patients living in private households enter nursing homes (Haupt and Kurz 1993). Longitudinal studies concur that between 65% (Bickel 1995) and 75% (Welch et al. 1992; Severson et al. 1994) move to nursing homes in the course of illness and remain there for an average of 2–3 years. Only one quarter to one third of patients can be cared for in private households until the end of their life. Relatives seem to be overtaxed in particular by home care if patients lose bladder and bowel control and behavioral problems increasingly appear (O'Donnell et al. 1992).

6 Development of Patient Numbers

The increase in chronic illnesses and handicaps combined with the constant growth in the aging population is confronting the health care system with mounting challenges. Since dementias, unlike other groups of illnesses, apparently play a decisive role in care needs in old age and placement requirements in residential care facilities, empirically based forecasts for changes in the numbers of patients are especially important for planning purposes. Jorm et al. (1988) have attempted, on the basis of demographic projections for 29 countries, to predict the development of numbers of dementia patients for the period between 1980 and 2025. They assume that the prevalence in all countries shows the same age dependency and that the age-specific rates remain constant over time. As their model calculations demonstrate, all countries have to prepare themselves for an increase in patient numbers in the wake of demographic changes. The expected increases will certainly be very different; Japan, for example, can count on an extreme increase of dementia patients of about 215%. However, the patient numbers will probably also double or triple in countries such as Australia, New Zealand, Canada, the United States, and some eastern European countries. In Germany and other western European countries, however, a greater proportion of the demographic aging process has already occurred. Future increase here among the elderly will, of course, bring with it more burdens that also need to be taken seriously. However, patient numbers will rise less steeply than in countries in which, at the beginning of the 1980s, a comparatively low proportion of the population was over 65. Thus, in what used to be West Germany, the estimated rise is about 40% by the year 2025. For the former East Germany, a slight decrease was predicted even far into the 1990s, only then to be followed by a continuous rise shortly before the turn of the millennium.

Häfner and Löffler (1991) were able to confirm the predictions for the former West German states on the basis of current data. Supported by a population prediction beginning with the year 1989, a growth of about 10% by the year 2000 can be expected according to their calculations. This is expected to rise to 30% by the year 2010 and to 40% by the year 2020. No changes worth mentioning should occur between 2020 and 2030, but the number of patients should again increase by the year 2040 and then be about 50% above the starting value in 1989.

According to available prevalence estimates (see Fig. 1), 780,000–990,000 dementia patients can be expected among the 12.2 million older people in Germany. This prediction, based on conservative assumptions, corresponds to an increase in patient numbers of about 400,000–500,000. A greater rise could occur with a further gain in life expectancy and a continuation of the tendency for a longer duration of illness. Furthermore, with the decreasing number of offspring, it can be expected that a growing proportion of patients will be dependent upon public care facilities. If lasting success is not achieved in the prevention and treatment of dementias, the foreseeable changes in the configuration of age-groups in Germany will also result in a constantly rising need for care for decades to come. A decrease in patient numbers cannot be anticipated until the year 2040 at the earliest, when the low birth-rate years reach the older age-groups.

Pharmacological and Nonpharmacological Approaches to the Treatment of Dementia

Translator: E. Taub

1 Introduction

All approaches to the treatment of dementia are intended primarily to improve cognitive deficits and the factors responsible for them, and secondarily to improve the accompanying "noncognitive" manifestations. Both of these types of disease manifestation are amenable to treatment by pharmacological and nonpharmacological means. In this chapter, we shall discuss the medical treatment of dementia and the social and psychological interventions that may be directed against the disease. The use of neuroleptics and antidepressants to treat disturbances accompanying dementia is discussed in Vol. 2, Part 1, Chap. 11.

2 Antidementive Agents

The class of nootropic agents includes a number of medications that have been reported in the international literature to have a beneficial effect on dementia. These agents are used to treat the primary clinical manifestation of dementia, i.e., the impairment of cognitive performance, and the resulting limitation of the patient's ability to carry out everyday activities (Table 1).

The term "nootropic" was coined by Giurgea (1982), who used it as a designation for cognition-enhancing agents (literally, substances directed at the mind, from the Greek *nous*, "mind"). The new term was inspired by the novel pharmacological properties of piracetam, the first nootropic agent. Unlike nonspecific stimulants, such as caffeine (Coper et al. 1987; Giurgea 1982), nootropic agents activate higher, integrative cerebral functions. Coper et al. (1987) suggested several years ago that the term nootropic be used for all substances that clinically improve disturbed adaptive performance in the context of age-related cognitive changes or in the dementia syndrome.

In the current extended definition, the term nootropic now refers to a class of substances that may differ from each other pharmacologically, but share common therapeutic properties. Thus centrally acting calcium antagonists such as nimodipine, glutamate antagonists such as memantine, and acetylcholinesterase inhibitors such as tacrine and donepezil are counted as neuroleptics, according to the current definition, because they are clinically effective in age-related cognitive disturbance or in the dementia syndrome. The term "antidementive agents" covers all of these agents as well and removes the ambiguity of classification brought about by conflicting older and newer uses of the term nootropic.

2.1 Mechanisms of Action

The primary neural mechanism of action of most of the currently available antidementive agents is unknown. The distinction previously drawn between primarily vasoactive and primarily metabolically active substances is no longer supported by more recent experimental data. The improvement of cerebral energy metabolism and (in some cases) of cerebral perfusion brought about by these agents is, in our opinion, not the source of their therapeutic efficacy, but rather a secondary effect and is thus a property of the entire group rather than of individual substances.

According to current concepts, most antidementive agents exert their beneficial effect by improving synaptic neurotransmission and thus improving the disturbed communicative ability of functionally impaired neurons (Müller 1988). Antidementive agents (with the exception of acetylcholinesterase inhibitors) probably do not exert their effect on the specific histopathological abnormalities found in neurodegenerative or vascular dementia, but rather cause a nonspecific improvement in the performance of retained normal structures. Recent studies have led to the conclusion that the normalization of membrane changes plays an important role in this process (Stoll et al. 1996; Müller et al. 1997). The presumed nonspecificity of the target of antidementive agents probably explains why they are just as effective in primary neurodegenerative as in vascular forms of dementia, as is now well documented for a few substances, including nicergoline. Acetylcholinesterase inhibitors, however, have been experimentally tested to date only in the treatment of Alzheimer's disease.

It is still too early for any definite conclusion concerning the extent to which an improvement of the rheological properties of the blood (e.g., by nicergoline, pentoxyphylline, and piracetam) contributes to the therapeutic effectiveness of these agents. Improvement of the rheological properties of the blood through changes in platelet aggregation and erythrocyte deformability probably does play a role in the effectiveness of some antidementive substances in the treatment of brain infarcts (e.g., piracetam; Herrschaft 1993; Orgogozo 1999).

There is evidence for well-defined targets for a few of these substances. Memantine acts as an antagonist at central *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (Müller et al. 1995). Nimodipine is an antagonist of voltage-independent calcium channels (type L), similar to the peripherally active substances verapamil and nifedipine. The original hypothesis that nimodipine protects the central nervous system from excessive amounts of free intracellular calcium

Table 1. The most important antidementive agents currently available for the treatment of senile impairment of cerebral function and of mild to moderately severe dementia syndrome

Substance	Trade name	Approval
Antidementive agents with unexplained preclinical mechanisms of action		
Bencyclane	Fludilat	–
Dihydroergotoxin	Hydergin	+
Cyclandelate	Natil	–
Ginkgo biloba extract	Tebonin forte	+
Meclofenoxate	Helfergin	–
Naftidrofuryl	Dusodril	–
Nicergoline	Sermion	+
Pentoxifylline	Trental	–
Piracetam	Nootrop, Normabrain	+
Pyritinol	Encephabol	+
Xanthinol nicotinate	Complamin	–
Antidementives with defined mechanisms of action		
Donepezil (acetylcholinesterase inhibitor)	Aricept	+
Memantine (glutamate antagonist)	Akatinol	–
Nimodipine (calcium antagonist)	Nimotop	+
Rivastigmine (acetylcholinesterase inhibitor)	Exelon	+
Tacrine (acetylcholinesterase inhibitor)	Cognex	+

The agents marked with a "+" have received formal approval for this indication (Müller 1995) (donepezil, metrifonate, rivastigmine, and tacrine only for Alzheimer's disease). As individual evaluation is difficult, it is recommended that only approved agents be used. A number of older agents have not received formal approval, not because clinical data are lacking, but because the available data could no longer be considered in the approval process as a result of time constraints.

($[Ca^{2+}]_i$) seems to be an oversimplification in the light of recent studies (Müller et al. 1996). Nimodipine probably protects the aging central nervous system less from $[Ca^{2+}]_i$ overload than from $[Ca^{2+}]_i$ oversensitivity.

Tacrine (Davis et al. 1992; Davis and Powchilk 1995; Watkins et al. 1994), donepezil (Rogers et al. 1996), and rivastigmine (Corey-Bloom et al. 1998; Rösler et al. 1999) are inhibitors of the enzyme acetylcholinesterase, which catalyzes the breakdown of the neurotransmitter acetylcholine not only in the brain, but also in peripheral synapses. All of these agents slow the breakdown of acetylcholine and thus contribute to a functional compensation for the loss of cholinergic neurons in the basal nucleus of Meynert, which are involved in the control of cognitive function (Levy et al. 1997). Their therapeutic effect, however, is rather modest; the cholinergic neurons of the basal nucleus are indeed strongly affected in Alzheimer's disease, but many other neuronal and neurotransmitter systems also participate in the neurodegenerative process (Benzi and Moretti 1998).

2.2 Effects in Animal Models

The analysis of the mechanism of action of nootropic agents essentially relies on experiments in animals. Such experiments are used to study either the ability of antidementive medications to stabilize adaptive behaviors or their protective properties against central nervous system injury. Important biochemical and pharmacological properties of the antidementive agents have been documented, albeit not equally well for all agents. Properties concerning the acute improvement of performance (up to 3 months) include the following:

1. Rather nonspecific improvement of disturbed mechanisms of central nervous function
   - Transmitter release
   - Receptor density and functionality
   - Glucose utilization
   - Membrane fluidity
   - Protection against hypoxia
2. Specific substitution of the cholinergic deficit
   - Acetylcholinesterase inhibitors; muscarinic and nicotinic agonists

Properties concerning the slowing of the neurodegenerative process include the following:

1. General mechanisms of excitotoxic and programmed cell death
   - Protection against hypoxia, mitochondrial function
   - Protection against oxidative stress
   - Repair of membrane defects
   - Improvement of neuronal communication

2. Interference with specific pathological processes
   - τ-Hyperphosphorylation
   - Amyloid anabolism, catabolism, and neurotoxicity

The goal of experimentation in animals is to delineate biochemical changes in the central nervous system, effects on physiological regulatory systems, and changes in the animals' behavior. Because therapeutic effects can usually be seen only when there is a prior functional deficit, various experimental models of dementia have had to be devised. The models in use include the physiological changes of normal aging, focal or global brain injuries (hypoxia, ischemia, intoxication, focal structural lesion), and functional impairment through stress.

The models currently used to investigate the mechanism of action of these agents may be classified into five groups (Herrschaft 1992; Schindler 1989; Müller 1988):

1. Biochemical, histological, and neurohistochemical studies of the central nervous system
2. Locomotor and exploratory activity and emotional behavior
3. Coordination
4. Experiments on adaptive behavior, coordination, and learning under 10% hypoxia at normal atmospheric pressure
5. Other cognitive tasks

2.3 Clinical Pharmacological Aspects

The pharmacological property common to practically all antidementive agents is that they improve cognitive functions such as memory, learning, and concentration. This property becomes evident primarily in the context of impairment of these functions of the central nervous system, on either an experimental or a pathophysiological basis (e.g., in dementia). This principal effect of the nootropic agents can be demonstrated not only in animal experiments (Schindler 1989), but also in clinical pharmacological studies on patients with impaired cognitive function (Coper et al. 1987). Furthermore, many antidementive agents bring about a normalization of the slowing in the α-frequency range of the electroencephalogram (EEG) often seen in the elderly, in addition to other signs of increased vigilance (Coper et al. 1987; Maurer et al. 1993).

2.4 Therapeutic Efficacy

Commonly raised objections to the antidementive agents concern the inadequacy of many early experimental studies, the inconsistent demonstrations of efficacy of individual agents, and the frequently small difference between the effect of the drug and that of a placebo. More recent studies reveal that a blanket rejection of the therapeutic efficacy of these agents is no longer tenable (Anonymous 1997; Ihl and Kretschmar 1997; Müller 1995).

Most of the currently available antidementive agents were developed and clinically tested in an era when research methods in clinical gerontopsychiatry were still inadequate. This is one of the reasons why the effectiveness of several agents was inadequately documented and why the clinical experimental findings have often been inconsistent. Now that "impairment of cerebral function," the diagnosis usually used in the past, has been abandoned, the primary target population for the testing of antidementive agents consists largely of patients with primary degenerative dementia of various types, particularly Alzheimer's disease. Only after the efficacy of a drug has been demonstrated by studies on patients of this type are further tests performed to study possible therapeutic effects against other disease entities, such as vascular dementia. As has already been found in other diagnostic categories of psychiatric classification, the rough description of disease entities provided by ICD-9 does not allow diagnoses to be made in a manner adequate for scientific purposes. An operationalized diagnostic system for dementia, such as those of DSM-IV and ICD-10, is considered to be essential.

Target variables used in studies of the efficacy of antidementive agents should cover at least the following three areas:

- Psychopathological level: assessment of disease manifestations by the psychiatrist by means of the applicable clinical scales
- Use of objective psychological testing procedures by the psychologist
- Everyday behavior: assessment by family or nursing personnel

The more concordant the findings on these three levels, the better the evidence for efficacy. Instruments of assessment should be chosen not only on the basis of test-theoretic considerations; practicality must also be taken into account.

It is difficult to say whether the differences in efficacy of agent and placebo that have been demonstrated in studies of antidementive agents are clinically relevant, because there is no accepted operationalization of the concept of clinical relevance with respect to these substances. The first attempts at such an operationalization were made only recently (Kanowski et al. 1990; Herrmann and Kern 1987; Oswald and Oswald 1988).

Table 2. Expected outcome of treatment as a function of severity of cognitive impairment, according to the Global Deterioration Scale (GDS) (after Steinwachs 1996)

GDS stage	Clinical manifestations	Expected outcome of treatment with nootropic agents
3	Decline of occupational performance, difficulty reading longer passages, difficulty remembering new names	Improvement possible (a comprehensive interview is necessary for assessment)
4	Decline of ability to carry out complex tasks, difficulty functioning in strange places	Improvement of the clinical impression, of performance in psychometric tests, and in everyday behavior has been demonstrated for various nootropic agents
5	Patients cannot get by without assistance; they are temporally and spatially disoriented; difficulty in serial subtraction of 4 from 40	Clinically, only a slowing of progression can be expected; the available studies provide initial documentation of this (e.g., piracetam, tacrine, donepezil, Ginkgo biloba extract)
6	May forget spouse's name; difficulty counting backwards from 10; incontinence; needs help functioning in familiar surroundings	No study findings are available for this stage; suitable and recognized tests for assessment of patients in this stage are a topic of current research

The following defining criteria were developed (among others) and are essentially the same as the current American criteria (Small et al. 1997):

- 15%–25% difference between agent and placebo if treatment with the agent results in a therapeutic response in at least 50% of patients
- Statistical concordance of significant differences between the effects of agent and placebo on the different levels of assessment
- Cumulation of therapeutic effects on several assessment levels in individual subjects (i.e., the existence of a responder type) in the group of patients treated with the agent
- More pronounced slowing of the progression of the illness in the agent-treated group in longitudinal studies

Because validated, generally applicable instruments are not available for the assessment of patients with severe dementia, such patients cannot now be included in studies of the efficacy of antidementive agents. These studies, therefore, are typically performed only on patients with mild and moderately severe forms of dementia. These are probably also the patients in whom an effect is most likely to be demonstrated, because the disease process is not yet far advanced. Nonetheless, the methodological restriction remains unsatisfactory, and methods must be developed by which severe forms of dementia may also be included in efficacy testing, so that it can be judged whether an attempt at therapy in this patient group is reasonable. At present, a positive answer to this question can be derived only from a less than fully justifiable extrapolation from the results of studies on patients with mild and moderately severe dementia. In general, as far as the clinical relevance of the antidementive agents is concerned, the goals of treatment should not be set too high. Instead, it should be borne in mind that, in treating dementia, we are treating a chronic, progressive disease. Table 2 shows what may realistically be expected.

In particular, the important question of the extent to which the nootropic agents slow or halt the progressive neurodegenerative process cannot yet be definitively answered. Longitudinal studies (1 year or more) are available only for a few substances (donepezil, *Ginkgo biloba* extract, piracetam, tacrine); these provide preliminary evidence that the disease process may be slowed (Croisile et al. 1993; Knopman 1995; Le Bars et al. 1997; Rogers and Friedhoff 1998). This "slowing," however, must be viewed critically. As mentioned above, the development of the acetylcholinesterase inhibitors was based on the premise that they could provide a compensatory mechanism for a specific neurochemical deficit in patients with Alzheimer's disease that is relevant to their cognitive performance. In comparison with this seemingly promising theoretical concept, the therapeutic results have been rather modest. The reasons for this have been extensively discussed by Benzi and Moretti (1998).

The question remains open whether the newer acetylcholinesterase inhibitors are more effective antidementive agents than the older nootropic substances, such as piracetam and *Ginkgo biloba* extract. No reliable answer can be given at present, because no relevant comparative studies have been performed. Indirect comparisons can be made, however, because a large, placebo-controlled, double-blinded study of the efficacy of one of the older nootropic agents (*Ginkgo biloba* extract) in patients with Alzheimer's disease was recently published (Le Bars et al. 1997). The method of this study was similar to that of studies on the newer antidementive agents (Table 3).

The primary target criterion in these studies was a cognitive parameter, the Alzheimer's Disease

Table 3. Comparison of the efficacy of various antidementive agents in patients with Alzheimer's disease (after Müller 1999)

Agent (study)	Dose, duration	ΔD[a]	Responder rate
Tacrine (Knapp et al. 1994)	60 mg, 30 weeks	2.2	Placebo 25% Agent 40%
Donepezil (Rogers et al. 1998)	10 mg, 24 weeks	2.9	Placebo 27% Agent 54%
Rivastigmine (Corey-Bloom et al. 1998; Rösler et al. 1999)	12 mg, 26 weeks	3.8 1.6	Placebo 16% Agent 24%
Egb 761 (Le Bars et al. 1997; only Alzheimer's disease)	120 mg, 52 weeks	1.7	Placebo 13% Agent 29%
Nimodipine (Morich et al. 1996)	180 mg, 24 weeks	0.5	?

[a]Because the severity of dementia differed among studies and the duration of treatment was not the same, the agent-minus-placebo differences ΔD on the ADAS-cog (intend-to-treat analysis, ITT), a commonly used test of cognition, cannot be directly compared with one another. Responders were defined as patients whose ADAS-cog scores improved by 4 points or more.

Assessment Scale (ADAS)-cog subscale, which is primarily a measure of the patient's global cognitive impairment. When this parameter was used to study the effect of the newer acetylcholinesterase inhibitors, a difference of 2–3 points between the treated group and the placebo group was found after 6 months of treatment. In the recently published *Ginkgo biloba* study, a difference of 1.7 points was obtained after 12 months. The United States Food and Drug Administration (FDA) regards an improvement of 4 points on the ADAS-cog subscale as a definite success of treatment. In the recently published donepezil study (Rogers et al. 1998), an improvement of this magnitude was obtained after 6 months of treatment by 53.5% of the patients receiving donepezil and by 26.8% of those receiving placebo. The studies of tacrine yielded similar findings. In the *Ginkgo biloba* study (Le Bars et al. 1997), the responder rate after 12 months was 22% with *Ginkgo biloba* extract and 10% with placebo treatment. Thus, in studies of both older and newer nootropic agents, there were approximately twice as many responders, according to the FDA criterion, to treatment with the agent as there were to placebo treatment.

Thus, when the urgently needed direct comparative studies are performed, we should not expect them to show any spectacular difference in the efficacy of nootropic agents of the two types, though a small difference may in fact be present. These studies may help answer the considerably more important question of which patients are more likely to respond to acetylcholinesterase inhibitors and which are more likely to respond to one of the other antidementive agents.

Theoretical considerations imply that combination therapy may be reasonable, i.e., a fairly nonspecific background therapy with older nootropic agents, combined with a pharmacologically specific therapy with acetylcholinesterase inhibitors.

2.5 Undesired Effects

The antidementive agents are, generally speaking, very well tolerated, and undesired effects are rare (exceptions include hepatotoxicity of tacrine and side effects of donepezil, rivastigmine, and tacrine that result directly from acetylcholinesterase inhibition). Gastrointestinal disturbances have been observed with practically all agents, however, as have increased irritability and sleep disturbances. Sedating effects (fatigue) have also been reported in rare cases for a few agents. Agents with a direct hypotensive effect (codergocrine mesilate, nicergoline, nimodipine) may lead to disordered circulatory regulation (hypotension, lightheadedness).

2.6 Treatment Process

The process of treatment of vascular and neurodegenerative forms of dementia can be carried out as shown in Fig. 1. The treatment must be adequately monitored, primarily by means of standardized cognitive testing and behavioral assessment. The agent should not be changed before the 12th week of treatment.

2.7 New Pharmacological Treatment Approaches

In recent years, a number of direct muscarinic receptor agonists have been developed as an alternative to the acetylcholinesterase inhibitors. It is hoped that the stimulation of muscarinic receptors in patients with Alzheimer's disease will be a more specific form of

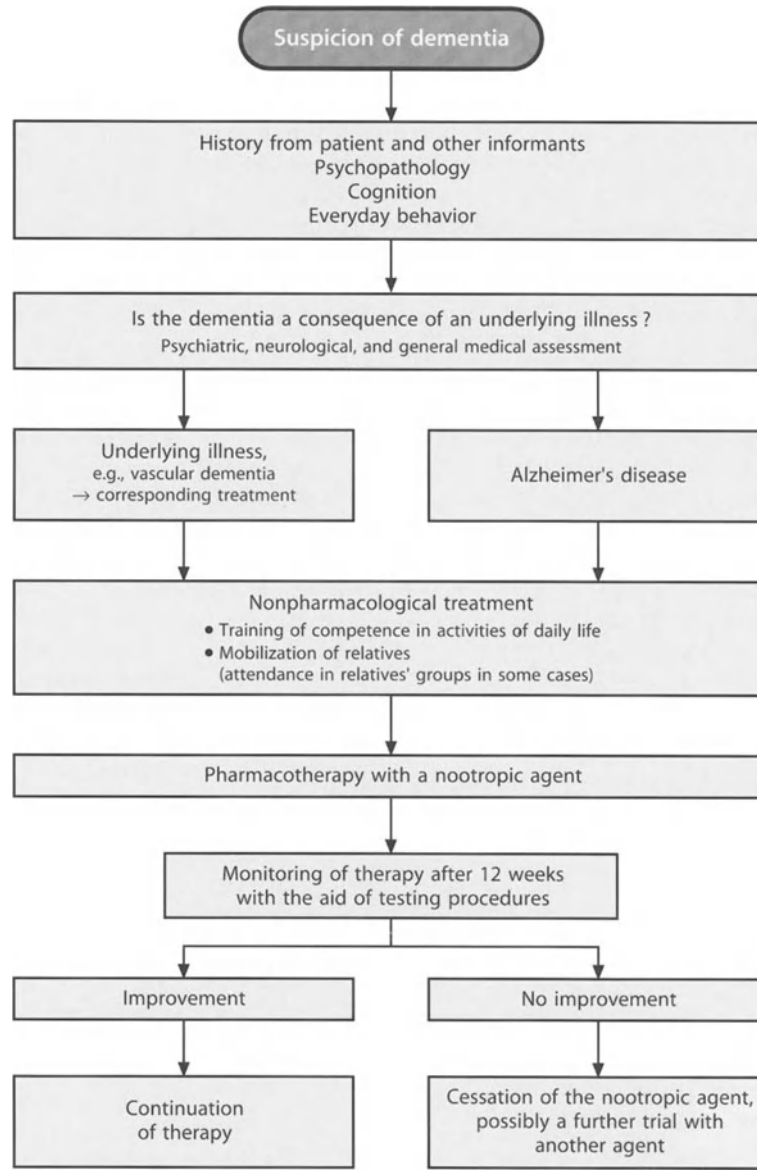

Fig. 1. Therapy for the dementias. (After Anonymous 1997)

treatment with fewer undesired effects. Initial clinical results are available from a controlled, double-blinded study of xanomeline, an M1- and M4-agonist (Bodick et al. 1997). Although a reliable comparison is difficult to make in this case, as in the other cases discussed above, it appears that the therapeutic effect of this agent is somewhat less than that of the acetylcholinesterase inhibitors. Furthermore, it is associated with an unexpectedly high frequency of undesired effects. Cautious interpretation of this study, as of previous studies, implies that cholinergic therapy of Alzheimer's disease with the current treatment strategies, as assessed by current diagnostic techniques, is of relatively limited usefulness. Proceeding from the assumption that β-amyloid is directly involved in the neurodegenerative process of Alzheimer's disease and that a sequence of further changes (including pathological membrane abnormalities, disturbances of intracellular calcium homeostasis, increased production of free radicals, secondary inflammatory processes, and, finally, cell death by exocytosis or apoptosis) is also involved, a number of agents are now undergoing clinical testing that might interfere with this cascade of different mechanisms (Heidrich et al. 1997). Among these substances are, for example, various antiphlogistic agents, the monoamine oxidase (MAO)-B inhibitor selegiline, the NMDA-antagonist memantine, the xanthine derivative propentophylline, and the free-radical scavenger ibendone. The clinical potential of these substances has not yet been definitively determined.

Thus, even when the second-generation drugs are considered, the therapeutic potential of the antidementive (nootropic) agents now available for the treatment of dementia remains modest. In the next few years, we must come to terms with this modest therapeutic potential and attempt to make optimal use of each of these agents. In the long term, we may expect, considering the major recent advances in the understanding of the pathogenesis of Alzheimer's disease, that new substances will be developed that will interfere more specifically with the mechanisms underlying neurodegeneration.

Many of the treatment strategies currently being pursued concern the anabolism, catabolism, and neurotoxicity of β-amyloid peptide, a substance of great importance in the pathophysiology of the disease. All of these developments are currently still in the preclinical phase. Even under the most optimistic projections, it will take several years before the first of these third-generation antidementive agents becomes available for clinical use.

3 Nonpharmacological Treatment Approaches

The pharmacotherapy of the dementias is fraught with side effects and high costs. The desired principal effects are often not obtained. Thus, nonpharmacological treatment approaches are more than merely auxiliary measures. Like symptomatically directed pharmacological treatment, these measures must be used in an individualized fashion based on the concerns of patients and others close to them. Nonetheless, there are standard situations and corresponding standard methods of treatment, even if their efficacy has not yet been adequately studied. Many reports of the use of these measures are of an anecdotal nature, and their efficacy has been assessed rather intuitively. The few systematic studies have been performed predominantly on institutionalized patients with Alzheimer's disease.

3.1 Psychotherapy, Cognitive Training, and Other Supportive Measures

When the diagnostic assessment of dementia is performed, careful attention must be paid to the patient's ability to understand and to his or her need for information. A desired explanation may not be withheld from the patient, nor may information concerning the diagnosed illness and its presumed prognosis be delivered in a perfunctory fashion. A mere act of informing, unaccompanied by an offer to help the patient come to terms with the illness, is not acceptable. Psychotherapeutic approaches, including attempts at cognitive restructuring, may yield a certain benefit in patients in the early phase of a degenerative brain illness who suffer from reactive depressive disturbances (Teri and Gallagher-Johnson 1991). Their efficacy, however, is temporally limited (if the course of illness indeed accords with the suspected diagnosis). Reactive depressive manifestations often improve as the cognitive deficits become more severe.

In mild dementia, cognitive training may lead to a certain improvement of memory and attention. A cognitive education program finely tuned to the specific deficits of a mildly affected patient may yield a small benefit (Commissaris et al. 1996). Nonetheless, a transfer of learned abilities leading to a lasting ability to cope with everyday demands cannot be demonstrated in patients with manifest dementia (Hofmann et al. 1996). Even the concrete training of practical functions (hygiene, dressing, kitchen work) has not yet been shown to be effective. Neuropsychological training methods found to be effective in the rehabilitation of head-injured and stroke patients yield only transient effects, at best, in patients with progressive brain diseases. These include the contextualization of information and visual associative learning (the "imagery method"), i.e., linguistic and visual double-coding of information.

The simplest mnemonic techniques, such as the use of a notebook, are also the most effective (Haupt 1997). On the other hand, so-called "brain jogging" in patients with manifest dementia is unfounded and deserves to be completely rejected. Even though suitable training methods may allow the recruitment of cognitive reserve abilities in normal aged persons, it is precisely these reserve abilities that are no longer present in demented patients. This is the central feature of the dementia syndrome (Zerfass et al. 1997). Frustration with such techniques is therefore inevitable and is much more disconcerting to the patients themselves than to their therapists and families. Reality orientation training (ROT) was developed for the treatment of patients with dementing illnesses and confusional states of other origins. Its aim is the improvement of orientation in space and time (Folsom 1986). The two forms of ROT are group ROT ("classroom ROT"), which involves a daily training program lasting half an hour with information about location, time, and situation, and 24-h ROT, which involves the continuous provision of orienting information. The ROT techniques are not fitted to the individual patient, and their effectiveness has not been satisfactorily demonstrated to date. It does seem that patients are more able to give verbal information about their

orientation after group ROT, and they are better able to locate themselves in the environment when they undergo 24-h ROT. This may be interpreted as a reinforcement and channeling of certain patterns of behavior and does not necessarily imply an improvement of cognitive functioning on a deeper level. The social contact, increased activity level, and improved mood associated with the performance of all of these techniques are important nonspecific factors that may make a major contribution to their effectiveness. It is worth noting that ROT has a positive effect on the caring persons' knowledge about the patients and their attitude to them.

Reminiscence therapy is intended to reinforce retained abilities through recollection of experiences and events that took place in the remote past. This approach thus emphasizes the patients' strengths and does not confront them with their weaknesses or subject them to an unnatural training setting. A prerequisite for this systematic occupation with one's own memories is a retained ability to communicate verbally. Aids to reminiscence used in treatment include pieces of music, photographs, newspaper clippings, and books (Norris 1986).

A variant of reminiscence therapy is self-preservation therapy (*Selbsterhaltungstherapie*), in which – with the participation of family members – the patient's personal identity is reinforced by the stimulation of autobiographical memories (Romero and Eder 1992). Validation therapy is based on a far-reaching recognition of the patient's "valid" point of view, which is supposed to be understood and accepted (Feil 1990).

3.2 Dealing with Patients and Structuring Their Environment

Because of their cognitive impairment, demented patients are scarcely able to learn and to adapt to their environment. These functions thus become largely the task of the caring partner or nursing staff. The care of the patient must be individually fitted to the patient's personality and current problems. Little can be said in general terms, and these few generalizations often sound trivial. For example, it is of little or no use to argue with or contradict patients, to lecture them, or to provoke a confrontation with them. The style of communication must be adapted to the patient's limited ability to understand and must thus be simple. Because patients can often receive nonverbal stimuli quite well even in advanced stages of disease, it is often helpful to combine verbal with gestural and mimetic signals. The most important factor is positive feedback, i.e., the acceptance and reinforcement of correct behaviors. Wrong responses can occasionally be steered back in the proper direction, or attention can be drawn away from them. When this no longer seems possible, a change of subject or a brief time-out may allow the conflict to be defused and forgotten.

The simplest behavioral-therapeutic techniques of positive and negative reinforcement prove effective as long as the patient's self-esteem is preserved by a basically positive attitude. It may be particularly important to discover the patient's retained abilities and needs (e.g., music, movement, social sense) and then rationally apply whatever competence is present to various tasks (e.g., setting the table, caring for pets, gardening).

Certain maladaptive and regressive modes of behavior require specific measures and should occasion a search for possible underlying factors. Patients often react aggressively when their intimate sphere is violated or when they feel threatened. Such reactions may also be fostered by delusions and hallucinations and may be treatable with neuroleptics, among other agents. Continuous shouting may be provoked by the pain of a treatable somatic illness or by an environment that provides the patient too little stimulation.

The patient's environment should be familiar and stimulating, but not alarming. Constancy of the environment is best maintained by people well known to the patient – close relatives, if possible – through the use of familiar clothing, pictures, and furniture, maintenance of the patient's dietary habits, and a regular program of daily activities. Holiday travels, transfers back and forth between the patient's home, the hospital, and the nursing home, renovation and overhaul of the living space, continuous change of personnel, and lack of people in a close relationship can all contribute to a deterioration of the patient's condition.

On the other hand, the patient's usual environment should not be too boring, but should include sources of stimulation. Sensory deprivation and social isolation should be avoided just as much as noise and commotion. Clear aids to orientation, pleasant colors and good lighting, visual and hearing aids, and pleasant music in line with the patient's taste are all beneficial. To be avoided is an uncontrolled exposure to stimuli that are easily misinterpreted, such as overhead announcements, frightening pictures, unsettling shadows, large mirrors, and constant bombardment with radio and television. Personal attention is irreplaceable, whether delivered in a fashion that places heavy demands on personnel – such as music therapy, art therapy, or ergotherapy – or simply by touching the patient. The strong need of many patients, even those with advanced dementia, for intimacy is often overlooked.

Patients should be allowed the freedom of movement they desire to the greatest possible extent. Limits should be set only when the safety of the patients

themselves, their partner, or those rendering care is threatened. It may suffice for a time simply to inform neighbors about the patient's condition, so that the patient can be taken home if required, or to make sure that bright clothing is worn, to lessen somewhat the danger of the patient's being struck by a passing vehicle. In later stages of illness, the possibility of injury must be dealt with even in the most narrowly confined environment.

3.3 Care of the Patient's Relatives

Relatives caring for the patient are subject to great mental stress, which – particularly in elderly women with elderly, demented husbands – leads to high morbidity (Rankin et al. 1992; Schultz et al. 1990). The attenuation of the caring partner's social network by the partner's own advanced age, as well as by the illness of the patient, is a major risk factor for mental illness in the caring partner, which, in turn, leads to the collapse of home care for the patient (Cooper et al. 1984; Gilhooly 1986; Zarit et al. 1986). The degree of mental stress is not closely related to the severity of dementia; rather, it is better accounted for by a number of concrete stress factors, such as the number and severity of nursing problems (e.g., incontinence), behavioral abnormalities (especially aggressive behavior), lack of peace and quiet at night, and lack of normal communication (Förstl and Geiger-Kabisch 1995; Hettiaratchy and Manthorpe 1993).

The possible forms of care of the patient's relatives are as different from each other as the relatives' expectations and needs. Care may take place during office visits, in extensive individual discussions with relatives, in a patient-oriented, long-term involvement, in a directed session when a patient is admitted to hospital, or in professionally conducted group therapy or a self-help group.

Jacques (1984) characterized three types of caring relatives with regard to their degree of engagement and their attitude:

- Relatives who gladly participate in care and require instruction and encouragement
- Relatives who feel a duty to sacrifice themselves to an unreasonable extent while caring for the patient
- Relatives who care for the patient against their own desires

There are significant differences between the attitudes of male and female caring relatives, as was shown in a study of groups of relatives of demented patients (Förstl and Geiger-Kabisch 1995). While wives and daughters mainly seek mutual emotional support and, by exchange with the group, allay their fears and learn to accept more easily what the future holds, men are more eager to obtain information about the causes of dementia and the possibilities of treating it and require concrete advice on how to deal with the patient.

Caring relatives' different degrees of engagement, and their different levels of "emotional" and "instrumental" interest, call for a large measure of flexibility in the kinds of help that are offered to them. The two goals of the care of the patients' relatives, i.e., support for the relatives themselves and improvement of their care for the patient, may be attained in various ways. An important feature of any such approach is a raising of the relatives' tolerance of the burdens placed on them by the patients' disturbing behavior; this will help lessen their frustration. These aims may be served not only by the provision of information, but also by acceptance into a group of patients' relatives who are undergoing similar experiences.

Clinical Aspects of Alzheimer's Disease

Translator: E. Taub

1 Introduction

In the last 15 years, Alzheimer's disease (AD) has become a major focus of interest in medicine and neuroscience. Significant advances in our understanding of this disease have emerged from modern basic research. In the clinical field, too, progress has been made, albeit to a less spectacular extent. AD is now one of the most thoroughly clinically characterized diseases. Its wide variety of clinical manifestations and the variations its course may take are now well known from numerous cross-sectional and longitudinal studies. The symptomatology of AD has recently been extended by studies of its early clinical phases.

Further progress in the clinical area is important, because our ability to provide answers to many questions of epidemiology, etiology, pathogenesis, and treatment largely depends on the state of the art of clinical assessment. Furthermore, the results of clinical research are of great practical importance. Patients and their families want to be as well informed as possible about the nature and prognosis of the disease, so that they may decide wisely as they plan for the future and make the necessary arrangements for long-term care.

Currently available treatments for AD, as well as newly developed ones, can be properly tested for effectiveness only if the diagnosis is made in an early stage of the disease and changes of the patient's condition are accurately monitored as the disease progresses. To achieve these goals, our diagnostic conventions and instruments of assessment must be continuously refined, adapted to meet specific purposes, and updated in accordance with new scientific knowledge and medical technology. Alongside the clinical phenotype, biological markers of disease are now being increasingly used for early diagnosis. In this chapter, we shall discuss some of these rapidly developing trends.

2 Diagnostic Criteria

2.1 Three Sets of Criteria for Clinical Diagnosis

The operational criteria used for the clinical diagnosis of AD divide the diagnostic decision-making process into two separate steps. First, the presence of a dementia syndrome must be demonstrated. Second, cerebral or systemic illnesses other than AD that are possible causes of dementia must be excluded.

The two psychiatric classification systems ICD-10 (Appendix A) and DSM-IV (Appendix B) list the diagnostic criteria for the dementia syndrome (defined somewhat differently in each system), state that these are also the defining features of AD, and further require the absence of neurological, systemic, or substance-induced illnesses or disorders that might be responsible for the cognitive disturbances and behavioral changes. Both sets of criteria require an insidious disease onset and continuous progression of the cognitive disturbances. According to DSM-IV, the dementia syndrome should not be better explained by another psychiatric disease, such as depression or schizophrenia. Both classifications provide further codes that take the age at onset of disease, the presence of depression, delusions, hallucinations, or behavioral disturbances, the occurrence of atypical features, or the superimposition of dementia on delirium into account.

Alongside the defining criteria of ICD and DSM-IV, a set of consensus criteria developed by a working group under the aegis of the National Institute of Neurological and Communicative Disorders (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) (McKhann et al. 1984) has long proved valuable, particularly for research purposes (Appendix C).

This set of criteria enables the identification of "definite," "probable," and "possible" AD. A diagnosis of *probable AD* requires the exclusion of other neurodegenerative or systemic illnesses as causes of dementia. Test findings that are compatible with the diagnosis of probable AD are listed, as are others that speak against it. If the exclusion of other causes of dementia is incomplete because of inadequate information or the presence of accompanying illnesses, or if the clinical picture is atypical, a diagnosis of *possible AD* can be made. Patients having the clinical features of AD and, at the same time, a prior history of cerebrovascular disease, such as major or lacunar strokes or diffuse white matter disease, also fall into this category. This is the important group of patients with mixed forms of AD and dementia of cerebrovascular origin. These patients often fail to fulfill the rigorous diagnostic criteria for vascular dementia, which require both the demonstration of a relevant cerebrovascular disease and a causal relationship between cerebral ischemia and the appearance or progression of the cognitive disturbance (Román et al. 1993). A diagnosis of *definite AD* requires both the fulfillment of the clinical criteria for the diagnosis of probable AD and histopathological confirmation by brain biopsy or necropsy.

The three sets of diagnostic criteria all possess satisfactory interrater reliability (Kukull et al. 1990a; Lopez et al. 1990; Blacker et al. 1994). They are largely similar in content, but differ from one another in

several ways. For a diagnosis of AD, DSM-IV requires that the cognitive deficits have led to "significant" impairment of social or occupational function, while ICD-10 requires only a mild impairment of the patient's ability to function in everyday life. According to both the NINCDS-ADRDA and the ICD-10 criteria, focal neurological abnormalities appearing in later stages of the disease are compatible with AD, while DSM-IV makes no mention of focal neurological signs or symptoms in AD and lists them only as features of dementia of cerebrovascular origin. Increased muscle tone, gegenhalten, and other parkinsonian manifestations may, however, occur even in intermediate stages of progression of AD.

2.2 Histopathological Criteria

If the validity of clinical diagnosis is judged by its neuropathological confirmation, then it may be safely stated that clinical assessment of patients yields sufficiently reliable diagnoses, as long as the sets of diagnostic criteria mentioned above are applied. The validity of clinical diagnosis is very high in typical cases. Validity depends strongly, however, on which standard criteria are used in the neuropathological diagnosis of AD (Tierney et al. 1988). The demonstration of histopathological changes in the cerebral cortex by biopsy or necropsy cannot be considered a gold standard against which the accuracy of clinical diagnosis can be measured, because the diagnostically relevant morphological features of AD are not uniformly defined, and the neuropathologist thus has considerable latitude in the provision of a diagnosis. Recent sets of histopathological criteria – the National Institute of Aging (NIA) criteria (Khachaturian 1985) and the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) criteria (Mirra et al. 1991) – use the semiquantitatively determined plaque density in several brain regions as the decisive factor in the morphological diagnosis of AD and its differentiation from the changes of normal aging. At the same time, however, account is taken of the age of the patient and the presence or absence of a clinical diagnosis of dementia. The inclusion of clinical information leads, of course, to an undesirable circularity of diagnostic logic when AD must be differentiated from the normal cerebral atrophy of advanced age.

Furthermore, the two neuropathological definitions of AD referred to above differ from each other in several important ways. Thus the NIA criteria require counting of all neocortical plaques, while the CERAD criteria require counting only of the neuritic plaques in the neocortex. The NIA criteria require the exclusion of other organic cerebral causes of dementia, such as infarcts or subdural hematomata, while the CERAD criteria allow the provision of a morphological diagnosis of AD even when another cerebral disease, e.g., a cerebrovascular process, is simultaneously present. Finally, the neuroanatomical diagnosis of AD according to the CERAD criteria relies exclusively on the counting of plaques and does not take the presence of neocortical neurofibrillary tangles into account, even though several studies (Bouras et al. 1994; Bierer et al. 1995; Nagy et al. 1995) have shown that the latter have a close relationship to the onset and degree of severity of clinical manifestations of AD and that they are an important element in the morphological differentiation of AD from the changes of normal aging.

These diagnostic difficulties are related to the fact that the morphological criteria for AD have not yet been adequately validated with reference to the brains of normal elderly individuals who had no clinical manifestations of dementia up to the time of their death. Available studies (Crystal et al. 1988; Katzman et al. 1988a; Snowdon 1997) do, however, reveal that widespread plaques and neurofibrillary changes can be demonstrated in the brains of at least a few individuals who were not demented during their lifetimes.

2.3 Accuracy of Clinical Diagnostic Criteria

In general, use of the clinical diagnostic criteria results in a correct diagnosis in approximately 75% of patients, with a sensitivity of approximately 90% and a specificity of approximately 75% (Khachaturian 1985; Boller et al. 1989; Kukull et al. 1990b). Recent clinicopathological comparisons have yielded still higher validity rates of 85% to over 90% (Galasko et al. 1994; Jellinger 1996). In interpreting such findings, it should not be forgotten that scientific studies are often performed on highly selected patient populations, from which poorly documented cases and cases with very mild or very early AD are automatically excluded, and in which diagnoses have often been made after long periods of observation by clinically experienced investigators.

In routine medical practice, and also in population-based research studies, the accuracy of diagnosis is probably considerably lower, because the patient histories and clinical findings are not as well documented and many patients are in early stages of the disease or have atypical manifestations. The relatively high concordance rate of the clinical and neuropathological findings should not, therefore, lead to a false sense of security in the diagnosis of AD in early stages.

2.4
Future Developments Toward Early Diagnosis

It may be expected that the clinical diagnostic guidelines will be modified in the future to take greater account of neurobiological factors. For the sake of diagnostic accuracy, it will probably be advisable to create a larger number of diagnostic categories than we now have with "possible" and "probable" AD and to make the defining features of the disease depend, in part, on the goal of the diagnostic assessment. Higher diagnostic accuracy is required for diagnostic and therapeutic research studies, or for problems of genetic counseling, than for early detection of the disease. It ought to be possible, under certain conditions, to diagnose AD before the cognitive disturbances and the restriction of the patient's everyday activities become severe enough to constitute a dementia syndrome, so that therapeutic or preventive measures may be introduced early and with the best prospect of success.

3
Clinical Manifestations

The clinical picture of AD has been described repeatedly since its classic statement by Alzheimer (1907, 1911) and, among others, Grünthal (1926), Sjögren et al. (1952), and Delay and Brion (1962); in the textbooks of Reisberg and colleagues (Reisberg 1983; Terry et al. 1993; Burns and Levy 1994; Gauthier 1996); and in the previous edition of this book (Lauter and Kurz 1989).

3.1
Cognitive and Noncognitive Disturbances

While the early authors, influenced by the then prevailing "cognitive paradigm" of the dementias, directed their attention largely to the cognitive disturbances of AD – impairment of memory and spatial orientation, word-finding difficulties, and other focal neuropsychological manifestations in which the patient's cognitive abilities seem to be "fading away" – interest has increased in recent years in other mental changes that are not related, or only indirectly related, to cognitive deficits (Burns et al. 1990; Förstl et al. 1992a,b, 1993; Absher and Cummings 1994; Folstein and Bylsma 1994; Kurz 1998). Among these are disturbances of initiative, of mood, of emotional control, of personality, and of the sleep–wake cycle and psychotic phenomena. Unlike the cognitive deficits and the limitation of everyday activities, these changes appear discontinuously. Among these changes, lessened initiative is the most likely to persist, and psychotic phenomena are the least likely (Devanand et al. 1997).

These noncognitive phenomena usually create much more stress for relatives and professional personnel than the cognitive impairment (Coen et al. 1997). They are also a common reason for the institutionalization of patients with AD in nursing homes. They are, however, more amenable to treatment than the cognitive deficits. The spectrum of available pharmacological treatments has recently been considerably widened and improved by the introduction of new neuroleptic and antidepressive agents that have fewer side effects than older preparations. Morphological changes in certain brain regions clearly play a major role in the appearance of noncognitive manifestations and behavioral changes; thus they may serve as a pathogenetic model for the generation of psychopathological disturbances in the psychoses, whose morphological substrate in the brain is less well defined (Förstl and Fischer 1994).

Changes of initiative are among the more common behavioral disturbances in AD. Typically, there is a diminution of initiative, along with a loss of interests, reduced readiness to communicate, and apathy, although restlessness and increased motor activity can also be seen, manifesting themselves as pacing, shouting, aggression, and socially disruptive personality changes. This category of noncognitive manifestations, in a broader sense, also includes changes of eating behavior, of the sleep–wake cycle, and of sexuality. These behavioral disorders generally become worse as the disease progresses.

3.2
Delusions

A total of 20%–30% of patients satisfying diagnostic criteria for AD have disturbances of thought content of various types. It is common for patients to think that they are being robbed or to suffer from jealousy; such ideas often serve as useful excuses for misperceptions or for having mislaid objects. Such delusions are usually more transient and less systematic than in schizophrenic or paranoid psychoses. They are not closely correlated with the severity of cognitive impairment. A relatively intact cerebral cortex seems to be a prerequisite for the elaboration of complex delusional ideas: computed tomography (CT) reveals that patients with such delusional disturbances have less marked ventricular dilatation than patients without paranoid manifestations (Burns et al. 1990).

3.3 Hallucinations

Hallucinations, usually visual, occur in 10%–20% of patients with AD. Perceptual disturbances of another kind, which may be designated illusory situational misperceptions, are considerably more common. These include, among other phenomena, the misidentification of near relatives (Capgras syndrome), a feeling of unfamiliarity with one's own usual living space (Landis und Cummings 1986), the nonrecognition of oneself in a mirror, or a confusion of televised images with directly experienced reality.

3.4 Depressive Manifestations

The simultaneous occurrence of AD and depressive disorders is of great practical and theoretical interest. The prevalence of depressive manifestations among AD patients is extraordinarily variable among published reports, in which it ranges from 0% to 86%. This variation is a product of differences in the origin and composition of patient collectives, in stages of progression of AD, in the length of time over which the patients were studied, in methods of assessment, and in the criteria used to determine whether a depressive disturbance was present. In the majority of recent studies containing adequate numbers of patients, the prevalence of depressive manifestations is on the order of magnitude of 15%–50% (Cummings et al. 1987; Rubin et al. 1988; Patterson et al. 1990; Förstl et al. 1992a,b, 1993). The prevalence of depressive disturbances in patients with AD is thus definitely higher than in age-matched nondemented individuals.

Many of the psychopathological features of depression overlap with those of dementia. The diagnosis of a depressive syndrome in AD is therefore difficult to make. Depressive illnesses such as major depression are rarer in patients with AD than depressive manifestations. Estimates of the prevalence of depressive manifestations based on information from patients' families are generally much higher than determinations based on information from the patients themselves (Mackenzie et al. 1989).

The relationship of depressive manifestations to the stages of AD is controversial. Most investigators report depressive manifestations to be more frequent in early disease stages, in patients whose cognitive abilities are still relatively well preserved (Reifler et al. 1982; Burns et al. 1990; Cooper et al. 1990). The Berlin Aging Study of the extremely old also revealed a higher mean severity of depressive manifestations, with increasing impairment of cognitive abilities, in mildly and moderately demented patients, while fewer depressive manifestations were seen in the severely demented (Helmchen and Linden 1993; Reischies et al. 1997).

The pathogenetic relationship of AD and depression is complex. The depressive manifestations might be regarded as the direct expression of the underlying neurobiological process. Evidence in favor of this point of view is provided by histopathological studies, which show more severe involvement of the aminergic neurons of the locus ceruleus, and of the dorsal raphe nucleus and the substantia nigra, in AD patients suffering from depression (Zubenko and Moossy 1988; Zweig et al. 1988), or else severe involvement of the noradrenergic locus ceruleus with relatively mild loss of cholinergic neurons in the basal nucleus of Meynert (Förstl et al. 1992a,b). On the other hand, depressed patients with AD also more frequently have a family history of affective disorders than nondepressed patients (Pearlson et al. 1990); this finding seems to indicate a specific genetic predisposition.

Although prior depressive illnesses (Jorm et al. 1991) – particularly when associated with reversible pseudodementia (Kral and Emery 1989; Alexopoulos et al. 1993) – elevate an individual's risk of developing AD, there is no evidence that the early phases of a depressive illness appear more frequently in AD patients with depressive manifestations than in patients whose AD is not associated with depressive features (Bolger et al. 1994). On the other hand, depressed AD patients probably differ from nondepressed AD patients, even before the appearance of dementia, in certain features of primary personality traits, such as greater fearfulness, depressivity, withdrawal, and sensitivity and lower self-esteem (Chatterjee et al. 1992).

The generation of depressive manifestations in patients with AD is perhaps a function not only of damage to the brain directly caused by the illness process, but also of an increased vulnerability of these patients to depression, which, in turn, represents a disposition of specific neuronal systems to become pathologically affected (Strauss 1995). Moreover, in the setting of this presumed biological vulnerability, the patients' awareness of their own cognitive deficits, of their reduced ability to cope with everyday life, and of the diagnosis of AD, with all that it implies, is a major stress factor that likely promotes the appearance of depressive manifestations.

3.5 Somatic Manifestations

Somatic signs and symptoms are not part of the typical clinical picture of AD in its early and intermediate

stages (for the stages of AD, see Sect. 4 below). Mild extrapyramidal signs, alterations of posture and gait, and disturbances of sphincter control do, however, appear in the stage of moderately severe dementia. In the stage of severe dementia, primitive reflexes, severe rigidity with gegenhalten, total incontinence, dysphagia, myoclonus, and grand mal seizures may occur.

4 Clinical Course

Recent neuropathological studies shed new light on the course of AD (Braak and Braak 1996). Because of these findings, it is now presumed that the neurodegenerative process leading to AD silently unfolds for many years, and perhaps decades, in the entorhinal cortex before it reaches the hippocampus, causing the appearance of the first clinical manifestations, and then goes on to affect the neocortex, thereby bringing the patient over the clinical threshold of dementia (Braak and Braak 1991; Gertz et al. 1996).

4.1 Clinical Silence, Predementia, and Dementia Stages

The course of AD may, therefore, be divided into three stages: a clinically silent stage, of as yet unknown length; a stage of so-called predementia, lasting at least 5 years (Reifler 1997), in which mild cognitive changes are noted; and a final stage of dementia, which lasts for a mean of 8–10 years (until the death of the patient). The latter stage is, in turn, subdivided into stages of mild, moderately severe, and severe dementia.

Unequivocal clinical deficits appear in the stage of predementia. They are produced by the involvement of the hippocampus in the pathogenetic process and are typified by mild cognitive impairment affecting the storage and retrieval of new information. Impairment of memory is usually noted. Tests of learning ability are, therefore, the most sensitive clinical instruments for the early detection of AD (Linn et al. 1995). At the same time, incipient thought disturbances and mild disturbances of attention may be present, and loss of initiative is also often noted (Linn et al. 1995). The ability to perform complex tasks is also sometimes impaired in the stage of predementia, even though this impairment does not lead to a restriction of the patient's usual everyday activities (Table 1).

The threshold of clinical dementia is reached when definite disturbances of executive functions, such as the ability to carry out complex activities, cope with professional duties, or organize the household (Barberger-Gateau et al. 1992; Oppenheim 1994), are added to the impairment of memory and when the deficits in these two cognitive areas limit the patient's ability to go about everyday activities.

Depending on the topographical spread of the neurodegenerative process, disturbances of language function, of object recognition, and of spatial ability may be present, sometimes to such an extent that they are among the patient's more prominent disease

Table 1. Cognitive symptoms over the course of Alzheimer's disease

Area of disturbance	Clinical stage of disease			
	Predementia	Mild dementia	Moderately severe dementia	Severe dementia
Storage of new information	+	++	+++	+++
Recall of memories ("remote memory")	–	(+)	++	+++
Thinking (drawing of logical conclusions, problem-solving, planning, organizing)	(+)	+	+++	+++
Spatial and temporal orientation	–	+	+++	+++
Orientation in a room	–	(+)	++	+++
Language (word-finding, naming, vocabulary, expression, reading, writing)	–	+/–	++	+++
Recognition of objects and persons	–	+/–	++	+++
Copying of figures, estimation of spatial relationships	–	+/–	++	+++
Manipulation of objects	–	+/–	++	+++

Degree of severity: –, absent; +/–, may or may not be present; (+), minimal; +, mild; ++, moderate; +++; severe.

Table 2. Impairment of activities of daily living over the course of Alzheimer's disease

Area of disturbance	Clinical stage of disease			
	Minor cognitive impairment	Mild dementia	Moderately severe dementia	Severe dementia
Occupation, financial matters	(+)	++	+++	+++
Household, shopping, hobbies	–	+	++	+++
Dressing, bathing, showering	–	–	+	+++
Eating, walking	–	–	–	++

Degree of severity: –, absent; (+), minimal; +, mild; ++, moderate; +++, severe.

manifestations. Disturbances of spatial orientation and word-finding difficulty are often noted very early in the course of the disease.

In the stage of moderately severe dementia, the cognitive disturbances become increasingly severe and, as a rule, spread to all areas of cognitive performance. The deterioration does not always proceed in linear fashion, however, and may be interrupted by long plateau periods (Haupt et al. 1993). As long as the patient can still mobilize sufficient reserve abilities and compensating mechanisms, the mental deterioration progresses relatively slowly. The progression accelerates as the dementia becomes worse.

As the patient's cognitive abilities become progressively more impaired, his or her ability to carry out the functions of everyday life also diminishes. At first, only the more demanding tasks are affected; later, however, even the simplest tasks involved in caring for oneself become impossible (Table 2).

The basic properties of the patient's personality, social conventions, and the ability to understand and express emotion are generally little affected by AD.

In the final stage of progression of the disease, all higher cognitive functions are extinguished and can hardly be differentiated from one another. Primitive motor routines, dysphagia, flexion contractures, incontinence, and persistent vegetative-apallic syndromes generally appear. Diminished resistance to somatic illness in combination with impairments of eating and swallowing promote the occurrence of pneumonia, which is the cause of death in approximately 70% of patients (Förstl et al. 1991). Severe damage of autonomic nuclear areas in the brain stem is certainly another possible direct or auxiliary cause of death.

4.2 Influence of Education and Occupation

The patient's level of education and occupational activity may exert an influence on the course of illness. More educated patients, and those whose occupations require the performance of complex tasks, high levels of exertion, or social communicative abilities, have more severe deficits of perfusion in the temporal and parietal lobes than those of less educated patients in occupations carrying less responsibility who are demented to a comparable extent (Stern et al. 1992, 1995a). They have a shorter duration of illness and a higher mortality (Stern et al. 1995b). The lifestyle of an individual thus clearly has an effect on the extent of his or her cognitive functional reserves. A higher level of education and the experience of lifelong coping with difficult professional tasks make some AD patients better equipped than others to compensate for the deficits that the illness produces. Consequently, these patients become overtly demented later in the course of disease and therefore seem to be less severely affected by comparable degrees of neuropathological abnormality, while the duration of illness is usually shorter.

4.3 Instruments for Monitoring Disease Course

Rating scales are often used to assess the progression of the disease. Three instruments have been commonly used. The Clinical Dementia Rating (CDR) Scale (Hughes et al. 1982) has five levels; an assessment of function in six specific areas is used to generate a score signifying absence of dementia (0) and questionable (0.5), mild (1), moderately severe (2), and severe (3) dementia. The CDR should be applied only on the basis of an extensive examination of the patient and an interview with a well-informed relative. The Global Deterioration Scale (GDS) (Reisberg et al. 1982), on the other hand, has seven levels. A score of 1 corresponds to a fully normal cognitive ability for the patient's age. Patients with a score of 2 complain of cognitive impairment, but none can be found on objective examination. A score of 3 corresponds to a mild cognitive impairment, such as an age-associated memory

disturbance. Scores of 4–7 correspond roughly to scores of 0.5–3 on the CDR. Lastly, the Functional Assessment Staging (FAS) scale (Reisberg 1988), which is used to assess the need for nursing care, makes finer distinctions in the later stages of the disease (the neglected second half of AD).

4.4 Duration and Mortality

Patients live a mean of 8 years from the appearance of the earliest manifestations of the disease; variation between individuals is considerable. The mortality of patients who become affected by the disease before age 65 is approximately 3.5 times higher than that of healthy individuals of the same age. The relative mortality is not as high in patients who develop the first manifestations of the disease in advanced age.

5 Heterogeneity

In general, the clinical manifestations are highly variable. In view of this heterogeneity, attempts have repeatedly been made to use the age of onset of the disease, psychopathological features, certain neurological manifestations, or histopathological characteristics to distinguish various subtypes of AD. Several authors (Bondareff et al. 1987; Blennow and Wallin 1992, 1994; Bondareff 1994; Wallin and Blennow 1996) speak of a classical type of AD, characterized by an early age of onset, quite severe parietotemporal manifestations, marked neuronal loss in the locus ceruleus, and a large number of neocortical plaques and neurofibrillary changes, and a second type, characterized by later onset, global cognitive deficits, confusional states, more severe leukoaraiosis and cerebrovascular changes. There is, however, a great deal of overlap between these two forms. There has been, as yet, no convincing demonstration that such subtypes are indeed distinguishable from one another and remain so over the course of the disease (Kurz et al. 1992; Förstl and Fischer 1994).

It cannot be stated with certainty whether the familial and sporadic forms of AD differ with respect to their clinical phenotype. Most of the studies performed on this question yielded a negative answer (Edwards et al. 1991; Duara et al. 1993). Loci on three different chromosomes are known to be responsible for autosomal dominant, familial AD in different families. Apparently, this genetic heterogeneity is reflected in an only modest clinical heterogeneity of familial AD (Rossor et al. 1996).

6 Neurobiological Markers

AD cannot be reliably distinguished from other cerebral diseases causing a dementia syndrome on the basis of clinical findings alone. A provisional clinical diagnosis of AD therefore requires the exclusion of other dementing diseases and can be definitively confirmed only by histopathological examination. This unsatisfactory situation has provoked a search for neurobiological features of the disease that might serve to differentiate AD from other causes of dementia. Candidates for such markers primarily include alterations of brain structure or function that can be detected with modern imaging techniques. Genetic and neurochemical markers are further possibilities.

6.1 Imaging Techniques

6.1.1 Structural Imaging

The two structural imaging techniques, computed tomography (CT) and magnetic resonance imaging (MRI), are used mainly to exclude cerebral diseases, such as mass lesions, inflammatory processes, infarcts, and disturbances of cerebrospinal fluid circulation, that may cause dementia but are not the result of a neurodegenerative pathogenetic process. Recently, however, a second mode of application of structural imaging has become increasingly important, namely, the detection of morphological changes in the brain that allow a differential diagnosis between AD and the cerebral involution accompanying normal aging, and also between AD and other causes of dementia. Planimetric and volumetric imaging of certain brain structures and the quantification of subcortical signal changes on T_2-weighted MRI have been used for these purposes.

A significant reduction in total brain volume and dilatation of the external and internal cerebrospinal fluid spaces are usually found in AD. There is, however, a significant range of overlap between the cortical atrophy and ventricular dilatation of AD and those of normal old age. The demonstration of generalized atrophy, therefore, is of little value in differential diagnosis.

Neuropathological findings support the conclusion that the structures of the mediobasal temporal lobe suffer quite extensive neuronal loss very early in the

course of the disease and thereby undergo a reduction of volume. These observations have been confirmed in vivo by MRI. Many studies have shown that the hippocampus is an average of 40% smaller in patients with intermediate-stage AD than in cognitively intact age-matched control subjects (Seab et al. 1988; Jack et al. 1992; De Leon et al. 1997) and that, even in mild AD, a 25% volume reduction is present (Killiany et al. 1993; Lehiricy et al. 1994; for further literature, see Hampel et al. 1997). The fact that the presence of hippocampal atrophy can be regarded as a very early diagnostic sign of the presence of AD was also confirmed in neuropathologically verified cases (Jobst et al. 1992, 1994). Nonetheless, all large studies revealed a significant range of overlap between the patient and control groups. Moreover, most studies to date have concentrated on the differentiation of AD patients from normal individuals of the same age. With regard to the clinical diagnosis of AD, however, it must borne in mind that other dementing illnesses may also lead to a significant volume reduction in the medial temporal lobe.

Medial temporal volume reduction apparently also allows a prediction of which individuals with mild memory impairment will likely develop dementia in the years to come. A longitudinal study was performed on 32 patients who had mild cognitive impairments, most of whom developed dementia over a 4-year period of observation (De Leon et al. 1996). Most of these cognitively impaired, elderly individuals already had a mild hippocampal volume reduction, demonstrable by MRI, on their initial imaging study, but, in contrast to patients with overt AD, the abnormality did not extend to the lateral portions of the temporal lobe or to other regions of the brain. This study provides no information as to whether hippocampal atrophy in cognitively normal individuals might also be associated with a greater than normal risk for the development of dementia.

Sequential study with CT or MRI may also help support a diagnosis of AD. The progression of brain atrophy from year to year is much more pronounced in AD patients than in cognitively unimpaired control subjects of the same age. This increased rate of progression of brain atrophy is particularly noticeable in the mediobasal portion of the temporal lobe. The reduction of hippocampal volume per year in AD patients is ten times as large as that in age-matched controls (Smith and Jobst 1996; A.D. Smith et al. 1996) and is closely related to the rate of cognitive deterioration.

A number of observations imply that longitudinal CT or MRI studies can also be used to predict the appearance of AD. In nondemented, mildly cognitively impaired individuals, an elevated rate of hippocampal atrophy is considered an early warning sign for the development of dementia (Fox et al. 1996; Smith and Jobst 1996; A.D. Smith et al. 1996). Repeated measurements reveal a nearly linear increase in the cerebrospinal fluid volume, even before the clinical manifestations become severe enough to cross the defining threshold of dementia.

A further attempt to obtain specific criteria for the diagnosis of AD from structural imaging techniques relies on the common white matter changes that are evident as hypodense zones in the periventricular white matter on CT images and are particularly well seen as areas of elevated signal intensity in T_2-weighted MRI sequences. The pathogenesis and clinical significance of this so-called leukoaraiosis is discussed in Chap. 8 (this volume, Part 2).

Moderately severe and severe leukoaraiotic changes are seen in 50%–80% of patients with vascular dementia and in 20% of age-matched normal control subjects older than 65. A possible connection to AD is evident from the studies of Brun and Englund (1986).

In 60% of neuropathologically confirmed cases of AD, these authors found white matter changes which they interpreted as incomplete infarcts secondary to fibrohyalinosis of the white matter vasculature and whose distribution was not correlated with the pattern of cortical degeneration.

Patients with presenile AD were, however, no different from normal control subjects in the extent of their leukoaraiotic changes. Only patients who developed AD in old age had significantly more areas of hyperintensity in the periventricular zone and deep white matter. These findings still require confirmation by comparative studies of patient cohorts with early and late disease onset. An unequivocal differentiation of AD from the normal physiological effects of aging on the brain and from vascular dementing processes is quite difficult because of the high degree of intergroup overlap, and also because the question of how best to quantify leukoaraiotic changes has not yet been satisfactorily resolved.

6.1.2 Functional Imaging

The functional imaging techniques include functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS), single photon emission computed tomography (SPECT), and positron emission tomography (PET). The latter two techniques are the ones most widely used at present. They allow the measurement of regional cerebral perfusion and metabolic rates, as well as the quantitative determination of the presynaptic uptake of neurotransmitters and their binding to various receptors. Even in mild AD, in which the presence of the typical defining features of dementia is questionable or these features are com-

pletely absent, a reduction of the metabolic rate for glucose can be demonstrated in several areas of the brain (G.S. Smith et al. 1992). The area most strongly involved is the temporoparietal association cortex, while the primary motor and sensory cortical fields are relatively spared.

The pattern of regional distribution of deficits of cerebral perfusion and metabolism in AD is different from that found in normal elderly individuals and in patients with other dementing illnesses (Herholz 1995) and can be found even in only mildly demented AD patients (Mielke and Heiss 1998). The extent of cognitive impairment is highly correlated with the metabolic rates of the most severely involved cortical association areas (G.S. Smith et al. 1992; Mielke et al. 1994). The diminution of neural activity that is reflected by the regional metabolic deficits is the result not only of neuron loss, but also of a functional impairment of residual neurons (G.S. Smith et al. 1992). Functional imaging techniques such as PET are also used to study the influence of therapeutic measures on cerebral perfusion and metabolism and the effects of drugs on certain neurotransmitter and receptor systems. Several brain-activating substances have been shown to produce a significant increase in cerebral metabolic rate (Heiss et al. 1988; Nordberg et al. 1998).

Cerebral perfusion and metabolism may also be studied during cognitive activation. Currently available data imply that measurements of metabolic rate during stimulation are a more sensitive test for neuronal dysfunction than measurements of glucose metabolism at rest (Pietrini et al. 1999). The pattern of activation of various brain areas by the performance of a given task is different in patients with AD than in normal control subjects. While performing a memory task, for example, the AD patients had a stronger activation of frontal areas, possibly reflecting compensatory recruitment of available neuronal resources (Woodard et al. 1998).

fMRI allows noninvasive measurement of regional cerebral blood flow by detection of the state of oxygenation of hemoglobin. Even in patients with mild AD, temporoparietal blood flow (compared to cerebellar blood flow) is diminished by approximately 20% (Harris et al. 1996). fMRI findings are highly concordant with PET findings. It may be inferred that these two techniques are of comparable usefulness in the diagnosis of dementing illnesses (Gonzalez et al. 1995).

MRS is a noninvasive method of quantitative measurement of biochemical parameters in the brain. In the study of neurodegenerative disorders, it is particularly helpful to use proton MRS (^{1}H-MRS) to measure the concentration of compounds that are markers for neuronal cell death (*N*-acetyl-aspartate, NAA) and glial proliferation (*myo*-inositol, MI) (Lazeyras et al. 1998). AD patients typically have a diminished level of NAA, and an elevated level of MI, in comparison to normal control subjects; these findings are independent of cerebral structural changes and are poorly correlated with the clinical severity of dementia (Heun et al. 1997; Schuff et al. 1998). These biochemical abnormalities are particularly marked in the temporal and parietal areas in AD and thus allow diagnostic differentiation from frontotemporal degenerative processes (Ernst et al. 1997). It is still unclear whether ^{1}H-MRS is a suitable method for the early diagnosis of AD.

The further development of imaging techniques will bring improvements both in hardware and in techniques of assessment. Higher resolution may enable the representation of cortical structures in the living brain all the way down to the cellular level. Interesting perspectives are also opened up by the development of radioligands that can be used in SPECT and PET for the imaging of cholinergic and serotonergic neurotransmitter systems. Combined structural and functional imaging, e.g., in the form of three-dimensional overlaid images, will certainly also gain in importance. Reliable measurement of changes in cerebral metabolism by PET is difficult to achieve in AD patients because of their concomitant loss of brain matter. The higher spatial resolving power of MRI can probably be used to distinguish genuine diminutions of brain activity from those that are merely secondary to volume reduction. Meanwhile, the interpretation of structural changes will also be facilitated by the concomitant use of functional imaging techniques.

6.2 Genetic Markers

Tests for the detection of mutations in the genes encoding amyloid precursor protein (APP) and presenilin-1 and presenilin-2, now known to be associated with autosomally inherited familial forms of AD, can now be performed in all laboratories of human genetics. The diagnosis of AD in affected family members can thereby be established with certainty. It can also be determined whether the healthy blood relatives of such patients carry the relevant mutation and are thus expected to develop the disease at some later time. Younger family members are often interested in such information so that they can decide to have, or not to have, children depending on the degree of their genetic load. It should be borne in mind, however, that the communication of a positive test result places a severe psychological burden on the affected person, and it may also have repercussions for other family members, who might thereby discover their own elevated risk of developing the disease. The performance of such a test

is ethically acceptable only after thorough counseling and adequate time for reflection and when provisions have been made for long-term psychotherapeutic care once the test result is delivered. Moreover, the genetic information thus obtained must, of course, be kept confidential (Lennox et al. 1994).

Most cases of AD are of multifactorial etiology, i.e., a combination of factors including brain aging, genetic factors, prior brain injury, and environmental influences is assumed to be responsible for the generation of the disease. The single genetic risk factor that has been identified with certainty to date is the ε4 allele of the gene for apolipoprotein E (ApoE) on chromosome 19 (see Chap. 7, this volume). This normal genetic variant is found three times as often in patients with AD as in normal age-matched controls (Kurz and Müller 1997). Approximately 50% of all patients do not have this allele, however, while it is indeed present in many healthy individuals. The ε4 allele is thus neither a necessary nor a sufficient condition for the development of AD. ApoE gene typing can, therefore, make only a limited contribution to the detection of AD.

In patients who already have unequivocal manifestations of dementia, however, the demonstration of the presence of an ε4 allele is of great value in differential diagnosis, increasing the likelihood that the affected individual has AD. Several studies of cases verified by necropsy (Roses 1996) have revealed that the overwhelming majority of demented patients carrying at least one ε4 allele satisfied the histopathological criteria for AD. Nonetheless, the specificity of this genetic marker is still less than 100%, as other dementing diseases are also associated with an elevated frequency of the ε4 allele. According to current concepts, ApoE gene typing cannot be used to replace any other diagnostic procedure that is normally required for the exclusion of causes of dementia other than AD (American College of Medical Genetics 1995).

In elderly individuals suffering from mild cognitive disturbances, the presence of an ε4 allele is a predictor for the progression of these deficits and the development of dementia (Coria et al. 1995; Petersen et al. 1995). Nonetheless, the present state of epidemiological knowledge does not permit reliable quantitative estimation of the risk of AD to which a person of a given age, with a given ApoE constellation, is subject, nor can the time of onset of the disease be predicted. ApoE gene typing is therefore not a suitable predictive test for asymptomatic individuals.

6.3 Neurochemical Markers

The search for neurochemical markers for AD proceeds from the conjecture that the formation of neurofibrillary tangles, the deposition of beta amyloid in brain tissue, and the loss of synapses that occur in AD might lead to detectable changes in the concentration of proteins participating in these processes in the cerebrospinal fluid or even in the blood. Many studies have been published recently showing that tau protein is elevated in the cerebrospinal fluid of patients with AD, as compared both with normal controls and with patients suffering from dementia of other causes (Galasko et al. 1996; Riemenschneider et al. 1997). The specificity of an elevated concentration of tau protein is only approximately 90%, however, as it may be found in patients with dementia of other causes or with other neurological illnesses (Schenk et al. 1996). There is controversy as to whether the elevation of tau protein concentration becomes even higher as the disease progresses and whether it is correlated with the severity of cognitive impairment. The concentration of tau protein is elevated in the cerebrospinal fluid of AD patients even in the very early clinical stage (Kurz et al. 1998) and in some patients with mild cognitive impairment. Elevated tau levels have also been found in healthy carriers of mutations on the APP or presenilin-1 genes.

Further studies are concerned with the various derivatives of APP. The ill members of a Swedish family with APP gene mutations were found to have significantly lower concentrations of soluble precursor protein in the cerebrospinal fluid (Almkvist et al. 1997). A lower level was also found in healthy carriers of the mutation in comparison to family members not affected by it. Several groups of investigators have recently shown that AD patients have a diminished concentration of insoluble beta amyloid protein in the cerebrospinal fluid (Galasko et al. 1998). The probable reason for this is the increased deposition of the protein in brain tissue, mainly in the form of plaques. Further neurochemical markers that may be of diagnostic significance include synapse-associated proteins and melanotransferrin.

7 Differential Diagnosis

AD must be distinguished from many other dementing processes. These may be grouped into four categories:

1. Dementias of cerebrovascular origin
2. States of dementia in degenerative illnesses of the basal ganglia and other focal cortical and subcortical processes
3. Hereditary metabolic disorders, most of which are evident in childhood, but some of which are not evident until adulthood

4. Potentially treatable dementias

The delimitation of these diverse dementing processes from one another is based on the acute or insidious nature of the onset of the illness, its temporal course, the presence or absence of other neurological manifestations, the cortical or subcortical character of cognitive impairment, and the nature and extent of personality changes, behavioral abnormalities, motor disturbances, and functional impairment in everyday life. Further information regarding the clinical manifestations, pathogenesis, and prognosis of these illnesses may be found in Chap. 9 (this volume, Part 2). The cerebral diseases most commonly misdiagnosed as AD are Parkinson's disease, cerebrovascular diseases, and frontal lobe degenerations (Klatka et al. 1996).

8 Combinations with Other Dementing Diseases

8.1 Cerebrovascular Diseases

AD and cerebrovascular diseases are the two most common causes of demented states in the elderly. Autopsy series of patients who had been demented during their lifetimes reveal the simultaneous presence of both cerebrovascular disease and AD in 10%–23% of patients (Katzman et al. 1988b; O'Brien 1988; Galasko et al. 1994; Jellinger 1996). Such cases are, therefore, just as common as the pure forms of dementia of cerebrovascular origin, which account for approximately 10% of patients.

The diagnosis of such a mixed form of dementia cannot be made reliably on clinical grounds alone. The ischemia score (Hachinski et al. 1975), like its various modifications, can indeed be used to distinguish AD from vascular dementia with sufficient accuracy; its sensitivity in the diagnosis of mixed neurodegenerative-vascular cases, however, is in the range of 17%–50% (Chui et al. 1992). The currently used systems of defining criteria for vascular dementia (Chui et al. 1992; Román et al. 1993) do not treat the definition of mixed vascular-neurodegenerative cases uniformly. The category of possible AD in the criteria of the NINCDS-ADRDA working group (McKhann et al. 1984) includes patients with the clinical features of AD in which marked cerebrovascular changes are also demonstrable, where the latter might constitute a separate contributing etiologic factor but are not considered the sole etiology of dementia. In view of the heterogeneity of these concepts of classification and the lack of validation for any of them, there are no currently available, generally applicable methods for the unequivocal diagnostic differentiation of AD and dementia of vascular origin from a mixture of these two types of illness.

There are a number of possible explanations of the manner in which vascular and neurodegenerative factors interact in the generation of these dementia syndromes of mixed etiology. Snowdon et al. (1997) studied the brains of 61 nuns (see also Sect. 9, below) in which the histopathological criteria for AD had been met. In nearly half of the subjects, one or more brain infarcts were also found. Dementia had been present during the lifetime of 57% of the subjects who had the typical changes of AD and no infarct, but in 75% of those who had AD changes combined with at least one large neocortical infarct, and in 93% of those who had AD changes and one or two lacunar infarcts in the basal ganglia, thalamus, or deep white matter. In a further group of patients who did not have the typical cerebral findings of AD, the frequency of infarcts was just as high, but there was no relationship between these infarcts and the development of clinical manifestations of dementia.

It may, therefore, be presumed that the occurrence of a few small infarcts in strategically located areas of the brain, superimposed on the histopathological changes of AD, places an excessive load on the functional capacity of the already damaged brain and leads to a considerable lowering of the clinical threshold for dementia. This may also explain the observation, made in recent case-control studies, that vascular risk factors also elevate the probability of a patient's developing clinically diagnosable AD (Hofman et al. 1997). The clinical picture of an AD patient with cerebrovascular changes is probably different from that of a patient with pure AD (for further details, see Chap. 8, this volume, Part 2).

8.2 Parkinson's Disease and Lewy Body Disease

Histopathological study of the brains of 650 patients who had been given the diagnosis of AD in various medical institutions was performed at a reference center for neurodegenerative diseases. Many of these patients were found to have had other causes of dementia. The disease most commonly misdiagnosed as AD was not vascular dementia, but Parkinson's disease, accounting for 6% of patients. A further 7.4% of the patients had a combination of AD and Parkinson's disease. The cognitive disturbances of Parkinson's disease usually correspond to a clinical syndrome characterized by bradyphrenia, memory impairment, difficulty with complex intellectual tasks, and changes in affectivity; this syndrome, when severe, resembles the picture of a "subcortical" dementia. These

disturbances are caused by a degeneration of neuronal systems in the brain stem that also affects their cortical projections. On the other hand, the great majority of patients who have both severe dementia and parkinsonian clinical manifestations have a combination of AD and Lewy body disease.

Lewy body disease is said to be present when the intracellular inclusion bodies discovered by Friedrich Lewy are found not only in subcortical nuclei (the substantia nigra and other brain stem centers), but also in the cerebral cortex. These changes have been repeatedly identified in recent years as a cause of dementia, and recent autopsy statistics document that they are among the more common causes of dementia in the elderly (Perry et al. 1990). The clinical manifestations of dementia in Lewy body disease are described in Chap. 9 (this volume, Part 2). A controversy exists as to whether the dementia of Lewy body disease should be considered an independent nosological category or a subtype of AD.

There is probably a spectrum of similar neuropsychiatric entities that has the following common features: (a) the presence of Lewy bodies in both the subcortical structures and the cerebral cortex and (b) a variable number of senile plaques, in the total, or near-total, or absence of neurofibrillary changes. The brain stem type, corresponding to idiopathic Parkinson's disease and presenting mainly with motor abnormalities, is at one end of this spectrum; here, the Lewy bodies are almost exclusively subcortical and are quite sparse in the limbic cortex and neocortex. At the other end of the spectrum, we find the cortical forms of Lewy body pathology, in which these inclusion bodies are extraordinarily profuse and widespread in the cerebral cortex, so that the presence of dementia is adequately explained whether or not plaques or neurofibrillary changes are also present. The motor manifestations are mild in these cases. The numerically most prominent Lewy body diseases, however, are those affecting children, which occupy the middle range of the Lewy body spectrum. Here, too, there are many cortical inclusion bodies, but they affect a lesser number of neurons. Plaques and neurofibrillary changes are also found, but in quantities and intensities that still remain under the threshold for clinical dementia. Cognitive deterioration is, therefore, presumably the combined effect of the AD-like changes and the presence of Lewy bodies.

9
Diagnosis in the Preclinical Stage

The current recognition of a protracted clinically silent phase of AD, followed by the stage of predementia, gives rise to the idea of new possibilities for early detection and even the hope that the dementia of AD might be preventable. We are immediately led to ask which of the currently available psychological and biological features of AD might be used as markers of the still latent disease process and might thus enable timely prediction of the later clinical onset of the disease.

9.1
Psychological Predictors

The search for predictors of AD begins with the search for abnormalities of behavior, personality, professional life, or cognitive performance that might be present before the onset of dementia; information about these abnormalities is obtained retrospectively from the patients and their families or from other, objective sources. Efforts of this type have, as a rule, not yielded any generally applicable conclusions.

One exception is provided by a study of Catholic nuns in the United States who were 75–95 years old at the time of the study (Snowdon et al. 1996). Use was made of autobiographical information that had been written down by the nuns when they had entered the order, at a mean age of 22 years. Higher levels of linguistic expression in these youthful writings were found to be correlated with better results on cognitive tests taken in old age. The 24 nuns who had died of neuropathologically confirmed AD belonged, without exception, to the group whose autobiographies had been characterized by a relative poverty of ideas. This interesting result does not, of course, allow us to determine whether the novices' inferior linguistic and cognitive abilities were a very early expression of subtle neuropathological changes or, alternatively, represented a normal cerebral variant that, for some unknown reason, provides a favorable substrate for the later development of Alzheimer's disease.

A second approach to the search for psychological predictors of disease consists of the performance of longitudinal studies on representative cohorts of originally healthy elderly individuals in order to determine which neuropsychological features may serve to distinguish those individuals who later develop AD from those who do not.

Predictors that emerged from such a study included poor performance with regard to learning ability, delayed reproduction of learned information, deficient use of semantic aids to memory, and disturbances in the areas of attention, verbal fluency, and nonverbal intelligence. These abnormalities appeared many years before the first clinical manifestations of dementia (Linn et al. 1995). Nonetheless, it must be

borne in mind in the interpretation of such results that samples of apparently healthy elderly individuals are inevitably "contaminated" by patients who already have minimal manifestations of the AD that will only later become overt. Lack of cognitive plasticity, i.e., an inability to improve one's level of cognitive performance through mental training, may also be regarded as a predictor of dementia in the elderly (Baltes and Raykov 1996). Although these findings have been validated by statistical group comparisons, they cannot be used reliably to predict dementia in individual cases.

Finally, it should be pointed out that individuals at especially high risk of developing AD were also included in studies that were intended to identify psychological risk factors for the disease. Individuals who complain of forgetfulness are not suitable for such studies. Complaints of forgetfulness are mainly associated with a depressive tendency, fearfulness, and neuroticism (Jorm et al. 1994), but are only poorly correlated with objectively demonstrable memory impairment and have almost no predictive value for the future development of AD (Flicker et al. 1993). In contrast, elderly subjects with objectively demonstrable memory disturbances, such as an age-associated memory disturbance or a mild cognitive impairment, very often go on to develop more severe cognitive impairment and then dementia (Flicker et al. 1991; Paykel et al. 1994; Grundman et al. 1996). Many such individuals probably already have AD in the stage of minimal clinical manifestations (Petersen et al. 1997).

9.2 Biological Predictors

Individuals at particular risk for the later development of AD include carriers of pathogenic mutations who have not yet reached the age of clinical onset. These carriers have been found to have abnormalities of verbal memory years before the clinical onset of the disease, which are later followed by abnormalities of visual attention, visual perception, and spatial analysis (Newman et al. 1994). Asymptomatic carriers of an APP or presenilin-1 mutation were found to have latent abnormalities of attention and memory (Amberla et al. 1996), as well as significant hippocampal volume reduction (Wahlund 1996), an elevated concentration of tau protein in the cerebrospinal fluid (Amberla et al. 1996), and a diminished concentration of soluble APP (Almkvist et al. 1997). All of these cognitive and neurobiological changes were absent in these individuals' healthy relatives who did not carry these mutations. It cannot be determined to what extent these results apply to families with other mutations or to cases of AD not caused by mutations of a single gene.

A preclinical diagnosis of AD cannot at present be made on the basis of psychological predictors alone. Progress in this area will probably come from various types of biological markers, including morphological predictors detectable by imaging techniques, genetic tests, and probably neurochemical findings as well. Studies in this area (Kennedy et al. 1995; Small et al. 1995; Reiman et al. 1996) have most often involved the combined application of PET and genetic and cognitive predictors. The cohorts of patients or probands studied were generally quite small; nevertheless, these studies represent a first step toward being able to distinguish mild, nonprogressive cognitive disturbances in the elderly from the first signs of a dementing illness. It is hoped that the preclinical diagnosis of AD will be enhanced by the combined use of neurobiological, genetic, and neuropsychological predictors.

In view of the wide variation in disease manifestations and the inadequate diagnostic accuracy of individual predictors, combinations of predictors will need to be used if the early diagnosis of AD is to be further improved. Such an improvement would be of great importance, as it would create an opportunity for the development of new strategies of therapeutic and preventive intervention that can be put into action in very early stages of the disease.

10 Institutional Care

Many patients with AD are cared for, not in institutions, but at home, by their families. The percentage of patients cared for at home varies across the industrial nations and is influenced by cultural traditions, governmental social and health policies, and the number of available institutional beds. Publications in German usually still refer to the findings reported more than 15 years ago by Cooper and Sosna (1983) to the effect that 20% of demented persons are cared for in institutions and 80% by their families. In the retrospective longitudinal study carried out by Bickel (1996), however, it was concluded that, if patients with very early and mild forms of dementia are excluded, 40% of demented patients are cared for in institutions. Indeed, most patients cared for at home at any given time will sooner or later, before they die, require transfer to an institution. Only about 35% patients live with their families until their death.

The likelihood of admission to an institution is increased by the same factors that generally determine the utilization of institutions and by the degree of severity of dementia, the extent of cognitive and functional impairment, and, above all, the presence

of noncognitive disturbances (Haupt and Kurz 1993). According to available data from Western countries (Bickel 1995), 17%–36% of the inhabitants of old people's homes and 51%–72% of the inhabitants of nursing homes are demented. The percentage of demented patients in residential homes, old people's homes, and nursing homes in Germany is currently 42.3%. Given that Germany has approximately 660,000 institutional beds, it can be calculated that there are approximately 280,000 demented patients in institutions, and their average length of stay is 2–3 years (Welch et al. 1992; Severson et al. 1994; Bickel 1996; Heyman et al. 1997). Even though these data are generally not broken down according to the cause of dementia (AD versus other causes), it can be safely assumed that most of these patients suffer from AD.

Because relatives are rarely able to provide the degree of care required by severely demented patients, even when assisted by outpatient services, and because psychiatric hospitals have now almost completely withdrawn from the long-term care of chronically ill elderly patients, nursing home care has become the standard mode of medical and nursing care for patients with AD who either can no longer be cared for by their families or have no families to care for them (see also Chap. 3, this volume, Part 2).

11 Cessation of Treatment

In the advanced stages of a dementing disease, when the patient is no longer capable of consenting to or refusing medical treatment, the question may arise whether life-prolonging treatment measures ought to be instituted or continued, e.g., in situations where the health and well-being of the patient are impaired by a second illness requiring treatment, or where his or her survival depends on the provision of nutrition and fluids by artificial means.

The decision-making process in such cases involves a consideration, among other questions, of whether the proposed medical intervention has a sufficient probability of success that it should be performed to lessen the patient's suffering or, alternatively, whether it would prolong the patient's life without lessening suffering and perhaps itself involve the infliction of additional suffering. A decision not to provide artificial nutrition or medical intervention may be well founded and ethically justified in some cases. Nonetheless, this must not become a routine matter. It cannot be assumed a priori that the quality of life of a patient in an advanced stage of dementia is necessarily negative, particularly because we know little about the experiential world of demented patients.

Despite the change of personality caused by the dementing illness, the patient's prior self is usually still perceptible in emotional contact. Thus the same ethical rules ought to apply to the question of cessation of treatment in these patients as in all other patients with severe physical illnesses who are no longer able to express their wishes. Moreover, the application of such principles is a demonstration of respect for the patient's self, which may still be perceived in communication even though it is overshadowed by illness, and counteracts the unfortunate human tendency to shut powerless, handicapped, or disagreeable individuals out of society (see also Chap. 12, Vol. 3). Society at large has a special responsibility to patients with AD and other dementing diseases. In an age when the costs of health care are increasing, these patients need and deserve our protection, now more than ever.

Appendix A. ICD-10 Clinical Diagnostic Guidelines for Dementia in AD

(a) Presence of dementia.
(b) Insidious onset with slow deterioration. While the onset usually seems difficult to pinpoint in time, realization by others that the defects exist may come suddenly. An apparent plateau may occur in the progression.
(c) Absence of clinical evidence, or findings from special investigations, to suggest that the mental state may be due to other systemic or brain disease which can induce dementia (e.g. hypothyroidism, hypercalcaemia, vitamin B12 deficiency, niacin deficiency, neurosyphilis, normal pressure hydrocephalus, or subdural haematoma).
(d) Absence of a sudden, apoplectic onset, or of neurological signs of focal damage such as hemiparesis, sensory loss, visual field defects, and incoordination occurring early in the illness (although these phenomena may be superimposed later).

Appendix B. DSM-IV Diagnostic Criteria for Dementia of the Alzheimer Type

A. The development of multiple cognitive deficits that manifest themselves as

1. an impairment of memory (impaired ability to learn new information or recall previously learned information) and

2. at least one of the following cognitive disturbances:
   a) aphasia (disturbance of speech)
   b) apraxia (impaired ability to carry out motor activities, despite intact motor function)
   c) agnosia (inability to recognize or identify objects, despite intact sensory function)
   d) disturbance of executive function (planning, organizing, sequencing, abstracting)

B. Each of the cognitive deficits in Criteria A1 and A2 causes significant impairment in social or professional functional areas and represents a clear deterioration from a previous level of function.
C. The course is characterized by insidious onset and continued cognitive decline.
D. The cognitive impairments in Criteria A1 and A2 cannot be attributed to:

1. other illnesses of the central nervous system that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal pressure hydrocephalus, brain tumor)
2. systemic illnesses known to cause dementia (e.g., hypothyroidism, vitamin B12 or folate deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
3. substance-induced illnesses.

E. Deficits are not exclusively present during delirium.
F. The disorder cannot be better explained by another disorder on Axis I (e.g., major depression, schizophrenia).

Appendix C. NINCDS-ADRDA Criteria for the Clinical Diagnosis of AD

(after McKhann et al. 1984)

I. The clinical criteria for the diagnosis of *probable* Alzheimer's disease include:

- dementia, demonstrated by clinical examination and documented by the Mini-Mental Status Test, the Blessed Dementia Scale, or a similar test, and confirmed by neuropsychological testing,
- deficits in 2 or more areas of cognition,
- progressive deterioration of memory and other cognitive functions,
- no disturbance of consciousness,
- onset between the ages of 40 and 90 years, usually over 65, and
- lack of systemic illnesses or other cerebral diseases that would alone suffice to explain the progressive deficits of memory and cognition.

II. The diagnosis of *probable* Alzheimer's disease is supported by:

- progressive deterioration of specific cognitive functions such as language (aphasia), motor performance (apraxia), and perception (agnosia)
- impaired everyday activities and altered behavioral pattern
- family history of the occurrence of similar illnesses, particularly when neuropathologically confirmed
- the following laboratory findings:
  - normal routine cerebrospinal fluid examination
  - normal findings or non-specific changes on EEG, such as increased slow-wave activity
  - evidence of brain atrophy by CT, with progression on repeated examination

III. After the exclusion of other causes of dementia, the following clinical features are compatible with the diagnosis of *probable* Alzheimer's disease:

- plateaus in the course of the illness,
- accompanying symptoms of depression, sleep disturbance, incontinence, delusions, illusory misperceptions, hallucinations, catastrophe reactions of verbal, emotional, or physical type, disturbances of sexual behavior, or weight loss,
- other abnormal neurological findings in a few patients, mainly in advanced stages of disease, including motor disturbances such as increased muscle tone, myoclonus, or gait disturbances,
- epileptic seizures in advanced stages of the illness, and
- normal CT findings for age.

IV. The following features make the diagnosis of *probable* Alzheimer's disease uncertain or unlikely:

- sudden "apoplectic" onset
- focal neurological findings such as hemiparesis, sensory loss, visual field defects, disturbances of coordination in the early stage
- convulsions or gait disturbances at the onset of the illness or very early in its course

V. The clinical diagnosis of *possible* Alzheimer's disease

- can be made when dementia is present and other neurological, psychiatric, or systemic illnesses are absent that would be sufficient to cause the dementia, and in the presence of variations with regard to onset, manifestations, and course,
- can be made if another systemic or cerebral illness is present that would be sufficient to cause dementia but cannot be regarded as the single cause of dementia in this case, and
- should be used in research studies when, in the absence of other identifiable causes, only a single, slowly progressive, severe cognitive deficit can be recognized.

VI. Criteria for the diagnosis of *definite* Alzheimer's disease are:

- the clinical criteria for probable Alzheimer's disease, and
- histopathological demonstration by biopsy or autopsy.

VII. The following findings may be suitable for the differentiation of subtypes of Alzheimer's disease, and are specified for research purposes:

- familial occurrence
- onset before age 65
- trisomy 21
- simultaneous presence of other relevant illnesses, such as Parkinson's disease

Risk Factors for Alzheimer's Disease

Translator: S. Henn

1 Introduction

Since Alzheimer's dementia is an illness probably characterized by an early, preclinical, neuropathological stage which can last several years to perhaps decades, an exact knowledge of specific risk factors could contribute both to early diagnosis of Alzheimer's disease and to estimating an individual prognosis. Reduction of specific risk factors could then become an important component of a multifactorial therapy.

Relative risk (RR) and odds ratio (OR) are frequently used as parameters for the relevance of a potential risk factor. These parameters are calculated from case control studies, which, in addition to cross-sectional studies and prospective longitudinal studies (cohort studies), are one of the most common study designs in psychiatric epidemiology (see also Chap. 2, Vol. 1). In the case control method, investigators attempt to compile two (random) samples in a retrospective analysis, in which only one has a particular distinguishing feature of the illness and relevant variables of age, gender, and other definable variables are the same. Both groups are then investigated with regard to possible risk factors, and the RR or OR values are calculated. The formulas for calculating the RR and OR are explained in Chap. 2 (Vol. 1, Part 1). Values greater than 1 indicate an increased risk, and those less than 1 a decreased risk. In addition, the confidence interval is cited as a measure of scatter. Case control studies have therefore found increasing application, since statistically more reliable risk data can be collected with this method than with the simpler cross-sectional studies. At the same time, costs are lower than in longitudinal studies.

Frequently cited case control studies include, among others, work from the EURODEM Project (European Community Concerted Action Epidemiology and Prevention of Dementia, Department of Epidemiology and Biostatistics, Erasmus University Medical School, Rotterdam, The Netherlands; see Breteler et al. 1991; Graves et al. 1991; Jorm et al. 1991; Mortimer et al. 1991; Rocca et al. 1991; van Duijn et al. 1991, 1994) and work from the Canadian Study of Health and Aging (University of Ottawa, see Canadian Study of Health and Aging 1994). Frequently cited longitudinal studies include, among others, work from the Hisayama Study, a 7-year follow-up study of 828 nondemented inhabitants of the Japanese city of Hisayama (Yoshitake et al. 1995), and work from the current Rotterdam Study, in the course of which baseline investigations with respect to various neurological and internal medicine illnesses were carried out between 1990 and 1993 as a prospective applied project (see Hofman et al. 1997; Ott et al. 1995). In the course of this study of 7983 individuals over 55 years of age from the Ommoord district of Rotterdam, dementia screening tests were carried out in conjunction with recording numerous other parameters.

It should be emphasized that the term "risk factor" is to be understood exclusively in the sense of a statistical association between the risk of becoming ill with Alzheimer's disease and an identifiable factor, and that very different factors affecting the illness can give rise to this association.

2 Family Burden

2.1 Dementia

Most cases of Alzheimer's dementia do not follow an autosomal dominant inheritance pattern, but occur "sporadically." However, the indication of genetic factors and separation from sporadic occurrence for illnesses which begin late is methodologically very difficult. Mathematical models that help to calculate the influence of genetic factors in late-onset sporadic illnesses are currently being developed. Nevertheless, it has also been shown that genetic factors play a certain role in cases of Alzheimer's disease which do not follow an autosomal dominant inheritance pattern. In a meta-analysis of several case control studies, van Duijn et al. (1991) showed that the risk of illness more than tripled with the occurrence of a dementia illness in at least one first-degree relative (OR, 3.5; 95% confidence interval, 2.6–4.6). Hirst et al. (1994) made use of the so-called Kaplan-Meier method, which allows risk to be estimated by using survival curves, in order to show that the life-time risk of becoming ill with dementia, though clearly higher (23.4% $\pm$ 3.0%), does not reach 50% of first-degree relatives of Alzheimer's patients, which would be compatible with an autosomal dominant inheritance course. In the Canadian Study of Health and Aging, the OR for the risk factor of a family history of dementia was 2.62 (range, 1.53–4.51). The OR values increased with the number of affected family members. Thus the RR varied with the amount of familial illness. Several investigators (see Li et al. 1995) were able to show that the probability of an increased family frequency was higher with early onset of illness than with late onset. The cutoff scores, which indicated a difference in genetic risk, were, interestingly enough, not at 65 years, but at 55, 70, and 75 years. These data suggest that genetic factors are most pronounced with very early

onset of Alzheimer's dementia, but also that genetic factors can play a role in late-onset Alzheimer's disease.

Care in the interpretation of genetic information from family "loading numbers" seems to be advisable though, if only because family members can also be exposed in common to certain environmental noxious substances. The present genetic data suggest that, in addition to the single gene-determined familial type of Alzheimer's dementia with autosomal dominant inheritance course, there is also a polygenetically determined type with a weaker familial frequency and a third, purely sporadic type.

2.2 Parkinson's Disease

Idiopathic Parkinson's disease is associated with Alzheimer's dementia on various levels. Parkinson's disease and Alzheimer's dementia exhibit partially similar histopathological changes. In addition, common etiological hypotheses have been formulated concerning energy and oxidation metabolism, among other things. Several case control studies showed a higher number of Alzheimer patients with a family history of Parkinson's disease compared with those in control populations. A meta-analysis in the EURODEM project resulted in an RR of becoming ill with Alzheimer's disease of 2.4 (range, 1.0–5.8) for probands with a positive family history of Parkinson's disease (van Duijn et al. 1991). This result could not be confirmed in the Canadian Study of Health and Aging (OR, 0.86; range, 0.28–2.61). Generally accepted pathogenetic models for the association between Alzheimer's dementia and Parkinson's disease described in the EURODEM project are, however, not available.

2.3 Down Syndrome

Patients with Down syndrome carry a high risk of becoming ill with Alzheimer's disease, especially after the age of 40. This is probably because of the threefold gene dosage of the amyloid precursor protein (APP) gene, which contains the β-amyloid sequence and is located on chromosome 21. It is suspected that the increased APP gene dose leads to an increased production of APP, subsequently followed by an overloading of the nonamyloid breakdown pathway of APP (α-secretase pathway) combined with a higher amyloid production (via the β- and γ-secretase pathway). Mutations in the APP gene are, moreover, associated with familial forms of early-onset Alzheimer's disease. More than 11 studies of the association between Alzheimer's disease and familial history of Down syndrome are now available. Eight studies show an increased frequency of family history of Down syndrome in Alzheimer's patients, although only four of them were statistically significant; three studies showed no association. Based on the lower frequency of Down syndrome in the general population, data about the statistical lack of association must be considered with caution. An RR of 2.7 (range, 1.2–5.7) was found in the EURODEM project (van Duijn et al. 1991).

3 Maternal Age at Birth

Based on the above-mentioned association of Down syndrome with Alzheimer's disease, the maternal age at birth was investigated in view of the risk of becoming ill with Alzheimer's dementia. There are 13 studies on this subject. Five show a statistically significant increased risk for a maternal age of over 40 at the time of birth, while eight studies did not show this result. A meta-analysis of four case control studies in the EURODEM project showed a positive association with an RR of 1.7 (range, 1.0–2.9) for a maternal age of over 40 at birth. Surprisingly, an increased RR (1.5; range, 0.8–3.0) was likewise established for a lower age at birth (15–19 years). Thus both a higher and a lower age at birth may represent a risk factor for Alzheimer's dementia (Rocca et al. 1991). Up to now there have been no conclusive pathophysiological explanations for either of these results.

4 Traumatic Head Injury

An increased RR value of 1.82 (range, 1.20–2.67) for the factor of traumatic brain injury (defined as skull–brain trauma with subsequent loss of consciousness) was calculated after a meta-analysis of 11 case control studies in the course of the EURODEM project (Mortimer et al. 1991). Newer studies showed that skull fracture without loss of consciousness could also present a risk factor (Rasmussen et al. 1995; van Duijn et al. 1994). Neuropathological consequences of head injury can include an increased number of amyloid immunoreactive neurons in the entorhinal cortex and other cortical areas (McKenzie et al. 1994), among other things. These results suggest that a skull fracture, but above all repeated head traumas (e.g., in professional boxers), may promote the amyloid deposition

process. Interestingly, the existence of the ApoE4 allele thus seems to exert a potentiating effect on the traumatic head injury risk factor (Mayeux et al. 1995). This was interpreted as indicating synergistic effects between genetic and environmental risk factors. In an interactions analysis of genetic and environmental factors of Alzheimer's disease, the traumatic head injury risk factor was independent of that of familial history of dementia illness (van Duijn et al. 1994).

5 Depression

From a prospective study by Kral and Emery (1989), indications became apparent that large numbers of depressive symptoms could appear before the onset of dementia. The authors showed that 79% of 44 older patients with depressive symptoms, above all those with simultaneous existence of pronounced cognitive disorders, developed Alzheimer's disease in a subsequent period of 4–18 years. Jorm et al. (1991), in a meta-analysis of 12 case control studies in the course of the EURODEM project, were able to show a statistically significant association of a history of depression with the appearance of Alzheimer's disease (RR, 1.82; range, 1.16–2.86). This association with the history of depression remained significant both for the period under 10 years and for the period over 10 years before the onset of dementia. A separate analysis of patients with early and late onset of Alzheimer's disease showed that the significant positive association was actually valid only for the subgroup of patients with late onset (RR of 4.46 in Alzheimer's disease with late onset vs. RR of 0.71 in Alzheimer's disease with early onset). Antidepressive therapy showed no influence on the RR. It was not further subclassified here, e.g., with regard to the use of substances with or without an anticholinergic spectrum of effect. Devanand et al. (1996) confirmed these results in a longitudinal study of 478 probands from a community in North Manhattan, New York, and calculated an RR of 2.94 (range, 1.76–4.91) for depression, documented on the basis of the Hamilton Rating Scale for Depression. The interactions analysis by van Duijn et al. (1994) showed no differences between Alzheimer's patients with and without a family history of dementia with regard to the risk factor of history of depression. No influence of burdensome life events (e.g., loss of life partner, divorce, loss of a child) showed an association with the appearance of Alzheimer's disease. Regarding the association of depression in the history and the appearance of Alzheimer's disease, the early involvement of the serotonergic and catecholaminergic systems might play a pathogenetic role in the course of neurodegeneration in Alzheimer's disease.

6 Influence of Education and Career

In the course of the above-mentioned longitudinal Rotterdam study, a cross-sectional analysis of a random sample showed a significant increase in the prevalence of Alzheimer's disease in probands with lower levels of education (Ott et al. 1995). The level of education was ascertained with the help of a standard instrument which made it possible to divide education levels into seven groups. The four highest levels of education were grouped together in one category. Thus there were four categories of education: (1) noncompletion of secondary school (26% of the probands), (2) vocational training (20%), (3) technical colleges (15%), and (4) higher education and university (39%). Using education level 4 as a reference, the risk of becoming ill with Alzheimer's disease rose with education level 2 to an RR value of 2.0 (range, 1.3–4.1) and with education level 1 to an RR value of 3.2 (range, 2.2–4.6). In the latter case, the risk for other forms of depression, including vascular dementia, also rose. This result agrees with at least seven other published articles. A certain diagnostic bias might be present due to the effect of the level of education on performance in the psychometric tests used to screen the patients.

Snowdon et al. (1996), with the help of linguistic methods, analyzed handwritten biographies that were written by novices before they finally entered their order (The Nun Study). These biographical sketches by the 75- to 95-year-old nuns were written an average of 58 years previously. In this study, the biographies of 14 patients who had later developed a confirmed Alzheimer's disease were characterized by linguistic defects and distinctive features, such as poverty of ideas and a low level of grammatical complexity. In the nuns in whom cognitive limitations were determined at higher ages, too, the analysis of biographies written during an earlier period of their live already showed comparable defects. Linguistic disorders at an early age were judged to be predictors for cognitive disorders at higher ages.

Stern et al. (1995) have pointed out that the survival time following diagnosis of Alzheimer's disease in patients with a high level of education is lower than in patients having less education. This was interpreted to mean that the causative neurodegeneration in patients with high educational levels is already further advanced at the time of diagnosis. A further possibility which needs to be considered is that factors of poor life style and nutrition, as well as higher exposure to

toxins, might also play a role which cannot be separated from that of the level of education.

7 Vascular Risks

Vascular factors were associated at various levels with Alzheimer's disease. Pronounced degenerative changes of cerebral microvasculature exist in Alzheimer's disease, and significant amyloid deposits also are found in the vascular system outside the brain parenchyma. A diffuse reduction in the density of bone marrow stores is associated with disease of the small vessels, but also with progression of Alzheimer's disease.

In the course of the Rotterdam study, Hofman et al. (1997) investigated 282 patients with dementia and compared them with 1698 controls with regard to indications for atherosclerosis. With the aid of ultrasound tests of vessels in the neck and blood pressure measurements, a scale with degrees of severity from 0 to 3 (absence of to severe atherosclerosis) was drawn up. All indicators for atherosclerosis increased the risk of becoming ill with Alzheimer's disease (OR, 1.3–1.8). The existence of severe atherosclerosis increased the OR to 3.0 (range, 1.5–6.0); with the additional presence of an ApoE4 genotype, the OR rose to 3.9 (1.6–9.6). In comparison, the OR for vascular dementia in the latter group was 19.8 (range, 4.1–95.0). Thus these studies provided new statistical indications of a clear association of atherosclerosis with Alzheimer's disease and confirmed a very strong association with vascular dementia.

In the Hisayama study mentioned at the beginning, various vascular factors were investigated with regard to the risk of Alzheimer's disease (e.g., smoking, overweight, high blood pressure, increased blood fats differentiated after subfractionation, diabetes mellitus). Significantly increased RR values were shown for lower high-density lipoprotein (HDL) cholesterol levels as well as for diabetes mellitus, frequently associated with angiopathies (RR, 2.18; range, 0.97–4.90) (Yoshitake et al. 1995).

Some studies were in agreement in showing a significantly lower risk for smokers. Graves et al. (1991), in a meta-analysis of 11 case control studies, calculated an RR value of 0.78 (range, 0.62–0.98); the Hisayama studies described an RR of 0.73 (range, 0.77–1.80). This result could not, however, be confirmed in the Canadian Study of Health and Aging (OR, 1.17; range, 0.77–1.80) or in a British Medical Research Council study from 1994 (Prince et al. 1994). These different results have not yet been explained.

8 Thyroid Insufficiency

Hyperthyroid and hypothyroid factors and goiter and general thyroid illnesses were investigated in the course of the EURODEM project in a meta-analysis of eight case control studies. Hypothyroidism resulted in a significantly increased risk for Alzheimer's disease with an RR of 2.3 (range, 1.0–5.4) (Breteler et al. 1991). The minimal interval between the appearance of hypothyroidism and the onset of dementia was 6 years, with a mean of 20 years. Attempts at pathogenetic explanation focused on the influence of thyrotrophic hormones on the maturation of the central nervous system (CNS) and on neuronal cell growth. The EURODEM results are in agreement with two other studies, but in contradiction to another seven investigations. Thus the results remain unclear at present.

9 Exposure to Toxic Substances

Exposure to potentially neurotoxic substances has been repeatedly considered as a risk factor for Alzheimer's disease. Results have been shown to be statistically significant for adhesives (OR, 2.16; range, 1.25–3.70), pesticides (OR, 2.17; range, 1.18–3.99) (Canadian Study of Health and Aging 1994), and solvents (OR, 2.3; range, 1.1–4.7) (Kukull et al. 1995).

Aluminum has also been discussed as a risk factor for Alzheimer's disease. Increased aluminum has been found in the plasma of Alzheimer's patients and in the cortex (Basun et al. 1991). Aluminum was also able to be detected in the specific histopathological depositions of Alzheimer's disease, in the senile plaques, and in neurofibrillary bundles. The epidemiological studies carried out so far do not fulfill the standard international criteria with regard to diagnostic precision, definition of population, and statistical power. In 1989, Martyn et al. reported an association between presenile Alzheimer's disease and an aluminum content of over 110 μ/l in drinking water. However, a major criticism of this study was the lack of diagnostic precision: the diagnosis of Alzheimer's disease was made exclusively on the basis of a certificate of referral for computed tomography of the head. The currently accepted criteria given in ICD-10, DSM-IV, or NINCDS-ADRDA (McKhann et al. 1984) were not fulfilled. Moreover, it should be noted that drinking water contributes only about 10% of daily aluminum intake; other, more important sources are tea, antacids, or industrial dust, for example. An association between

Table 1. Risk factors for Alzheimer's disease

Factor	RR/OR value[a]	Reference
Familial burden with dementia	OR 3.5 (2.6–4.6)	van Duijn et al. (1991)

Solvents	OR 2.3 (1.1–4.7)	Kukull et al. (1995)
Alcohol abuse	No increased RR	Graves et al. (1991)

RR, relative risk; OR, odds ratio.
[a]Confidence interval, 95%.

Alzheimer's disease and antacid consumption has not yet been substantiated (for a summary, see Nicolini et al. 1991).

10 Alcohol Abuse

In the course of the EURODEM analyses, Graves et al. (1991) documented weekly alcohol consumption and divided it into three categories of light (below 3.2 oz, approx. 96 g), medium (3.2–5.95 oz, approx. 96–185 g), and heavy consumption (more than 5.95 oz, approx. 185 g) of pure alcohol per week. In no category did alcohol consumption influence the risk of becoming ill with Alzheimer's disease. These results agree with those of the Canadian Study and the Hisayama Study.

11 Concluding Comments

The aforementioned risk factors are listed and summarized in Table 1. Pathogenetic models so far account for only part of these factors. In addition to the influence of risk factors (e.g., atherosclerosis, exposure to toxic substances, hypothyroidism), future therapeutic relevance may also lie in deciphering basic mechanisms relating to potential protective factors (e.g., smoking). Such knowledge might contribute to the development of causally orientated therapeutic strategies.

Molecular Genetics and Molecular Biology of Alzheimer's Disease

Translator: E. Taub
We thank Prof. Dr. Christian Haass for critically reviewing the manuscript.

1 Introduction

Basic research on the molecular biology of Alzheimer's disease began with the study of the characteristic histopathological features of the disease, which revealed that β-amyloid (Aβ), amyloid precursor protein (APP), and tau protein all participate in the disease process at the molecular level. The molecular genetic characterization of the various genetic etiologies of the disease then led not only to confirmation that Aβ is important in pathogenesis, but also to the identification of further genes and gene products involved in the production of Alzheimer's disease – the presenilins and apolipoprotein E, whose ε4 allele is a risk factor for the disease.

Research today focuses on the identification of further genes conferring a risk of developing the disease and, above all, on the further characterization of the interactions between the various molecules that may participate in the disease process and on the description of their roles in it. It must be borne in mind that Alzheimer's disease is clearly an etiologically heterogeneous group of phenotypically very similar diseases or disease forms. This review article can only cover a relatively small and subjective selection of all relevant studies that have contributed to our current understanding of Alzheimer's disease on the molecular level; for further information, the reader is referred to the works mentioned in the text and to other review articles.

2 Histopathological Features as the Starting Point of Molecular Biological Research

According to the usually applied diagnostic criteria, such as those of the National Institute of Neurological and Communicative Disorders and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) (McKhann et al. 1984), a definitive diagnosis of Alzheimer's disease can only be made *postmortem* through the additional demonstration of certain neurohistopathological features. These features were first associated with the clinical picture of dementia by Alois Alzheimer in 1906 and were subsequently the principal justification for the definition of Alzheimer's disease as an independent disease entity (Alzheimer 1907). As these histopathological characteristics were the starting point for molecular biological research in Alzheimer's disease, they will now be briefly summarized.

In several areas of the brains of patients with Alzheimer's disease, certain regular and characteristic depositions may be demonstrated with special staining methods, such as amyloid staining with Congo red or thioflavin or silver staining. These include the profuse extracellular amyloid deposits, whose principal component has been identified with molecular biological methods as Aβ (also called βA4-amyloid), a proteolytic breakdown product of APP (see below; Kang et al. 1987; for reviews, see in Müller-Hill and Beyreuther 1989; Selkoe 1994).

Aβ aggregates into fibrils of less than 10 nm in diameter, which are deposited in solid form and are histopathologically recognizable as amyloid plaques of up to 0.2 mm in diameter (Fig. 1). Aβ deposition in cerebral parenchyma may take the form of senile or neuritic amyloid plaques or of amorphous (diffuse) plaques without amyloid properties, depending on the form of aggregation of Aβ, and other factors. One of the most important factors is the length of Aβ. There are two forms of Aβ, which differ with respect to the presence or absence of extra amino acid residues at the carboxyl terminal: the more prevalent form by far, which has 39 or 40 amino acid residues (Aβ40), and another form with 42 or 43 residues (Aβ42/43), which aggregates considerably more readily and is, therefore, more amyloidogenic (for reviews, see Hardy 1997; Sandbrink and Beyreuther 1996; Sandbrink et al. 1996a; Selkoe 1997; Younkin 1995). This is discussed in detail in a later section.

In some patients with Alzheimer's disease, aggregated Aβ additionally appears as vascular amyloid in the cerebral and meningeal blood vessels; this condition is known as congophilic angiopathy or cerebral amyloid angiopathy (CAA). Interestingly, the amyloid of CAA is largely composed of the "short" Aβ40, while plaque amyloid is predominantly composed of the "long" Aβ42/43 (Iwatsubo et al. 1994). Even before Aβ was identified as their major component, it was presumed that plaques, which are demonstrably present in practically all patients with Alzheimer's disease, were closely related to the pathogenesis of the disease. This was because a histologically very similar amyloid pathology is found, at an early age of onset, in Down's syndrome (trisomy 21), in which, in addition to the typical oligophrenia, patients frequently develop an age-dependent dementia syndrome similar to Alzheimer's disease (Iwatsubo et al. 1995). This, too, will be discussed further below.

A further characteristic feature is the formation of so-called neurofibrillary tangles (NFT; see Fig. 1). These are flame-shaped agglomerations of abnormal filaments within neurons; when these cells die, the tangles may persist as extracellular objects ("ghost tangles"). The double helix-shaped, twisted filaments

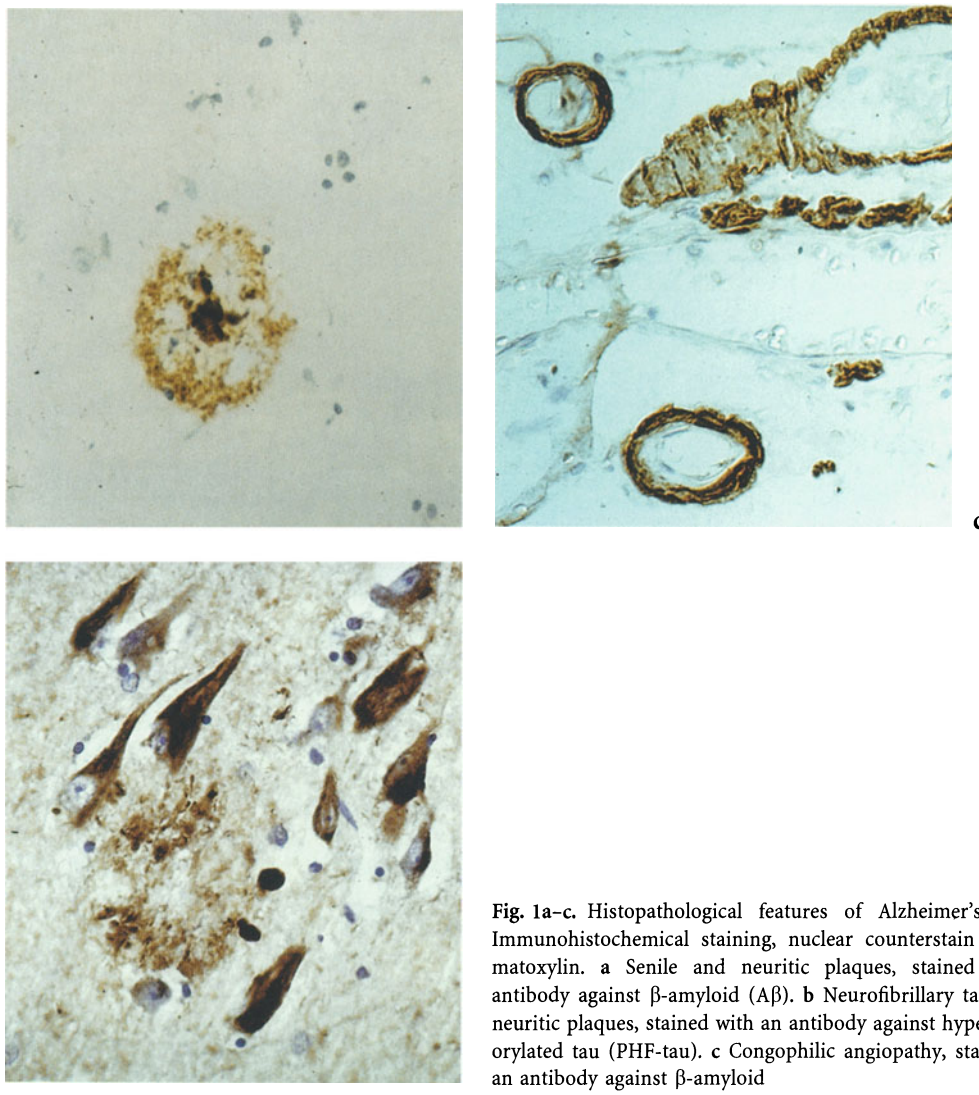

Fig. 1a–c. Histopathological features of Alzheimer's disease. Immunohistochemical staining, nuclear counterstain with hematoxylin. **a** Senile and neuritic plaques, stained with an antibody against β-amyloid (Aβ). **b** Neurofibrillary tangles and neuritic plaques, stained with an antibody against hyperphosphorylated tau (PHF-tau). **c** Congophilic angiopathy, stained with an antibody against β-amyloid

of the neurofibrillary tangles are called paired helical filaments (PHF) (Kidd 1963). These are aggregates with a diameter of 10–20 nm that are also found in a similar form in neuritic plaques and as threadlike structures in the neuropil (see Fig. 1).

These neurofibrillary tangles are primarily composed of pathologically altered tau protein, a neuronal microtubule-associated protein (Grundke Iqbal et al. 1986a,b; Kosik et al. 1986). The tau protein of paired helical filaments, unlike normal, soluble tau protein, is not bound to microtubules, but rather highly phosphorylated and partially fragmented (see below; for reviews, see Billingsley and Kincaid 1997; Goedert 1995; Trojanowski and Lee 1995). Neurofibrillary tangles are also found in other neurodegenerative diseases (for a review, see Feany and Dickson 1996). Furthermore, other varieties of tau protein deposition in neurons and glial cells are found in other diseases, including frontotemporal dementia with parkinsonism of chromosome-17 type (FTDP-17), which, as recently demonstrated, is caused by mutations in the tau protein gene (see below).

Both amyloid plaques and neurofibrillary tangles also appear in clinically healthy individuals at a rate that increases with age. This phenomenon may be interpreted as representing a "silent" preclinical phase of the disease; in other words, the first histopathological changes may take place several decades before the overt onset of the disease. With regard to amyloid deposition, the molecular genetic findings in hereditary (familial) Alzheimer's disease (discussed below) gave rise to the hypothesis of the Aβ cascade, according to which the formation and/or deposition of Aβ (in particular, Aβ42/43) sets in motion a complex series of pathological changes, ultimately leading to neurodegeneration, which produces the clinical picture of dementia (for reviews, see Hardy 1997; Sandbrink and Beyreuther 1996; Sandbrink et al.

1996a; Selkoe 1997; Younkin 1995). Before discussing these matters in detail, we will first provide a brief survey of the clinical genetic and molecular genetic findings in Alzheimer's disease.

3 Clinical Genetics and Etiological Heterogeneity

Alzheimer's disease accounts for at least half of all cases of dementia. In the English-speaking world, the disease is customarily designated as late-onset Alzheimer's disease (LOAD) when it becomes clinically manifest at an age of 65 years or older, and as early-onset Alzheimer's disease (EOAD) when it becomes manifest at an earlier age (in approximately 15%–20% of all patients with Alzheimer's disease). In the German-speaking countries, the same entities are often also called *senile Demenz vom Alzheimer Typ* (senile dementia of Alzheimer type, SDAT) and *präsenile Demenz* (presenile dementia), and the latter term has long been understood to refer to Alzheimer's disease in the proper sense. At present, the segregation of presenile cases into a separate disease entity on the basis of age alone is no longer viewed as justified, because the senile and presenile types have an essentially identical clinical course and identical histopathological features. An increasing number of authors now prefer to place the border between LOAD and EOAD at 60 years (EOAD patients would then account for 5%–10% of the total), as this is thought to be more in accordance with the current understanding of the various genetic etiologies of the disease.

Familial cases of Alzheimer's disease with autosomal dominant inheritance and complete penetrance were first described more than 60 years ago (Lowenberg and Waggoner 1934). In the prevailing current usage, as in this chapter, only these truly hereditary forms of Alzheimer's disease are referred to as familial Alzheimer's disease (FAD). For a large fraction of these FAD cases, the etiologically responsible, "deterministic" FAD gene can be identified. As discussed further below, the important genes are those encoding the presenilins (PS1 and PS2) and APP. The onset of disease is earlier in FAD than in Alzheimer's disease in general, but patients with FAD nevertheless account for only a small fraction (estimated at 5%–10%) of patients with Alzheimer's disease of onset before the age of 60 (Cruts et al. 1998; Sandbrink et al. 1996a). They thus presumably account for less than 1% of all cases of Alzheimer's disease.

In the great majority of patients with Alzheimer's disease, however, the disease is thought to be of multifactorial origin. Those cases often called "familial" in the purely descriptive sense, i.e. cases of patients with at least one first-degree relative with Alzheimer's disease, also belong in this category (for a review, see Sandbrink et al. 1996a). In such cases, which make up approximately 40%–50% of the total, a combination of genetic and other factors is thought to be etiologically responsible for the disease, just as in the so-called "sporadic" cases. As discussed below, the ε4 allele of the apolipoprotein E (APOE) gene has been identified as a genetic risk factor ("susceptibility gene").

A meta-analysis of several case-control studies yielded the conclusion that the first-degree relatives of a patient with Alzheimer's disease have a risk of contracting the disease that is approximately 3.5 times higher (confidence interval, 2.6–4.6) than that of control subjects (van Duijn et al. 1991). This finding was essentially confirmed by a more recent meta-analysis (Lautenschlager et al. 1996). In most of these studies, no statistically significant difference was found between EOAD and LOAD patients, which indicates that the patient cohorts studied included only a very small number of FAD patients. The clinical concept that the diagnosis of "probable Alzheimer's disease" is made by exclusion of other possible causes of dementia allows for the possibility that the disease may be heterogeneous (McKhann et al. 1984). As is now clear from the existence of different forms of Alzheimer's disease with different degrees of heritability, as well as from the existence of different molecular genetic findings, the disease is heterogeneous in etiology and might, indeed, be referred to as the group of "Alzheimer-type diseases," a term being used with increasing frequency. Despite many attempts, it has not been possible to date to provide a clear system of classification of subgroups of Alzheimer's dementia based on their clinical manifestations alone, although there may well be differences in the individual distribution of the cognitive and neurological deficits. Molecular biochemical methods might conceivably enable parameters to be defined which, in addition to the molecular genetic features described below, could be used to develop a reliable subclassification of Alzheimer's disease. This would be of great importance not only to scientific research, but also to treatment.

4 Molecular Genetics of Alzheimer's Disease

4.1 Amyloid Precursor Protein Gene

Three genes have been identified to date in which mutations can give rise to a familial form of Alzheimer's disease (FAD) (for reviews, see Hardy 1997; Sandbrink

et al. 1996a; Selkoe 1997). The earliest FAD gene to be identified was the APP gene on chromosome 21, i.e. the gene encoding the precursor protein of Aβ (Kang et al. 1987). APP is a glycoprotein with a single transmembrane domain that exists in eight different forms, depending on alternative splicing of three of a total of 18 exons (exons 7, 8, and 15) (Sandbrink et al. 1994a); these forms are named with reference to their length in amino acid residues (see below). The APP gene was recognized as a candidate FAD gene as soon as it was cloned in 1987. An FAD locus on chromosome 21 was demonstrated at approximately the same time (the AD1 locus).

There had been much earlier evidence for the existence on chromosome 21 (at least) of a genetic locus which, even in a nonmutated form, might be associated with the occurrence of pathological changes similar to those of Alzheimer's disease through a gene dosage effect: as already mentioned, such changes are regularly observed in Down's syndrome (trisomy 21). The first known mutation of the APP gene (at position 22 of the Aβ sequence) was described in 1990 (Levy et al. 1990; Van Broeckhoven et al. 1990). This APP-E693Q mutation was demonstrated in patients with hereditary cerebral hemorrhage with amyloidosis of the Dutch type (HCHWA-D), a rare disease in which recurrent cerebral hemorrhages occur and whose ultimate prognosis is poor; the hemorrhages occur because of massive Aβ deposition in the meningeal and cerebral microvasculature (see Fig. 1). Mutations of the APP gene are usually given geographical names; thus APP-E693Q is referred to as the Dutch mutation.

Shortly afterward, several point mutations at the valine site at position 46 of the Aβ sequence were demonstrated; these mutations are associated with an EOFAD phenotype (FAD with early onset of disease) (Chartier Harlin et al. 1991; Goate et al. 1991; Murrell et al. 1991). One of these mutations, the APP-V717I mutation (London), is the only APP mutation to date that has been found in a relatively large number of distinct FAD families. The average age of onset of Alzheimer's disease in patients with this V717I mutation is approximately the middle of the sixth decade of life.

A further APP mutation, the A692G mutation at position 21 of the Aβ sequence (Flemish mutation) (Hendriks et al. 1992), gives rise to the phenotype of Alzheimer's disease and/or massive CAA. The variable clinical expression of this mutation and its location one amino acid residue away from the site of the HCHWA-D mutation (E693Q) imply that HCHWA-D and FAD are phenotypic variants of a single disease (allelic phenotypes).

The Swedish FAD mutation, which was found in a large Swedish pedigree and is associated with an average age of onset of 55 years, consists of a K670N + M671L double mutation directly N-terminal to the Aβ sequence (Mullan et al. 1992). The recently identified mutation I716V, or Florida mutation, like

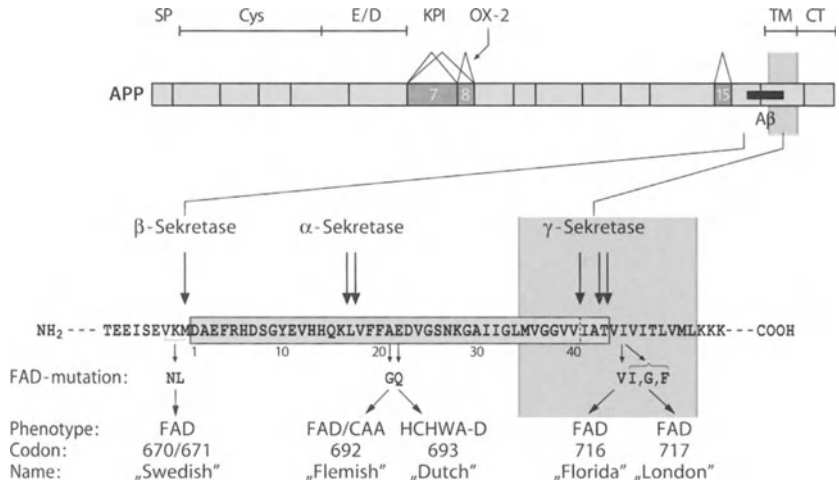

Fig. 2. Amyloid precursor protein (APP) and β-amyloid protein (Aβ). *Top*, exon and domain structure of APP; *bottom*, sequence in the area of the Aβ region with proteolytic cleavage sites (α-, β- and γ-secretase, *arrows*) and the six known familial Alzheimer's disease (FAD) mutations of the APP gene. APP domains: *SP*, signal peptide; *Cys*, cysteine-rich domain; *E/D*, domain with high percentage of negatively charged amino acid residues; *KPI*, Kunitz protease inhibitor domain; *OX-2*, domain resembling the lymphocyte receptor protein MRC OX-2; *TM*, transmembrane domain; *CT*, cytoplasmic domain. The different APP mutations bear geographic names. Phenotype: *FAD*, familial Alzheimer's disease; *CAA*, cerebral amyloid angiopathy (congophilic angiopathy); *HCHWA-D*, hereditary cerebral hemorrhage with amyloidosis – Dutch type

the London mutation, is located at the C-terminal end of the Aβ sequence (Eckman et al. 1997).

The age of onset of FAD resulting from one of these APP mutations varies, depending on the particular mutation, between approximately 40 and approximately 65 years. A typical feature of the FAD-APP mutations, although not of the FAD-presenilin mutations (see below), is an apparent influence of the APOE genotype (see below) on the age of onset of the disease (Houlden et al. 1998). No more than 20 families worldwide have been identified with such FAD-APP mutations; most of them have the V717I mutation (Fig. 2; Table 1; for reviews, see Hardy 1997; Sandbrink et al. 1996a).

As described in greater detail below, all FAD mutations of the APP gene lead to amino acid substitutions in the vicinity of one of the three secretase cleavage sites relevant to the pathogenesis of amyloidosis, which are designated α, β, and γ (see Fig. 2). These mutations lead to increased cleavage of APP at the corresponding sites, which, in turn, leads either to selectively increased formation of Aβ42/43, the longer form of Aβ, as in the London and Florida FAD-APP mutations (Eckman et al. 1997; Suzuki et al. 1994; for reviews, see Hardy 1997; Sandbrink et al. 1996a; Selkoe 1997), or to increased formation of all forms of Aβ, as in the Swedish FAD-APP mutation (Cai et al. 1993; Citron et al. 1992). Similarly, it is presumed that the pathological changes seen in Down's syndrome that resemble those of Alzheimer's disease come about through a gene dosage effect, in which the presence of an extra copy of the APP gene leads to overexpression of APP and thereby to increased production of Aβ.

4.2 Presenilins

Two further FAD genes were identified in 1996; their gene products are now known as presenilins (PS). The presenilin-1 (PS1) gene was the first of these to be found; with the aid of positional cloning, it was identified as the long-sought FAD gene on chromosome 14 (AD3 locus) (Sherrington et al. 1995). PS1 mutations are the most common known cause of FAD, but as far as can be determined from recent studies, they account for only about 20% of all cases of autosomal dominant FAD (Cruts et al. 1998). To date, at least 44 different PS1 mutations, located throughout

Table 1. Genes that play a role in Alzheimer's disease

Chromosome	Gene	Genetic defect or type of predisposition	Age of onset of disease (years)	Percentage of total cases of Alzheimer's disease	Molecular effect
FAD genes (autosomal dominant pattern of inheritance with, as a rule, complete penetrance)					
21	APP	Missense mutations: K670N+M671L ("Swedish"), A692G ("Flemish"), E693Q ("Dutch", phenotype: HCHWA-D), I716 V ("Florida"), V717I or G, F ("London")	Mid-50s (40–65)	<0.5% (≤20 families known, mainly V717I)	K670N+M671L and A692G: → Aβ elevated in general; I716 V and V717I (G, F): → Aβ42/43 elevated
14	PS1 (S182)	Missense mutations: at least 44 different kinds affecting 34 amino acid residues, including two splicing mutations (exons 4 and 9)	Mid-40s (24–78)	<1%–2%?, approx-20%–50% of all FAD cases	All mutations studied to date: → Aβ42/43 elevated
1	PS2 (STM2, E5–1)	Missense mutations: N141I (most cases), M239 V	Mid-50s (40–75)	<0.5%	N141I: → Aβ42/43 elevated
Susceptibility genes (risk genes)					
19	APOE	Polymorphism: ε4 allele associated with elevated risk of Alzheimer's disease (allele frequency in the normal population, 14%)	≥55	Approximately 30%–50%? (allele frequency in Alzheimer's disease)	Histopathology: → elevated β-amyloid plaque density

A role in the pathogenesis of Alzheimer's disease is certain for four genes: three familial Alzheimer's disease (FAD) genes and one susceptibility gene (APOE). Other proposed susceptibility genes whose association with the disease has not been confirmed are not listed in this table. The existence of further genes in both groups is assumed.

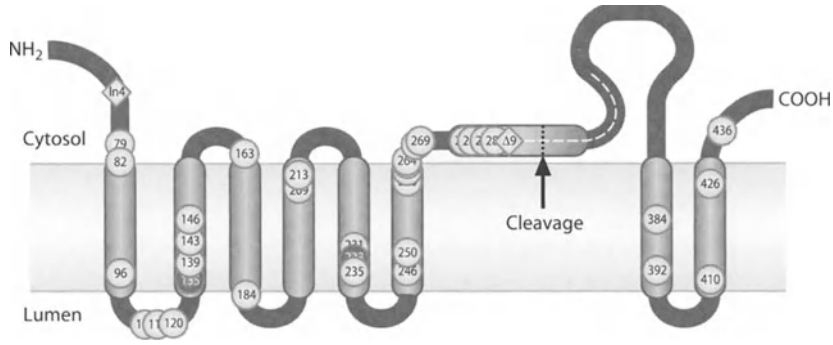

Fig. 3. Model of presenilin structure and position of the known familial Alzheimer's disease (FAD) mutations in the presenilins. *Open circles*, PS1 mutations; *cross-hatched circles*, PS2 mutations. The *Δ*exon-9 mutation (*Δ9*) in the splicing acceptor site in front of exon 9 of the PS1 gene leads to a frame-preserving deletion of exon 9 and to a missense mutation (*dotted*), while the mutation in the 5′ splicing donor region of intron 4 (*In4*) leads to shortened gene products. *Cleavage* denotes the site of proteolytic cleavage of PS1, which is thought to be similar for PS2; other processing pathways also exist

the coding region of the gene and affecting at least 34 different amino acid residues, have been identified in more than 72 families with FAD (and in two sporadic cases of Alzheimer's disease) (Fig. 3; see Table 1).

All but two of these mutations are missense mutations leading to the alteration of a single amino acid residue. One mutation is a nonsense mutation, resulting in the formation of an abnormally short gene product (Tysoe et al. 1998), and another mutation destroys the splice acceptor position before exon 9 and thereby causes a deletion without frameshift, involving a single amino acid substitution (see Fig. 3). Also worthy of mention is the recent demonstration that one particular amino acid substitution in the hydrophilic loop, E318G (exon 9), is not associated with an increased risk of developing Alzheimer's disease. This is apparently a rare polymorphism without pathological relevance (Mattila et al. 1998; Sandbrink et al. 1996b).

The average age of onset of Alzheimer's disease in patients with PS1 mutations ranges from 30 to 58 years, depending on the mutation (average, 45 years). The P117L mutation is associated with a particularly early mean age of onset (30 years); one patient even developed the disease at age 24 and died at 28 (Wisniewski et al. 1998). This mutation is located on exon 5, which encodes transmembrane domain II (see Fig. 3). Other mutations on exon 5 are also associated with a relatively early age of onset (average, approximately 40 years). Patients with the L235P mutation also tend to develop the disease at an early age (average, 32 years). All but one of these FAD-PS1 mutations (Rossor et al. 1996) have complete penetrance as far as can be determined at present. The great majority of PS1 mutations were found in only one FAD family each, so it may be safely assumed that further PS1-FAD mutations will be discovered in the future. The gene for presenilin-2 (PS2) on chromosome 1 (AD4 locus) was discovered only a short time after the discovery of that for PS1 because of the homology of these two substances (Levy-Lahad et al. 1995; Rogaev et al. 1995). Two PS2 mutations, both of the missense type, have been demonstrated in three families, at least one of which was very large. The better known of these mutations is the N141I mutation found in the so-called Volga German pedigree with an average age of onset of disease of 52 years (range, 40–85 years). This mutation is incompletely penetrant. The identification of the presenilin mutations led immediately to the question of whether these mutations, like FAD mutations in the APP gene, increase the production of Aβ42/43. That this is indeed so has been demonstrated for all FAD mutations in the presenilin genes, as for the FAD mutations in the APP gene, both in vivo (with plasma samples) and in vitro (with fibroblasts derived from FAD patients and in transfected cells) (Scheuner et al. 1996; reviews in Haass 1997; Hardy 1997; Sandbrink and Beyreuther 1996; Sandbrink et al. 1996a; Selkoe 1997). An increased amount of Aβ and, in particular, of the highly amyloidogenic protein Aβ42/43 is thus a common feature of all hitherto studied FAD mutations of the three currently known FAD genes.

4.3 Apolipoprotein E

The great majority of cases of Alzheimer's disease are of multifactorial etiology, with the participation of so-called risk or susceptibility genes. The APOE gene on chromosome 19 was identified as such a susceptibility gene in 1993 (Corder et al. 1993; Strittmatter et al. 1993a; for reviews, see Roses 1996; Sandbrink et al. 1996a), and this finding has subsequently been confirmed in a great many studies (AD2 locus). The APOE gene mainly appears as three different alleles, which are called ε2 (frequency in Europe, approximately 7%), ε3 (78%), and ε4 (15%). The corresponding gene products, designated as apoE, differ in two amino acid

residues, at positions 112 (C in E2 and E3, R in E4) and 158 (C in E2, R in E3 and E4).

The presence of the ε4 allele of APOE increases the risk of developing Alzheimer's disease, possibly in part because it lowers the average age of onset of disease. Specifically, a meta-analysis carried out several years ago of studies published up to that time revealed that the frequency of the ε4 allele of APOE in late-onset familial Alzheimer's disease is 48% (95% confidence interval, 45%–51%), and in the late-onset sporadic form 37% (confidence interval, 35%–39%), while it is somewhat lower in early-onset Alzheimer's disease (42% and 28% in familial and sporadic forms, respectively) (Van Gool et al. 1995).

It has been reported that, in LOAD families, the age of onset of Alzheimer's disease is lowered by approximately 59 years by each copy of the ε4 allele. In comparison to individuals without an APOE-ε4 allele, homozygous carriers of the APOE-ε4 gene have an approximately eightfold elevation of the risk of developing Alzheimer's disease at the age of 70 or older. Other studies yielded estimates of the relative risk of Alzheimer's disease (odds ratio) of 2.2–4.4 (in the presence of a single APOE-ε4 allele) and 5.1–17.9 (with two ε4 alleles) (for reviews, see NIA/AA 1996; Roses 1996; Sandbrink et al. 1996a).

A recent, comprehensive meta-analysis including 5930 patients and more than 8000 control subjects yielded a relative risk of developing Alzheimer's disease (odds ratio) of 14.9 (confidence interval, 10.8–20.6) in ε4/ε4 homozygotes of caucasian descent, 3.2 (2.3–3.8) in ε3/ε4 heterozygotes, and 2.6 (1.6–4.0) in ε2/ε4 heterozygotes, all of these in comparison to ε3/ε3 homozygotes (Farrer et al. 1997). Another recent study involving 310 LOAD families revealed a particularly strong effect of APOE-ε4 in the cohort between 61 and 65 years of age. Nonetheless, the influence of APOE-ε4 on the age of onset of disease, as determined by this study, is considerably less than that originally reported (Blacker et al. 1997).

Several studies provide evidence for a protective effect of the APOE-ε2 allele on the risk of developing Alzheimer's disease. The presence of APOE-ε2 not only diminishes the risk of developing the disease, but also raises the age of onset. According to the recent meta-analysis mentioned above, the relative risk in comparison to ε3/ε3 was 0.6 for both ε2/ε2 and ε2/ε3 (confidence intervals, 0.2–2.0 and 0.5–0.8, respectively). There is, however, controversy in the literature regarding the influence of the ε2 allele (for a review, see Sandbrink et al. 1996a).

According to a recent epidemiological study, carriers of the APOE-ε4 gene have an even higher risk of developing AD when arteriosclerotic changes are also present (Hofman et al. 1997). The association of the APOE-ε4 allele with arteriosclerotic changes and myocardial infarcts has been known for many years (see below); the novelty of this finding, therefore, is in the association of arteriosclerotic vascular disease and Alzheimer's disease. It must be pointed out explicitly that the APOE-ε4 "only" elevates the risk of developing the disease; more than half of all patients with Alzheimer's disease do not have even a single APOE-ε4 allele, and only some of the carriers of the ε4 gene are actually affected by the disease.

Like the FAD mutations, the various alleles of apolipoprotein E also seem to modulate the metabolism of Aβ. The principal piece of evidence for this is the multiply replicated finding of an association of the APOE-ε4 allele with the number and density of Aβ deposits in the brain (Rebeck et al. 1993; Schmechel et al. 1993). Biochemical studies suggest that the Alzheimer's disease-promoting effect is based not on altered production of Aβ, as in the case of the FAD mutations, but rather on increased aggregation or lessened degradation of Aβ (see below). Assuming that apoE has a "chaperone" function, it is conceivable that reduced binding of Aβ to apoE4 promotes the development of the disease, as has been suggested on the basis of in vitro studies (see below; Strittmatter et al. 1993b). In any case, several studies have shown that the overwhelming majority of patients with sporadic Alzheimer's disease do not have increased plasma concentrations of Aβ42/43 (e.g. Ida et al. 1996; Motter et al. 1995).

A recent study revealed that a certain variant of the APOE promoter, based on a polymorphism at position 491 of the APOE gene, seems to be associated with an increased risk of developing Alzheimer's disease, regardless of APOE genotype (ε2, ε3, or ε4) (Bullido et al. 1998). Because this variant is associated with increased expression of the APOE gene, this finding indicates a relationship between apoE formation and the risk of developing Alzheimer's disease. According to another study, a certain variant of another APOE promoter polymorphism is also associated with an increased risk of Alzheimer's disease (Lambert et al. 1998). The results of these studies accord with the observation that the development of amyloid pathology is significantly delayed in APOE knockout mice ($APOE^{-/-}$) that are simultaneously transgenic for the human V717I FAD mutation of the APP gene (see below; Games et al. 1995), as compared to transgenic control animals (Bales et al. 1997).

4.4 Other Possible Susceptibility Genes, Including Mitochondrial Mutations

Several genes other than APOE have been proposed in recent years as possible susceptibility genes, including

the A allele of the α_1-antichymotrypsin gene (ACT-A) and the five-repeat allele of the very low density lipoprotein (VLDL) receptor gene VLDL-R; the general validity of these proposed associations has not yet been conclusively proved. The HLA-A2 gene also seems to be associated with early onset of the disease (for a discussion, see Sandbrink et al. 1996a). Great interest was aroused by the observation that one of two alleles of a polymorphism in intron 8 of the PS1 gene seems to be associated with an increased risk of Alzheimer's disease (Wragg et al. 1996), but this finding could not be replicated in subsequent studies. More recently, an association of the K variant of the butyrylcholinesterase gene with an increased risk of LOAD was reported (Lehmann et al. 1997), as was a possible association between a particular allele of the bleomycin hydrolase gene and Alzheimer's disease (Montoya et al. 1998).

Very recent results confirming the presence of a long-conjectured relationship between Alzheimer's disease and certain mitochondrial mutations are particularly noteworthy (Davis et al. 1997). The abnormally low level of cerebral energy metabolism in Alzheimer's disease has been recognized for years (for a review, see Hoyer 1998). It has now been reported that patients with Alzheimer's disease have a significantly higher frequency of specific mutations of two mitochondrial genes, CO1 and CO2, that code for the catalytic center of cytochrome oxidase and, further, that these mutations occur simultaneously in most cases (Davis et al. 1997). More than 20% of mitochondrial genomes were in the mutated form in more than 60% of the patients with Alzheimer's disease who were studied, while such a high percentage of mutated mitochondrial genomes was found in only 20% of the control subjects. It was shown in vitro that these mutations cause dysfunction of the respiratory chain, one of whose effects is the increased production of free oxygen radicals (Davis et al. 1997). Such free radicals have long been suspected to participate in the pathogenesis of Alzheimer's disease, because they promote Aβ aggregation in vitro and, furthermore, in vitro experiments have revealed increased formation of APP as a result of an abnormality of cytochrome oxidase (see below).

Studies performed even more recently, however, indicate that the association reported by Davis and colleagues can be attributable to an artificial contamination of mitochondrial DNA preparations with nuclear DNA, which contains the sequences of certain CO1 and CO2 pseudogenes (Hirano et al. 1997; Wallace et al. 1997). The validity of the reported association of Alzheimer's disease with mitochondrial mutations has thus been put in doubt and requires further clarification.

5 β-Amyloid Cascade Hypothesis

The identification of FAD mutations in the APP gene was the first demonstration that a genetic alteration of the precursor protein of Aβ suffices to produce Alzheimer's disease (in its autosomal dominant hereditary form). In view of the facts that Aβ deposition is a typical feature of Alzheimer's disease, and that amyloid pathology is also regularly present in combination with dementia in Down's syndrome (trisomy 21, see above), the hypothesis of the so-called Aβ cascade was developed. According to this hypothesis, the formation and/or deposition of Aβ in Alzheimer's disease is thought to lead, by way of a complex pathological cascade, to neurodegeneration, and ultimately to the clinical picture of dementia (Hardy and Allsop 1991; for reviews, see Haass 1997; Hardy 1997; Sandbrink and Beyreuther 1996; Sandbrink et al. 1996a; Selkoe 1997).

As discussed above, molecular biological analysis of the various FAD mutations of the APP gene revealed that the common feature of these mutations is an increased production of the long form of APP, namely, Aβ42/43; its production is either selectively increased, as in the London and Florida mutations, presumably because of increased γ-secretase cleavage (Eckman et al. 1997; Suzuki et al. 1994), or else increased in tandem with increased production of all forms of Aβ, as occurs in the Swedish mutation because of increased β-secretase cleavage (Cai et al. 1993; Citron et al. 1992) and in the Flemish mutation because of decreased α-secretase cleavage (Haass et al. 1994). The Aβ cascade hypothesis was therefore modified to include the formation of Aβ42/43 as the decisive pathogenetic factor (Younkin 1995). The characterization of the presenilin mutations then showed that, to the extent that they have been studied, these mutations also lead to increased formation of Aβ42/43 both in vivo (plasma samples) and in vitro (in fibroblasts from FAD patients and in transfected cells) (Scheuner et al. 1996), as the Aβ cascade hypothesis would predict. Increased formation of Aβ and, in particular, of its strongly amyloidogenic form Aβ42/43 has thus been found in all hitherto studied FAD mutations of the three currently known FAD genes.

According to the Aβ cascade hypothesis, overexpression of Aβ42/43 in mice might also be expected to produce pathological changes similar to those of Alzheimer's disease. Corresponding transgenic animal models have, in fact, been established in the last few years, after many unsuccessful earlier attempts. Extensive amyloid deposition was demonstrated in the brains of a transgenic mouse line (the Athena exemplar

mouse) carrying an APP minigene (APP-cDNA, including abbreviated segments of introns 6, 7, and 8) with the V717F mutation under control of the PDGF promoter, in which there is an approximately fivefold overexpression of APP messenger RNA (APP-mRNA) [80% Kunitz protease inhibitor (KPI)-APP] (Games et al. 1995). It is not yet known with certainty whether these mice are behaviorally abnormal. Remarkably, they seem not to have neurofibrillary tangles, but they do have a certain degree of tau pathology in some of the plaques and in the neuropil (Games et al. 1995; Irizarry et al. 1997).

Extensive age-dependent amyloid deposition and a marked elevation of Aβ concentrations in the brain were also found in another transgenic mouse line (Tg2576), which expresses APP695sw (APP695 with the Swedish double FAD mutation) under control of the prion promoter (Hsiao et al. 1996). In these mice, too, neuritic plaques with reactive astrocytes and microglia seem to be present at 12 months (Frautschy et al. 1998), and they also develop memory deficits (Holcomb et al. 1998; Hsiao et al. 1996). Similar constructs in another murine strain (FVB) led to marked APP expression, severe neurological deficits, and death at the age of approximately 6 months in the absence of any demonstrable amyloid deposition (Hsiao et al. 1995). These findings suggest, and breeding experiments have since confirmed, that there are genetic factors in the murine genome that appear to modulate the formation and deposition of amyloid and the type of neurological manifestations produced.

A further FAD-APP transgenic mouse with severe amyloid pathology was recently described, the Sandoz mouse, which expresses APP751sw (APP751 with the Swedish double FAD mutation) under the control of a Thy1 promoter (Sturchlerpierrat et al. 1997). In all of these successful transgenic "murine models of Alzheimer's disease," the critical factor for the generation of amyloid pathology – aside from the use of a strain of mice with the right genetic background – is the adequate expression of the constructs, which is associated with extensive production of Aβ, in accordance with the amyloid cascade hypothesis.

The elevation of Aβ42/43 in the presenilin FAD mutations, which has been observed both in patients and in transfected cells (see above), was also demonstrated in corresponding transgenic mouse lines, which express PS1 with either the A246E mutation (Borchelt et al. 1996) or the M146L mutation (5.1 line; Duff et al. 1996). Both of these lines, however, lack amyloid pathology at any age studied to date, despite the elevation of Aβ42/43. A doubly transgenic mouse line obtained by crossing the 5.1 line with the Tg2576 line, which is transgenic for APP695sw (see above), was found to have a greater elevation of Aβ42/43 production than either of the singly transgenic lines. This was associated with a more rapid development of amyloid pathology than in the Tg2576 line and also with more pronounced behavioral abnormalities, although no neurofibrillary tangles were found at any age studied to date (Holcomb et al. 1998).

The same was demonstrated for the second mouse line named above; here, too, it was found that doubly transgenic mice expressing both FAD-PS1-cDNA with the A246E mutation and a chimeric murine/human FAD-APP construct with the Swedish mutation develop amyloid pathology significantly earlier than corresponding control animals that express either APP Swedish with wildtype PS1 or only the APP Swedish construct (Borchelt et al. 1997).

The Aβ cascade hypothesis receives further support from findings documenting the neurotoxicity of Aβ42/43, although it is unclear whether its important neurotoxic effects in vivo are actually of the same type (see below). In view of the molecular genetic findings, the Aβ cascade hypothesis is widely accepted today, at least for the familial form of Alzheimer's disease (FAD), even if it is perhaps a simplistic model of the pathogenesis of the disease. The literature does, however, contain discussion of other mechanisms of FAD pathogenesis, which will be dealt with further below.

Moreover, the validity of the Aβ cascade hypothesis in this simple form for the much more common, multifactorially based form of Alzheimer's disease is debated; the pathogenesis of these cases is presumed to be much more complex. It will, therefore, be necessary for us to discuss the molecular biology and cellular biology of APP and Aβ in detail in what follows and thereafter to describe the present state of understanding of further molecules that may be of importance in pathogenesis (presenilin, apolipoprotein E, tau etc.).

6
β-Amyloid and Amyloid Precursor Protein

6.1
Structure and Expression of Amyloid Precursor Protein

APP is a glycoprotein with a receptor-like structure consisting of a large N-terminal domain, a single transmembrane domain, and a short intracytoplasmic C-terminal segment (Dyrks et al. 1988; Kang et al. 1987; see Fig. 2). The Aβ sequence is 39–43 amino acids long; approximately one third of it lies in the transmembrane domain and the rest in the N-terminal ectodomain (see Fig. 2). The latter is characterized by

(proceeding from the N-terminal) a rather large region rich in cysteine lying behind the signal peptide and an acidic domain.

Alternative splicing of three of a total of 18 exons (7, 8, and 15) of the APP gene results in the production of APP in eight different isoforms (Sandbrink et al. 1994a), which are named in accordance with their length in amino acid residues. Neurons which show a particularly marked expression of APP predominantly produce APP695, which was the first APP isoform to be identified (Kang et al. 1987). APP695 was later shown not to contain the regions encoded by exon 7 (the KPI domain) and exon 8 (see Fig. 2). Non-neuronal cells, in contrast, predominantly produce APP isoforms that do possess the KPI domain (Kitaguchi et al. 1988; Ponte et al. 1988; Tanzi et al. 1988); the most important of these are the isoforms APP770 (with exons 7 and 8) and APP751 (with exon 7, but without exon 8), and also the two isoforms L-APP752 and L-APP733, which lack the region encoded by exon 15 (Sandbrink et al. 1994a).

APP isoforms without exon 15 are referred to as L-APP because they were first found in leukocytes and microglia (Konig et al. 1992). These L-APP isoforms can sometimes account for more than 50% of the total APP-mRNA in rat tissue, but they are not produced in neurons, as far as is known (Sandbrink et al. 1994a). Interestingly, it has been found in vitro that the L-APP isoforms are less amyloidogenic than APP695, which is produced mainly by neurons, possibly because of a difference in intracellular sorting (Hartmann et al. 1995). This effect appears to be independent of an L-APP-specific post-translational modification that is enabled by the formation of an ENE-GSG fusion sequence in the absence of the segment encoded by exon 15 (Pangalos et al. 1995a,b; Sandbrink et al. 1995; Thinakaran et al. 1995). This modification creates a recognition signal for a xylosyltransferase that can specifically modify L-APP by the addition of chondroitin sulfate moieties to proteoglycans; the L-APP thus produced is also designated appican (Pangalos et al. 1995a,b).

APP is ubiquitously expressed, with a strongly tissue-dependent distribution of its different isoforms (Sandbrink et al. 1994a). The APP gene thus possesses the characteristic features of a housekeeping gene, in accordance with the absence of a TATA box in the APP promoter (Salbaum et al. 1988). The promoter does contain several stress-responsive elements, including two binding sequences for the transcription factor NF-κB (Grilli et al. 1995; Salbaum et al. 1988). The latter probably form the basis for the induction of APP-mRNA expression, as has been observed in vivo in astrocytes and microglia, e.g. after ischemic lesions or axotomy (e.g. Banati et al. 1993, 1995; Siman et al. 1989).

6.2 Amyloid Precursor Protein Gene Family

APP is only one member of a family of genes displaying remarkable similarities in domain structure and also, to some extent, in alternative splicing. The APP gene family further includes the two APP-like proteins APLP1 and APLP2, which do not, however, contain the Aβ sequence; the different members of the APP gene family differ strongly from each other in this segment (the divergent domain), which lies N-terminal to the transmembrane region. APLP1 and APLP2 do, however, show close homology in their cysteine-rich domains and "acidic" domains as well as in their cytoplasmic portions. The APLP1 gene lacks exons corresponding to exons 7 and 8 of APP and therefore exists in only a single neuronally expressed isoform (Paliga et al. 1997; Wasco et al. 1992).

APLP2 resembles APP more closely than APLP1 does, not only in the extent of its homology to APP (Sprecher et al. 1993; Wasco et al. 1993), but also with respect to alternative splicing (Sandbrink et al. 1994b). The APLP2 gene possesses an alternatively spliced KPI exon (exon 7), although an exon corresponding to exon 8 is lacking. It is noteworthy that a portion of the divergent domain of APLP2 is encoded by an exon that is alternatively spliced in a tissue-dependent manner, like exon 15 of APP. Despite major differences in the sequence of this segment, an ENE-GSG fusion sequence appears in the L-APLP2 isoforms, as in the L-APP isoforms, that can serve as a recognition sequence for a xylosyltransferase (Sandbrink et al. 1995).

6.3 Amyloid Precursor Protein Processing: Secretory Amyloid Precursor Protein and β-Amyloid

APP undergoes numerous post-translational modifications in the endoplasmic reticulum and the Golgi apparatus, including sulfation and glycosylation in the ectodomain region N-terminal to the divergent region (Weidemann et al. 1989; see Fig. 2). Moreover, phosphorylation of APP has been described, not only in the N-terminal ectodomain (Hung and Selkoe 1994), but also in the cytoplasmic segment, in which there are several potential phosphorylation sites (Caporaso et al. 1992).

It was found quite early in the characterization of APP metabolism that APP is proteolytically cleaved N-terminal to the transmembrane domain; corresponding soluble derivatives of APP were demonstrated both in cell culture medium and in vivo (Weidemann et al. 1989). These derivatives are known

as secretory APP (APP_S or sAPP). Because sAPP does not contain the Aβ sequence (at least not completely), it is not a precursor of Aβ. It has been shown that sAPP is typically produced by proteolytic cleavage in the region of lysine 16 of the Aβ sequence, i.e. within the Aβ sequence (Esch et al. 1990).

This cleavage is catalyzed by a protease that has not yet been identified, which is provisionally designated α-secretase. The sAPP derivatives thus produced are correspondingly designated sAPPα. This α-secretase cleavage in the midst of the Aβ sequence prevents the proteolytic liberation of Aβ, which could then be deposited in aggregated form in the senile plaques; it is therefore referred to as the non-amyloidogenic metabolic pathway. The α-secretase cleavage apparently occurs during the transport of APP from the endoplasmic reticulum, via the Golgi apparatus and secretory vesicles, to the plasma membrane, i.e. in the course of the classical secretory metabolic pathway. α-Secretase may, in fact, be a group of several proteases that catalyze proteolysis at certain distances from the cell membrane in a manner largely independent of sequence (Maruyama et al. 1991). In any case, the Flemish FAD mutation referred to above is associated with diminished α-secretase cleavage (Haass et al. 1994).

There must, however, be a second, amyloidogenic metabolic pathway in addition to the nonamyloidogenic degradation of sAPP by α-secretase cleavage. Indeed, it was shown in 1992 that Aβ peptides are produced under physiologic conditions not only in vivo, but also in vitro (Haass et al. 1992a,b; Seubert et al. 1992; Shoji et al. 1992). The as yet unidentified one or more proteases that cleave Aβ in its N-terminal region are provisionally designated β-secretase, and the soluble APP derivatives thus formed are correspondingly designated sAPPβ. In a further step, the potentially amyloidogenic C-terminal derivatives can then be proteolytically cleaved in the C-terminal region, so that the intact Aβ molecule is released. Aβ molecules of different lengths are formed, varying between 39 and 43 amino acid residues long (see Fig. 2). The one or more proteases responsible for this step, the so-called γ-secretase(s), can also further cleave the C-terminal APP derivative formed by α-secretase cleavage, with resulting release of p3 peptide, whose molecular weight (MW) is approximately 3000 (for reviews, see Evin et al. 1994; Haass and Selkoe 1993; Selkoe 1994).

The soluble Aβ and p3 produced in this way were first demonstrated in cell culture media and in body fluids (Haass et al. 1992a,b; Seubert et al. 1992; Shoji et al. 1992). This Aβ turned out to be predominantly Aβ40, i.e. the shorter form of Aβ. The site of production of this secreted Aβ was then found to be a cellular compartment of low pH. It was inferred that APP is degraded by an endosomal-lysosomal pathway: APP molecules of the full length and potentially amyloidogenic C-terminal APP fragments produced by β-secretase cleavage, as well as no longer amyloidogenic APP fragments produced by α-secretase cleavage, are reinternalized from the cell surface and cleaved in an acidic intracellular compartment (by γ-secretase); the Aβ and p3 thus released are then newly secreted (Haass et al. 1992). The reinternalization of APP is probably mediated by an NPXY motif in the cytoplasmic segment of APP, which is also present in many cell surface receptors, e.g. the low density lipoprotein (LDL) receptor, and effects endocytotic uptake in clathrin-coated vesicles, followed by further processing in the endosomal-lysosomal metabolic pathway.

It was recently shown that large amounts of Aβ are present within cells as well, mainly in neurons (Tienari et al. 1997). The Aβ in question here is predominantly the "long" Aβ42/43 molecule, while Aβ40 is found in neurons in much smaller amounts than in non-neuronal cells. This intraneuronal Aβ42/43 in formed mainly in the endoplasmic reticulum, while intraneuronal Aβ40 is produced mainly in the Golgi apparatus and the trans-Golgi network (TGN) (Cook et al. 1997; Hartmann et al. 1997; Wild-Bode et al. 1997). Thus, in neurons (the cells that are damaged by Alzheimer's disease and that also have the most pronounced expression of APP in vivo), the highly amyloidogenic Aβ42/43 is produced in the same cellular compartment as that in which the presenilins are localized.

6.4 Regulation of Amyloid Precursor Protein Processing

A large number of studies document that the proteolytic processing of APP is regulated by numerous physiological and pathophysiological factors. For example, it has been shown that α-secretase cleavage is induced in PC12 cells by acetylcholine and after membrane depolarization (Nitsch et al. 1992). The increase in sAPPα production was more pronounced in NGF-differentiated PC12 cells, in accordance with the increased expression of both muscarinic receptors and APP itself in cells of neuronal phenotype (Haring et al. 1995). The production of sAPPα was similarly induced by electrical stimulation in cultured adult rat hippocampal slices, and maximal production was obtained under conditions considered optimal for the induction of long-term potentiation (LTP) (Nitsch et al. 1993).

The activation of metabotropic glutamate receptors also induces the production of sAPPα in hippocampal cultures (Lee et al. 1995). Induction of sAPPα release was similarly demonstrated for other receptor types

that are intracellularly coupled to the activation of the phospholipase C-dependent signal transduction pathway, i.e. the hydrolysis of phosphatidylinositol-4,5-diphosphate. In accordance with these findings, it had been previously been found that activators of protein kinase C, such as phorbol ester, have similar effects (Buxbaum et al. 1990). As shown by a recent study involving C6 glioma cells, the protein kinase C-dependent induction of sAPPα production and also basal sAPPα production can be inhibited by a high concentration of cyclic amino monophosphate (cAMP) (Efthimiopoulos et al. 1996).

These and other findings reveal that there are complex, phosphorylation-dependent regulatory mechanisms of APP processing. It appears, however, that these mechanisms do not depend upon phosphorylation of APP itself in the region of its cytoplasmic domain, because the effects described above also occur in the presence of a deletion of the cytoplasmic domain (Efthimiopoulos et al. 1996; Hung and Selkoe 1994) or of mutation of the phosphorylation sites that have been discussed (Efthimiopoulos et al. 1994; Jacobsen et al. 1994).

APP processing is also influenced by growth factors and cytokines. It was thus shown that nerve growth factor (NGF) and epidermal growth factor (EGF) induce sAPPα production in PC12 cells (Refolo et al. 1989). In general, factors promoting the production of sAPPα also appear to have neurotrophic effects, e.g. lengthening neuronal life span in vitro or promoting the growth of neurites. These effects are possibly due to the action of sAPPα itself (see below).

In many of these studies, it was found (insofar as the matter was studied) that the induction of sAPPα production was associated with a reduction of Aβ production, and vice versa. Thus the effect of protein kinase C activation on APP processing described above involved not only the induction of sAPPα production, but also reduced formation of Aβ (Hung et al. 1993; Jacobsen et al. 1994). Environmental influences, too, may act similarly; it was shown, for example, that glucose deprivation leads both to increased release of Aβ into the medium and to lessened formation of sAPPα (Gabuzda et al. 1994).

Conditions have also been described, however, under which both sAPPα formation and Aβ production are induced; this is the case when the intracellular calcium concentration is elevated by means of ionophors, for example (Buxbaum et al. 1994; Querfurth and Selkoe 1994). As intracellular calcium concentration can also be elevated by phospholipase C activation, this may provide a mechanism for protein kinase C-independent regulation of APP processing, through the appropriate receptors.

It must be emphasized that the studies published to date have all concerned the release of sAPPα and Aβ into medium. This fact alone should lead us to expect a more or less reciprocal relationship, because secreted Aβ seems to be formed predominantly by the endosomal–lysosomal pathway, which presumably requires endocytosis of the plasma membrane and can therefore no longer lead to Aβ production after α-secretase cleavage of APP. Such a reciprocal relationship need not exist, however, for intraneuronally formed Aβ42/43 and α-secretase. It does seem likely that conditions leading to a slowing of the passage of APP through the endoplasmic reticulum, for example, may be linked to increased production of Aβ42/43 and, simultaneously, to decreased formation of sAPPα (see Wild-Bode et al. 1997). For most of the experimental conditions referred to above, however, the corresponding studies have yet to be performed.

An inverse relationship of this sort between the formation of Aβ42/43 and of sAPPα does, in fact, appear to be present for the known FAD mutations of the APP gene; thus the Swedish FAD mutation also leads to decreased production of sAPPα (Cai et al. 1993; Citron et al. 1992), and similar findings were made for the London FAD mutation (Suzuki et al. 1994).

6.5 Amyloid Precursor Protein Function

The ubiquitous expression of APP indicates that this protein has a very basic function. It is quite conceivable that there is a spectrum of functional activity that depends on the APP isoform and post-translational modifications and, above all, on cell type. It may further be suspected that the transmembrane isoforms of APP and its secretory derivatives (sAPP) have distinct functions, and the possibility of a biological function for Aβ itself has also been discussed (for a review, see Mattson 1997).

Knockout mice whose APP genes have been inactivated ($APP^{-/-}$) have been used to show that lack of the APP gene in mice is associated with only mild neurological deficits at first, including reduced locomotion and gliosis (Zheng et al. 1995). At the age of approximately 7 months, there are cognitive deficits (revealed by the Morris water maze test) and a loss of synapses, and the average life expectancy is reduced (Zheng et al. 1995). Delayed neurite formation and shortened survival times have been described for in vitro cultured hippocampal neurons from these $APP^{-/-}$ mice, and even wild-type neurons in the vicinity of astrocytes from these $APP^{-/-}$ mice showed reduced axon growth and increased dendritic branching (Perez et al. 1997).

The relatively mildly affected phenotype of $APP^{-/-}$ mice probably results from a partial functional substi-

tution for APP by other members of the APP gene family, mainly APLP2, and vice versa (see above); thus APLP2 knockout mice ($APLP2^{-/-}$) also have a mildly affected phenotype, while approximately 80% of double knockout mice ($APP^{-/-}$ und $APLP2^{-/-}$) die in the first week of life, and the surviving 20% have marked neurological abnormalities (von Koch et al. 1997).

The actual function of APP, however, has not yet been precisely characterized. In general, a regulatory role of APP in cell–cell and cell–matrix interactions, in neurite growth, and, possibly, as a transient cell surface receptor is assumed. Such a function would also accord well with the ligand-binding properties of APP and the high degree of APP expression in stimulated, adhesive lymphocytes as well as in activated microglia. In the corresponding resting, nonadhesive cells, no APP expression is detectable.

These and other findings have led to the hypothesis that APP may function in the context of wound healing and repair processes. In neurons, which express APP constitutively in large amounts, APP has been found not only in perikarya but also in axons, dendrites, and synapses. APP is located both in the presynaptic membranes of the axons and in the postsynaptic membranes of the dendrites (Schubert et al. 1991). It appears that APP does not participate in the release of neurotransmitters or their binding to receptors, but, rather, plays a role in the maintenance, repair, and stabilization of synaptic contacts.

A receptor function for APP was suggested as soon as it was cloned, because of its structure as a glycoprotein with a single transmembrane domain (Kang et al. 1987). In accordance with such a function, APP is localized at the cell surface and reinternalized into the endosomal–lysosomal metabolic pathway in a manner mediated by the above-mentioned NPXY sequence; all of these features also characterize the LDL or EGF receptor, for example. Although a number of binding partners for APP have been suggested (as discussed below), a ligand internalized in this manner has not, as yet, been demonstrated.

If APP is to function as a cell surface receptor, coupling to an intracellular signal transduction pathway must also be postulated. It has been suggested that APP might activate the $G_{(0)}$ protein (Nishimoto et al. 1993). This observation in fact leads to an alternative model of Alzheimer's disease pathogenesis, in addition to the amyloid cascade hypothesis; there is evidence that FAD-APP (APP695 with the London mutation) effects a constitutive activation of the $G_{(0)}$ protein in neurons (Okamoto et al. 1996). This might, in turn, induce a predominantly negative transactivation of the cAMP-responsive element (CRE) (Ikezu et al. 1996) and/or a fragmentation of nucleosomal DNA mediated by the $G_{(0)}$ protein (Yamatsuji et al. 1996), as has been observed in apoptosis.

With respect to a possible receptor function of APP, it is also of interest that newly synthesized APP in neurons is transported first into the axons and then from the axons into the dendrites (Simons et al. 1995). The existence of this process, which is known as transcytosis, implies that APP might be able to bind to substances on the surface of axons and then transport them into the cell and to the dendritic surface. Substances that bind to APP and are possibly transported by it include very large molecules of the extracellular matrix, such as collagen and heparin sulfate proteoglycans, and also the two metal ions copper and zinc (Bush et al. 1993; Multhaup et al. 1996). The latter participate as cofactors in many important biological reactions, including the regulation of transcription, wound healing and repair processes, and the defense against reactive oxygen radicals. In the brain, disturbances of zinc and copper ion metabolism lead to severe impairments of neuronal function. It is of particular interest in this connection that it is precisely the Aβ domain of APP that is responsible for the (initial) axonal sorting (Tienari et al. 1996).

The neurotrophic activity of APP and its derivatives, already mentioned in the context of $APP^{-/-}$ knockout mice, has been documented many times. In PC12 cells, for example, both transmembrane APP and sAPP cause increased neurite growth (Milward et al. 1992). In another study, a corresponding effect of sAPP on neuroblastoma cells was traced to a particular region of the molecule (RERMS sequence, amino acids 328–332) (Jin et al. 1994). In the case of transmembrane APP, the promotion of neurite growth may be due to the already mentioned cell adhesion function of APP, which has been repeatedly demonstrated (see e.g. Schubert et al. 1989; Small et al. 1994). The binding of APP to molecules of the extracellular matrix has also been investigated and more precisely characterized in many studies (e.g. Kibbey et al. 1993; Multhaup 1994; Narindrasorasak et al. 1991). Interestingly, the biosynthesis of APP is also influenced through the extracellular matrix (Monning et al. 1995).

Modulation of the intracellular concentration of calcium has been discussed as a possible mechanism for the neurotrophic activity of sAPP, i.e. its promotion of neurite growth and synapse formation. The intracellular calcium concentration of hippocampal neurons in vitro was relatively reduced when sAPP was present, both in the resting condition and in the presence of glutamine-induced calcium inflow (Mattson et al. 1993b). It is suspected that sAPPα limits in this way the rise of intracellular calcium concentration that is responsible for the neurotoxic effect of Aβ (discussed above). In any case, sAPPα seems to protect neurons from Aβ toxicity and other oxidative injuries (Goodman and Mattson 1994). At

the same time, the intracellular calcium concentration also influences APP processing (see above), so complex feedback mechanisms are probably operative. The relationship of APP and its derivatives to calcium homeostasis, and other possible functions of APP, were recently discussed in an extensive review article (Mattson 1997).

In view of the fact that increased Aβ production is often associated with reduced sAPPα production, as discussed in Sect. 6.2, while sAPPα has a neuroprotective effect against a great many damaging processes, including Aβ toxicity (discussed below), many authors have concluded that a reduction of sAPPα itself figures importantly in the pathogenesis of Alzheimer's disease (for a review, see Mattson 1997). Reduced formation of sAPPα was seen in the FAD-APP mutations (see above), so such a mechanism is quite conceivably relevant to the pathogenesis of FAD as well.

The isoforms of APP that contain KPI domains are naturally thought to possess a corresponding function as protease inhibitors. This might be of importance in blood coagulation, for example, as factor IXa is inhibited by KPI-APP (APP770 and APP751) (Mahdi et al. 1995). The secretory derivatives of APP751 (sAPP751) are identical with the protease nexin II and are present as such in high concentration in platelet α-granules, which are secreted during platelet activation (Van Nostrand et al. 1991).

6.6 β-Amyloid Aggregation and Neurotoxicity

According to the amyloid cascade hypothesis, "short" Aβ40 and "long" Aβ42/43 differ considerably in their pathogenetic significance. The physicochemical properties of these two substances are such that Aβ42/43 has a markedly greater tendency toward aggregation. In general terms, it may be suspected that the driving force for the aggregation of Aβ protein into Aβ filaments, of which amyloid plaques are composed, lies in a change of conformation of regions of the Aβ protein that participate in polymerization. As an integral component of APP, this region of Aβ probably has an α-helical structure, while the amyloid filaments in aggregates take the form of a β-pleated sheet. These aggregates are insoluble, and the continued deposition of Aβ eventually leads to the formation of amyloid plaques, which consist of a multitude of such filaments, and are a pathological hallmark of Alzheimer's disease.

It is still not adequately known what factors in Alzheimer's disease provoke the aggregation of Aβ, which is clearly also formed under "normal" conditions, or how these factors may be reinforced. Relevant factors other than the above-mentioned production or impaired degradation of Aβ might include conformation-altering influences. The possible participation of radicals and pathological chaperones in such processes has also been discussed. It has been shown that reactive oxygen compounds can lead to the aggregation of synthetic Aβ protein in vitro (Dyrks et al. 1992). As aggregated Aβ also induces the formation of reactive oxygen radicals – as will be discussed – the possibility exists of a pathogenetically relevant positive feedback mechanism.

The most recent findings concerning the presence of mitochondrial mutations in patients with Alzheimer's disease, and the effect of antioxidants such as tocopherol (vitamin E) and estrogen, support the hypothesis that radicals play an important role in the pathogenesis of Alzheimer's disease. The disease-promoting effect of the E4 form of apolipoprotein E may also be due to a mechanism involving free radicals. A possible chaperone function has also been proposed for apolipoprotein E4 and other proteins, in which these proteins dispose of Aβ in the brain only in the reduced form. Their aggregation-promoting effect might then also be manifest in the setting of an elevated concentration of (free) Aβ, as will be discussed in the next section.

The observation that Aβ is produced in vivo and released by cells cultured in vitro into the culture medium, even under nonpathological conditions, led to the performance of many studies on the question of whether extracellular Aβ has a toxic effect on neurons (for reviews, see Iversen et al. 1995; Mattson 1997; Yankner 1996). In fact, such Aβ toxicity has been repeatedly found, but not in all studies. Later studies revealed that only the aggregated, fibrillary Aβ seems to be toxic and may even induce the formation of hyperphosphorylated tau (see below). This might provide an explanation for the stronger neurotoxic activity of the "long" Aβ42/43 in comparison to Aβ40, in accordance with the "simplest form" of the amyloid cascade hypothesis, which holds that it is the excessive quantities of aggregated Aβ42/43 in the extracellular space that cause toxic injury to neurons and, thereby, the neurodegeneration of Alzheimer's disease. The toxic effect may be due to an elevation of intraneuronal calcium concentration, which is attributed to the irreversible opening of non-*N*-methyl-D-aspartate (non-NMDA) calcium channels (Blanchard et al. 1997; for reviews, see Behl 1997; Mattson 1997; Mattson et al. 1993a).

In many studies, which are discussed in these reviews in greater detail, it was shown that aggregated Aβ induces oxidative stress in vitro, which appears to be associated primarily with an accumulation of hydrogen peroxide (H_2O_2) and membrane lipid oxidation (Behl et al. 1994; Harris et al. 1995). This oxidative stress and/or the possible activation of the RAGE receptor by Aβ (see below) might, in turn, result in the induction of the transcription factor NF-κB, for which a role in the

generation of neurodegenerative illnesses has long been hypothesized (Kaltschmidt et al. 1993) and whose transcription in vivo in fact appears to be activated in the neighborhood of amyloid plaques (Kaltschmidt et al. 1997). This factor might also release a pathogenetically relevant positive feedback mechanism by way of an elevation of APP expression, because corresponding elements are present in the APP promoter (Grilli et al. 1995). Increased neuronal transcriptional activity of NF-κB may have a neuroprotective effect, however, in that it counteracts oxidative stress and is, furthermore, anti-apoptotic (Barger and Mattson 1996; Lezoualc'h et al. 1998), so that the role of NF-κB in the pathogenesis of Alzheimer's disease currently remains unclear (for reviews, see Lezoualc'h and Behl 1998; O'Neill and Kaltschmidt 1997).

It is unclear whether such an extracellular toxic effect of Aβ, and particularly Aβ42/43, is actually relevant in vivo. In view of the micromolar concentrations used in most in vitro experiments on Aβ toxicity, it may be suspected that the local extracellular Aβ concentration in vivo is probably not high enough to have a toxic effect. Microglial cells, however, may function as mediators of Aβ toxicity in vivo, in that extracellular Aβ may stimulate them to release toxic radicals, etc. On the molecular level, specific binding of Aβ to the scavenger receptor of microglia (Elkhoury et al. 1996; Paresce et al. 1996) and/or to the receptor for advanced glycation end products (RAGE; Yan et al. 1996) has been proposed recently; binding of this type might lead, among other effects, to the above-mentioned activation of NF-κB and formation of reactive oxygen radicals. Perhaps this will explain the apparent protective effect of nonsteroidal anti-inflammatory drugs (NSAID) against Alzheimer's disease (Breitner 1996).

It is also worth noting that there appears to be no correlation between the extent of the increase of Aβ and the typical age of onset of illness in a particular FAD mutation, even though, in accordance with this model, an increase of extracellular Aβ42/43 has indeed been found, both in vitro and in vivo, in all FAD mutations. In view of the exclusively intracellular localization of the presenilins, intracellular Aβ may actually be the factor responsible for neurodegeneration; this would, of course, represent a deviation from the simple form of the amyloid cascade hypothesis. As described above, hippocampal neurons in vitro produce large quantities of Aβ42/43 intracellularly (Hartmann et al. 1997; Tienari et al. 1997). It may, therefore, be suspected that the corresponding intracellular compartments contain Aβ42/43 in much higher concentrations than the extracellular space. This Aβ42/43 could then fold into a β-pleated sheet structure within the neuron and interfere with its function. Under certain circumstances, however, it is precisely the still soluble low molecular weight aggregates (e.g. dimers, trimers) that are particularly active in this respect (for a discussion, see Sandbrink and Beyreuther 1996; Wild-Bode et al. 1997).

It should be pointed out once again in this connection that elevated plasma levels of Aβ42/43 are generally not found in patients with sporadic Alzheimer's disease (Ida et al. 1996). Younkin and colleagues found elevated Aβ42/43 levels in only about 10% of such patients studied (Scheuner et al. 1996). This finding, too, is consistent with an intracellular but not extracellular rise in Aβ42/43 concentration (Sandbrink and Beyreuther 1996).

6.7 A Physiological Function of β-Amyloid?

It remains unclear at present whether free Aβ protein has a physiological function or is "merely" a waste product of APP metabolism that takes on pathogenetic significance in high concentration. Furthermore, "short" Aβ40 and "long" Aβ42/43 might possibly have different functions.

A possible physiological function of Aβ has been sought in very many studies in which Aβ was given in far lower concentrations (pico- to nano-molar) than are necessary for its neurotoxic effect. The earliest studies of this type indicated a neurotrophic effect of (nonfibrillary) Aβ; it prolonged the survival of neurons in primary culture (Whitson et al. 1989; Yankner et al. 1990).

Nanomolar concentrations of Aβ are said to produce blockade of a certain potassium channel that also appears to be disturbed in Alzheimer's disease (Etcheberrigaray et al. 1994). In low concentrations, Aβ (in this case Aβ40) seems to promote the phosphorylation of various neuronal proteins at tyrosine residues (Luo et al. 1995) and thereby to lead to the activation of phosphatidylinositol-3-kinase (PI_3-kinase) (Luo et al. 1996). As tyrosine phosphorylation seems to play a decisive role in receptor regulation, e.g. with regard to growth factors and molecules of the extracellular matrix, Aβ in this form might possibly play a role in the modulation of neuronal plasticity and survival.

The induction of reactive oxygen molecules by Aβ may play a role in the regulation of vascular tone. Aβ has been shown to induce the production of superdioxide radical anions in endothelial cells in vitro, leading to inactivation of endothelium-derived relaxing factor (EDRF) and to lipid peroxidation, so that vasoconstriction or a diminution of vasodilatation occurs (Thomas et al. 1996). Aβ apparently also prevents the vasodilator effect of acetylcholine in this way, as has been demonstrated in coronary resistance vessels (Thomas et al. 1997).

A role for Aβ peptides as direct modulators of the neurotransmitter function of acetylcholine has also been proposed (for a review, see Auld et al. 1998). In

very low concentrations, and thus apparently independently of any detectable neurotoxic effect, Aβ seems to inhibit various cholinergic neurotransmitter functions, including the release of acetylcholine (Kar et al. 1996) and the reuptake of choline, as well as the regulation of cholinesterase activity (Pedersen et al. 1996). It is proposed that Aβ may contribute in this way to the often discussed vulnerability of certain cholinergic neuron populations, the loss of whose function is said to be related to the (limited) therapeutic effectiveness of acetylcholinesterase inhibitors in Alzheimer's disease.

7
Presenilins

7.1
Structure and Expression

The two presenilin genes, PS1 and PS2, are remarkably similar in structure: both consist of 13 exons with practically identical exon–intron borders, of which the first three (exons 1a, 1b, and 2 – the numbering is of historical origin) contain no coding (translated) sequences (for a review, see Hutton and Hardy 1997). Alternative splicing of both genes has been reported, but occurs differently in each: in the PS1 gene, for example, a VRSQ motif (codons 26–29), containing a potential phosphorylation site for protein kinase C and casein kinase II is alternatively spliced in a manner largely independent of the tissue in which it is found (Clark et al. 1995). Several other alternatively spliced transcripts have also been described (see Hutton et al. 1996).

The sequences of the presenilins are 67% identical at the protein level, and both are presumed to contain eight hydrophobic transmembrane domains and one membrane-associated domain. These are connected to one another through one large and several small hydrophilic loops (see Fig. 3). Both the N-terminal and the C-terminal segment, and the hydrophilic loops, appear to be cytoplasmically oriented (Doan et al. 1996) in accordance with the lack of a signal peptide. This model of presenilin structure was derived (among other techniques) from an analysis of the sel-12 protein of *Caenorhabditis elegans* (Li and Greenwald 1996), which possesses approximately 50% homology to the presenilins and which presumably has a closely related function in the "notch" signal pathway, as discussed further below (Levitan and Greenwald 1995).

Analysis of the expression of PS1 and PS2 shows that, like APP, both of these are ubiquitously expressed. Interestingly, PS1 mRNA is present in different tissues in very similar quantities, while the expression of PS2 is markedly tissue dependent (Kovacs et al. 1996; Levy-Lahad et al. 1995; Rogaev et al. 1995; Sherrington et al. 1995). The expression of PS1 and that of PS2 in the brain are quite similar and most intense in neurons (Kovacs et al. 1996).

7.2
Cell Biology and Function

The presenilins have been detected in transfected mammalian cells as full-length molecules (MW of PS1, approx. 43,000–45,000; of PS2, approx. 53,000–55,000; Kim et al. 1997a; Podlisny et al. 1997; Thinakaran et al. 1996; Walter et al. 1996). In contrast, few or no full-length presenilin molecules have been found to date in native cell lines or in vivo, because a saturable, constitutive endoproteolytic processing takes place (Kim et al. 1997a; Thinakaran et al. 1996). Proteolytic cleavage occurs in the region of the hydrophilic loops, chiefly at position 292 (Podlisny et al. 1997), resulting in the creation of two fragments, a longer N-terminal fragment (MW, approx. 27,000–28,000) and a shorter C-terminal fragment (MW, approx. 17,000–18,000); the latter, in the case of PS1, seems to be an in vivo substrate for protein kinase C (Seeger et al. 1997; Walter et al. 1997). When the presenilins are overexpressed, the surplus full-length presenilin molecules are degraded by an alternative metabolic pathway (Thinakaran et al. 1997), possibly with the participation of the proteasome; this was proposed for PS2 at least (Kim et al. 1997a). It is suspected that the proteolytic fragments of PS1 form heterodimers (Capell et al. 1998), in accordance with the observation that overexpression of the N-terminal PS1 fragment also leads to accumulation of the C-terminal fragment (Lee et al. 1997).

In addition to this first-described mode of proteolytic splicing, an "alternative" proteolytic splicing of both presenilins at a distal position was recently described (Grunberg et al. 1998; Kim et al. 1997b; Loetscher et al. 1997). This occurs with the assistance of one of the caspases, a gene family of cysteine proteases that play an important role in apoptotic cell death. The presenilins thus appear to be proteolytic substrates in programmed cell death, which indicates that apoptosis-associated presenilin fragments may have proapoptotic properties (for reviews of the cellular biology of the presenilins, see Haass 1997; Hardy 1997; Kim and Tanzi 1997).

The results of in vitro studies according to which FAD presenilin has a stronger apoptosis-inducing effect than wild-type presenilin (Guo et al. 1996; Wolozin et al. 1996) may be relevant in this connection. Both FAD-PS1 and FAD-PS2 were found to be associated with an increased sensitivity to Aβ-induced apoptosis, which, in the case of PS1, might be due to a disturbance of calcium homeostasis (Guo et al. 1996);

in the case of PS2, however, it was described as being mediated by G-protein (Wolozin et al. 1996). Alternative models of FAD pathogenesis other than the amyloid cascade hypothesis may be derived from these experiments (for a review, see Mattson et al. 1998).

At the subcellular level, the presenilins are located mainly in the endoplasmic reticulum and, in lower concentrations, in the Golgi apparatus. Accordingly, the presenilins are found mainly in the somatodendritic compartment of in vitro cultured neurons (Capell et al. 1997; Cook et al. 1996; Kovacs et al. 1996; Walter et al. 1996).

This localization of the presenilins corresponds to the neuronal compartments in which Aβ42/43 appears to be formed, as discussed above (Cook et al. 1997; Hartmann et al. 1997; Wild-Bode et al. 1997). As all hitherto studied FAD mutations in the presenilin genes are associated with increased production of Aβ42/43 both in vivo and in vitro (Borchelt et al. 1996; Citron et al. 1997; Duff et al. 1996; Scheuner et al. 1996), this localization indicates that the presenilins evidently play a role in the cleavage of APP and, in particular, that they influence the activity of γ-secretase (for reviews, see Haass 1997; Hardy 1997; Sandbrink and Beyreuther 1996; Selkoe 1997).

It is not yet clear in detail how the FAD mutations in the presenilin genes induce increased formation of Aβ42/43. It has been shown both for wild-type PS2 and for PS2 FAD mutants that presenilin in fact co-precipitates in vitro with APP, which implies a direct interaction between APP and the presenilins, or at least PS2 (Weidemann et al. 1997). These results were recently confirmed by other authors and were also confirmed for PS1 as well (Xia et al. 1997), but are currently the subject of intense discussion. Another possibility is that the presenilins may influence APP transport and thereby the amyloidogenic processing of APP.

Recent studies of neurons from PS1 knockout mice ($PS1^{-/-}$) in primary cell culture reveal that the absence of PS1 is associated with a dramatic increase in transmembrane C-terminal fragments of APP, the result of lessened γ-secretase activity in the presence of unchanged α- and β-secretase activity (De Strooper et al. 1998). While the secretory derivatives of APP (sAPP) were unchanged, the formation of Aβ, in both Aβ40 and Aβ42/43 forms, was greatly reduced. These findings show that the γ-secretases cut sequentially after α- and β-secretase and that the activity of the γ-secretases is strongly regulated by PS1. A possible explanation would be, for example, that the presenilins bind to the C-terminal fragments of APP as chaperones, and only this complex is accessible to proteolytic cleavage by the γ-secretases.

7.3 Biological Function

Major evidence for a possible biological function of the presenilins also comes from its close structural resemblance to sel-12 (50% homology). Sel-12 is a protein of the nematode *C. elegans* that serves as a coreceptor for lin-12, a notch receptor. Loss-of-function mutations of the sel-12 gene lead in recessive fashion to constitutive activation of lin-12, which results in a defect in egg-laying (Levitan and Greenwald 1995). With the aid of transgenic *C. elegans* lines, it was shown that this phenotype can be reversed not only by wild-type sel-12, but also, to a large extent, by human PS1 and PS2 cDNA (Baumeister et al. 1997; Levitan et al. 1996).

This implies a functional equivalence of sel-12 and the presenilins. The presenilins are thus thought to play a role in fetal development and/or cellular differentiation in mammals, too, through participation in the notch signal pathway. This hypothesis was supported by an analysis of the above-mentioned PS1 knockout mice ($PS1^{-/-}$), which die before or very shortly after birth and have defects in the axial skeleton and in somite segmentation. In the central nervous system, these mice display a loss of neurons and a pronounced disposition toward hemorrhages (Shen et al. 1997; Wong et al. 1997). Similar defects in somite formation have been described for both notch1 knockout mice ($notch1^{-/-}$) (Conlon et al. 1995) and dll1 knockout mice ($dll1^{-/-}$) (Hrabe de Angelis et al. 1997) (dll1 is the mouse gene homologous to δ and thus codes for a ligand of the notch receptor). It is unknown, however, whether and in what way a function of the presenilins in the notch signal pathway might contribute to the pathogenesis of Alzheimer's disease.

8 tau Protein

In 1975, Weingarten et al. described a heat-stable protein (tau) which is apparently able to induce the formation of microtubules (Weingarten et al. 1975). Microtubules are linear polymers in the form of a hollow tube, assembled from tubulin units, and tubulin is a heterodimer of two globular proteins. Microtubules are important components of the neuronal cytoskeleton and play a role in major neuronal functions, such as neurite growth and the transport of cytoplasmic components. A number of proteins, called microtubule-associated proteins (MAP), are bound to microtubules, and tau is one of these.

The tau protein is found primarily in neurons and is predominantly localized in the axon (Binder et al. 1985). In 1986, several groups demonstrated that tau is the major component of paired helical filaments (PHF), and thereby also of the neurofibrillary tangles (NFT) that have been a histopathological hallmark of Alzheimer's disease as mentioned above (Grundke Iqbal et al. 1986a,b; Kosik et al. 1986; Wood et al. 1986). Because of these findings and those of further studies (Lee et al. 1991; Hasegawa et al. 1992), it was concluded that the tau protein of neurofibrillary tangles predominantly has an abnormally hyperphosphorylated form (so-called PHF-tau) (for reviews, see Billingsley and Kincaid 1997; Goedert 1995; Trojanowski and Lee 1995).

Many studies have revealed that tau is actually a family of proteins arising from a single gene by alternative splicing. In addition to the six isoforms of tau that are expressed in the brain (Goedert et al. 1989), there are also other isoforms, including the so-called big tau, that are expressed in the peripheral nervous system and will not be discussed here. Depending on alternative splicing of exon 10, the tau isoforms expressed in the brain contain, at their C-terminal end, either three or four similar repeats of a segment of either 31 or 32 amino acids, which is responsible for the binding of tau to microtubules. At their N-terminal end, the cerebral isoforms of tau have either an insert encoded by exons 2 and 3 (58 amino acids), an insert encoded by exon 2 only (29 amino acids), or no insert at all (Goedert et al. 1989).

The tau protein displays a total of 17 serine–threonine–proline motifs, as well as several more serine–threonine residues, and is therefore a potential substrate for protein kinases of the corresponding specificity. It is phosphorylated in vitro by many different protein kinases, including calcium- and calmodulin-dependent protein kinase II (CaMKII; Steiner et al. 1990), casein kinase II (Greenwood et al. 1994), cAMP-dependent protein kinase (cAMP-PK; Litersky and Johnson 1992), mitogen-activated protein kinase (MAP kinase), also known as ERK2 (Drewes et al. 1992), a neuronal cdc2-like protein kinase (cdk5/p35; Paudel et al. 1993), glycogen synthase kinase 3 (GSK3; Mandelkow et al. 1992), and microtubule affinity-regulating kinase (MARK; Drewes et al. 1995).

The dephosphorylation of tau is catalyzed in vitro by several protein phosphatases, including phosphatase 1 (PP1; Gong et al. 1994a), phosphatase 2A (PP2 A; Goedert et al. 1992; Gong et al. 1994b), and calcium- and calmodulin-dependent phosphatase, also known as phosphatase 2B (PP2B) or calcineurin (Goto et al. 1985). It is not yet known which of these protein kinases and phosphatases are active in vivo. It has been suggested that, under normal in vivo conditions, there is an equilibrium between protein kinases and phosphatases, leading to a stable phosphorylation of "adult" tau at (probably) five epitopes (Watanabe et al. 1993). As early as 1980, there was evidence that the degree of phosphorylation of tau and other microtubule-associated proteins affects their microtubule-stabilizing activity (Jameson et al. 1980). In the case of tau, this activity has been traced in recent studies to very specific phosphorylation sites, of which Ser262 is considered especially important, as this residue is the only one localized within the microtubule-binding domains.

An at least partial hyperphosphorylation of tau was found at 19 different epitopes in the postmortem analysis of the brain of a patient with Alzheimer's disease (Grundke Iqbal et al. 1986b; Lee et al. 1991; Matsuo et al. 1994; Morishima Kawashima et al. 1995). Even if many of these epitopes also seem to be partly phosphorylated in so-called "fetal" tau, the phosphorylation of PHF-tau is generally much more extensive (Morishima Kawashima et al. 1995). The same apparently holds for soluble tau in the brains of patients with Alzheimer's disease (Kopke et al. 1993). It is thought that this finding particularly reflects the protein kinase activity of GSK3 and cdk5/p35 (Morishima Kawashima et al. 1995; Watanabe et al. 1993), and of MARK as well, which induces extensive phosphorylation of Ser262 in vitro (Drewes et al. 1995). Independently of the state of phosphorylation, sulfated glycosaminoglycans such as heparin and heparin sulfate apparently induce the formation of aggregates similar to PHF-tau (Goedert et al. 1996).

Fibrillary Aβ, but not soluble Aβ, has also been found in vitro to induce the phosphorylation of tau at several serine residues in primary cultures of human and rat neurons (Busciglio et al. 1995). In this hyperphosphorylated form, tau was no longer associated with microtubules in the neurons studied and was unable to bind to microtubules in vitro either, but could do so again after renewed dephosphorylation (Busciglio et al. 1995). Thus it is possible that in vivo Aβ formation is responsible for the hyperphosphorylation of tau, and hence for the tau pathology observed in vivo, in Alzheimer's disease.

A recently published study yielded the surprising finding that a homogenate of biopsy material contained demonstrable reactivity for antibodies previously thought to be specific for PHF-tau and fetal tau (Matsuo et al. 1994). This implies a rapid dephosphorylation of this epitope in human adult tau in the postmortem brain by phosphatases, probably including PP2A and/or PP2B. The conclusion must then be drawn that the hyperphosphorylation of tau found in the postmortem brain affected by Alzheimer's disease is primarily the consequence of lessened activity of these phosphatases (Trojanowski and Lee 1995).

In any case, a faulty regulation of the protein kinase–phosphatase system in Alzheimer's disease must be assumed, perhaps mediated by Aβ (Busciglio et al. 1995). In combination with an increase in oxidative stress and in intracellular calcium concentration, perhaps also mediated by Aβ, this could create conditions contributing to neuronal dysfunction in Alzheimer's disease by way of a disturbance of the microtubule-stabilizing (and other) function or functions of tau protein, resulting in damage to the neuronal cytoskeleton (for reviews, see Behl 1997; Smith et al. 1996). Neuronal damage might lead not only to increased APP expression and Aβ formation, which might be pathogenetically relevant in the form of a positive feedback mechanism, but also to increased release of tau into the interstitial fluid. This is thought to explain the frequently replicated observation that the cerebrospinal fluid concentration of tau is significantly higher in patients with Alzheimer's disease, or other neurodegenerative illnesses, than in control subjects (Vandermeeren et al. 1993).

It was recently shown that mutations of the tau gene can produce another neurodegenerative illness known as frontotemporal dementia with parkinsonism of chromosome-17 type (FTDP-17). Individuals suffering from this autosomal dominant hereditary illness have atrophy of the frontal and temporal cortex, the basal ganglia, and the substantia nigra, associated with neuron loss and gliosis. Furthermore, tau deposits are found which, unlike those of Alzheimer's disease, are located both in neurons and in glial cells and also have different structural and biochemical properties. A number of groups have now been able to show that point mutations (missense mutations and splicing mutations) of the tau gene cause the disease FTDP-17 (Hutton et al. 1998; Poorkaj et al. 1998; Spillantini et al. 1998). These findings prove that a disturbance of the structure and function of tau protein suffices for the production of a neurodegenerative disorder leading to dementia, which, however, is not the same as Alzheimer's disease.

9 Apolipoprotein E

Mature apolipoprotein E (apoE) is a protein with 299 amino acid residues whose three most important variants, E2, E3, and E4, differ at two positions (112 and 158; see above). The N-terminal segment of apoE contains a domain that binds to the lipoprotein receptor, and the C-terminal end contains the most important lipoprotein (lipid)-binding domain (for a review, see Weisgraber and Mahley 1996). The three apoE variants apparently differ with respect to the types of lipoprotein to which they preferentially bind; while apoE2 and apoE3 bind preferentially to high-density lipoproteins (HDL), apoE4 binds primarily to VLDL. This is regarded as the reason for the elevated plasma cholesterol and LDL concentrations that have been found in carriers of the APOE-ε4 gene and their ensuing elevated risk of developing atherosclerosis. It is suspected that the influence of APOE genotype on the risk of Alzheimer's disease may also be related to this differential effect on lipid metabolism. This hypothesis was supported by the Rotterdam study referred to above, in which carriers of the APOE-ε4 gene have an even higher risk of developing Alzheimer's disease when arteriosclerotic changes are also present (Hofman et al. 1997). For this reason, the role of apoE in cerebral lipid metabolism is now being intensively studied.

In the brain, apoE is produced by astrocytes. The lipoprotein–apoE particles, bound to VLDL, are taken up by neurons with the aid of either the LDL receptor or the so-called HSPG-LRP pathway, which involves binding to heparin sulfate proteoglycans (HSPG) at the cell surface, followed by internalization via the LDL receptor-related protein (LRP) receptor. By this pathway, apoE might conceivably reach the cytoplasm (Han et al. 1994), although the mechanism for this is not yet adequately understood. In any case, the uptake of apoE4 into neurons has been found to be of much lesser magnitude than that of apoE3 (Nathan et al. 1994); this might be a consequence of differing affinities for the HPSG-LRP receptor. These findings might explain the observation that apoE3, but not apoE4, promotes neurite growth in vitro, presumably by way of binding to this receptor (Holtzman et al. 1995; Nathan et al. 1994; Nathan et al. 1995).

The inhibitory effect of apoE4 on neurite growth may also be explained by its much lower binding affinity to tau, compared with that of apoE3, as observed in vitro (Strittmatter et al. 1994a,b). As the phosphorylation of tau seems to reduce its binding to apoE3, it has been proposed that apoE3, by binding to tau, prevents the hyperphosphorylation of tau and thereby protects microtubules from destabilization (Strittmatter et al. 1994).

Another hypothesis concerning the role of apoE in the pathogenesis of Alzheimer's disease emerges from the in vitro observation that the different variants of apoE have different affinities for Aβ. Lipid-free apoE4 makes a much more stable complex with Aβ than apoE3 (Strittmatter et al. 1993b), although this effect seems to be reversed in the presence of lipids (Ladu et al. 1995). The different affinities of the different apoE variants may explain the multiply replicated observation of an association of the APOE-ε4 allele with the number and density of Aβ deposits in the brain (Rebeck et al. 1993; Schmechel et al. 1993). The findings of these and other studies (Castano et al.

1995; Evans et al. 1995) have led many current authors to hypothesize, as mentioned above, that the Alzheimer's disease-promoting effect of apoE4 is due not to altered production of Aβ protein, as in FAD, but to an increased aggregation or decreased degradation of Aβ.

The recent findings that not only the APOE genotype, but also the intensity of gene expression, influence the risk of developing Alzheimer's disease have already been mentioned (Bullido et al. 1998; Lambert et al. 1997, 1998). It is postulated that formation of larger amounts of apoE is associated with a greater risk of developing Alzheimer's disease, regardless of APOE genotype (Bullido et al. 1998; Lambert et al. 1997). This hypothesis gains further support from the observation that APOE knockout mice ($APOE^{-/-}$) that are simultaneously transgenic for the human V717I-APP-FAD gene (see above) develop amyloid pathology much more slowly than transgenic control animals, although they have the same amount of Aβ in the brain (Bales et al. 1997). These findings indicate that apoE promotes Aβ aggregation in vivo, but to an extent that differs depending on the particular apoE variant or variants present.

10 NAC Precursor/α-Synuclein

In 1993, Ueda and colleagues analyzed an amyloid preparation from the brain of a patient with Alzheimer's disease and identified two previously unknown peptides, whose deposition in neuritic and diffuse plaques, as well as in vascular amyloid, was demonstrated with immunohistochemical methods (Ueda et al. 1993). They were then able to isolate the cDNA of a protein, 140 amino acids in length, that contained these amyloid sequences in two segments of a hydrophobic domain. The authors designated the peptide of these amyloid sequences (MW, approx. 35,000) non-Aβ component of Alzheimer's disease amyloid, or NAC, and its precursor, i.e. NAC precursor (NACP) (Ueda et al. 1993). Analyses of secondary structure revealed that NAC has a marked tendency to assume the structure of a β-pleated sheet, which is presumably the basis of its association with Aβ.

Sequence comparisons revealed that NACP is the human homologue of synuclein, a synaptic protein previously described in the torpedo and in the rat (Campion et al. 1995). There are two synucleins encoded by different genes, α-synuclein (=NACP) and the closely related β-synuclein, both of which are specifically expressed in the brain, are localized in presynaptic terminals, and bind strongly to Aβ (Jensen et al. 1997; Yoshimoto et al. 1995).

It was recently shown in several families that a missense mutation (A53T) in the α-synuclein gene on chromosome 4 can produce an autosomal dominant hereditary form of Parkinson's disease (PARK1; Polymeropoulos et al. 1997). A further mutation (A30P) was identified very recently (Kruger et al. 1998). Aside from the early onset of disease (at an average age of 46 years), the first family to be identified with this disease has a typical and well-documented phenotype of Parkinson's disease, including the formation of histopathologically recognizable Lewy bodies in the brains of the affected individuals.

Lewy bodies are intracytoplasmic inclusion bodies found in approximately 20% of cases of dementia that come to autopsy (McKeith et al. 1996). They have been shown to contain NACP/α-synuclein in aggregate form (Spillantini et al. 1997). Lewy bodies are found not only in Parkinson's disease, but also in related neurodegenerative illnesses, which are currently designated as dementia with Lewy bodies (McKeith et al. 1996). Illnesses of this class include so-called diffuse Lewy body disease and the Lewy body variant of Alzheimer's disease, which lies in a region of transition to Alzheimer's disease and involves not only the deposition of Lewy bodies in the cerebral cortex, but also the typical histopathological abnormalities of Alzheimer's disease (neuritic plaques and NFT). The Lewy body variant of Alzheimer's disease is now increasingly interpreted as a coexistence of Alzheimer's disease and dementia with Lewy bodies (McKeith et al. 1996).

The demonstration of α-synuclein in both Lewy bodies and senile plaques indicates a possible role for NACP/α-synuclein in the pathogenesis not only of Parkinson's disease, but also of Alzheimer's disease (for a discussion, see Heintz and Zoghbi 1997). An earlier study of 26 EOFAD patients revealed no mutation in the α-synuclein gene (Campion et al. 1995), but another study yielded certain pieces of evidence for an interaction of a particular allele of the α-synuclein gene with apolipoprotein E with regard to the risk of developing Alzheimer's disease (Xia et al. 1996). This will certainly require further careful investigation in larger studies.

11 Implications for Diagnosis

The diagnosis of Alzheimer's disease is, above all, a clinical diagnosis and must always be accompanied by a differential diagnostic evaluation for other potential causes of dementia. The accuracy of clinical diagnosis can be improved by the ancillary use of modern diagnostic imaging techniques. To increase diagnostic

accuracy still further, making use of additional biochemical and molecular biological studies of various "biological markers" of the disease may be considered (see Chap. 5, this volume, Part 2).

A molecular genetic study with respect to one of the FAD mutations may be used to confirm, although not to exclude, a clinically suspected diagnosis of FAD if the pedigree data support an autosomal dominant pattern of inheritance and if the age of onset is no higher than 50–55 years (with unambiguous pedigrees, the age of onset may be higher). Even if the age of onset is in the range of 50–55 years, it must first be established whether the APOE-ε4/ε4 genotype is present, in which case the probability of FAD is considerably lower.

A molecular biological investigation with respect to a FAD mutation necessarily begins with the study of the PS1 gene. Because FAD mutations are generally missense mutations, and because such mutations are distributed throughout the coding region of the PS1 gene (exons 3–12), the diagnostic assessment may begin with screening for the presence of such a mutation or may proceed directly to sequencing. If no PS1 mutation is found, a directed assessment with regard to the known APP and PS2 mutations can then be performed. If no FAD mutation is identified in this way, the presence of FAD still cannot be ruled out, not least because it has to be assumed that FAD genes exist that have not yet been identified.

The children of a FAD patient generally have a 50% risk of developing Alzheimer's disease at a comparable age. Thus, as soon as the diagnosis is clinically suspected, the affected patient or caregiver should be informed of the opportunity of receiving thorough human genetic counseling, which should, of course, be available to other family members as well, if they wish. It goes without saying that the appropriate ethical guidelines should be applied in such cases. In Germany, guidelines for the genetic counseling of families of patients with (as yet) untreatable neurodegenerative illnesses have been developed for Huntington's disease by the Professional Association for Medical Genetics (*Berufsverband für medizinische Genetik*). For patients' relatives desiring predictive assessment, these guidelines recommend a neurological examination and accompanying psychotherapeutic care, as well as an adequate period for reflection before the drawing of blood for molecular genetic study (Konsortium zur molekulargenetischen Diagnostik der Huntington-Krankheit 1996).

Similarly, with respect to APOE gene typing, the recommendations of existing consensus statements should be followed, e.g. that of the National Institute of Aging/Alzheimer's Association Working Group (NIA/AA 1996). This consensus statement emphasizes that the sensitivity and specificity of APOE gene typing in asymptomatic persons are not sufficient to allow a recommendation of such gene typing for predictive diagnosis. For the estimation of an individual's risk of developing Alzheimer's disease, too, just as for predictive diagnosis, the data currently available do not justify a recommendation that gene typing be performed in view of the lack of therapeutic consequences of such a determination and the manifold social, legal, and ethical implications that it would have.

In the presence of clinical manifestations of dementia, however, APOE evaluation may be ordered by the physician as a supplementary diagnostic technique, in addition to other diagnostic studies. In such cases, the demonstration of positivity for APOE-ε4 raises the probability that a suspected diagnosis of Alzheimer's disease is correct. This was shown in a recently published study, in which the clinical diagnoses of 2188 patients with dementia were compared with their (later) pathological diagnoses, and the addition of APOE genotypic information was found to enhance the specificity of the clinical diagnosis (Mayeux et al. 1998).

12 Therapeutic Approaches

If intraneuronal Aβ indeed plays a decisive role in the pathogenesis of neurodegeneration in Alzheimer's disease, this still does not rule out an important pathogenetic influence of Aβ-amyloid plaques as well, e.g. through the activation of microglia or the inhibition of axonal transport with consequent accumulation of APP. Assuming that Aβ does play a major pathogenetic role, the Aβ plaques clearly bear a close relation to the pathogenetically relevant parameter, whatever it may be.

Studies concerning the occurrence of Aβ deposition in the general population are, therefore, of great significance. Immunohistochemical studies of postmortem brains in various age categories have revealed, for example, that about 20% of individuals between 50 and 60, and 80% of those between 80 and 90, show Aβ-positive changes (Rumble et al. 1989). If we consider that approximately one in five individuals between the ages of 80 and 90 has Alzheimer's disease, it follows that approximately 30 years pass between the appearance of the earliest Aβ deposits and the onset of manifestations of Alzheimer's disease.

More recent studies further showed that the formation of Aβ plaques is an even earlier sign of Alzheimer's disease; in accordance with the special pathological significance of Aβ42/43, these plaques seem to contain predominantly this longer form of Aβ (Iwatsubo et al. 1994; Tamaoka et al. 1995). If intra-

neuronal processes, as suspected, indeed precede the extracellular deposition of β-amyloid, then the preclinical phase of Alzheimer's disease must be still longer than this. This hypothesis accords with the observation that the phosphorylation of tau protein and the formation of neurofibrillary tangles also considerably precede the clinical onset of the disease, by as long as four decades, according to recent studies (Braak and Braak 1995).

These studies reveal that the preclinical phase of Alzheimer's disease stretches over at least three decades before the first signs of the disease can be recognized. By then, however, the irreparable loss of neurons and synapses in certain regions of the brain has already occurred to the extent of more than 90%. The goal of any truly effective therapy must, therefore, be to delay entry into the disease phase by preventive measures instituted during the preclinical phase. The discoveries of basic research discussed in this chapter yield clues as to how this goal might be achieved.

Six strategies may be considered that either directly address the process of generation of Aβ or else are intended to block the consequences of Aβ formation:

1. Lowering the rate of synthesis of APP itself.
2. Modulating the rate of conversion of APP into Aβ protein, i.e. lowering the rate of formation of Aβ, e.g. by inhibition of the β- or γ-secretases; γ-secretase activity, in particular, might be influenced by modulation of the presenilins, for example.
3. Promotion of Aβ degradation or – more generally – elimination of Aβ from the brain.
4. Inhibition of the formation of the β-pleated-sheet structure of Aβ (by alteration of conformation) and inhibition of Aβ aggregation.
5. Inhibition of a pathological activation of microglia, which might critically reinforce the toxic effect of Aβ or act to mediate this toxicity.
6. Protection of neurons on many levels of the Aβ cascade, e.g. protection against the consequences of Aβ production, of β-pleated-sheet formation, of Aβ aggregation and deposition, and of the pathological activation of microglia, if such indeed occurs.

At present, the modulation of amyloid formation is the most important target for rational therapeutic research. The best opportunity of prolonging the preclinical phase of the disease is thought to lie in the inhibition of Aβ production or aggregation. Beyond this, other approaches include the use of anti-inflammatory substances, which might lessen neuronal damage by counteracting the activation of microglia by amyloid deposition, or the formation of radicals secondary to the accumulation of APP. The most promising concept appears to be that of a combination of measures, which, it is hoped, will lessen neuronal damage, improve neuronal function, and thereby prevent the emergence of the clinical symptoms of Alzheimer's disease within the natural lifetimes of at least some of the patients at risk.

There are increasing signs that the prospect of diagnosing Alzheimer's disease in an early enough stage to enable successful therapy will in fact be achieved. The use of genetic and biological (i.e. phenotypic) markers, in combination with sensitive diagnostic imaging techniques, may one day make this hope a reality. These techniques, however, should not be used for diagnostic purposes in the preclinical phase of the disease until effective prevention or treatment is available. This holds especially for the investigation of susceptibility genes, whose cumulative occurrence might predict a very high risk of developing Alzheimer's disease (for a discussion, see Roses 1998).

Vascular Cognitive Impairment and Dementia

1 Introduction

Vascular dementia (VD)[1] has been known, diagnosed, and investigated for more than 100 years and still many questions remain unanswered. The titles of two recent reviews on this disease are highly demonstrative of the confusion and disagreement that surround the field of cognitive decline due to cerebrovascular disease: *Vascular Dementia: Persisting Controversies and Questions* (Moncayo and Bogousslavsky 1996) and *Vascular Dementia: Still a Debatable Entity?* (Loeb and Meyer 1996). As of today, no reliable, validated diagnostic criteria are available and its epidemiology remains unknown. Prevalence and incidence figures are extremely variable, and different studies cannot be compared. Clinical and neuroradiological manifestations are not fully understood and remain tied to old preconceptions. The definition of dementia, for instance, is uncritically derived from the clinical picture of Alzheimer's disease (AD), and memory impairment is still taken as the hallmark of dementia. Moreover, while it is generally accepted that VD is heterogeneous, its different clinical and etiopathogenic subtypes have not been clearly separated and patients with different diseases are still grouped together.

Words such as "treatable" or "preventable" are inseparable from VD. Paradoxically, the definition of dementia currently in use, which requires a degree of severity high enough to affect the social or occupational functioning of the individual, leaves little room for preventive or therapeutic actions. No early detection can be attempted if diagnostic criteria do not move away from this concept. Similarly, little prevention of VD can be made if its risk factors remain unknown and it is not established whether they are the same as those for stroke. Hachinski and Bowler (1993) suggested the concept of vascular cognitive impairment (VCI)[2] to encompass all different degrees of intellectual decline related to ischemic cerebrovascular disease, highlighting the importance of early detection and the compelling need for new diagnostic criteria based on prospectively collected experience and not on uncontestedly collected literature. Throughout this chapter, the authors will use the term VCI instead of VD whenever possible.

[1]As defined by current criteria, the diagnosis of dementia requires the development of deficits in memory functions and one or more other areas of cognition which are severe enough to impair social or occupational functioning and represent a significant decline from a previous level of performance. VD is dementia due to ischemic vascular lesions.

[2]Cognitive impairment is a decline in any cognitive domain regardless of its severity. Memory loss is not necessarily required. Dementia would represent the most severe stage of impairment. VCI is a term that would encompass all types and degrees of cognitive impairment, from early intellectual changes to dementia, due to ischemic cerebrovascular disease.

2 Epidemiology of Vascular Cognitive Impairment

2.1 Prevalence of Vascular Dementia

The prevalence of VD is difficult to establish, as it shares so many features with diseases such as stroke or AD and no reliable diagnostic criteria have been developed (see below). The frequency of VD varies depending on the sample under survey and the diagnostic tool applied, especially whether or not a neuroimaging technique is applied. Autopsy series have the highest diagnostic accuracy but are necessarily biased, and only series of patients with dementia and not general consecutive autopsies have been analyzed. In such studies, the frequency of VD varies from 0% to 19% (Jellinger et al. 1990). Interestingly, among patients with a clinical diagnosis of AD, 3% may receive a diagnosis of pure VD at autopsy. Frequency figures from hospital-based series or memory clinic registries are not adequate, as stroke patients will be overrepresented in the former and AD patients in the latter.

Population-based studies offer the best scenario to control for selection biases but at the expenses of diagnostic accuracy, as neuroimaging investigation cannot always be applied. Hébert and Brayne (1995) reviewed ten population-based studies from different countries that applied the same diagnostic criteria and used similar sampling frames. Prevalence figures for VD in these surveys varied between 1.2% and 5.6% of the population. Methodological issues rather than geographic differences appeared to explain such variation. The highest figures were obtained in studies that included a computed tomography (CT) scan as part of the evaluation. A significant bias leading to underestimation was introduced by the exclusion of institutionalized patients in some studies. Contrary to what has been traditionally thought, no significant differences in the prevalence of VD were observed in these surveys between men and women. In addition to diagnostic accuracy, another source of confusion when epidemiologists attempt to estimate the contribution of vascular causes to the prevalence

of dementia is the way in which patients with mixed dementia[3] are classified, as some studies include them with VD patients and others count them as AD patients. Prevalence rates may vary from 14% to 1% depending on this factor (Skoog et al. 1993; Ott et al. 1995). Unfortunately, the clinical diagnosis of mixed dementia does not differentiate patients in which stroke is just a coincidental association with AD from those patients that would not be demented had they not presented with a stroke.

2.2 Dementia After Stroke

It is now well established that having a stroke is a significant risk factor for dementia. Almost 30% of stroke patients develop dementia in the first 3 months after stroke. The risk is nine times higher than that in the general population. Perhaps surprisingly, the type of dementia that stroke patients develop is both VD and AD (mixed dementia?), and in many cases no new cerebrovascular events precede dementia (Tatemichi and Desmond 1996). In population-based longitudinal studies, the incidence of total dementia among patients with stroke at study entry is nine times higher and the incidence of AD is twice that in the general population (Kokmen et al. 1996). Some authors have suggested the term "poststroke dementia" to include all possible mechanisms of dementia after stroke.

2.3 Prevalence of Vascular Cognitive Impairment

As outlined in the previous paragraphs, epidemiological research has focused only on patients with dementia, i.e., those in which the severity of intellectual decline is sufficient to fulfill diagnostic criteria. However, the impact of vascular causes on cognition may be much more important if all degrees of cognitive decline are considered. Prevalence and incidence figures for VCI will remain undetermined until valid diagnostic criteria are developed and validated. However, the Canadian Study of Health and Aging has provided some data in this respect. In this survey, approximately 10,000 subjects older than 65 were screened for cognitive decline. Among those who screened positive, subjects with dementia were distinguished from those with cognitive decline not severe enough to be labeled as dementia. Vascular causes were found to be the second most frequent cause of cognitive decline without dementia after the condition known as age-associated memory impairment. If subjects with cognitive impairment due to vascular causes are grouped together with those diagnosed with VD and mixed dementia, it can be said that 4.8% of the Canadian population older than 65 had some degree of VCI (Rockwood et al. 1997). This number may, however, underestimate the prevalence of VCI, as no neuroimaging studies were performed in these subjects.

With regard to mild cognitive impairment, data from numerous studies have provided sufficient evidence to stress the importance of vascular factors. Hypertension and diabetes are significant negative predictors of cognitive function in nondemented subjects in population-based studies, and this effect appears to be independent of the presence of stroke (Martinez-Lage et al. 1996). The deleterious effect of hypertension on cognitive function has been known for years, and it has been related to the presence of white matter changes. Additional epidemiological studies have shown that the presence of electrocardiographic evidence of myocardial infarction, peripheral artery disease, or the presence of carotid atheromatous changes doubles the proportion of subjects scoring 23 or less in the Mini-Mental State Examination (MMSE). History of stroke increases this proportion by three (Breteler et al. 1994). In stroke-free subjects, diabetes and hypercholesterolemia were independent correlates of abstract reasoning/visuospatial deficits and memory dysfunction, respectively (Tatemichi and Desmond 1996).

2.4 Cognitive Impairment After Stroke

The appearance of cognitive impairment in patients with stroke is now receiving significant attention. Some degree of cognitive impairment may be detected in up to 60% of stroke patients. However, the proportion depends on which diagnostic tool is applied and the level at which cutoff points are placed. Pohjasvaara and colleagues (1997) found that 61.7% of 486 stroke patients had deficits in at least one cognitive domain, 34.8% in one or two domains, and 26.8% in three cognitive areas or more, as measured by the modified MMSE (3MS) and other brief tests. Using a comprehensive neuropsychological battery, Grace and colleagues (1995) found that 46% of their stroke patients were cognitively impaired (scored two standard deviations below the norm in at least two cognitive

[3]This term is applied to cases of dementia in which the presence of both degenerative and vascular changes is suspected on clinical or radiological grounds or demonstrated at autopsy. Unfortunately, no clinical or even pathological criteria have been developed to distinguish cases in which both lesions are required to produce dementia from those in which either degenerative or vascular lesions would have been sufficient to cause dementia had they occurred on their own.

domains). Interestingly, more than half of these patients had scored higher than 24 on the MMSE and 31% had obtained more than 79 on the 3MS, hence questioning the sensitivity of these cognitive scales. Tatemichi and Desmond (1996) used similar criteria and required failure (scoring below the fifth percentile of the control sample) in at least four of the 17 items of their neuropsychological battery, which evaluated memory, orientation, language, visuospatial ability, abstract reasoning, and attention. Cognitive impairment was detected in 35% of their 227 stroke patients. Remarkably, cognitive impairment had a significant effect on functional impairment and was a significant predictor of dependent living even after adjusting for physical disability.

In summary, the impact of vascular factors on cognitive impairment and dementia may prove to be more significant than considered traditionally. The presence of clinical stroke may aggravate this effect, but the effect may be mediated by other mechanisms. Longitudinal studies are urgently needed to determine whether these forms of cognitive decline associated with vascular risk factors, especially hypertension and diabetes, with or without clinical stroke herald dementia or not. The answer to this question will provide clues for the early detection of VD and will allow rational strategies for prevention and treatment to be designed. Unfortunately, all these cases of VCI will go undetected in the population if diagnostic criteria are not developed and validated.

2.5 Risk Factors for Vascular Cognitive Impairment

Risk factors for VD remain unclear despite intensive and extensive research in this field (Table 1). Investigation of risk factors for a particular disease requires, first, that patients be clearly separated from those not suffering from the disease and, second, that presence or absence of a specific factor be reliably established. The first condition is not fully met in investigations on VD. As will be discussed, current diagnostic criteria show deficiencies and their validity has not been neuropa-

Table 1. Risk factors significantly associated with vascular dementia in different studies

Reference	Risk factors	Sampling frame	Analysis
Compared to general population			
Meyer (1988)	Hypertension, cardiopathy, diabetes, smoking, carotid bruit	175 MID patients vs. 125 neurologically normal controls	Chi-squared
Katzman (1989)	Prior stroke, diabetes	15 MID/MIX patients vs. 350 unselected volunteer controls (stroke patients allowed)	Chi-squared
Lindsay (1997)	Hypertension, alcohol abuse, cardiopathy, pesticide exposure, low level of education, current use of aspirin	129 VD patients vs. 531 controls from a population-based study	Logistic regression
Yoshitake (1995)	Age, alcohol use, diabetes, stroke, systolic BP	828 subjects from a population-based study on dementia followed for 7 years; 50 developed VD	Logistic regression
Compared to nondemented stroke patients			
Ladurner (1982)	Hypertension	40 MID vs. 31 nondemented stroke patients	Chi-squared
Loeb (1988)	Hypertension, cardiopathy, associated hypertension, cardiopathy, and diabetes	40 MID vs. 30 normal and 30 stroke controls	Chi-squared
Tatemichi (1990)	Previous stroke, previous MI	726 patients from a stroke database; 116 were demented	Chi-squared
Gorelick (1993)	Hypertension, MI, age, low level of education, smoking, obesity (OR<1), systolic BP (OR<1)	61 MID vs. 86 nondemented patients with two or more strokes	Logistic regression
Tatemichi (1993)	Age, race (non-white), low level of education, diabetes, previous stroke	66 VD vs. 185 nondemented stroke patients	Logistic regression
Kokmen (1996)	Age, sex (male), second stroke, mitral valve prolapse	971 stroke patients followed for 6782 person-years (196 developed dementia)	Cox proportional hazards

MID, multi-infarct dementia; VD, vascular dementia; MI, myocardial infarction; BP, blood pressure; OR, odds ratio.

thologically contrasted. Moreover, given the degree of severity required by these criteria, a substantial proportion of patients with early cognitive changes will be excluded and considered as controls. Moreover, the absence of etiopathogenic classification forces the researcher to include patients with different diseases in the same group. With regard to the second requirement, the presence of risk factors has often been used to establish the diagnosis of VD, and the conclusion that vascular risk factors are indeed risk factors for VD may be significantly biased. The question of whether VD is associated with the same circumstances that determine the risk of stroke or whether there are additional factors remains unanswered. Remarkably, research in this area has been limited to traditionally known risk factors (hypertension, diabetes, hypercholesterolemia, cardiopathy). Other conditions such as increased fibrinogen, hypotension, hemodynamic states, immunological changes, or genetic factors are only recently starting to be acknowledged (Martinez-Lage and Hachinski 1998).

When patients with VD are compared with neurologically normal controls, diabetes, heart disease, hypertension, and carotid bruits are significantly associated with VD (Meyer et al. 1988). However, if stroke patients are allowed in a nonselected control group, only prior stroke and diabetes reach significance (Katzman et al. 1989). Studies on population-based surveys are scarce (Table 1). Using incident cases with a high rate of autopsy confirmation, Yoshitake and colleagues (1995) found age, systolic blood pressure, history of stroke, and alcohol abuse to be significant predictors on a multivariate analysis. Diabetes, diastolic blood pressure, and increased hematocrit were significant only on univariate analysis. History of hypertension, alcohol abuse, heart conditions, and exposure to pesticides/fertilizers or liquid plastics or rubbers as well as low educational level showed a significant effect in analysis performed in the Canadian Study on Health and Aging database (Lindsay et al. 1997). In this study, diagnosis of VD followed ICD-10 criteria, and no neuroimaging study was required. Patients with cognitive decline and no dementia were excluded from the control group, but also from the patient group.

Several hospital-based studies have attempted to analyze which are the factors that determine the development of dementia in some stroke patients but not in others (Table 1). In the series presented by Ladurner and colleagues (1982), only hypertension was found to be more frequent among demented stroke patients. Investigating patients with multiple infarcts, Loeb and colleagues (1988) reported a higher prevalence of hypertension, cardiopathy, and diabetes in those with dementia. In the Stroke Data Bank Cohort, only myocardial infarction and prior stroke were significantly associated with dementia (Tatemichi et al. 1990). Reports from the population-based study by Rochester have described the significant effect of age, male sex, recurrent stroke, and mitral valve prolapse on incident dementia (Kokmen et al. 1996). In a prospective study, Tatemichi and colleagues (1993) found a significant association of dementia and age, education, race, history of prior stroke, and diabetes. Gorelick and colleagues (1993) investigated patients with two or more infarcts and found that age, hypertension, proteinuria, myocardial infarction, smoking, and systolic blood pressure were significant predictors of dementia. Both hypertension and proteinuria lost significance when analysis were adjusted for educational level. Surprisingly, the presence of high systolic blood pressure showed a "protective" effect.

All these results are too varied to draw any conclusions. Methodological differences probably account for a significant proportion of such variability. In addition, different categories of VD have not been separately analyzed, and only traditional risk factors have been taken into consideration. Isolated reports have claimed the importance of other conditions such as increased platelet activation, increased fibrinogen, immunological abnormalities, or hypoxic–ischemic diseases. Some studies have claimed a role for allele 4 of apolipoprotein E as a genetic risk factor for VD, but anatomopathological studies have not confirmed this finding. Familial or genetic factors have received little attention in VD. Analysis of all these data and the fact that incidence of VD has not decreased significantly despite intensive control of vascular risk factors for several decades lead to the conclusion that further research is needed in this field.

3 Neuropathology of Vascular Cognitive Impairment

For many years, dementia of vascular origin, so-called arteriosclerotic dementia, was thought to be the consequence of chronic cerebral ischemia. The prevailing hypothesis was that aging would be accompanied by a gradual narrowing of brain arteries that would compromise cerebral blood flow and lead to a state of neuronal nutritional insufficiency. This would cause neuronal loss, atrophy, and dementia. In 1970, Tomlinson and colleagues clearly identified neurodegenerative and vascular conditions as the most frequent causes of dementia and put forward the notion that brain infarction, and not chronic ischemia, was the true mechanism of intellectual impairment. A thorough review of available pathological data and of several blood flow studies, including their own, led Hachinski et al. (1974) to

conclude that vascular disease causes dementia through the occurrence of multiple small or large cerebral infarcts and to propose the term multi-infarct dementia (MID).[4] This view has been confirmed by the observation that surgical interventions intended to increase cerebral blood flow (endarterectomy or extracranial–intracranial bypass) did not significantly change neuropsychological outcomes. Moreover, positron emission tomography (PET) studies showing that decreased blood flow in patients with AD or MID is not coupled with an increased oxygen extraction fraction have provided further evidence against chronic ischemia (Tatemichi et al. 1994). However, chronic ischemia should not be confused with brain infarction from a hemodynamic mechanism (hemodynamic dementia).[5] Infarcts in the boundary territory of two different cerebral arteries or ischemic necrosis in vulnerable regions may occur after sustained hypotension, and possibly in relation with severe carotid occlusive disease, but even in these cases it is the presence of focal damage and not chronic hypoperfusion that causes cognitive decline. Focal vascular damage to the brain is then considered the pathological substrate of VCI.

The neuropathologic expression of focal vascular damage to the brain in patients with VD is varied and heterogenous (Munoz 1991; Olsson et al. 1996). Different cerebral and blood vessel pathologies may be found alone or in combination in the same patient (Table 2). The most common changes consist of macroscopic arterial infarcts, lacunes, and white matter vascular damage.

Arterial infarcts occur in the territory of large or medium-sized arteries. They appear as areas of cavitated necrosis with abundant inflammatory cells, including activated astrocytes. They usually involve the cortex, although the underlying white matter and basal ganglia may be affected as well. Location, number, and total volume of these type of lesions have been described as significant determinants for the presence of dementia, but data from different studies are controversial.

Lacunar infarcts are small, up to 1.5-cm cavitary lesions in the territory of deep penetrating arteries. They appear most frequently in the basal ganglia, thalamus, basis pontis, or the white matter. Lacunes

Table 2. Neuropathological findings in the brain and blood vessels in patients with vascular demetia (VD): potential etiopathogenic mechanisms

Lesion	Neuropathological findings
Brain vascular lesions	
Cortical infarcts	
Large/medium-sized arterial infarcts	Atherothrombosis Cardioembolism Coagulopathies
Cortical microinfarcts (granular cortical atrophy)	Small-vessel disease Amyloid angiopathy Multiple microemboli/ microthrombosis Angiitis obliterans
Watershed infarcts	Hypoperfusion states Severe carotid stenosis/occlusion (?)
Other ischemic lesions	Selective ischemic necrosis: Laminar necrosis Hippocampal sclerosis Incomplete infarction (?) Global anoxia Mild focal ischemia (?) Hypoperfusion states
Subcortical infarcts	
Lacunes	Arteriolosclerosis Microthrombosis
Deep infarcts	Atherothrombosis Embolism Amyloid angiopathy (familial?) Hereditary arteriopathies (CADASIL)
Watershed infarcts	Hypoperfusion/hypoxic states Severe carotid stenosis/occlusion (?)
White matter vascular damage	
Lacunes/infarcts, spongiosis, "incomplete infarcts", perivascular demyelination	Astrocytic reaction, small-vessel disease, ischemia/hypoxia, increased permeability, increased fibrinogen
Vessel wall disease	
Large-artery disease	Atherosclerosis (aortic, carotid, cerebral arteries) Giant cell or other inflammatory arterities
Small-vessel disease	Arteriolosclerosis Hypertensive Nonhypertensive – hereditary (CADASIL), diabetic (?), other Amyloid angiopathy Sporadic, familia AD-associated Inflammatory/noninflammatory arteritis

CADASIL, cerebral autosomic dominant arteriolopathy with subcortical strokes and ischemic leukoencephalopathy; AD, Alzheimer's disease.

[4]MID is a term that was originally defined to highlight the fact that dementia from vascular causes (all types of VD) is due to the accumulation of infarcts and not chronic ischemia. At present, the use of this term is restricted to cases of VD with multiple macroscopic cortical infarcts.

[5]Hemodynamic VD refers to cases of VD in which the cause of cerebral infarction is hemodynamic (hypofusional states, hypotension, global anoxia) and should not be confused with chronic ischemia.

have to be clearly distinguished from dilated perivascular Virchow-Robin spaces, which are characterized by their smooth, membrane-covered margins and the presence of a central vessel. In this respect, lacunar and cribiform states should not be taken as synonyms.

The presence of white matter rarefaction (leukoencephalopathy) was initially highlighted by Binswanger and Alzheimer (Mast et al. 1995) and is a frequent neuropathological and radiological finding in patients with VD. Histologically, white matter lesions include cavitated infarcts (lacunes), focal areas of astrocytosis (glial scars, noncavitated infarcts), demyelination, and diffuse areas of vacuolization (edema) of oligodendrocytes and neuroglia with decreased oligodendrocyte density. Sometimes these areas of vacuolization are localized and surround a blood vessel. In most cases, white matter changes are accompanied by arteriolosclerosis.

Together with these three basic types of lesions, other neuropathological findings are less conspicuously described. The term incomplete infarction is usually ascribed to white matter lesions, as Brun and Englund (1986) applied it to designate areas of myelin and axonal loss with glial reaction but no necrosis or cavitation. However, the concept of incomplete infarction was originally suggested by Lassen (1982) to describe ischemic lesions involving gray and white matter that did not show cavitation or emollision. Such lesions are characterized by neuronal death with little or no glial reaction (García et al. 1996).

Laminar necrosis might be interpreted as an example of selective ischemic necrosis and has been described in patients with dementia. It appears as a destructive lesion selectively involving neurons in the vulnerable layers of the cerebral cortex and seems to be common in the boundary zones of two different vascular territories.

In hippocampal sclerosis, selective neuronal destruction in segments CA_1 and the subiculum of the hippocampal formation is accompanied by severe gliosis. This has been reported as a frequent finding in aged subjects with dementia. Since these changes occur in patients with global cerebral anoxia–ischemia, a vascular mechanism has been claimed for this type of neuropathological findings, but whether this is true for all cases of hippocampal sclerosis is under discussion, as other neurodegenerative findings are associated in some cases (Corey-Bloom et al. 1997).

Other ischemic lesions described as the only finding in patients with dementia include cortical microinfarcts, which appear as small brownish gliotic scars that distort the cortical ribbon. The term granular cortical atrophy is used in these cases to describe the macroscopic appearance when cortical microinfarcts are multiple and widespread.

Vessel wall lesions in patients with VD include atherosclerosis of the large or medium-sized cerebral arteries and small-vessel disease (Olsson et al. 1996). Atherosclerotic changes with accumulation of lipids, extracellular matrix components, and fibroblast proliferation are mainly distributed in the extracranial trunks, the circle of Willis, and the leptomeningeal arteries. Aortic atheromatous changes are also gaining significance as a possible source of artery-to-artery emboli. Two different pathologic entities are encompassed under the term of small-vessel disease: arteriolosclerosis and amyloid angiopathy. Arteriolosclerosis is characterized by the loss of muscular and elastic components of small arteries and arterioles, which are substituted by a hyaline material and collagenous strands (hyalinosis, fibrohyalinosis). Lipid-laden macrophages (lipohyalinosis) and fibrinoid necrosis may be added in some vessels. This type of angiopathy has been classically described in chronic hypertension, but may be present in normotensive subjects. Almost identical changes are described in patients with hereditary forms of VD. In amyloid angiopathy, a proteinaceous material that stains with Congo red is deposited in the wall of meningocortical arterioles, inducing media degeneration. It has been described in both sporadic and familial cases and is a common finding in patients with AD. Other forms of inflammatory or noninflammatory angiopathies may involve small vessels in rare and selected cases of VD (Table 2).

4 Vascular Mechanisms of Cognitive Impairment

Two hypothesis have traditionally been held to explain how a focal process such as cerebrovascular disease affects a global capacity of the brain such as cognition or intelligence. The volumetric hypothesis was initially formulated by Tomlinson et al. (1970). These authors argued that there is a threshold of volume of infarcted brain that, once reached, would induce dementia. A second line of thought has identified the topography or location of vascular lesions as the crucial factor. The first explanation would be based in a model of functional reserve of the brain to sustain cognition, while the second stresses the extremely complex topic of the anatomy of intelligence. Topographical or anatomical correlations of dementia and vascular lesions have always been biased by the requirement of memory impairment in the definition of dementia, as patients with cognitive decline without memory impairment have been systematically excluded. Cognitive functions may be classified as localized or disperse, depending on whether they have a concrete neuronal representation in one hemisphere, or a part of hemisphere, or not. Language, praxis, calculation, or visuospatial and

visuoconstructional abilities are examples of localized functions that may be damaged by focal vascular lesions. On the other hand, disperse functions include attention/concentration, memory, and executive functions, the most genuine functions involved in the definition of VCI and dementia. If intelligence or cognition is defined as "the aggregate or global capacity of the individual to act purposefully, to think rationally, and to deal effectively with the environment," this can only be sustained by the brain working as a whole. Consequently, any focal lesion, apart from those involving primary motor or sensory areas or vegetative control centers, could potentially affect cognition. In this respect, it may be important to bear in mind the model of anatomical correlations of complex functions based on large-scale neurocognitive networks reviewed by Mesulam (1990). This model includes the following points:

1. Components of a single function are represented in different interconnected locations throughout the brain.
2. Individual cortical or subcortical areas may belong to different overlapping networks and participate in several complex functions.
3. Lesions confined to a single region may result in multiple deficits.
4. Impairment of an individual complex function usually requires simultaneous involvement of several regions to be severe and persisting.
5. The same cognitive function may be affected by a lesion in different brain areas. According to this simplified, but useful model, cerebrovascular disease can affect cognition by destroying neuronal components of the cognitive networks both in the cortex or subcortical relay nuclei as well as by lesioning their connections (white matter disease). Both size and location of infarcts are important, and no assumptions should be made as to what cognitive functions are to be impaired.

If infarct volume or infarct location are the only important determinants of cognitive decline and dementia from vascular causes, all efforts should be invested in the investigation of stroke alone. Defining new entities such as VCI or even VD would be unnecessary, confusing, and time-wasting. However, after decades of investigation, numerous studies on dementia and stroke-related variables have yielded contradictory results that are by no means sufficient to explain all the questions surrounding the etiopathogenesis and pathophysiology of cognitive decline due to vascular causes.

The prevalence of cognitive impairment among stroke patients is much higher than that in the general population, and stroke survivors develop dementia five times more frequently than normal controls (Tatemichi and Desmond 1996). Nevertheless, the factors that determine why some stroke patients present with cognitive decline while others do not remain unclear. Some neuropathologic and radiologic studies have emphasized the volume of infarcted tissue. Tomlinson et al. (1970), for instance, placed the critical threshold at 100 ml infarcted brain, but other studies have shown that dementia may appear with as little as 1% of infarcted brain (del Ser et al. 1990). Regarding infarct location, the presence of infarcts in both hemispheres has been highlighted by some authors (Erkinjuntti et al. 1987), while others claim the importance of dominant hemisphere involvement (Liu et al. 1992). Some studies have not found any significant effect of infarct location or even clinical severity on the subsequent rate of dementia (Kokmen et al. 1996). The role of the type of ischemic lesion has also been analyzed, and the relevance of subcortical lacunar infarcts versus cortical lesions has been reported in some studies, but not all. Data considering the presence or absence of white matter changes are also controversial. Moreover, risk factor profiles do not differentiate between stroke patients with or without cognitive impairment including dementia. The problem is even more complicated if we take into account the increasingly recognized fact that VD may ensue in the absence of any clinical history of stroke. All these data lead to the conclusion that, in addition to volume and location, there must be other factors by which focal vascular brain damage induces intellectual impairment (Martinez-Lage and Hachinski 1998). Perhaps a better understanding of the intrinsic cellular and molecular mechanisms underlying brain ischemia may help to solve this question. Recent advances in our knowledge of the molecular biology of ischemia allow us to interpret cerebral infarction as a concept that surpasses that of the classical necrotic, cavitary lesion.

As previously described, Lassen and his colleagues introduced the concept of incomplete infarction to describe ischemic lesions that did not show "emollision" or cavitation. The term was later applied by Brun and Englund (1986) to describe similar lesions in the white matter. This type of "selective ischemic necrosis" may occur in cases of global cerebral ischemia as well as in the periphery of classical cavitary infarcts. It has been suggested that episodes of short-lived mild ischemia might induce these changes without causing radiologically detectable lesions, i.e., they would not be taken into account in volumetric or topographic studies. Whether these lesions may be detected by functional neuroimaging and whether they contribute to cognitive impairment is a matter for further research (García et al. 1996). Another form of neuronal death that may be induced by ischemia is that of apoptosis. There is enough

experimental evidence that ischemic injuries may cause delayed "programmed" neuronal death, thus opening the question of whether such a process might become uncontrolled or self-perpetuating and lead to progressive cell loss (Bredesen 1995). In this respect, the profound changes that ischemia induces at the gene expression level may become particularly relevant (Matsushima et al. 1996). Immediate-early genes, the amyloid precursor protein gene, and genes coding for proteins involved in stress or inflammatory responses are upregulated in ischemic conditions (Higashi et al. 1995). Again, dysregulation of these responses might induce further radiologically undetectable vascular brain damage and contribute to cognitive decline. The role of non-neuronal cell populations should also be considered. Astrocytes and microglia may become rapidly activated by ischemia and contribute to exaggerated acute-phase or inflammatory responses with overproduction of nitric oxide, cytokines, and free radicals that could mediate postischemic brain damage (Gehrmann et al. 1995). Remarkably, all these changes might be induced by mild short-lived ischemic insults that could be insufficient to cause clinical symptoms or radiologically detectable infarcts. Oligodendrocytes, for instance, are highly susceptible to ischemia and may be affected by mild focal or global hypoxic–ischemic injuries, with the subsequent white matter damage and dysfunction (Yamanouchi 1991).

In summary, the pathophysiology and etiopathogenesis of ischemic brain damage is multiple and varied. Cognitive impairment must be the result of the destruction of brain areas that sustain intellectual functions, but also of those regions that allow for compensation. It is possible that the instruments or methods currently used to quantify, add, or locate vascular brain damage are not accurate enough. A similar situation has occurred in AD. Counts of what could be easily seen (plaques and tangles) correlated poorly with cognitive decline or dementia severity. It was synaptic density reduction that best explained intellectual deficits. Apart from established stroke, the clinical and pathogenic relevance of short-lived or mild episodes of ischemia insufficient to cause symptoms or cavitary infarcts – whether embolic, thrombotic, or hemodynamic in origin – might be more important than traditionally believed. The value and applicability of new diagnostic tools, such as functional magnetic resonance imaging (MRI), receptor-oriented PET or single photon emission computed tomography (SPECT), and the relevance of analytical determinations of acute-phase proteins or inflammation mediators in blood or cerebrospinal fluid (CSF) should be further investigated, as they might well detect cellular and subcellular changes induced by ischemia.

5
Categorization of Vascular Cognitive Impairment

The unquestionable evidence that VD has multiple etiologies is one of the big paradoxes of the literature on vascular neurology. On the one hand, almost any text on VD includes a section on the classification of the different types of VD, but on the other, all sets of diagnostic criteria ignore this question (Bowler and Hachinski 1996). The confusion that this creates is easy to understand using the following analogy. It is difficult to imagine a study in which patients with dementia due to hypothyroidism and patients with vitamin B_{12} deficiency are analyzed together under a diagnosis of metabolic dementia. However, a similar, if not identical, situation is occurring in the field of VD. It is beyond doubt that clinical manifestations, neuroimaging features, risk factors, and treatment in patients with dementia due to multiple cardioembolic infarcts must be different from those concurring in patients with dementia due to multiple lacunes. Surprisingly, all these patients are grouped together with a diagnosis of VD in epidemiological, clinical, and radiologic studies and even in clinical trials. There is little doubt that this leads to uncertainty and prevents progress in the understanding of cognitive impairment and dementia due to vascular causes.

Several proposals to classify and categorize VD are available in the literature. Unfortunately, anatomic and pathophysiologic criteria are confusingly mixed, and only a few authors have proposed clinically recognizable categories. To be clinically useful, any classification of VCI should be based on etiology. The different categories should be supported by pathologic data and, more importantly, should be clinically recognizable. The first step consists in the characterization of neuropsychological deficits and their combination into clinical syndromes. A systematic definition of the clinical manifestations together with neuroradiological findings will allow the topography of vascular lesions to be determined and a diagnosis of the type of infarcts and subsequently their etiology to be approximated (Martinez-Lage and Hachinski 1998).

Two main types of clinical situations may be distinguished: (1) those in which cognitive deficits are restricted to one cognitive area and (2) those involving two or more intellectual functions (Table 3).

5.1
Syndromes Restricted to One Area of Cognition

Syndromes restricted to one area of cognition usually include all those patients with deficits in localized cognitive functions, i.e., functions with a concrete

Table 3. Categorization of vascular cognitive impairment

Clinical picture	Neuropathology/ neuroradiology findings
Circumscribed cognitive deficits	
Localized functions	Cortical infarcts
	Cortical microinfarcts
	Watershed infarction
	Laminar necrosis (?)
Disperse functions	
Memory	Selective vulnerability (hippocampal sclerosis)
	PCA infarcts
	Subcortical infarcts (thalamus, basal forebrain)
	Lacunes (thalamus, basal forebrain?)
Executive functioning	Cortical infarcts/ microinfarcts (frontal)
	Lacunes, subcortical infarcts (frontal white matter, basal ganglia, thalamus, capsular genu)
	White matter disease
Multiple cognitive deficits	
With focal lesions	
Angular gyrus	Cortical infarct
PCA infarcts	Cortical infarct
Capsular genu	Lacunes/subcortical infarcts
Basal forebrain	Lacunes/subcortical infarcts
Thalamus	Lacunes/subcortical infarcts
Multiple lesions	
Cortical VCI	Multiple cortical infarcts/ microinfarcts
	Watershed infarction
	Selective vulnerability (laminar necrosis?)
Subcortical VCI	Lacunes (lacunar state)
	Lacunes (lacunar state) + white matter disease
	Watershed infarction
	Subcortical infarcts
White matter VCI	Vascular white matter disease

PCA, posterior cerebral artery; VCI, vascular cognitive impairment.

neuronal representation (Freeman et al. 1989). Disturbances of language (aphasia), reading/writing (alexia/agraphia), praxis (apraxia), and recognition (agnosia, neglect) will usually respond to cortical lesions. Exceptions include cases of transcortical aphasia or hemineglect syndromes caused by subcortical lesions involving the thalamus or basal ganglia. In both cases, atheroembolic/cardioembolic infarcts will be the underlying pathogenic mechanism in the majority of cases. Some cases of isolated transcortical aphasia or visuospatial disturbance may occur in patients with watershed infarcts with a possible hemodynamic mechanism.

Isolated impairment of memory functions is rare in cerebrovascular disease (Bowler and Hachinski 1996). Thalamic lesions and basal forebrain infarcts cause severe memory impairment, but are usually accompanied by other deficits. Episodes of global anoxia–ischemia may damage both hippocampi and produce amnesia. A similar mechanism has been claimed to explain a new neuropathological entity known as hippocampal or subicular sclerosis. This condition, characterized by profuse neuronal loss and astrocytosis in both hippocampal formations, has been described in old patients with dementia and has been hypothetically ascribed to ischemia. However, previous history of episodic anoxia cannot always be elicited, and some patients present other neuropathological findings that may suggest a neurodegenerative disease (senile plaques, neurofibrillary tangles, ballooned neurons, argyrophilic grains).

Executive functions include tasks such as attention, planning, programming, anticipation, set shifting, or memory search strategies, so that describing an "isolated" compromising of executive functions may be imprecise. Syndromes of executive dysfunction may result from different lesions with different etiopathogenic mechanisms: cortical infarcts in the territory of the anterior cerebral artery or the anterior branches of the middle cerebral artery; lacunar infarcts in the subcortical frontal white matter, thalamus, capsular genu; deep infarcts in the caudate; or basal forebrain infarcts (Mahler and Cummings 1991). Together with the syndromes of executive dysfunction, disturbances of motivation or drive and profound personality changes may characterize the clinical picture.

5.2 Focal Lesions Causing Syndromes Involving More than One Cognitive Domain

Whimsically placed infarcts (i.e., rare infarcts that occur in places in the brain where anatomical substrates for different cognitive functions coincide) may cause significant impairment in several cognitive areas, regardless of whether or not dementia (strategic infarct dementia[6]) ensues. Typical examples include the angular gyrus syndrome (aphasia, alexia, visuoconstructional disturbances, and Gerstmann syndrome) due to atheroembolic occlusion of the posterior branches of

[6]This term is applied to describe cases in which a single infarct, whimsically placed, causes a clinical picture of dementia. Infarcts in different locations, such as the angular gyrus, thalamus, basal forebrain, or capsular genu, which respond to different etiopathogenic mechanisms (lacunar, atheroembolic, or cardioembolic) are included.

the middle cerebral artery; paramedian unilateral or bilateral thalamic lacunar or embolic infarcts that may cause severe amnesia, apathy, and executive deficits, with or without aphasia; basal forebrain lesions secondary to anterior communicating aneurysm rupture or surgery that cause severe amnesia and personality changes; lacunar infarcts in the caudal capsular genu that may cause severe apathy, personality changes, and amnesia (Tatemichi et al. 1994). Similarly, embolic or atherothrombotic infarcts in the territory of the posterior cerebral artery may cause different combinations of visual agnosia, aphasia, reading or writing disturbances, and memory loss. Most proposed classifications of VD have considered strategic infarct dementia as a separate entity; however, as can be seen, the mechanisms leading to these type of lesions are varied and the category should disappear if etiopathogenic criteria are to prevail in the categorization of VCI.

Most of the conditions included in the two previous categories of VCI are clinically recognizable and their etiopathogenic implications may be easily interpreted. One of the most important aspects of this proposed classification is to detect these cases of focal or localized cognitive syndromes as cases of VCI in which cognitive changes may progress and worsen in the direction of dementia. Further research is needed to understand the mechanisms and risks factors by which such potential progression takes place.

5.3 Syndromes Involving Multiple Cognitive Areas

Patients with multiple cognitive syndromes which cannot be ascribed to a single lesion will probably represent the most frequent type of VCI in daily clinical practice. Detailed studies are still needed to establish the different categories following clinical and etiological criteria. Meanwhile, it can be hypothesized that most patients will have one of the following three clinical forms according to the pattern of neuropsychological deficits: cortical, subcortical, or white matter forms.

5.3.1 Cortical Forms

Patients with cortical forms of VCI will present with deficits in cognitive areas with a clear cortical representation such as language, praxis, memory, visuospatial and visuoconstructional functions, or calculation. Such deficits would be expected in patients with multiple cortical infarcts that usually respond to atherothrombotic or embolic mechanisms. Cortical damage (granular cortical atrophy) may also occur in the context of small-vessel disease. Amyloid angiopathy may potentially cause cortical microinfarcts, and it might be recognized in the absence of other cardiovascular processes, especially if there is positive family history or concomitant history of lobar hemorrhage. However, the clinical pattern in these patients may be dominated by those deficits due to an associated AD. Moreover, amyloid angiopathy may also cause subcortical deficits due to white matter ischemic changes. Multiple microembolic or thrombotic occlusion of cortical vessels has been described associated with cardiac surgery, ischemic heart disease, and thromboangiitis obliterans (Erkinjuntti and Hachinski 1993). Hemodynamic disorders and distal field ischemia may also lead to selective ischemic necrosis of vulnerable cortical layers and induce cortical cognitive syndromes in the absence of radiologically detectable infarcts. In such cases, blood pressure monitoring and functional neuroimaging techniques may prove useful for clinical diagnosis.

5.3.2 Subcortical Forms

Symptoms and signs of executive deficits, disturbances of motivation and drive, attentional deficits, personality changes, and affective disorders are the predominant features of subcortical cognitive syndromes (Cummings and Benson 1992). Memory loss may also be prominent but, in contrast to cortical forms of amnesia, patients may show good performance in cued recall or assisted learning tasks. Disturbances of motor control, including gait disturbances, slowness, rigidity, tremulousness, or pseudobulbar syndrome, are usually present. Subcortical cognitive syndromes have traditionally been regarded identical to either lacunar state or Binswanger's disease (Loeb and Meyer 1996). This remark needs further consideration. On the one hand, they probably represent the same clinical and radiological entity. Binswanger's disease is characterized by the presence of white matter disease and small subcortical lacunar infarcts, while lacunar states that cause cognitive decline are frequently accompanied by white matter disease. On the other hand, a diagnosis such as Binswanger's disease may be misleading in terms of etiology and pathogenesis. There are several processes that may cause subcortical cognitive deficits with white matter changes and small subcortical infarcts or lacunes. Hypertension is probably the most frequent one, but other entities such as amyloid angiopathy, hereditary forms of small-vessel disease, or coagulation disorders with increased fibrinogen should be taken into consideration, especially in normotensive patients (Caplan 1995). Hypotension and other processes leading to global brain ischemia or anoxia have also been associated with subcortical cognitive deficits (Brun 1994). Among the hereditary forms, the condition known as cerebral autosomic dominant arteriolopathy with subcortical strokes and

ischemic leukoencephalopathy (CADASIL) may prove to be more frequent than initially considered (Chabriat et al. 1995). It is characterized by the presence of subcortical strokes and dementia at unusually early ages as well as migraine with aura, psychiatric disorders such as depression, or symptomatic/asymptomatic white matter changes (leuko-araiosis, L-A) detected by CT or MRI in members of the same family. The responsible mutation has been located in the Notch-3 gene on chromosome 19.

Subcortical forms of VCI should be identified as clinical syndromes and subsequently classified by etiology. Terms such as Binswanger's syndrome or subcortical VCI are acceptable if they are followed by a statement about possible or probable etiopathogenic mechanisms. A distinction between hypertensive and nonhypertensive forms could be a first useful step toward a better categorization and understanding of this frequent form of VCI and its potential treatment and prevention.

5.3.3 White Matter Forms

There is enough evidence to support the hypothesis that white matter disease may occur in the absence of lacunes or other small infarcts. Some studies in which patients with discrete lesions are excluded have shown that white matter disease is associated with deficits in attention, speed of mental processing, and frontal lobe functions, while memory, verbal, and visuospatial abilities may be preserved. It may be interpreted that isolated white matter changes may induce similar but more restricted or less severe deficits than subcortical nuclei lesions. The clinical distinction is important if mechanisms leading to isolated white matter disease are different from those leading to white matter changes with white matter infarcts (Martinez-Lage and Hachinski 1998).

In summary, classification and categorization of VCI is a complex and laborious task. However, avoidance of this crucial question may lead to confusion and misunderstanding. If patients are not grouped together according to possible or probable etiologic criteria, no conclusions can be reached regarding pathophysiology or detection of risk factors. If patients with different diseases are mixed, no efficient preventive or therapeutic measures can be adequately tested.

6
Neuroimaging in Vascular Cognitive Impairment: The Matter of White Matter

That VCI can not be diagnosed in the absence of evidence of cerebrovascular disease requires little discussion. Such evidence must be obtained from any of two sources, clinical and/or radiological evaluation. In a patient with a sudden onset of hemiplegia and corticospinal signs on examination few clinicians would doubt the vascular etiology, and a CT scan would be requested to detect a hemorrhagic or an ischemic lesion. Even if brain CT shows no changes the diagnosis of ischemic stroke would be maintained if symptoms or signs lasted more than 24 hours. In patients with cognitive complaints, usually in the form of poor memory or disorientation, things are not that simple. First, clinical information is difficult to collect. The onset of symptoms is usually poorly recalled by patients or relatives and when it is, the fact that it is not abrupt does not rule out a vascular origin. With regard to examination, the importance of focal motor, sensory, visual signs has received significant attention but the fact that cognitive deficits, if well characterized, constitute focal signs themselves has been overlooked. Examination of cognition requires time and experience and the pattern of intellectual deficits is not always easy to establish. In such situation it is difficult to ascribe symptoms and signs to a particular neuroradiological finding. The role of neuroimaging techniques in detecting vascular lesions in patients with cognitive decline is evident, but information provided by clinical and radiological sources must be carefully contrasted.

Together with the inherent difficulty of establishing clinico-topographic correlations, controversies and disparities in the field of neuroimaging and VCI are easily explainable. To date, only patients fulfilling current criteria for VD, that is, patients with memory impairment and with advanced and severe cognitive decline (sufficient to impair social or occupational functioning), have been analyzed. If part of the cognitive pattern (memory) and the degree of severity are pre-established, conclusions are necessarily biased. In addition, given the degree of severity required, enough time may have been allowed for different vascular mechanisms to concur in the same patient and the specific role of each one of them can not be discerned. This is the other indispensable role of neuroimaging in the diagnosis of VCI: to assist in the etiopathogenic classification of patients.

6.1
Brain Infarction

Neuroimaging studies in patients with VCI or VD may show any kind of infarcts which appear as hypodense areas on CT and hyperintense/hypointense areas on T_2-weighted/T_1-weighted MRI images (Cummings and Benson 1992). The size and distribution of lesions,

together with clinical manifestations, may help in the differential etiologic diagnosis. Medium-sized or large infarcts involving the cortical areas in an end-artery distribution usually respond to atherothrombotic or cardioembolic mechanisms. The presence of multiple wedge-shaped cortical infarcts or evidence of hemorrhagic transformation (which can be demonstrated in the chronic phase by the low signal intensity of ferritin and hemosiderin on T_2-weighted MRI images) may reinforce the latter. Evidence of hemorrhagic infarction may also suggest an underlying amyloid angiopathy. Cortical infarcts involving the posterior frontal lobe and posterior parieto-occipital regions are compatible with watershed or border-zone infarction and might suggest a hemodynamic origin. Subcortical lesions include lacunar infarcts, but also atheroembolic and border-zone infarcts, which may be distinguished according to size, distribution, and other clinical and laboratory data. Lacunar infarcts appear as small lesions, less than 1.5 cm in size, and are distributed in the territory of deep penetrating arteries (white matter, thalami, basal ganglia, brainstem). Dilated Virchow-Robin spaces, which show similar behavior to the CSF on the different MRI sequences, should not be confused with lacunes, which appear hyperintense with respect to the CSF on proton density images. All these data, adequately combined with appropriately collected clinical and neuropsychological information as outlined in the previous section, will surely help to classify patients with VCI according to possible and probable etiologies, and those at risk of developing further cognitive decline will be better identified and characterized. In this respect, two additional neuroimaging findings are relevant: atrophy and white matter changes.

6.2 Atrophy

Cortical and/or subcortical atrophy is a frequent finding in patients with cerebral infarcts and dementia when compared to nondemented stroke patients (Gorelick et al. 1992; Chiu et al. 1992). This has been expressed by different parameters, such as generalized atrophy, atrophy of the third ventricle, ventricle to brain ratio, mean ventricular volume, lateral ventricle enlargement, total ventricular and subarachnoid space areas, or ventricular index. The importance of this finding resides in the fact that it may be a significant predictor of future dementia in patients with stroke, as was demonstrated in the longitudinal follow-up of the Stroke Data Bank Cohort (Tatemichi et al. 1990). Both previous stroke and cortical atrophy at stroke onset, as detected by direct visual analysis of CT scan, were the most important predictors of incident dementia. Other parameters, such as atrophy of the corpus callosum, have been reported as radiological correlates of cognitive impairment of vascular origin.

6.3 White Matter Vascular Damage

The introduction of CT scanning in the diagnostic evaluation of neurological patients allowed the detection of changes in the white matter in a substantial proportion of the adult population. This white matter rarefaction, which appears as a hypodense area surrounding the ventricles and spreading into the subcortical white matter (centrum semiovale) in the most severe cases, was soon related to the presence of cognitive decline, dementia, and a higher incidence of vascular risk factors (Meyer et al. 1992). Many authors hurried to diagnose patients with this finding as Binswanger's disease patients, and an "epidemic" of this previously rare disease invaded the literature (Román 1987). Pathologic studies described lacunar infarcts, areas of demyelination, and arteriolosclerosis in many cases, but also dilated perivascular spaces, hydrocephalus, and ependimitis granularis as the histologic substrate. To emphasize this heterogeneity and avoid any presumptions about etiology, the term leuko-araiosis (L-A) was introduced and widely used (Hachinski et al. 1987). The introduction of MRI brought more confusion and misunderstanding. Due to its high sensitivity, MRI detected some changes in the white matter in up to 80%–90% of healthy subjects older than 60. It was not surprising that L-A detected on MRI did not correlate with cognitive dysfunction or vascular risk factors (Chimowitz et al. 1989). Only when periventricular and deep white matter changes were distinguished and semiquantitative or quantitative grading approaches were applied were the clinical significance and the vascular origin of L-A identified (Schmidt et al. 1993). Pathological studies confirmed that small areas of L-A surrounding the frontal horns corresponded to a normal anatomical structure, the subcallosal fascicle. Similarly, thin areas adjacent to the body of the lateral ventricle ("rims" or "halos") and the frontal/occipital horns ("caps") were the expression of ependimits granularis, caused by ependimal disruption and periventricular gliosis. However, when periventricular changes extended into the subcortical white matter vascular, changes such as arteriolosclerosis and ischemic demyelination were present. Deep white matter changes were classified as punctate, patchy, patchy–confluent, and diffuse and were related to perivascular demyelination, spongiosis, gliosis, decreased oligodendrocyte densities, and lacunar or other infarcts. Small-vessel disease was present

in most cases. In some instances, punctate lesions corresponded to dilated perivascular Virchow-Robin spaces (Hachinski and Munoz 1991). With regard to VD, several studies showed that a moderate to severe degree of L-A was present in 50%–80% of patients as compared to 20% of healthy controls or 25%–30% of AD patients. In addition, it is important to emphasize that the presence of L-A on CT has been associated with an extra risk of future stroke in patients with transient ischemic attacks (TIA) or minor stroke, as well as with cerebrovascular progressive disease in patients with symptomatic lacunes (Van Zagten et al. 1996).

The etiopathogenesis of L-A remains a matter of open debate. Together with ischemia and infarction, some authors have suggested that small-vessel disease could lead to increased permeability of the vessel wall and leakage of serum proteins to the surrounding white matter (Munoz 1991; Erkinjuntti et al. 1996). This could lead to an astrocytic reaction, gliosis, spongiosis, and further ischemia. The role of hypotension and short-lived episodes of ischemia leading to white matter "incomplete infarction" has been emphasized by some groups (Brun 1994). In this respect, it is well known that oligodendrocytes are highly vulnerable to mild ischemia. White matter changes are also frequently associated with amyloid angiopathy, which typically affects meningocortical and not white matter vessels. A mechanism of distal field ischemia has been suggested to explain these cases. In summary, there may be different mechanisms leading to white matter changes, but all of them share a vascular origin. Subjects with moderate to severe L-A, especially if involving the deep white matter, show cognitive deficits in executive functions and speed of mental processing as well as a higher incidence of vascular risk factors such as hypertension and less frequently diabetes or cardiac disease. Increased fibrinogen or factor VIIc activity (Breteler et al. 1994), hypotension (Tarvonen-Schröder et al. 1996), and genetic factors (CADASIL and other hereditary angiopathies) have also been implicated and require further investigation.

CT neuroimaging criteria for the diagnosis of VD have been proposed (Pullicino et al. 1996). According to number and volume of infarcts, severity of L-A, and brain atrophy (ventricular index), the presence of cerebrovascular disease is graded on a scale from 0 to 3. These criteria were developed to improve the reliability of National Institute of Neurological Disorders and Stroke–Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria. This was the main outcome measure to which they were compared, and they were subsequently subjected to the limitations that apply to the use of these diagnostic rules.

7
Clinical Diagnosis of Vascular Cognitive Impairment: Usefulness of Current Diagnostic Criteria for Vascular Dementia

There are two types of diagnostic criteria sets available for clinical practice or research purposes. On the one hand, the criteria from the *Diagnostic and Statistical Manual IV* (DSM-IV; American Psychiatric Association 1994) and those from the *International Classification of Diseases 10* (ICD-10; World Health Organization 1993) are included as general diagnostic tools and outline general principles for the diagnosis of dementia and its different types, including AD, VD, and others. In both sets of criteria, dementia is defined by the presence of memory impairment plus deficits in other cognitive areas, and these deficits must be sufficiently severe to interfere with social or occupational functioning. With regard to VD, history of TIA or stroke, presence of focal signs, and laboratory data would provide evidence of underlying cerebrovascular disease. How this relates etiologically to the cognitive deficits is left to the clinician and is a subjective matter. On the other hand, the NINDS-AIREN criteria (Román et al. 1993) and the criteria from the State of California AD Diagnostic and Treatment Centers (ADDTC; Chui et al. 1992) were specifically designed and operationalized for the diagnosis of VD.

The NINDS-AIREN criteria add little regarding the definition of dementia, which is described as a "decline from a [...] level of functioning manifested by impairment of memory and of two or more cognitive domains." Again, the degree of severity is required to be serious enough to interfere with activities of daily living. Once dementia is considered to be present, a diagnosis of probable VD requires the presence of focal signs consistent with stroke (with or without history) and (not or) radiological evidence of cerebrovascular disease (including large arterial infarcts, multiple lacunes, or extensive white matter lesions). Once dementia and cerebrovascular disease are present, they are considered etiologically related only on a pathochronological basis, i.e., if dementia appears 3 months after a clinical stroke or if cognitive decline starts abruptly or follows a fluctuating or stepwise course. The NINDS-AIREN criteria define a category of "possible VD" for patients with dementia and focal signs when brain imaging studies to confirm vascular disease or the pathochronological criteria are missing. The ADDTC criteria offer two original and interesting modifications. First, no specific patterns of cognitive impairment are required as far as it is not "isolated to a single narrow category"; in other words, presence of

memory impairment is not compulsory for the diagnosis of dementia. Second, the diagnosis of VD can be established when there is history of two clinical strokes and radiological evidence of at least one infarct outside the cerebellum. Clinical history of stroke or presence of focal signs is not considered necessary in all cases if there is evidence of two or more ischemic strokes on neuroimaging studies. The temporal coincidence of clinical stroke and dementia onset is considered relevant in patients with only one clinical stroke but is not necessary, and no specific chronological pattern of cognitive decline is required. Those patients with dementia and a single stroke not clearly related to the onset of dementia and those with a Binswanger's syndrome who also show vascular risk factors and extensive white matter changes may be diagnosed as possible VD patients.

The applicability of all these criteria in daily clinical practice is seriously limited. With regard to the definition of dementia, most of them require the presence of memory loss as well as an advanced degree of severity. Hence patients with VCI who do not have amnesic deficits and, most importantly, those early cases in which preventive measures may prove more efficient are left undiagnosed. Moreover, the requirement of clinical symptoms of stroke, presence of focal signs, and a specific pattern of temporal relationship between stroke and dementia onset or a stepwise progression is based on generally accepted hypotheses that have never been specifically tested (Bowler and Hachinski 1996). Epidemiological studies have shown that a large proportion of patients with VD have never had symptoms of stroke or TIA (Yoshitake et al. 1995). The important question of white matter changes on CT or MRI is treated too superficially by the summary of the NINDS-AIREN criteria. The way this matter is discussed in the text of the paper is acceptable, but when summarized in the operational criteria leads to confusion. White matter changes are considered a matter of future research by the ADDTC criteria (published in 1992). Finally, none of the criteria attempts to propose a classification of the different etiopathogenic types of VD. By avoiding this matter, entities as different as dementia due to cardioembolic infarcts and that due to multiple lacunes or watershed infarcts are all considered a single condition. None of the criteria sets has been validated in neuropathologically confirmed patients, and the inter-rater reliability of some of them has been questioned. It is also important to note that the different sets are not interchangeable and the frequency of VD in the same population may vary from 6% to 25% depending on the applied criteria (Pohjasvaara et al. 1997).

The alternative concept of VCI will probably shed light in this respect. New criteria to diagnose VCI should be the result of prospective studies on patients with early cerebrovascular disease (from those with only risk factors present to those with established stroke) in which functional, neuropsychological, and neuroimaging data are gathered systematically and analyzed without preformed ideas. A selected comprehensive neuropsychological battery administered to these patients would allow cognitive impairment to be defined according to consentaneous cutoff values in each test without emphasizing memory or any other cognitive domain. Short screening tests would be developed and validated from these neuropsychological tests. The MMSE is widely used, but its sensitivity in detecting cognitive decline in cerebrovascular patients may be too low (Grace et al. 1995). Patients could be classified according to possible or probable etiopathogenic criteria. Patterns of cognitive deficits could then be defined for each group of cerebrovascular disease. Patients with cognitive decline, from early changes to dementia, could be then compared to those without such decline in terms of clinical and neuroimaging features. Results from such an analysis could lead to the formulation of rational and reliable criteria for the diagnosis, early detection, and differentiation of VCI from other forms of cognitive decline such as AD. Using the current criteria, a differential diagnosis between AD and VD is theoretically impossible on a clinical basis, as dementia is identically defined in both cases. However, if patients are detected early and cognitive deficits are thoroughly characterized, both diseases should be clearly distinguished. AD patients may show impairment of orientation, memory, and language, while VD patients tend to be more impaired in executive functions such as attention, self-regulation, planning, and fine motor coordination (Villardita 1992).

8 Cerebrovascular Pathology in Alzheimer's Disease: New Concepts on Mixed Dementia

Mixed dementia is frequently mentioned as the third most frequent cause of dementia after AD and VD in numerous studies. To a significant extent, its study and characterization have been systematically avoided. This is understandable if the label of mixed dementia is only applied to those patients in which AD and vascular lesions coincide but both are severe enough to cause dementia on their own. This is how Tomlinson and colleagues originally defined the term. However, data reported in the last years on the association of vascular pathology and AD suggest that, in a proportion of patients, there might be patho-

physiologic interactions in the production of dementia and even a common etiopathogenic origin of the two processes. Epidemiologic data have shown that hypertension (Skoog et al. 1996), diabetes (Ott et al. 1996), and atrial fibrillation are significant risk factors for AD. Moreover, as mentioned, stroke patients develop AD more frequently than the general population. Numerous autopsy series have demonstrated the presence of ischemic infarcts in up to 30% of patients with a pathologic (not clinical) diagnosis of AD (not mixed dementia) (Olichney et al. 1995). Interestingly enough, in a group of patients with similar AD changes at autopsy, those who also had small infarcts in the thalamus, basal ganglia, or frontal white matter had symptoms dementia while they were alive much more frequently than those without infarcts. The risk of having symptoms of dementia increased by a factor of 20 in association with ischemic infarcts (Snowdon et al. 1997). Other studies show that, when infarcts are present, the density of neurofibrillary tangles is significantly lower and, contrary to what happens in "pure" AD, cognitive scores do not correlate with this pathological marker (Nagy et al. 1997). Another difference, from the clinical point of view, involves the age of onset, which is delayed at least 6 years in patients with vascular lesions. There is therefore enough neuropathological and clinical evidence to suggest that some cases of AD with vascular lesions behave differently to pure AD. Hypothetically, these patients might have remained free of dementia had they not had any cerebrovascular disease. Further research is required to solve the question of whether the association of the two pathologic processes is merely coincidental or whether they are etiopathogenically related. AD is usually accompanied by amyloid angiopathy, and this increases the risk of having an infarct at autopsy, especially if hypertension is present. Amyloid angiopathy may also increase the incidence of white matter ischemic changes. On the other hand, cerebral ischemia may upregulate the expression of the amyloid precursor protein gene and facilitate the deposition of β-amyloid in a similar way to brain trauma.

9 Conclusions and Outlook

Cerebrovascular disease with or without clinical stroke is a frequent cause of cognitive impairment and dementia. VD has traditionally been considered treatable and preventable, but many questions are still unclear regarding its risk factors. More importantly, early detection is not possible as no diagnostic criteria exist. Current diagnostic criteria for VD are only fulfilled by patients with advanced cognitive decline that matches a specific neuropsychological pattern. For these reasons, the concept of VCI was formulated as a necessary new approach to this important medical challenge. VCI should not be considered a new entity, but rather a change of perspective. Cognitive decline from vascular causes should be identified in its initial stages, diagnosed on the basis of reliable clinical and radiologic criteria and classified according to its multiple etiologies. As has been suggested, an international database of prospectively collected and longitudinally followed patients will certainly be the best scenario to achieve this task. Clinical data on age, symptoms and mode of onset, history of cerebrovascular events, and pattern of progression as well as demographic data regarding level of education, employment, and physical and intellectual activities should be systematically collected. Results from clinical neurological and cardiovascular examinations and measures of functional and physical disability should be gathered on standardized forms. Information on risk factors should be simple and complete, including traditional and putative risk factors as well as information on whether they are treated and effectively controlled. Exhaustive questionnaires on family history are essential, and quantitative and comparable data on cognitive functions are mandatory. While valid short screening tests are selected or developed, a comprehensive battery of neuropsychological tests would be desirable. Neuroimaging data should provide information on number, type, and location of infarcts, and white matter changes should be classified according to type, location, and degree of severity. Simple consentaneous measures of brain atrophy should be obtained. Genetic testing for apolipoprotein E genotypes has been recommended for any research project on cognitive decline and dementia. DNA should be stored as new susceptibility genes will soon be discovered. Laboratory tests including SPECT, echocardiogram, carotid ultrasound, Holter-ECG, blood pressure monitoring, autonomic function tests, tests for sleep apnea, vasculitis screening, and others may prove useful in selected cases. The combination of clinical and laboratory data would allow patients to be classified according to possible or probable etiopathogenic mechanisms. By doing so, it will be possible to discern what cognitive deficits are caused by what cerebrovascular process, and reliable diagnostic criteria will be formulated. Longitudinal follow-up will help to detect and understand the factors that determine further progression of cognitive deficits and ultimately dementia. The rationale for future therapy and prevention of VCI will then be established.

Dementias in Other Brain Diseases

Translator: S. Johnson

1 Introduction

Dementia can essentially result from any illness or insult to the brain which causes a certain critical quantity of brain damage. Thus damage to the brain may involve morphologically visible loss of brain substance or may consist of reduction in specific populations of neurones. It may also involve specific transmitter systems or originate in disturbances of metabolism. The list of diseases which may be associated with dementia is therefore long.

The modern concept of dementia, as formulated in ICD-10 and DSM-IV, is essentially based on the pattern of symptoms found in Alzheimer's disease. In a variety of other dementias, the ICD-10 and DSM-IV criteria are not so straightforwardly applicable. This applies especially to the group of conditions defined as subcortical dementias, where pathology mainly involves the basal ganglia, mid-brain and brainstem and there is a prominent disturbance of the retrieval of stored memory contents. For a range of conditions whose characteristic clinical picture is traditionally designated by the term dementia, no appropriate methods of examination with standardised psychiatric instruments are available.

A further characteristic of both ICD-10 and DSM-IV is that the critical threshold for a diagnosis of dementia is strongly tied to the area of activities of daily living. Most of the dementia syndromes discussed in this chapter are associated with a cluster of serious general medical and neurological symptoms, which are generally pointers to the diagnosis of the underlying illness. These medical and neurological illnesses are often in themselves associated with substantial impairments in daily living activities. Thus in this situation the usefulness of making classifications on the basis of limitations in social and occupational role functioning, as ICD-10 requires, is questionable.

The characteristics of the dementia syndromes described in association with different illnesses tend to be rather non-specific, and it is therefore rarely possible to make a convincing judgement regarding differential diagnosis on the basis of psychopathology. The observation of the early twentieth century German psychiatrist Karl Bonhoeffer about the great diversity of underlying illnesses and the contrasting similarity between psychopathological pictures is also applicable to the dementias.

Classification in terms of aetiology or pathogenesis is more likely to be possible in the earlier phases of illness. However, differentiation between patterns of psychopathology in the forms of dementia described here is important, as psychopathology provides clues to the localisation of pathological processes, giving significant insight into the mechanisms of pathogenesis in the dementing syndromes.

2 Degenerative Dementias

Degeneration is a summary term for a large number of aetiologically and pathogenetically unclear processes, in which morphological appearances suggest neither an inflammatory nor a vascular basis. Degeneration is often used as a synonym for the process of atrophy. Historically, the expression "degeneration" was closely linked to heritability. That the concept of degeneration is used to refer to processes which are actually very heterogeneous is indicated by the fact that Creutzfeldt-Jakob disease and the leucodystrophies, previously believed to be classical examples of the neurodegeneration process localised in the grey or white matter, now have to be classified in the group of infectious and metabolic illnesses.

In addition to the examples discussed more fully below, there are a variety of very rare degenerative dementias. Examples include primary progressive aphasia, regarded by some authors as closely related to Alzheimer's disease or Pick's disease, and progressive subcortical gliosis. The clinical picture in progressive subcortical gliosis resembles that of the fronto-temporal dementias. Its name describes the main histological process which characterises it, slowly advancing gliosis involving not only the cortex and basal ganglia but also the brainstem (Civil et al. 1993).

Other forms of dementia have thus far been defined exclusively in neuropathological terms, such as dementia lacking distinctive histological features (Knopman et al. 1990) or dementia with cortical and subcortical argyrophilic grains (Braak and Braak 1989), which may be a variant of Alzheimer's disease. A variety of so-called systemic degenerations, such as striatonigral degeneration, olivopontine cerebellar atrophy and Friedrich's ataxia, are sometimes associated with dementing syndromes, but these have so far been characterised only very imprecisely.

2.1 Fronto-temporal Dementias

The term fronto-temporal dementia is used here to refer both to Pick's disease in the narrower sense and to frontal lobe degeneration of non-Alzheimer type (Brun et al. 1994). The psychopathology characterising motor neurone diseases with dementia is similar.

Whereas motor neurone disease with dementia can be distinguished on the basis of the associated neurological symptoms, Pick's disease and frontal lobe degeneration of non-Alzheimer type are differentiated on histopathological grounds. In ICD-10, Pick's disease in the narrower sense and frontal lobe degeneration of non-Alzheimer's type are subsumed under the expression "dementia in Pick's disease", which is thus defined very broadly. Historically, the ICD-10 definition is close to the intentions of Pick, whose initial description was simply of dementias with a tendency towards focal atrophy, a categorisation which he considered nosologically non-specific. Neary et al. (1998) have suggested that fronto-temporal dementia, progressive aphasia and semantic dementia should all be referred to as subtypes within an overall "fronto-temporal lobar degeneration" category.

Because of the great lack of international consensus on nosology and definition of syndromes, it is very difficult to make generalisations from prevalence figures. Neary et al. (1988) suggest that fronto-temporal dementias make up around 20% of presenile dementias. Gustafson and Brun (1997) report an average age of onset for Pick's disease and frontal lobe degeneration of non-Alzheimer type of 51–54. The duration of illness is usually around 8 years, but courses lasting up to 17 years have been reported.

The early stage of the illness is characterised by a variety of changes in personality. These include disturbances of impulse control, such as highly irritable or aggressive reactions, psychomotor agitation and restlessness. Patients lose their spontaneity, neglect themselves and become impassive, insensitive and apathetic. A coarsening of social behaviour develops, in which usual social rules and norms are heeded less and less. Transient forms of Klüver-Bucy Syndrome may be observed (Cummings and Duchen 1981). Intellectual functions are often preserved for a long time, especially recent memory abilities and orientation in space. Verbal utterances diminish progressively, become monotonous and eventually consist largely of stereotyped, repetitive utterances. Finally, a general poverty of speech develops, which may be associated with total lack of expression and finally progresses to a mute state. Neary et al. (1998) have undertaken the task of trying to bring together the various psychopathological symptoms described in operational diagnostic criteria.

Currently, there seems little point in trying to distinguish between the psychopathologies in Pick's disease and in frontal lobe degeneration of non-Alzheimer type, since this classification has to be made on the basis of histopathology (Gustafson and Brun 1997).

Computed tomography (CT) and magnetic resonance imaging (MRI) show variable frontal or fronto-temporal atrophy, which in some cases may be extremely severe. Single photon emission CT (SPECT) shows diminished frontal blood flow. An unremarkable electroencephalogram (EEG) is a further characteristic finding in fronto-temporal dementia and can thus contribute to making a differential diagnosis from Alzheimer's disease. Even when slow waves appear, the α-rhythm is generally better preserved than in Alzheimer's disease (Neary et al. 1988).

The characteristic histopathological findings of frontal lobe degeneration of non-Alzheimer type and of Pick's disease are loss of cortical cells, gliosis and spongiform changes in the frontal and temporal cortices. The gliosis may also extend into the subcortical white matter. Typically, structures such as the amygdala, the hippocampus and the basal nucleus of Meynert, which are highly abnormal in Alzheimer's disease, are affected only to quite a limited extent.

The round argentophilic intraneuronal inclusion bodies called Pick bodies, together with ballooned Pick's cells, are indicators of Pick's disease in the narrower sense. Neither of these changes features in definitions of frontal lobe degeneration of non-Alzheimer type. At an ultrastructural level, Pick bodies consist of straight filaments, paired helical filaments and also endoplasmic reticulum. In terms of immunohistochemistry, they are characterised by antibodies against ubiquitin and against the tau protein. Thus they have antigenic characteristics which are similar to those of the neurofibrils of Alzheimer's disease. Mutations of the tau gene, coded on chromosome 17, have recently been found in numerous families with fronto-temporal dementia (Gertz et al. 1999).

In contrast to Alzheimer's disease, cortical choline acetyltransferase is not reduced in Pick's disease or frontal lobe degeneration of non-Alzheimer type, while reports regarding muscarinic receptors in the cortex are inconsistent (Hansen et al. 1988).

The aetiology of the illness is unknown. A number of cases of autosomal dominant inheritance have been described. The similarity of antigenic characteristics between Pick bodies and Alzheimer fibrils and occasional descriptions of co-existence of the two types of change in one and the same cell would be compatible with the conclusion that there may be a common metabolic defect or related responses to differing aetiological stimuli.

2.2 Progressive Supranuclear Palsy

Progressive supranuclear palsy is characterised by an initial paralysis of vertical gaze, pseudobulbar paralysis, dysarthria and rigidity (Steele et al. 1964). The illness is rare: only one to four cases are observed per

100,000 people (Globe et al. 1988). Dementia occurs in 20%–60% of patients.

Progressive supranuclear palsy illustrates the principle that standard operationalised psychiatric criteria are not generally applied to subcortical dementias. Most authors refer to the definition proposed by Albert et al. (1974). Typically, forgetfulness is limited, but slowing of thinking and changes in personality and mood are observed. In some cases, extreme slowing of thinking may be mistaken for memory disturbance. Milberg and Albert (1989) found no differences in memory performance in patients with progressive supranuclear palsy compared with control subjects. In the majority of patients, disturbed affect is manifested as indifference, apathy or depressiveness. Occasionally, there is increased irritability and/or euphoric mood. In a third of patients, there is intermittent, unprovoked forced laughter or crying. Podoll et al. (1991) related deficits in speech performance, as well as visual dyslexia, constructional dysgraphia and a raised rate of failure in object naming, to a primary disturbance in visual perception. The consensus is that primary aphasic symptoms are not normally present.

CT scans and MRI show mid-brain atrophy early in the course of the illness. As the illness progresses, brainstem atrophy also becomes apparent. Examinations with positron emission tomography (PET) and SPECT have shown some indications of reduced glucose metabolism in the subfrontal area and also the brainstem and basal ganglia (Karbe et al. 1992). However, these functional changes are not accompanied by neuropathologically demonstrable degeneration of the frontal lobes. They are regarded much more as a manifestation of disordered transmission between the mid-brain and the frontal cortex.

Neuropathologically, the illness is characterised by nerve cell loss, gliosis and globular Alzheimer fibrils, especially in the subthalamic nucleus, globus pallidus, substantia nigra and superior colliculus. Neurofibrils are also found in the neocortex in occasional cases. In contrast to the neurofibrils of Alzheimer's disease, the globular neurofibrils in progressive supranuclear palsy are made up of 15 nm thick, straight filaments, without the coiled filaments characteristic of Alzheimer's disease (Rewcastle 1991).

These typical neuropathological findings have also been described in some patients without gaze paralysis. It is interesting that nerve cell loss has been observed in the basal nucleus of Meynert in progressive supranuclear palsy, as memory impairments in Alzheimer's are attributed to cell loss in this region, yet such impairments are absent or very limited in progressive supranuclear palsy. It may be that this region becomes involved only in very advanced progressive supranuclear palsy.

Nothing is known about the aetiology of this rare disease. It occurs sporadically.

The major neurochemical changes in progressive supranuclear palsy are a fall in dopamine levels, reduced numbers of D_2 receptors in the striatum and a drop in choline acetyltransferase levels.

Dopamine agonists in low doses are thought to treat the motor disturbances more effectively than in idiopathic Parkinson's syndrome. Physostigmine is thought to improve visual attention and memory impairments. Gheka et al. (1991) reported therapeutic success with Idazoxan, a selective alpha-2 blocker, which intensifies noradrenergic transmission.

2.3 Parkinson's Disease with Dementia and Dementia with Lewy Bodies

In terms of clinical neurology, Parkinson's disease is characterised by rigidity, tremor and hypokinesis. Diagnostic indicators at a neuropathological level are Lewy bodies in the substantia nigra and some other brainstem nuclei. A dementia may develop in the course of the illness. This is termed Parkinson's disease with dementia. However, where the dementia develops concurrently with or only slightly after the specific movement disturbance, this is referred to as dementia with Lewy bodies. In such cases, Lewy bodies are also found in the cerebral cortex. The significance attributed to dementia with Lewy bodies has recently increased. The question of whether discrete illnesses can really be clearly differentiated here is still open, as is the question of how dementia with Lewy bodies relates to Alzheimer's dementia.

2.3.1 Parkinson's Disease with Dementia

The idiopathic form of Parkinson's disease is one of the commonest neurological illnesses. For every 100,000 people in the general population, there are around 80–100 cases of this illness (Mayeux et al. 1992). Risk increases with increasing age.

The risk of developing dementia is substantially increased in individuals with Parkinson's disease. Rajput et al. (1987) found a cumulative probability of dementia of 21% among subjects with Parkinson's disease, compared with 5.7% in control subjects of the same age. Mayeux et al. (1988) estimated a cumulative incidence of dementia of 65% by the 85th year of life in people with Parkinson's disease.

Risk factors for developing dementia in an established Parkinson's syndrome include advanced age and also the first occurrence of motor disturbances after the age of 70. Patients with a Parkinson's syndrome in

which tremor is particularly prominent are less likely to develop dementia than those in whom akinesis and marked gait disturbances dominate the picture. Dementia is more frequent where a depressive syndrome is already present (Stern et al. 1993). There seems to be no connection between risk of dementia and neurological impairments which are more severe unilaterally.

Bradyphrenia is a characteristic early intellectual disturbance in individuals with Parkinson's disease. Bradyphrenia is believed to indicate a slowing of the thinking process, which constitutes an intellectual equivalent of hypokinesis. A clear relationship between the occurrence of bradyphrenia and hypokinesis has not, however, been demonstrated, and it remains an open question as to how far the presence of bradyphrenia is a predictor for the later development of a dementia. The fully developed dementia syndrome should be regarded as rather uncharacteristic in Parkinson's disease (Pillon et al. 1991). People with Parkinson's rarely develop disturbances of the cortical association areas, such as aphasias or agnosias, and in the early stages tend to fit the clinical picture of frontal or subcortical types of dementia. However, cortical dementia syndromes do occur.

MRI findings in Parkinson's disease with dementia cannot be differentiated from those in whom the idiopathic Parkinson's syndrome is confined to motor manifestations.

The most significant neuropathological findings in Parkinson's disease are cell loss and gliosis in the pars compacta of the substantia nigra and in some other brainstem nuclei such as the locus coeruleus and the dorsal motor nucleus of the vagus, as well as the basal nucleus of Meynert in the basal forebrain. Lewy bodies are also found in these nuclei, confirming the diagnosis of idiopathic Parkinson's syndrome.

Lewy bodies are intraneuronal eosinophilic inclusion bodies. They occur predominantly in cell bodies but also in neuritic processes. The Lewy bodies found in the subcortical areas are denser centrally, with a lighter periphery. Immunocytochemically, Lewy bodies can be demonstrated with antibodies to neurofilaments and to ubiquitin. However, ubiquitin positiveness is not specific, but can also be demonstrated in Pick's bodies and in Alzheimer neurofibrils.

There has been considerable controversy as to whether the aetiological basis of the dementia syndrome in idiopathic Parkinson's disease is the same as that for the motor disturbances, whether it represents a variant of dementia with Lewy bodies or whether it should be related to concurrent Alzheimer's disease (Paulus and Jellinger 1991). The heterogeneity of clinical presentations of the dementia syndrome in Parkinson's disease permits a variety of aetiological models to be used by way of explanation.

Treatment with medication for dementia in idiopathic Parkinson's syndrome is not very satisfactory. The co-occurrence of cholinergic deficit and relative cholinergic overactivity makes administration of either cholinomimetic or anticholinergic substances rather problematic. Assuming that a common pathological process underlies both cognitive and motor disturbances, use of deprenyl may be a promising avenue (Korczyn 1995).

2.3.2 Dementia with Lewy Bodies

The first reports of a dementing syndrome with cortical Lewy bodies came from Japan. In a series of recent clinical autopsy investigations, the prevalence of Lewy body dementia has been given as 15%–25% of all dementing syndromes in old age. This figure suggests that dementia with Lewy bodies is the second commonest cause of dementia after Alzheimer's disease.

People with dementia with Lewy bodies have difficulties in retrieving memory contents. As well as reduced verbal fluency, disturbances in executive functions and problem-solving are also considered characteristic, as tested in the Wisconsin Card-Sorting Test or in the Trail-Making Test. Thus the clinical picture fits with a subcortical form of dementia. However, as dementia advances, these characteristics become less prominent.

In addition to cognitive impairments similar to those of progressive supranuclear palsy, fluctuating course, hallucinations and the motor symptoms of Parkinson's syndrome are characteristic of the illness. Both cognitive abilities and attention and conscious level tend to fluctuate. Although hallucinations in a variety of modalities occur, optical hallucinations are especially common. They are not generally present for extended periods, but often occur when alertness is reduced or also in the presence of impaired vision. A delusional elaboration of these hallucinations is rare. Accompanying motor symptoms are rigidity and hypokinesis, while tremor is less often seen. Other Parkinson's symptoms such as mask-like expression, hypophonic speech and gait disturbances also occur. Typically, motor and psychopathological disturbances begin around the same time.

Extrapyramidal motor symptoms may, however, precede the psychopathological disturbance or else follow it only after a gap. Recently, operationalised diagnostic criteria have been proposed for dementia with Lewy bodies (McKeith et al. 1996).

In contrast to subcortical Lewy bodies, cortical Lewy bodies stained with haemotoxolyn-eosin dye appear homogenous and evenly pink, and a very careful search is therefore required to find them.

It can be substantially easier to detect them by using ubiquitin antibodies. Cortical Lewy bodies primarily occur in the cingulate gyrus and the entorhinal cortex. Within the neocortex, they are found more often in the temporal than in the frontal or parietal lobes (Kosaka 1990). Ubiquitin-positive degenerated neurites also occur in area CA2/3 of the hippocampus, in the basal nucleus of Meinert and in some brainstem nuclei.

In a small group of "pure" cases of dementia Lewy bodies, there is quite a high density of Lewy bodies in the favoured neocortical sites, without additional Alzheimer's pathology being demonstrable (Kosaka 1990). However, in the majority of patients, the presence of cortical Lewy bodies is accompanied by the appearance of senile plaques and Alzheimer neurofibrils. This "common" form of dementia with Lewy bodies resembles Alzheimer's disease in that it is associated with a raised apolipoprotein E-epsilon 4 allele frequency, which is found neither in "pure" dementia with Lewy bodies nor in idiopathic Parkinson's syndrome.

Establishing the boundary between the "common" form of dementia with Lewy bodies and Alzheimer's disease raises considerable difficulties. However, in group comparisons, senile plaques and Alzheimer's neurofibrils are numerous enough to differentiate individuals with dementia with Lewy bodies from non-demented controls. Thus the Alzheimer-type pathology in dementia with Lewy bodies cannot be understood as a coinciding "normal" ageing process.

On the other hand, the Alzheimer-type pathology in dementia with Lewy bodies is less extensive than in Alzheimer's disease. Patients with dementia with Lewy bodies have a lower density of Alzheimer neurofibrils in the entorhinal cortex, the hippocampus and the neocortex than patients with Alzheimer's (Hansen 1994). The quantity of senile plaques is similar in dementia with Lewy bodies to that in Alzheimer's disease, but with amyloid plaques making up a higher percentage of the diffuse plaques in dementia with Lewy bodies (Dickson et al. 1987).

Interestingly, the activity of neocortical enzymes of cholinergic transmission, such as choline acetyltransferase and acetylcholinesterase, is more clearly reduced in dementia with Lewy bodies than in Alzheimer's disease (Perry et al. 1994).

CT and MRI show a predominantly frontal atrophy in some cases (Förstl et al. 1993). SPECT findings show a similar pattern to Alzheimer's disease.

No specific treatment is known for the cognitive impairments of dementia with Lewy bodies, although attempts at treatment with acetylcholinesterase inhibitors seem worth pursuing. An important consideration is that typical neuroleptics, which may be given in response to hallucinations occurring in dementia with Lewy bodies, exacerbate movement disturbances. They are therefore contraindicated in dementia with Lewy bodies.

2.4 Huntington's Chorea

The neurological clinical picture in Huntington's chorea is characterised by a hypotonic hyperkinetic syndrome. According to Harper (1992), the prevalence is between 4 and 8 cases per 100,000 people. This autosomal dominant illness is believed to occur in all populations, but seems to occur relatively infrequently in Finland, Japan and Central Africa. A raised rate has been reported from Venezuela and Zimbabwe. In most cases, the onset of illness is between the ages of 35 and 50 years. Manifestations before the age of 20 have also been reported, for which the prognosis is especially poor.

Cognitive impairment is frequently found in Huntington's chorea. There are grounds for a diagnosis of a dementing syndrome in two thirds of sufferers (Pillon et al. 1991). Various authors have classified dementia in Huntington's chorea as a subcortical type. This seems justified in view of the absence of aphasia and agnosia even at advanced stages. However, there are a number of differences from dementia in progressive supranuclear palsy, an important example being the absence of slowing down. Verbal recall and recognition are impaired to equal extents in people with Huntington's chorea and those with Alzheimer's disease (Brandt et al. 1992). Hodges et al. (1990) found that, compared with people with Alzheimer's disease, people with Huntington's chorea had greater difficulties in verbal fluency tasks, word recognition and copying of geometric figures. Word-finding difficulties are seen by these authors as the result of perceptual disturbances and not as an impairment in semantic speech organisation.

With CT and MRI, a flattening and shrinking of the caudate nucleus and the putamen can be shown, in the area where these form the ventrolateral wall of the lateral ventricles. There is generally also external brain atrophy, which in advanced cases can be substantial. On PET scans, diminished glucose metabolism has been shown primarily in the striatum, and to a lesser extent it is also seen in the frontoparietal and temperooccipital regions. A greater severity of dementia is associated with diminishing rates of cortical metabolism (Kuwert al. 1990). Reduced glucose consumption in the striatum can also be demonstrated in asymptomatic patients. Leenders et al. (1986) used the selective D_2-ligand *N*-methyl-spiperon to show a reduction in D_2 receptors in the striatum. On the other hand, uptake of ^{18}F-labelled levodopa did not

differentiate individuals with Huntington's chorea from normal controls. This suggests intact presynaptic and impaired postsynaptic functions.

In 30%–80% of patients, the illness process leads to low voltages on EEG, with amplitudes below 10 μV. This reduction in amplitude is thought to be correlated with changes in the caudate nucleus, but it only becomes evident with the fully established clinical syndrome (Fenton 1994).

A significant histopathological finding is the loss in the striatum of small neurones containing γ-aminobutyric acid (GABA), encephalin and substance P. Neurones containing somatostatin and neuropeptide Y are relatively preserved, as are large cholinergic neurones. Even though changes in the corpus striatum dominate the pathological picture, changes can also be found in the cerebral cortex. The cortex shows a volume reduction of 21%–29%, the white matter 29%–34%, and the thalamus 28% (De la Monte et al. 1988). Nerve cell loss can be observed especially in the upper frontal cortex and the cingulate gyrus. The cell populations of the basal nucleus of Meynert, the locus coeruleus and the dorsal raphe nuclei do not appear to be involved.

Huntington's chorea is an autosomal dominant illness with full penetrance. It is caused by a mutation on the short arm of chromosome 4. The gene codes for a protein referred to as Huntingtin, whose function is unknown. The mutation consists of the repetition more than 38 times of the trinucleotide cytosine-adenine-guanine (CAG) (Huntington's Disease Collaborative Research Group 1993). This trinucleotide codes for the amino acid glutamine. In the German population, this trinucleotide is normally repeated 11 to 32 times. In juvenile cases of Huntington's chorea, up to 180 repetitions may be found. The abnormal expansion of this trinucleotide repeat and thus of glutamine is reflected in a mutation in Huntingtin, as a result of which it appears to take on amyloid and therefore cytotoxic properties (Scherzinger et al. 1997).

The direct evidence now available concerning the nature of the mutation in Huntington's chorea allows DNA diagnosis in clinically asymptomatic people. This is feasible as early as the first trimester of pregnancy with the aid of chorionic villous sampling. However, it is essential to consider the serious ethical and psychological problems associated with presymptomatic diagnosis in a late-manifesting and incurable illness.

3 Infectious Diseases

Other illnesses which may underlie dementing syndromes include meningitis and encephalitis of viral, bacterial or protozoal origin. Important examples of viral encephalitides are herpes simplex encephalitis, the subacute sclerosing panencephalitis caused by the measles virus and progressive multifocal leucencephalopathy caused by papovavirus (McArthur et al. 1993). Neurosyphilis and tuberculous meningitis are among the most significant of the bacterial illnesses which can cause dementing syndromes. Among protozoal infections, toxoplasmosis has taken on a new significance among adults as a result of the human immunodeficiency virus (HIV; Ashe et al. 1993).

3.1 Acquired Immunodeficiency Syndrome

Infection with the HIV-1 virus generally leads to development of acquired immunodeficiency syndrome (AIDS) after a 10-year latency period. It is thought that 40%–70% of individuals with AIDS develop neuropsychiatric abnormalities. In up to 20% of patients, neuropsychiatric disturbances appear to be the first manifestation of the illness. Navia et al. (1986) introduced the term "AIDS dementia complex", which by the authors' definition encompasses the triad of "cognitive, motor and behavioural disturbance".

On the basis of this concept of AIDS dementia complex, very high prevalence rates have been reported for the dementia. However, a dementia as defined by ICD-10 is observed in only 4% of HIV-positive patients (Naber 1993).

The most frequent early neuropsychological disturbances are impairments of concentration and memory, slowing, apathy and reduced spontaneity, generally also accompanied by motor slowing. Discrete neuropsychological abnormalities in those with HIV infection should not be uncritically accepted as indicators of central nervous system (CNS) manifestations of the illness. In at least part of this population, neuropsychological abnormalities are present as a result of a pre-existing or concurrent neuropsychiatric illness (Pakesch et al. 1992). Paranoid psychotic syndromes with hallucinations and severe depressive episodes are rare as manifestations of HIV infection. With such syndromes, accurate differential diagnosis again requires pre-existing or concurrent separate illnesses to be distinguished from the manifestations of HIV infection.

CT and MRI may show discrete areas of atrophy. MRI, especially in T_2-weighted views, shows more clearly than CT that there are focal or confluent areas of high signal intensity in the white matter (Keiburtz et al. 1990). In asymptomatic patients, there tend at most to be smaller focal lesions in the white matter (Post et al. 1991).

In autopsy series, 75% of people dying of AIDS have neuropathological changes and 30% show multiple

CNS changes (Janssen et al. 1992). Where macroscopic appearances indicate diffuse atrophy, on microscopic examination circumscribed zones of demyelination are found, especially in the subcortical white matter. Axonal degeneration and the development of microglial nodules and multinuclear giant cells are also observed in these regions. By comparison, the cerebral cortex is affected relatively little (Budka 1991). Numerous opportunistic infections and tumours can complicate the picture.

The mechanisms behind the CNS abnormalities which HIV-1 can cause in the absence of superimposed infection are unclear. It is certain that the HIV-1 virus penetrates the blood–brain barrier at an early stage in the illness and replicates itself in the brain tissue, using mono- and multinuclear macrophages as host cells. Whether the virus causes the CNS pathology by direct or indirect means has not so far been established. The virus capsule protein gt 120 and quinolic acid have been discussed as possible candidates for involvement in this process (Heyes 1995).

It is hoped that recently developed combination therapies may reduce the incidence of neuropsychiatric symptoms (Vitkovic and Tardieu 1998). However, the CNS does constitute a virus reservoir, which for pharmacokinetic reasons is only accessible to pharmacological interventions to a very limited extent (Schrager and D'Souza 1998). Zidovudine is believed to improve the neuropsychiatric symptoms in AIDS at least transiently (Tozzi et al. 1993). This effect may be confined to cases which are already advanced. There have been individual case reports of a positive effect on bradyphrenia by psychostimulants (Fernandez and Levy 1991).

3.2 Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease is one of the transmissible spongiform encephalopathies. Kuru, Gerstmann-Sträussler-Scheinker syndrome and the animal diseases scrapie and bovine spongiform encephalopathy (BSE) also belong to this group. The illness occurs world-wide with a prevalence of 1–2 cases per 1 million people. The highest rate of 42 per million is found among Jews of Libyan origin (Zilber et al. 1991).

In 39% of sufferers, the initial symptoms are non-specific prodromal ones such as tiredness, apathy, disturbances in concentration, attention and memory, increased irritability, depressed mood, dizziness or headaches. In 37% of patients, the first symptoms are neurological. The dementing syndrome which soon appears is distinguished not so much by a specific psychopathological form as by its dramatic course. It is accompanied by primitive reflexes, spasticity and pyramidal tract signs and extrapyramidal motor disturbances, which can take the form of hypokinesis and rigidity or of dystonic or choreiform movements. In around half of the patients, a cerebellar ataxia occurs, preceding the appearance of pyramidal and extrapyramidal disturbances. Impairments of vision in the form of partial or total cortical blindness occur in around a quarter to a third of those with the illness. The frequency of myoclonic jerks, which are held to be especially characteristic, has been quoted as 56%–86%. The end-stage is often akinetic mutism. As a rule, the illness leads to death after 6–20 months, although courses of illness lasting many years have also been reported (Brown et al. 1984). While for the sporadic form the average age of onset is around 64 years, new-variant Creutzfeldt-Jakob disease, which was first described in Britain, has a much earlier average onset around the age of 26. The symptom pattern of the new variant has been characterised as beginning with psychiatric symptoms, such as anxiety, depression and behavioural abnormalities.

The only signs of Creutzfeldt-Jakob disease on CT scanning are some indications of internal and external atrophy. However, MRI, particularly using T_2-weighted views, shows changes in the cortex and basal ganglia with greater sensitivity. A series of examinations have shown localisation of raised signal intensity in T_2-weighted views to correspond to the pattern of neuropathological damage (Gertz et al. 1988a; Röther et al. 1992).

Initially, EEG shows non-specific changes, such as a gradual slowing of the background rhythm. Periodic eruptions of steep bi- and triphasic waves have been regarded as characteristic of Creutzfeldt-Jakob disease (Brown et al. 1979). An almost unvarying interval between these eruptions of around 1 s has often been described. Reports of how frequently such periodic complexes are observed in proven Creutzfeldt-Jakob disease lie between 50% and 90%. The need for serial measurements has repeatedly and rightly been emphasised, so that these typical changes, often crucial for making a clinical diagnosis, may be captured.

Histopathologically, the illness is characterised by the pathognomonic triad of nerve cell destruction, spongiform vacuolisation and proliferation of astroglia. Various subtypes have been identified on the basis of the distribution of morphological changes, including simple polydystrophic, thalamic, cerebellar and panencephalopathic forms (Mitzutani and Shiraki 1985). The last of these is believed to be very rare in Western Europe, but in contrast appears to occur relatively frequently in Japan (Gertz et al. 1988b).

In diagnostically doubtful cases, the immunohistochemical demonstration of proteinase-resistant prion protein in the grey matter of the brain may help to provide clarification. The sensitivity of the corresponding antibodies appears high. Use of brain biopsy

is recommended only where treatable differential diagnostic alternatives are seriously being considered (Budka et al. 1995). New-variant Creutzfeldt-Jakob disease is characterised and distinguished from the sporadic form by the appearance of amyloid plaques in the cerebral cortex and cerebellum.

Most cases of Creutzfeldt-Jakob disease are sporadic. Cases of spongiform encephalopathies have, however, occurred after administration of contaminated growth hormone, use of contaminated deep EEG electrodes, corneal transplantation and also general surgical operations. The illness can be transmitted to primates. In 5%–10% of patients, there appears to be autosomal dominant inheritance with variable penetrance. New-variant Creutzfeldt-Jakob disease, which has so far predominantly been observed in Great Britain, has been connected with BSE. Evidence for this has been produced on neuropathological, molecular biology and epidemiological levels. A direct route of infection from cattle to humans has not been proved with certainty, but is probable (Almond 1998).

The illness is thought to be transmitted and triggered through so-called prions. Prions are thought to be cellular proteins which have pathogenic variants that possibly induce their own formation in a previously unknown way (Prusiner et al. 1989). Whether there are virus-like polynucleotides within the prion has not been conclusively established. It seems certain that the formation of pathological, i.e. amyloid proteinase-resistant prion protein requires the presence of physiological proteinase-resistant prion protein. Mice in which gene technology has been used to remove the proteinase-resistant prion protein gene do not become ill after inoculation with various infectious scrapie isolates. These findings also prove that the spongiform encephalopathies do not originate from loss of a normal isoform of proteinase-resistant prion protein.

The human proteinase-resistant prion protein gene is situated on the short arm of chromosome 20. Point mutations occur in this region as well as repetition four to nine times of an octapeptide on codon 53 (DeArmond and Prusiner 1995). These mutations can be demonstrated by molecular genetic analysis, which can be used as a diagnostic procedure. The infectious agent in Creutzfeldt-Jakob disease is resistant to all conventional sterilisation procedures; 1.2% solution of chlorhexidine or 10% solution of stericol are suitable for disinfecting. No treatment is known.

4 Reversible Dementias

Dementias caused by metabolic disturbances or toxic conditions may be reversible through successful treatment of the underlying illness. Medications prescribed by doctors are especially prominent among causes of toxic conditions, particularly diuretics, cardiac drugs and insulin (Larson et al. 1986). Where such toxic conditions have led to dementia, it can be assumed in older patients that some brain damage has occurred.

Endocrinological disorders such as hypothyroidism or hyperparathyroidism rarely lead to a full-blown dementia syndrome. Vitamin B_1 or B_2 deficiency can be associated with a dementing syndrome. However, replacement often fails to reverse the psychopathological phenomena.

Hakim and Adams (1965) described the clinical picture of normal-pressure hydrocephalus, characterised by the triad of dementia, gait disturbance and urinary incontinence. The symptoms improve after insertion of a shunt. The frequency of normal-pressure hydrocephalus in dementias in adult life has been given as between 1.6% and 7.0%. Normal-pressure hydrocephalus is thought to account for a quarter of all reversible cases of dementia. The onset of illness generally occurs between the ages of 50 and 70.

The gait disturbance often precedes the incontinence and dementia. It is generally described as a gait apraxia or frontal ataxia. The patient walks slowly with small steps and a rather groping broad base. Electromyographic investigations show simultaneous contractions of agonists and antagonists and a permanent activation of the gravity-opposing muscles during walking (Knutsson and Lying-Tunnell 1985).

In psychopathological terms, the cognitive deficit tends to be of a subcortical type, with disturbance of attention, drive and frontal executive functions. Generally, speech is also slowed and has little spontaneity. In neuropsychological investigations, attention and short-term memory are impaired, as are writing and drawing. Functional disturbances associated with the cortical association areas, such as aphasia and agnosia, do not occur (Filley et al. 1989).

Typical signs on CT and MRI are markedly enlarged inner ventricles, especially in the anterior horns of the lateral ventricles, with little or no brain atrophy. More recently, an MRI finding (albeit a non-specific one) of periventricular signal hyperintensity has been reported (Bradley et al. 1991). On SPECT and PET scans, diminished frontal global metabolism has been reported.

A substantial diagnostic work-up is a prerequisite for a successful shunt insertion operation. The method of choice is intraventricular brain pressure measurement, which in typical cases shows intermittent plateaux or peaks in intracerebral pressure, termed Lundberg-B waves. Good results can be expected from shunt insertion in patients in which, during 48-hour recording, intraventricular pressure has been raised in the Lundberg-B wave form at least twice.

A simpler and less invasive investigation procedure is the removal of 20–50 ml of cerebrospinal fluid by lumbar puncture. Around 30–60 min after this procedure, the gait abnormality and psychometric test results should improve, an improvement which may be sustained for several months.

Around 70% of patients with normal-pressure hydrocephalus have a history of subarachnoid haemorrhage, brain injury or meningitis, which probably causes this clinical picture through the mechanism of impaired absorption of cerebrospinal fluid.

Vanneste et al. (1992) reported that, even after careful diagnosis, a convincing improvement after shunt insertion can be demonstrated in only 21% of all patients.

5 Others

Head injuries are the most frequent cause of neurological disturbances in young adults. Duration of unconsciousness and of post-traumatic illness appear to be quite robust predictors of the severity of later residual symptoms (Mendez 1993). A further important differential diagnosis for dementing syndrome in younger and middle-aged adults is multiple sclerosis. A total of 2%–7% of patients with multiple sclerosis have neuropsychological deficits sufficiently severe to be defined as dementia. In some cases, the dementing syndrome may initially be most prominent and may only later be accompanied by neurological deficits (Rao et al. 1989).

CHAPTER 10

F.M. Reischies

Mild Cognitive Disorders

Translator: S. Henn

1 Introduction

If a person suffers impairment in cognitive function, it can mean serious disability in everyday life; this also applies to mild cognitive impairments, e.g. if a person works in an intellectually demanding career. Because of the new skills and re-training increasingly necessary in today's careers, an excellent ability to learn is essential, and people are frequently pensioned off as a result of decreased cognitive and mnemonic capability. Mild cognitive disorders are therefore becoming increasingly important.

The designations of organic brain syndromes or psycho-organic syndromes, previously frequently used, do not exclusively describe cognitive features of organic brain disorders. With the development of diagnostic classification systems, a distinction has been attempted to be made for cognitive and other psychopathological features; consequently, as an example, organic affective disorder and organic personality disorder are classified separately (see Chap. 12, Vol. 2, Part 2). The present article will describe those acquired disturbances of cognitive abilities which do not meet the quantitative dimensions and qualitative criteria of dementia, delirium and amnestic syndromes (see Chap. 11, Vol. 2, Part 2). The diagnostic category "mild cognitive disorder" does not pertain to a psychiatric illness or even to a psychiatric syndrome; instead, various psychological disorders with many diverse aetiologies, symptoms and syndrome developments are subsumed under this heading.

Cognitive impairments have specific causes and effects in each of three age-groups:

1. Perinatally acquired disorder with consequences for psycho-social development is already manifested in early childhood or adolescence and is constitutional or acquired. This group of mild cognitive impairments is excluded here or mentioned only in passing (see Chaps. 2 and 3, Vol. 2, Part 1). Diagnostic systems generally provide a category for borderline intellectual capabilities, i.e. for low intelligence. The intelligence quotient in this case is between 70 and 84, i.e. in the range of 1 to 2 standard deviations below the norm. This is also the range of test performance expected for individuals with mild cognitive disorder.
2. Mild cognitive disorders appear in middle and older age-groups, for example, as a result of brain insults with a reversible or persistent deficit.
3. In old age, more pronounced age-related changes of cognitive abilities have to be distinguished by differential diagnosis from early stages of degenerative dementia illnesses, e.g. Alzheimer's dementia.

The different nosological concepts will be addressed first. Two concepts are directly opposed to one another. On the one hand, there are psychiatric syndromes, which appear following clearly diagnosed brain diseases. They present as milder or atypical syndromes in contrast to other organic psychiatric illnesses. This is how they are viewed by both the ICD-10 (WHO 1992) and DSM-IV (APA 1994; see also below) diagnostic systems. The other case concerns those cognitive disorders in which brain injury can be suspected, but proof is lacking. This is especially the case for early stages of a dementia disease, in which the progressive decline of cognitive capabilities is striking, but the criterion for the diagnosis of dementia is not yet fulfilled and no clear evidence results from brain imaging investigations. Highly gifted individuals, in particular, remain in this unsatisfactory differential diagnostic situation for a long time due to their higher initial level of ability in intelligence and memory functions.

Some disease courses are progressive according to reports by the patient or relatives; they begin insidiously and later turn into a dementia syndrome. The problem of differentiating a dementia illness from normal age-related changes in cognitive function, which is especially difficult in the elderly, is presented in more detail below. Secondly, courses which are stable over time are observed, e.g. deficits following various brain insults. Frequently, brain injuries which result in impairment of already acquired cognitive functions show a plateau at a lower level following initial improvement. Thirdly, there are forms which disappear over time – whether following localized brain lesions or caused by a temporary disorder in brain function.

Similar diverse causes are possible for mild cognitive disorders as for dementia and for delirium (Gutierrez et al. 1994). Whether, for example, one of the progressive dementia illnesses develops in old age or a Wernicke encephalopathy or a brain trauma has led to a residual deficit state, clinical identification of the underlying brain disease is often difficult, although diagnosis is possible in specific cases.

2 Definitions

Mild cognitive disorder is a category which describes a clinical picture showing deficits in multiple cognitive functions quantitatively characterized as mild. Quantitatively, it has to be differentiated from the normal variance in cognitive abilities on the one hand and severe cognitive disorders, dementia, delirium and

amnestic syndrome on the other. Following the new international World Health Organization (WHO) classification (ICD-10; WHO 1992), the concept replaces the ICD-9 diagnosis 310.1, non-psychotic forms of intelligence disorders following brain insults (WHO 1978). The concepts such as "organic brain disorder of non-psychotic form" (ICD-9) were also common, but were not, however, limited to cognitive impairment.

2.1 Mild Cognitive Disorder According to ICD-10

Some cognitive features of dementia are listed in the diagnostic criteria for research of ICD-10 as criteria for mild cognitive disorder. The neuro-psychological dimensions of memory, attention, speed of mental processes, thinking, speech and visuo-spatial functions are essentially the same in both classifications. Although cognitive symptoms of dementia are named in the ICD-10 and DSM-IV criteria, the disorder is defined such that it does not reach the severity seen in dementia. Signs of severe cognitive dysfunctions, such as in orientation and judgement, are not accepted as criteria. Mild cognitive disorder is thus primarily a diagnostic category for a group of individuals who fall in the border area between cognitive health and dementia. ICD-10 does not specify how many symptoms are necessary to determine the diagnosis.

The ICD-10 definition of mild cognitive disorder requires objective proof of brain disease or systemic illnesses which lead to dysfunctions of the brain (see below). For example, these can appear on the basis of a cerebrovascular accident or intoxication. According to ICD-10, the diagnosis can only be reliably confirmed if the mild cognitive disorder is later reversed as the primary organic illness subsides (WHO 1992; Christensen et al. 1995). This additional requirement contributes to the considerable uncertainty present in the concept of mild cognitive disorder. A reason for this determination can be seen in that only when the beginning and end of the organic brain disorder coincide in time with that of the psychopathological symptoms can the cognitive impairment be considered to be caused by the organic brain event. However, if this requirement is strictly followed, then a relatively mild delirium in response to a traumatic event, for example, also falls under the definition. In the older literature, the term "acute exogenous reaction type" was used. Brain lesions and brain diseases usually lead to long-term consequences precisely in the cognitive area; however, with persistent brain injuries, the diagnosis of mild cognitive disorder cannot be determined with exactly the same degree of certainty as it can for a mild brain injury with reversible cognitive symptoms or temporary toxic-metabolic disorders.

A progressive illness at an early stage is ruled out if there is no objective proof of an organic origin of the cognitive disorder. However, if this proof is present, then the illness can be classified under the ICD-10 category of "mild cognitive disorder". The diagnostic criteria of delirium are described in detail in Chap. 11 (Vol. 2, Part 2).

In contrast to age-associated cognitive impairment (see below) and related concepts, ICD-10 does not limit the mild cognitive disorder to older age-groups; the American diagnostic system DSM-IV proceeds in the same way.

2.2 Mild Neurocognitive Disorder According to DSM-IV

In contrast to ICD-10, the corresponding DSM-IV category "mild cognitive disorder" (APA 1994) also includes cognitive impairment at an early stage of progressive dementia; however, damage to the brain has to be substantiated. This additional condition is currently problematic in many patients with early dementia diseases.

In contrast to ICD-10, DSM-IV sets a minimum for disturbed cognitive areas: two or more areas of disrupted cognitive ability are required. In addition, the cognitive dysfunction has to be confirmed by tests, which in ICD-10 are only demanded by the research criteria. DSM-IV lists essentially the same elements for cognitive disorder as ICD-10; however, it subsumes planning, organization, etc. under executive functions. Furthermore, DSM-IV does not include the subjective impairment of cognitive abilities (see Caine 1994). It is emphasized that mild neurocognitive disorder has to involve a clear suffering, but this can also refer to a reaction when confronted with psychosocial effects of the disorder (APA 1994).

According to DSM-IV, the cognitive disorder has to reach a degree of severity such that they result in an impairment of daily living. Heaton and Pendleton (1981) report relevant daily impairment with mild disorders of cognitive function. In addition to deficits in memory and in the area of speech, attention disorders and disorders involving abstraction and decision-making are also of direct social significance. The latter appear, for instance, following frontal brain injuries.

At this point, the significance of mild cognitive disorders in terms of the demands made by the social environment and a person's career need to be looked at. Slight impairments already have a marked effect on intellectually demanding careers. The same is also true for everyday life in culturally elite social circles. The demands of daily life can, however, generally be adapted to individual cognitive losses. If the patient copes without any problems in the adapted

environment, adaptation has also to be considered in assessing the impairment. The requirement that mild cognitive disorder should be related to performance of daily activities is certainly reasonable for psychiatric case definition and the classification as a "disorder", but it makes the differential diagnosis of dementia more difficult.

As Fig. 1 shows, with the differential diagnosis of mild cognitive disorder the quantitative dimension, i.e. the severity of cognitive impairment and the number of cognitive symptoms, has to be differentiated from the qualitative dimension, the additional criteria such as objective documentation of organic origin, the predisposition, or time of acquisition of cognitive impairment and the existence of non-organic psychiatric illnesses such as depression, schizophrenia and histrionic disorder. The amnestic syndrome is subsumed under severe disorders of cognitive abilities with the neuropsychological syndrome to which aphasia and apraxia belong.

2.3 Objective Proof of the Organic Origin

Both diagnostic classification systems demand proof of an organic cause, be it a brain disease or a systemic illness with effects on brain function. The criteria of the diagnostic classification systems take as a starting point the current diagnoses of organic brain diseases such as stroke, brain trauma or encephalitis. As a consequence of these illnesses, temporary or persistent mild disorders of cognitive abilities can be observed, which are then classified as mild cognitive disorder.

The neuropsychological symptoms in mild cognitive disorder are indicators of a primary brain disease, but can also be observed in psychiatric illnesses in which factors of brain dysfunction or neurophysiological correlates are not yet otherwise explained, for example. The demand for substantiation of the organic origin of cognitive function disorders can be understood such that the cognitive impairment should not be both a classified symptom and proof of the causation by a brain disease. Independent medical findings are called for.

There is still no consensus as to what constitutes valid objective evidence. Findings from imaging methods are frequently invoked in which the validity with regard to proof of organic brain injury is doubtful. For example, a finding by computer tomography may be cited showing "mild cortical atrophy" or "mild ventricular enlargement". A similar situation arises with patchy signal enhancement on magnetic resonance tomography in subcortical areas, findings which are

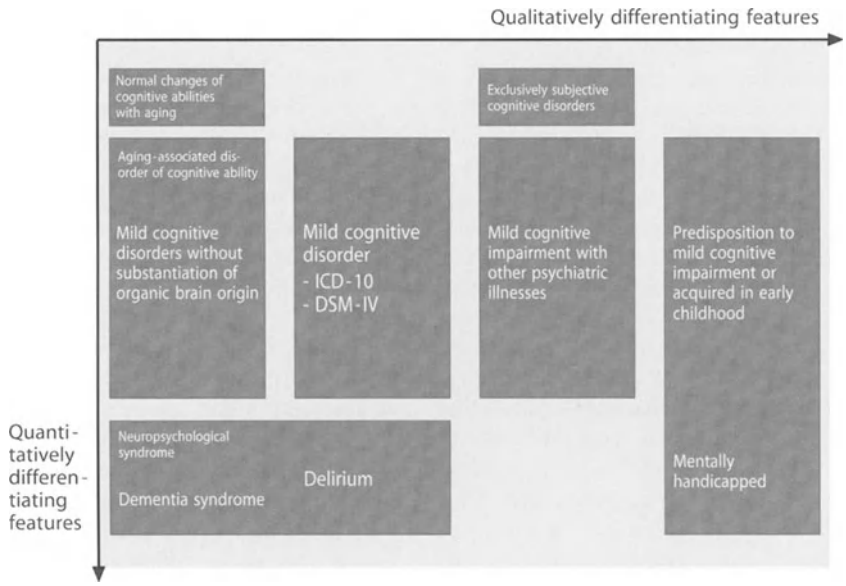

Fig. 1. Differential diagnosis of mild cognitive disorder in the quantitative dimension with regard to the severity of cognitive impairment and number of cognitive symptoms and in the qualitative dimension with regard to additional criteria such as objective proof of organic origin, predisposition, or the time of acquisition of cognitive impairment, and the presence of non-organic psychiatric illnesses such as depression, schizophrenia, and histrionic disorder. The exclusively subjective impairment of cognitive performance is separated here from the category of mild cognitive disorder (see text). Amnestic syndrome is subsumed under the severe disorders of cognitive performance, the neuropsychological partial syndromes to which aphasia and apraxia also belong.

aetio-pathogenetic, diagnostically non-specific and heavily age-dependent.

Since normal values for these findings are still frequently lacking for older age-groups and cut-off values are not validated, considerable research effort is needed in the area of neuroradiological validation of organic brain injuries in mild cognitive disorder. The difficulty that, depending on the state of diagnostic tests for organic brain illnesses, different numbers of patients fall into the group of mild cognitive disorder according to ICD-10 or DSM-IV is only mentioned in passing.

Laboratory findings which prove a dementia are presently not available. Genetic markers refer only to predisposition, but do not prove that the clinically recorded cognitive disorder marks the beginning of the development of a dementia syndrome, since other causes of cognitive disorder are not ruled out.

It is uncertain whether, for early dementia, clinical evidence of a typical time course, such as the typical sequence of appearance of neuropsychological disorders, for example, can also serve as required proof of an organic brain illness. It is also still unclear whether additional borderline values suffice if they complement one another with regard to the diagnosis of organic brain disease; examples worth mentioning include borderline signs of atrophy, a genetic load and the typical course of progression or characteristic sequence of symptoms.

2.4 Definition of Mild Cognitive Disorder Without Proof of an Organic Origin

In a large patient group, the diagnosis of mild cognitive disorder is, in fact, suggested by mild cognitive impairment itself and, where applicable, also by its course without, however, the diagnostically required brain damage being proven through additional medical findings. Practically speaking, this second concept of mild cognitive disorder is significant in the clearly ascertainable progressive decline of cognitive ability in a patient in whom an early dementia is suspected on clinical grounds and in whom the criteria for dementia syndrome are not yet fulfilled. The use of the term "mild cognitive disorder" appears justified here, even if the criteria of the diagnostic systems ICD-10 and DSM-IV are not fulfilled. A long series of terms have been proposed for the cases described, including "questionable dementia" or, to differentiate from normal cognitive ageing, "ageing-associated cognitive decline" (Henderson and Huppert 1984; Levy and Working Party of the International Psychogeriatric Association 1994; see also below). It should be emphasized here that ageing-associated cognitive decline and other suggested definitions require no everyday relevance of the cognitive change (Rediess and Caine 1996).

This second concept for mild cognitive disorder is described here because otherwise a large group of patients in psychiatric treatment and geriatric psychiatry would not be diagnosed. Since there is a heterogeneous category with the diagnosis "mild cognitive disorder", it is also necessary in this chapter to discuss patients who fall into this second concept. It must again be emphasized, however, that formal diagnosis according to the diagnostic systems does not allow for the classification of mild cognitive disorder in this case. An ICD-10 classification section for otherwise unclassified mild organic brain syndrome exists, which also includes mild cognitive impairment (ICD F. 07.8). Mild cognitive disorder without proof of organic origin will be discussed in the next section in its relationship to normal cognitive age-related changes. In the following, the common reference to both concepts of mild cognitive disorder with and without medical findings of organic origin is made, and only when a fact relates specifically to one of the two concepts is the specific concept referred to.

2.5 Mild Cognitive Disorder in Old Age

Because of the clinical significance of diagnostic differentiation between normal age-related changes in cognitive abilities, an accelerated decline of cognitive function in old age and a dementia syndrome, intensive geriatric psychiatry research work is being carried out with the aim of identifying an intermediate group of patients who certainly show cognitive abilities differing from the norm, but do not show dementia. A series of concepts have now been proposed in the literature which are distinguished in many different respects (see Zaudig 1995).

Kral (1962) already proposed a differentiation between age-related forgetfulness in the elderly with a good prognosis and that with a poor prognosis. The favourable type of age-related forgetfulness, benign senescent forgetfulness, is understood such that a further course of development of dementia is no more frequently observed than in non-forgetful individuals of the same age. It is described as stable over time; only normal age-related changes of cognitive abilities will gradually cause a further worsening. In a follow-up study after 4 years, Kral was able to show a clearly lower mortality rate in individuals classified as having the benign type of age-related forgetfulness. Features of benign senescent forgetfulness are that individuals forget relatively unimportant detailed information after a while, but important dates or appointments

are reliably stored and can be remembered. This characteristic was able to be confirmed as a normal age-related change in memory functions (Reischies et al. 1996). Furthermore, memory disorder not associated with dementia is restricted to intermittent problems, repeating names and dates from memory, and to slight temporary orientation disorders. Disorders which go beyond those of memory functions are less favourable or are diagnostic for the assessment of development of dementia. A further feature of benign senescent forgetfulness is that the patients themselves are aware of memory impairment and try to circumvent the gaps in memory or conceal them.

Benign senescent forgetfulness defines a boundary between mild ageing-dependent cognitive impairment on the one hand and cognitive-mnestic disorders which establish a dementia syndrome on the other. In recent years, additional results have been gathered which more closely describe the characteristics of the memory disorders belonging to the dementia syndrome, e.g. decreased ability to learn and reduced capability of increasing recall through semantic support (see Reischies et al. 1996). This confirms the possibility of distinguishing benign and prognostically unfavourable memory disorders on the basis of qualitative and quantitative features.

A disadvantage of the concept of benign senescent forgetfulness is the lack of definite criteria and quantitative cut-off values. In addition, studies on normal ageing of memory functions have only recently become available, enabling the criteria to be further developed. Another disadvantage of the concept is the restriction to memory disorders. These are certainly by far the most significant symptoms of early dementia illness for diagnostic purposes, but extending them to include cognitive impairments in the light of prognostically favourable and unfavourable features would be desirable. DSM-IV provides an additional diagnosis for mild cognitive impairments of normal ageing, age-related cognitive decline (780.9); this is intended essentially for the cases of even milder, but still age-related cognitive impairment. Since by definition it deals with normal ageing changes, a more fundamental consideration is necessary as to whether it is even justified to make a psychiatric diagnosis here.

In contrast to benign senescent forgetfulness, the concept of age-associated memory impairment (Crook et al. 1986) emphasizes the distinction between healthy ageing and mild cognitive impairment (see also Fig. 1). This concept therefore mainly attempts to clarify the transition by individuals with barely discernible impairment in cognitive abilities to the designated intermediate group. The essential feature of this concept is the classification of abilities below a constant test value as pathological, even at a very high age. The test values refer to healthy 50-year-olds. As a result, practically every elderly person over 90 years, for example, is given a diagnosis of an age-associated memory impairment. This circumstance contradicts the validity of the concept just discussed of differentiating prognostically favourable and unfavourable changes in cognitive abilities in old age. Within this concept, the cut-off value of the Mini-Mental State Examination (MMSE; Folstein et al. 1975) is additionally taken as the threshold for dementia.

Another kind of definition follows the typological approach. Using assessment scales, such as the Global Deterioration Scale (GDS; Reisberg et al. 1982), the conditions "healthy", "very mild cognitive deterioration" (intermediate group) or "demented" are described. The clinician can classify the patients according to their neuropsychological impairment and psychopathology. In the GDS, the cognitive ability of an older individual should be compared with a healthy person of the same age.

The proposed concepts are further differentiated by the separate elements of cognitive ability which are listed in the definition; in addition to memory disorders, these also include problem-solving, as found in the "questionable dementia" of the frequently used Clinical Dementia Rating (Hughes et al. 1982), or language comprehension disorders. In addition, the concepts are also differentiated in light of the question of whether or not a progressive deterioration of cognitive abilities is required.

Furthermore, there is a difference in treating the subjective cognitive impairment and awareness of the deficit. Some concepts depend only on objective impairments (e.g. the GDS), while others take into account the complaints made by the patients about an impairment or the fact that the patients themselves are aware of the impairment.

In summary, the heterogeneity of the diagnostic categories and concepts for mild cognitive impairments in the elderly must be emphasized. None of these concepts has been satisfactory in solving the difficult problem of differentiating a group of individuals with mild cognitive impairments, slow progression and without sure proof of brain lesions from normal cognitive ageing on the one hand and from dementias on the other hand, either theoretically or technically in terms of measurements and procedures. We will have to wait to see to what extent the diagnostic criteria as presented in ICD-10 and DSM-IV can be invoked with and without valid proof of brain injury in psychiatric diagnosis in the elderly.

3 Diagnosis

3.1 Differentiation from Normal Age-Related Changes in Cognitive Abilities

Performances on cognitive tests deteriorate in old age. This has been shown both in the course of longitudinal studies and in cross-sectional studies in comparing groups of individuals of varying ages (Schaie 1989; Salthouse 1985). All cognitive abilities appear to be affected by this age effect. It is more strongly evident in speed-dependent tasks. It has even been suspected that the general cognitive ageing is mediated by cognitive slowing (Salthouse 1985; Lindenberger et al. 1993).

Age effects on memory primarily concern the encoding and retrieval of information; however, the ability to store in itself is not decreased (see Reischies et al. 1996). In other words, if something is successfully stored, it will not be more quickly forgotten. Although it is more difficult to retrieve content from memory in old age, it can either be recalled with help or can be recognized from choosing among stimuli. There are clearly observable effects of ageing on the recall of learned material, but they do not in themselves inevitably lead to an impairment in everyday life (Reischies and Lindenberger 1996).

In the area of language abilities, finding a word becomes more difficult in old age, both in naming and in "fluency tasks" (see Table 1). The structure of semantic knowledge is apparently not altered in old age, but retrieval from semantic memory, i.e. lexical knowledge (Light 1988), is slowed down and runs less reliably (Light 1988).

Tests of visuo-spatial abilities (e.g. drawing, putting pieces of figures together) likewise show clear effects of old age (see Koss et al. 1991). This is especially true if the tasks are required to be done quickly.

The effect of old age presumably behaves linearly from about 70 years of age into the oldest age-range (Lindenberger et al. 1995). In practically all tested activities, a decrease was found in the test values in the range of 1–2 standard deviations when healthy 70- to 74-year-olds were compared with those over 95 years of age (Reischies et al. 1996).

In summary, the studies on cognitive performance of healthy older people show that practically no area of performance remains unaffected by impairment related to ageing. In other words, no test for the diagnosis of mild cognitive disorder can be selected which shows no ageing effect at all, and such a test presumably does not exist.

If a mild cognitive disorder is to be clinically identified as the early stages of a dementia disease, it has to be differentiated from the normal age effect of decline in cognitive performances. It should be pointed out here that the ability to substantiate an organic origin of cognitive performance disorders is for the most part lacking at this time for classification under the ICD-10 and the DSM-IV categories. The disorder corresponds to the second concept of mild cognitive disorders as discussed above. There are differences between individuals in the extent of cognitive ageing, and this has been discussed in terms of looking at dementia syndromes as illnesses that can be distinguished from normal cognitive ageing on the one hand or as extreme forms of cognitive ageing characterized only by intensity and rapidity of development on the other hand. The latter, of course, would suggest that everybody would eventually develop dementia if they only lived long enough (Drachman 1994). This would be the consequence of viewing the dementia syndrome as a non-specific symptom of the ageing brain. According to this thesis, all old age-associated cognitive impairments and mild cognitive disorders in old age could be regarded as outpost symptoms of a later dementia.

A differentiation between normal cognitive ageing and a typical development of dementia succeeds at least in many cases on the basis of the course. This means that, within the diagnostic category of mild cognitive disorder, assessing the more rapid progress of dementia diseases can distinguish them from other forms of mild cognitive disorder.

Table 1. Ranges of mild cognitive disorder between -1 SD and -2 SD in the distribution of test performances

Performance	-2 SD	-1 SD	Mean	+1 SD
Digit span[a]	4	5	6	7
Remember 15 words[b]	5.6	7.1	8.6	10.1
Name animals, 60 s[c]	8.4	13.2	18.0	22.8

[a]HAWIE (Tewes 1991): sequence of numbers is repeated (in correct order).
[b]Rey Auditory Verbal Learning Test (Lezak 1995): immediate recall without consideration of the order of presentation.
[c]"Fluency": to name as many animals as possible as quickly as possible; data for 68-year-olds, $n = 278$ (Morris et al. 1989).
SD, standard deviation.

3.2 Methodological Aspects of Diagnosis

Making certain of the diagnosis of mild cognitive disorder is not straightforward when differentiating it

from normal ageing and is not always satisfactory following brain injuries if the effect of injuries has to be distinguished from the normal range of cognitive performances in adults. This is related on the one hand to the basic defining concepts. On the other hand, a series of viewpoints, which will be presented briefly below, can be observed in assessing cognitive performances by means of tests. Since evaluation of subtle deficits in performance are involved in diagnosing mild cognitive impairments, it is probably considerably more crucial than is the case with other diagnoses to have neuropsychological testing methods in addition to the clinical examination. This testing can be carried out by neuropsychologists or clinical psychologists or by psychiatrists after appropriate training. The application of diagnostic test takes account of two quantitative limits which have already been mentioned, the lower limit for the dementia syndrome and the upper limit for the normal variance, for which the clinical validation of this limit presents an additional problem.

Although at first it appears to be clear what mild cognitive disorder means, difficulties arise with the details. With mild neuropsychological partial syndromes, e.g. mild memory disorders, a diagnostic dilemma frequently arises: a mild amnestic disorder is equated with mild dementia, i.e. the beginning of clinical dementia is suspected and it is then assumed that only in later stages will the remaining cognitive impairments be observed. An early progressive dementia illness usually first manifests itself by memory disorders. However, the amnesia syndrome alone may increase, with the other cognitive functions remaining undisturbed. Until disorders are seen in other neuropsychological areas, the dementia is more or less in a diagnostic grey area (Reischies 1996) or a diagnostic "detection zone" (Plassman and Breitner 1996).

The DSM-IV criteria of mild neurocognitive disorder take as a starting point a multidimensional neuropsychological impairment: deficits in at least two cognitive dimensions are required for the diagnosis. If on the other hand, as in ICD-10, it is not required that multidimensional performance disorders are present in the profile, then the question arises as to which critical cognitive functions have to be present for the diagnosis. Even with uniformly lower cognitive performance, the patient is particularly impaired with regard to everyday function only in some areas, such as attention or the ability to concentrate on a task. In old age, primarily memory disorders are noticed. This relates to the differential diagnosis of a development of early dementia. However, the consequences of a memory disorder are also directly relevant to everyday life. This cannot be claimed for many other partial performance disorders, e.g. impairment of musical achievements in a person who is not musically active. The mild cognitive disorder, if not present in all areas, must at least have an impact on critical areas of everyday life.

In child and adolescent psychiatry, attention is particularly paid to development disorders in language abilities (Stevenson et al. 1985). This is reasonable because of the prominent role of language in social contact and knowledge acquisition; language communication disorders are also probably underestimated in old age as the reason for inadequate social contact. The role of mild disorder of judgement after frontal lobe lesions is often neglected in psychiatric evaluation.

But how many people have a balanced achievement profile in the various cognitive dimensions, as shown in the standardized battery of tests? There is no satisfactory data about this in the literature, and there is no agreement about the question of interpretability of the test profile. Mitrushina and Satz (1995) found that only 3.8% of their sample of healthy 70-year-olds showed no conspicuous test result, i.e. most individuals had at least one abnormal subtest in the Wechsler Intelligence Test, which deviated by more than 3 points from the mean; a point difference of 3 points is viewed as clinically significant. The performances in the different domains of intelligence tests therefore usually show a considerable variance within the individual. The danger arises that, with the suspicion of mild cognitive disorder following an organic brain injury, chance deviations in the test profile will be judged to be evidence of the diagnosis.

The susceptibility of certain brain areas and corresponding particular cognitive abilities in comparison with non-specific brain injury is undisputed. The differentiation between fluid and crystallized intelligence can be cited in this connection (Horn 1982). The fluid abilities – with marked effect of ageing – include the time-dependent and visuo-spatial performances, while the crystallized abilities having higher persistence of achievement level following non-specific injury to the central nervous system include above all linguistic knowledge and motor skills. Thus it follows that, with non-specific brain injuries, it is more likely that impairments in fluid performances result.

The normal standard distribution of intelligence encompasses a wide range of cognitive capability. The range of the distribution of cognitive achievements is important for mild cognitive disorder. If we compare the groups of individuals with intelligence test results which are 1 standard deviation above or below the norm, the difference can be clearly seen, as is shown in Table 1. Education-specific norms for tests are uncommon and for the most part not available for old age.

At the same time, Table 1 shows the range in which individuals with a standard deviation between −1 and −2 perform and how those with mild cognitive disorder can be expected to perform. Performance in many

intelligence tests which require more complex and not everyday functions are too difficult for individuals with borderline abilities (IQ 71–85). This is especially true at higher ages.

The statistical frequency of individuals with mild cognitive performance impairment can also be seen from the normal standard distribution. About 2% of the population are below the range of 2 standard deviations, and about 16% below 1 standard deviation. It therefore follows that about 14% of the population fall between 1 and 2 standard deviations below the norm in cognitive performance. The reason for the lower test achievement may be slight limitation in cognitive achievements originating either constitutionally or in early childhood. These individuals do not fall under the diagnosis of mild cognitive disorder according to ICD-10 or DSM-IV. The appraisal of premorbid intelligence is sometimes difficult, and objective validation is most successful using vocabulary tests.

Clinicians can place only limited confidence in the test results which are referred to for assessment: if the reliability of a test is established by correlation of the test results in two stages, then it turns out that mostly 10%–40% of the performance tested twice is random variation. In addition to the random variations and fluctuations, there are all sorts of changes in temporary performance factors such as motivation, alertness and general state (Cohen 1992). The description of the complexity of test diagnostics makes it clear that the diagnosis of mild cognitive disorder, at least in problem cases, can often only be safely made in experienced specialized outpatient clinics such as memory clinics or neuropsychological departments.

Many patients cannot appropriately estimate their own cognitive achievements. This is shown by the comparison of subjective assessment with objective performances in tests. The correlation between subjective and objective disorder of cognitive achievements without exception turned out to be very low (Feehan et al. 1991; O'Connor et al. 1990). Many reasons may be given for this: the cognitive ability has to be observed by the patients; often, however, they lack a standard of comparison and probably also the ability to assess themselves appropriately. Demented individuals frequently minimize or do not admit to their deficits – out of shame or deficits in judgement. Furthermore, self-image also plays a role, both the image that a person has of him- or herself and the one which they want others to have of them. Expectations relating to the social effects of such a statement can therefore be observed. There is also a certain tendency to aggravation. It should be mentioned here that an objective diagnosis of mild cognitive disorder may be difficult if the patient wants to be underrated with respect to the performance level. This also holds true for neuropsychological test results. Often, only the consistency of the pattern of test results can support the validity of a low level of test performance.

Subjective cognitive impairment is frequent. Of those individuals who were not demented in the study by Livingstone et al. (1990), 23% complained of failing cognitive abilities, and Christensen et al. (1995) found subjective cognitive disorders in 17% of their probands. Subjective impairments alone are accepted by some authors and also by the ICD-10 classification of mild cognitive disorder as an essential component of a clinical syndrome diagnosis (Christensen et al. 1995). The suffering of individuals who perceive their own cognitive performances as disturbed, although this assumption is false, can certainly represent a symptom, e.g. of depression. Many researchers emphasize the strong dependence of subjective impairment of performance upon depressive symptoms, and in many patients a symptom of depression can be recorded, e.g. with the ICD-10 criteria of a mild cognitive disorder (Christensen et al. 1995).

According to results in the literature, subjective impairment cannot be used as a basis to predict a progressive course towards dementia (Reisberg et al. 1986; O'Brien et al. 1992). It is doubtful whether it is reasonable to accept purely subjective cognitive impairment as a sufficient criterion for mild cognitive disorder. As an additional feature, however, the everyday relevance of mild cognitive disorder appears justified in the criteria.

4 Differential Diagnosis

In addition to the differential diagnosis of dementia syndrome and ageing-related deterioration in performance discussed above, mild cognitive disorder also has to be differentiated from other organic brain syndromes such as delirium and amnestic syndrome (see Fig. 1 and Chap. 11, Vol. 2, Part 2). One of the important differential diagnostic features is the severity of cognitive disorder: first of all it is milder. In contrast to a delirium, additional differential diagnostic features include disturbance in consciousness (Gutierrez et al. 1994) and vegetative symptoms. There are fluctuations in the psychiatric symptoms of delirium. In benign senescent forgetfulness, however, inconsistent amnestic failures are not remembering a name once, whereas otherwise this name is confidently remembered, for example (see above). A need to differentiate with respect to amnestic syndrome arises; it was discussed in connection with the differential diagnosis of mild cognitive disorder and early dementia.

Mild disorder of cognitive performances in other psychiatric illnesses, e.g. affective or schizophrenic

psychoses, can be mentioned here only briefly. The validity of the results obtained in patients with these illnesses frequently remains unclear (Cohen 1992). On the one hand, an organic brain injury with mild cognitive impairment can produce a disposition for an affective or schizophrenic illness or at least can strengthen a constitutional disposition. One example is the connection which can be made between a mild form of frontal and mediotemporal brain dysfunction with schizophrenia (Bogerts et al. 1985; Weinberger et al. 1986). However, an impairment of test performance can also be caused by disorders of various pathophysiological or psychopathological levels of function in an affective or schizophrenic illness.

Reversible mild cognitive impairments in the context of a non-organic psychiatric illness are not subsumed under the diagnosis of mild cognitive disorder. A person who is depressed does not achieve optimal performance in cognitive tasks. However, the effect of depression on testing is overestimated, as has been shown by recent investigations (Burt et al. 1995; Reischies 1993).

More subjective than objective disorders of cognitive performance characterize a depressive illness (see above and Feehan et al. 1991). Patients with depression complain of inhibition. They compare themselves with the highest performances and thereby strengthen their negative self-image. In contrast, many patients with dementia tend to consider their test results to be better than they are, while depressed patients show surprisingly good test performance in contrast to their self-perception (O'Connor et al. 1990). This makes it clear that testing is necessary. It should, however, be brief and carried out with care, taking into consideration the low self-confidence of the patients.

Some patients with depression have memory disorders, are mildly disoriented and show a clear slowing down. Earlier, this would have been referred to as a depressive pseudo-dementia (Kiloh 1962; Lauter and Dame 1991), although clinically there is no problem in differentiating the syndrome from a fully developed dementia in most cases, but possibly with an early stage of dementia. In the subsequent course, in some of the patients with initially reversible disorders of cognitive abilities, it turns out that a dementia illness begins after a few years, although the proportion to which this unfavourable course applies has not yet been agreed on (Kral 1982; Sachdev et al. 1990). In investigations of progression in depressive patients with disorders of cognitive performance, no substantial improvement or normalization of test results usually occurs with recovery of mood (Abas et al. 1993; Reischies 1993). The question is raised for depression – as for schizophrenia – of the frequency of comorbidity with mild cognitive disorder. Results from imaging studies of these patients indicate organic brain-related neuropsychological disorders. A pathogenetic or a pathoplastic role of these mild cognitive impairments in depression needs to be further elucidated, i.e. whether or not the diagnosis of comorbidity of depression and mild cognitive disorder with or without a pathogenetic or pathoplastic aspect could better describe the facts.

5 Course and Prognosis

Studies which have followed the course in individuals with benign senescent forgetfulness or the classification of questionable dementia show that a rapid progression to a fully developed dementia is not common. Studies of the course of mild cognitive disorder lead to the conclusion that, especially in old age, a higher probability of transition to dementia can generally be established (Peterson et al. 1999). Nonetheless, the cognitive performance of a large group of patients remains constant for years without these patients developing dementia, and sometimes cognitive achievements may even improve or normalize (O'Connor et al. 1990; Copeland et al. 1992; Cooper et al. 1996). In investigations of course with initially detailed neuropsychological testing, it turns out that, in addition to memory deficits in reporting learned materials, a disorder in finding words – apparently a sign of a progressively developing aphasia – is also valuable in making a prognosis; it indicates a rapidly progressive course towards dementia (Storandt et al. 1992). Clusters of different patterns and time course of mild cognitive deficits have been described (Ritchie et al. 1996).

The decline in performance in patients with degenerative dementias is usually noticed by the family within 1 year; it can be recorded in tests for dementia. Thus Burns et al. (1991), for example, found a decrease of about 3.5 points in the MMSE per year in patients with Alzheimer dementia. The pure effect of ageing on dementia tests can be estimated from cross-sectional studies: Crum et al. (1993) found a decline in performance in the MMSE of about 1.3 points per 10 years, while Bleeker et al. (1988) found 0.8 points per 10 years. The data from the Berlin ageing study gave an ageing decline of about 1.6 points per 10 years (Reischies et al. 1996). In longitudinal studies of MMSE performance in healthy individuals, there turned out to be only an insignificantly small decline per year. So far, few studies have been devoted to reliability of measurement of changes using the MMSE (see Schmand et al. 1995). In summary, investigation of the progression of dementia in individuals in the grey area between normal ageing and dementia is very valuable. It is questionable, however, whether it can be

proved that, in addition to the distinction between the normal speed of cognitive ageing and the clearly more rapid cognitive decline in dementia, there is yet a third speed, that of an intermediate group with an age-related mild disorder of cognitive performance.

At present, an intensive search is being made for factors that can predict the further progress of cognitive disorders. An isoform of a protein involved in lipid metabolism, ApoE4, has been described as a predictor of deterioration in mild cognitive disorders (Petersen et al. 1995; Plassman and Breitner 1996). Major advances can be expected in this area in the coming years (see Chap. 6, Vol. 2, Part 2; Chaps. 8–12, Vol. 2, Part 1).

The frequency of mild cognitive disorder in the population is not yet well investigated using the new definitions. Christensen et al. (1995) found the disorder corresponding to the ICD-10 definition in 6% of those over 70 years of age. The authors describe a close relationship between this syndrome and a depressive syndrome. Within the epidemiological catchment area programme in the United States of America, mild to moderate cognitive impairment, including cases of various aetiologies, was found in 5.1% (Robins et al. 1991).

The diagnosis of mild cognitive disorders following brain lesions is significant for early retirement: among patients with psychiatric illnesses which lead to retirement, 1.3% are women and 4.1% are men who are unable to work because of mild cognitive impairments (Verband Deutscher Rentenversicherungsträger 1995). The significance of the diagnosis of mild cognitive disorder for early retirement will probably increase in the near future, as indicated in the discussion above. It is difficult to compile and assess the data for care needs following brain lesions, but, with the estimated 500,000 cases of brain lesion per year in Germany, which include various aetiologies (Kasten et al. 1997), significant numbers of mild cognitive disorders will certainly arise or remain. In addition, data from the Framingham study have shown that there is a higher mortality rate for individuals with lower cognitive performance (Liu et al. 1990).

6 Conclusion

Mild cognitive disorder comprises temporary symptoms or persistent residual symptoms of a disorder of brain function because of a brain disease or systemic disease with consequences of a disturbance of cerebral functions. It may appear following various kinds of brain lesions (e.g. brain trauma, infection, intoxication) or with various systemic illnesses. In old age, it is sometimes a precursor of clinical dementia syndromes. These aspects find different expression in the various diagnostic concepts, and a uniform and generally accepted, criterion-related diagnosis of mild cognitive disorder has therefore yet to be found. Mild cognitive disorder is neither a disease nor a syndrome, but rather a classification unit within the diagnostic classification systems. Mild cognitive disorder is, to our knowledge, quite a common disorder with different social consequences and an unfavourable prognosis in old age. The diagnosis of mild cognitive disorder according to ICD-10 and of mild neurocognitive disorder according to DSM-IV is substantiated by independent proof of an injury to or disorder in the brain coupled in time to the appearance of clinical symptoms. However, in many patients with a cognitive disorder exceeding that of normal ageing, a brain disease or brain lesion cannot be objectively verified; such patients were presented here under the category "mild cognitive disorder without proof of organic origin". At present, the most reliable criterion differentiating this disorder from the early stage of dementia is its relative stability over time in contrast to the rapid progression of dementia syndromes.

Exclusively subjective complaints of cognitive impairment appear not to be a reliable symptom of brain injury and to have little prognostic significance. Clinical research will show how this feature should be included in the diagnostic criteria of mild cognitive disorder. Further dimensions of psychopathological disorders following brain injuries, e.g. affective, compulsive or paranoid symptoms, are classified separately as comorbidity. Further research will be required to answer the question of whether or not a complex syndrome following brain injury might have clinical significance; one possibility is a syndrome that includes both cognitive and affective symptoms as well as personality changes.

Delirium, Amnesic Syndromes and Other Cognitive Disorders

Translator: S. Davison

1 Introduction

This chapter will discuss delirium, amnesic syndromes and other organic mental disorders characterised predominantly by cognitive dysfunction. These disorders are classified within the ICD-10 classification system under organic mental disorders (F0), except where they occur as a consequence of alcohol or substance misuse, in which case they are classified as mental and behavioural disorders due to psychoactive substance use (F1) (World Health Organisation 1992). The DSM-IV classification system uses the term amnestic disorder rather than amnesic syndrome (American Psychiatric Association 1994). Within DSM-IV, delirium, amnestic and other cognitive disorders, including dementia, are grouped within a single section, in which disorders are differentiated on the basis of their aetiology. The causes listed are general medical conditions, effects of a psychotropic substance (alcohol, drugs of abuse and medication side-effects are included under this heading) and multiple aetiologies.

2 Delirium

2.1 Symptomatology

The core symptom of delirium is a rapidly developing disturbance of consciousness accompanied by altered cognitive function. The term delirium was traditionally used within German psychiatry to describe a syndrome characterised by a disturbance of consciousness, manifest mainly as impaired wakefulness and orientation, in association with a number of other symptoms, namely, psychomotor agitation, florid perceptual disturbances such as visual hallucinations, and autonomic symptoms such as tremor, tachycardia and sweating. The disturbance of consciousness ranged along a continuum from reduced vigilance and fatigue through increased drowsiness and sleep to unconsciousness and coma. Disturbance of orientation likewise had a quantitative dimension ranging from a discrete disturbance of the ability to order time correctly through topographical uncertainty to a loss of orientation for person.

However, ICD-10 and DSM-IV have moved away from this narrow definition of delirium and broadened it to include those syndromes which previously were referred to as acute confusional states on the basis of disturbance of attention.

According to the clinical descriptions and diagnostic guidelines of ICD-10, delirium is described as follows: an aetiologically non-specific syndrome characterised by concurrent disturbances of consciousness and attention, perception, thinking, memory, psychomotor behaviour, emotion and the sleep–wake cycle. It may occur at any age but is most common after the age of 60 years. The delirious state is transient and of fluctuating intensity; most cases recover within 4 weeks or less. However, delirium lasting, with fluctuations, for up to six months is not uncommon, especially when arising in the course of chronic liver disease, carcinoma or subacute bacterial endocarditis. The distinction that is sometimes made between acute and subacute delirium is of little clinical relevance. The condition should be seen as a unitary syndrome of variable duration and severity ranging from mild to very severe. A delirious state may be superimposed on, or progress into, dementia (World Health Organisation 1992, pp. 57–58).

DSM-IV specifies the following diagnostic features of delirium:

- Criterion A: a disturbance of consciousness (i.e. reduced clarity of awareness of the environment) with reduced ability to focus, sustain or shift attention
- Criterion B: a change in cognition (such as memory deficit, disorientation, language disturbance that is not better accounted for by a pre-existing, established or evolving dementia
- Criterion C: develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day
- Criterion D: evidence from the history, physical examination or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition

DSM-IV describes disturbances of the sleep–wake cycle, psychomotor behaviour and emotions as associated features which are not essential to make the diagnosis. On the other hand, disturbances of the sleep–wake cycle and of psychomotor behaviour are considered essential diagnostic features in the ICD-10 research diagnostic criteria (World Health Organisation 1993). These criteria are particularly restrictive in their formulation in order to facilitate the grouping of homogeneous patient groups for research purposes. They emphasise the non-specificity of affective symptoms.

2.2 Epidemiology

Figures for the prevalence and incidence of delirium inevitably depend on the context in which they are measured. In childhood, delirium associated with

febrile illnesses predominates. In adulthood, delirium most commonly occurs as a result of alcohol withdrawal. In the elderly, delirium often presents within the context of dementing illnesses. In a review of existing studies, Lipowski (1990) concluded that about 10% of medical and surgical in-patients suffer from delirium at any one time. About 20% of patients in general hospitals that also admit elderly patients have been found to be suffering from delirium on admission or at some point during their stay. In surgical specialities, figures of 25%–50% have been reported. Because of this, delirium is one of the most common syndromes seen in neurology, general medicine, surgery and general practice (Hewer and Förstl 1994). These syndromes are commonly misdiagnosed or not recognised. Thus their prevalence tends to be underestimated.

2.3 Clinical Examination

Clinical assessment is based on three components: observation of behaviour, mental state examination and neuropsychiatric assessment. Any assessment must be repeated regularly because of the fluctuating course of delirium. A thorough assessment must also include taking a general history, including an account of the presenting complaints, and medical, developmental, family, social and personality histories.

A suspicion of delirium is justified if, on first meeting the patient, psychopathological symptoms of any sort appear to develop or change within a short space of time. This may be evident from a patient's speech and language, variable psychomotor speed, fluctuating affect or changeable social interactions.

The mental state examination must aim to elicit cognitive and affective abnormalities which are not immediately observable. Perceptual disturbances may present as symptoms of global cognitive dysfunction. These consist mainly of illusions, (visual) hallucinations and delusional percepts. Patients often maintain a delusional conviction that their hallucinations contradict reality and can react with intense emotion.

Finally, cognitive functions can be assessed in more detail by means of a neuropsychiatric assessment. Disturbance of consciousness and attention must each be observed accurately and repeatedly. For example, patients with impaired vigilance are noted to be easily fatigued. They generally show reduced interest in the outside world and are slower in their readiness to answer. Drowsy patients on the other hand keep falling asleep and can only be roused by strong external stimuli. The most severe degree of impaired vigilance is coma, in which the unconscious patient is no longer able to respond to stimuli from the outside world.

Impaired attention can also occur in wakeful patients. It is manifest as a decreased concentration span (e.g. questions have to be repeated to the patient), increased distractibility in response to external stimuli or perseveration, in which the patient repeats answers to earlier questions. It may sometimes be difficult or even impossible to conduct a conversation with the patient. Disorientation for time or place, but seldom for person, often presents as the first symptom.

Disorders of short-term memory are seen. However, abnormalities can extend to affect learning, encoding, recognition and recall of stored material. Memory is examined by giving the patient the names of several unrelated objects or a short sentence that they must repeat after about 5 min of distraction. Disorders may be observed in the comprehension of language and meaning. Language disturbance may also present as word-finding difficulties (nominal dysphasia) or writing disorders (dysgraphia). Sometimes speech is circumlocutory, loosened in its associations or even incoherent.

Delirium can be quantified by the use of standardised assessment instruments. The Mini-Mental State Examination (MMSE; Folstein et al. 1975) can be used to assess the severity of cognitive impairment. It covers in particular orientation, attention, higher speech, arithmetical and visuospatial functions. However, its use is limited because it does not directly measure the fluctuating vigilance that often characterises delirium. This can only be assessed indirectly via its effect on cognitive functions. There is less experience available in the use of the Delirium Rating Scale (Trezpacz et al. 1988) and the Confusion Assessment Method (Inouye et al. 1990), which have hitherto only been available in English. The Clinical Institute Withdrawal Assessment for Alcohol Scale (Sullivan et al. 1989) and the Mainz Alcohol Withdrawal Scale (Banger et al. 1992) are specialised instruments for the assessment of alcohol withdrawal.

Laboratory investigations are crucial in determining the aetiology of the delirium. Systemic or organ-specific diseases may be diagnosed by their characteristic test results. Routine investigations include full blood count and film, erythrocyte sedimentation rate (ESR), electrolytes (including serum calcium and phosphate), blood sugar, serum urea and creatinine, liver function tests and thyroid function tests. Where there is a clinical indication, more specialised investigations should be undertaken. These may include blood investigations, such as blood cultures, human immunodeficiency virus (HIV) and syphilis serology, and measurement of serum heavy metals, copper, caeruloplasmin, vitamin B_{12} and folic acid. They may include urine investigations, including culture and sensitivity, and screening for drugs and heavy metals. Finally, they may also include examination of

cerebrospinal fluid, including measurement of glucose and protein, cell count and cultures for bacteria, viruses and fungi. If intoxication is suspected, then blood or urine should be tested for alcohol and/or drugs, including medications.

Electroencephalography (EEG) is particularly important in the differential diagnosis of delirium. This non-invasive method can be used and repeated at any time. It has the advantage of high sensitivity, although specificity is lower. Evidence of a metabolic disorder (generalised EEG changes), a space-occupying lesion (focal changes) or complex partial epileptic seizures (spike-wave activity, 2–3/s) may be inferred from typical EEG abnormalities.

Computed tomography (CT) is particularly useful in the diagnosis of acute bleeds, whereas magnetic resonance imaging (MRI) is preferable for the investigation of pathological processes occurring within white and grey brain matter. However, the latter method may not produce definitive results in uncooperative or restless patients. Assessment of brain blood flow using single photon emission CT (SPECT) and of brain metabolism using positron emission tomography (PET) currently have no practical clinical use in the assessment of patients with delirium. However, these procedures should be used increasingly in research into the neurochemical and physiological bases of delirium.

2.4 Aetiology

Delirium is a manifestation of acute decompensation of cerebral functioning. It can usually be attributed to cerebral processes, general medical conditions, exogenous toxins or addictive withdrawal syndromes. The most common factors which affect cerebral functioning and may give rise to delirium are listed in Table 1. Older age has also been shown in many studies to be a general risk factor.

The most important aetiological medical disorders from a general medical point of view are cardiovascular disorders, respiratory disorders and infections. They affect central nervous system functioning via metabolic mechanisms with often unknown metabolic products or via hypoxic mechanisms in particularly sensitive brains. Similar pathogenetic processes are involved in primary renal, hepatic or endocrine metabolic disorders, gastrointestinal disorders and malnutrition. Delirium is not uncommon following heart and eye operations or after burns. Decreases in blood pressure, cardiac volume and partial pressure of oxygen are considered to be relevant in delirium occurring after cardiotomy; sensory deprivation and organic cerebral factors are thought to precipitate delirium following cataract operations; and loss of electrolytes and protein play a vital part in the decompensation of cerebral functioning following burns.

Table 1. Aetiological factors in delirium

Aetiology	Specification
Tumours	Cerebral
Trauma	Cerebral contusion Subdural haematoma
Infection	Cerebral (e.g. meningitis, encephalitis, syphilis, HIV) Systemic (e.g. sepsis, urinary tract infection, pneumonia)
Vascular	Cerebral (e.g. infarction, bleed, vasculitis) Cardiac (e.g. cardiac failure, shock)
Metabolic	Hypoxia, electrolyte disturbance, acidosis, alkalosis, liver or kidney failure, hypo- and hyperglycaemia, post-ictal phenomena Endocrine: thyroid or adrenal disorders Nutritional: thiamine or vitamin B_1 deficiency, pellagra
Intoxication	Poisons, heavy metals, therapeutic drugs
Withdrawal from substances	Alcohol, sedatives, hypnotics

HIV, human immunodeficiency virus.

As far as neurological syndromes are concerned, both pre-existing generalised brain disorders (such as vascular dementias, primary degenerative dementias or acquired immunodeficiency syndrome, AIDS) and localised disorders (such as tumours or trauma) may produce delirium. Delirium following brain injury usually presents in its typical form. However, psychopathological syndromes in the absence of pronounced disturbance of consciousness ("transit syndromes" as described by Wieck; see Scheid 1983, p. 64) may sometimes be encountered. Finally, in patients with multiple disorders and brain insults, different aetiological factors all act synergistically in precipitating delirium. In these patients, it is impossible to specify the relative importance of any single pathogenic factor. In all patients, the likelihood of delirious episodes increases sharply with increasing age and increasing severity of dementia.

Table 2 shows the medications which may precipitate delirium. Overdosage does not have to occur. Even at therapeutic doses, the individual sensitivity of a patient (which may often only first be recognised when delirium is precipitated) and a combination of medications (especially of psychotropic medications with anticholinergic side-effects) can both play crucial roles in the genesis of a delirium. Delirium is often due

Table 2. Medications with the potential to cause delirium

Type of medication	Drug
Antibiotics	Acyclovir Amphotericin B Cephalexin Chloroquine Chinolones Cycloserine
Drugs with anticholinergic effects	Tricyclic antidepressants Antihistamines Anti-Parkinsonian drugs (e.g. biperiden) Atropine Diphenhydramine Phenothiazines Clozapine Scopolamine Antispasmodics
Anticonvulsants	Phenobarbitone Phenytoin Sodium valproate
Anti-inflammatory agents	ACTH Corticosteroids Ibuprofen Indomethacin Phenylbutazone
Cytotoxic drugs	5-Fluorouracil
Antiparkinsonian agents	Amantidine Carbidopa Levodopa Bromocriptine
Anti-tuberculous drugs	Isoniazid Rimfampicin
Analgesics	Opiates Aspirin Synthetic opioids
Cardiac drugs	Beta blockers Clonidine Digoxin Lidocaine Methyldopa Quinidine Procainamide
Sedatives and hypnotics	Barbiturates Benzodiazepines Glutethimide
Sympathomimetics	Amphetamine Phenylephedrine
Miscellaneous	H2 blockers (e.g. cimetidine) Disulfiram Lithium Metronidazole Propylthiouracil Theophylline

ACTH, adrenocorticotrophic hormone.

to drugs with anticholingeric properties, but it can also occur after intake of L-dopa or amantadine, indicating dopaminergic mechanisms, or after benzodiazepines, indicating GABAergic mechanisms (which can also be observed after antibiotics of the chinolone type, which also interfere with GABAergic neurotransmission). Even glutamatergic mechanisms may be implied, as is indicated by cycloserine, which has properties of a glutamatergic agonist (Müller and Hartmann 1999). Delirium caused by medication is seen in about 1% of psychiatric in-patients treated with tricyclic antidepressants and medium-potency neuroleptics (phenothiazines). The risk of delirium is highest with clozapine (Schmidt et al. 1987).

Finally, alcoholic intoxication and withdrawal syndromes are often associated with delirium and are usually present with particularly prominent autonomic symptoms.

2.5 Clinical Presentation

A diagnosis of delirium should be suspected if there is a sudden onset or rapid fluctuation of psychiatric symptoms in patients with altered consciousness and prominent cognitive disturbances, particularly of attention and memory.

Prodromal phenomena such as anxiety, restlessness and irritability, so-called hyper-aesthetic emotional weakness disorders, as described by Bonhoeffer (1912, p. 37), may precede delirium. At the same time, lucid intervals become less frequent. Hyperactivity and hypoactivity alternate. Restlessness at night and tiredness during the day become more noticeable. The symptoms may stop at any time and resolve. This is then known as pre-delirium.

Full-blown delirium usually develops within a few hours or days, and the duration is usually cited as being anything from a few days to a few weeks. Alcohol withdrawal delirium most commonly begins 2–3 days after alcohol was last consumed, with symptoms reaching their maximal intensity after 4–5 days. In these patients, delirium is usually precipitated by a reduction or cessation of alcohol consumption, particularly in alcoholics who have been drinking excessively for 5–15 years and who develop a physical illness as a result of a road traffic accident, other trauma or an infection, for example.

Overall, the clinical course of delirium is characterised by great variability and fluctuation and is not usually predictable. The amount of alcohol consumption is a predictor of the severity of withdrawal. Exacerbations may occur at night and in unfamiliar surroundings because environmental cues can no longer be relied on for orientation.

The sense of time disintegrates and spatial orientation becomes uncertain. Retrograde and anterograde amnesia become apparent before orientation for person is lost. Confabulation may be observed in this phase.

Next, thinking becomes more loosely associated before becoming disjointed and incoherent. Illusions and visual hallucinations can occur and may be interpreted in a paranoid way. Unlike delusions seen in functional psychoses, those presenting in the context of delirium are typically moulded by the immediate situation and are less systematised and fully formed.

Affect is labile and very dependent on environmental stimuli. Some patients can seem emotionally indifferent and show diminished psychomotor activity. This is known as hypoactive delirium and is easily missed or misdiagnosed as depression. On the other hand, other patients are highly agitated and may display a tendency to become aggressive in response to anxiety or euphoria. This is referred to as hyperactive delirium. There is also a mixed variant. Thus a rapid change of the symptomatology may be a characteristic of a fully developed delirium. Aphasia, apraxia and agnosia may occur. In this context, they have no meaning in terms of cerebral localisation, as they arise as a result of generalised disturbances of cerebral functioning.

2.6 Neurobiological Background

Ever since the classical work by Engel and Romano (1959), it has been universally assumed that delirium arises out of a global disturbance of cerebral functioning. This is reflected in a slowing of background activity and an increase in the appearance of slow theta and delta waves on the EEG. A close correlation exists between slowing of background activity and the degree of disturbance of consciousness. Often, EEG analysis also reveals a flat, fast and irregular electrical picture. The earlier assumption that cerebral metabolism was universally decreased in delirium has so far not been confirmed. Despite the availability of functional imaging techniques such as SPECT and PET, there has hitherto been too little systematic research to enable the pathophysiology of delirium to be understood with regard to cerebral blood flow and oxygen consumption.

Functional neuroanatomical studies have shown that delirium may also occur in connection with focal lesions. In particular, disorders of the ascending reticular activating system in the brain stem may be associated with disturbed vigilance (reduced arousal). Severe disorders result in coma and unconsciousness. Lesions of medial brain structures such as the thalamus and hypothalamus have been blamed for changes in the level of consciousness (Wise and Brandt 1992). Furthermore, the posterior part of the left cerebral cortex is thought to be involved in conveying the contents of consciousness. It has been shown that disruption of the left posterior cerebral arterial supply to the temporo-occipital gyrus predisposes to delirium. Internal and cortical atrophy in the region of these association areas has frequently been demonstrated. It is assumed that the damage observed to these areas causes a separation of the neocortical association areas from the posterior hippocampus, thus disrupting the mobilising and sustaining of attention, thought to be a function of the non-dominant hemisphere.

The neurochemical changes associated with delirium are varied. Central to aetiology is a final common pathway characterised by disturbances of cerebral blood flow, oxygen consumption or glucose metabolism, resulting in a lack of energy-enriched phosphates in the CNS. Among other disturbances, this decrease leads to an imbalance of homeostasis, since the sodium-potassium ATPase is particularly vulnerable to disturbances of energy metabolism. These imbalances lead firstly to release of neurotransmitters due to increased calcium, which is particularly relevant for dopamine, noradreanaline and glutamate, and secondly to a decrease in reuptake of neurotransmitters, since active transport processes are driven by a gradient. Thus both mechanisms lead to an increase in neurotransmitters in the synaptic cleft. Interestingly, this is not true for acetylcholine, as synthesis and release of the neurotransmitter is reduced under hypoxia conditions (Müller and Hartmann 1999). Cholinergic neurons are also particularly vulnerable to alcohol. Thus post-mortem examination of brains of alcoholics have revealed a significant reduction (about 45%) in the number of cholinergic receptors (Freund and Ballinger 1988). These findings point to the importance of cholinergic neurons in the genesis of both delirium and dementia. Finally, the anticholinergic side-effects of different medications also suggest a similar mechanism in precipitating delirium. Noradrenergic overstimulation is responsible for the autonomic features of delirium and probably for the restlessness and agitation. Thus increased cerebral levels of noradrenaline have been found in patients with Parkinson's disease being treated with L-dopa. In addition, increased noradrenaline breakdown products (such as 3-methoxy-4-hydroxyphenylglycol, MHPG) have been found in the cerebrospinal fluid, blood and urine of patients with alcohol withdrawal delirium. Increased levels of corticotrophin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH) and cortisol are also found during alcohol withdrawal. These return to normal as the clinical symptoms subside, providing evidence of activation of the hypothalamo-pituitary-adrenal axis, the so-called stress axis (Hawley et al. 1994).

The psychotic symptoms such as hallucinations that are often observed in alcohol withdrawal may be related to dopamine binding to an increased number of receptors. This hyperdopaminergic condition might be a rebound phenomenon from the decreased numbers of dopaminergic receptors that have been demonstrated autoradiographically during chronic alcoholic intoxication. Likewise, reduced concentrations of the dopamine metabolite homovanillic acid (HVA) are found during withdrawal. The convulsions associated with complicated alcohol withdrawal are attributed in particular to the increased activity of the glutaminergic system as a result of increased numbers of *N*-methyl-D-aspartate (NMDA) receptors and of a reduced function of inhibitory mechanisms with slow restitution of γ-aminobutyric acid $(GABA)_A$ receptors (Rommelspacher et al. 1991). Finally, decreased levels of somatostatin and beta endorphin immunoreactivity have been found in the cerebrospinal fluid of delirious patients with differing causative illnesses (Koponen et al. 1994).

2.7 Differential Diagnosis

From a diagnostic point of view, delirium should be distinguished from other organic syndromes, in particular dementia. However, delirium and dementing syndromes can overlap. As a rule, the correct diagnosis depends on the history, the time course (e.g. whether it has an acute onset and whether it is progressive) and the results of laboratory investigations. Delirious patients are more likely to exhibit autonomic symptoms than those with dementia. Occasionally, a previously unrecognised dementing illness is diagnosed for the first time following an episode of delirium. Furthermore, delirium should be distinguished from psychotic disorders in which features of confusion may be present (e.g. confusion psychosis as described by Leonhard 1995, p. 72).

EEG can play an important role in distinguishing delirium from functional psychiatric disorders. A slowed frequency on the EEG can be a useful pointer towards a delirium, and a normal EEG more or less rules out the diagnosis.

2.8 Treatment

Delirium may precede other manifestations of a physical illness. Alternatively, it may mark the worsening of an already recognised clinical condition. Investigations must be carried out immediately to establish the cause of the delirium. However, this does not succeed in ascertaining the cause of the delirium in 20% of patients diagnosed with delirium (Lipowski 1990).

Alcohol withdrawal delirium is a potentially life-threatening condition. Death rates of about 20% used to be quoted where there were associated physical illnesses or multiple trauma. Newer statistics suggest a death rate closer to 1%. Overall, the mortality rates in patient groups with delirium are higher than those without delirium, whatever the underlying disease process. This is valid not only during the period of the illness, but also for a period afterwards. Death may be caused by a number of factors, including concurrent infections, fat embolisms, cardiac dysrhythmias, electrolyte imbalances, metabolic disturbances, fever or pancreatitis. Toxic delirium caused by anticholinergic medication is milder and without fatal complications. Whatever the cause, patients who develop delirium have, on average, longer hospital admissions than those who do not.

Management of delirium should be directed at treating the underlying medical condition. If there is pneumonia, then effective antibiotics and antipyretics should be administered. If blood pressure is pathologically elevated or there is papilloedema, anti-hypertensive treatment should be commenced immediately. In the case of an alcohol withdrawal delirium, thiamine therapy (100 mg i.m. daily) should be initiated along with an anti-delirium therapy. An appropriate first-line choice of treatment is chlormethiazole (as a liquid or in capsules). However, chlormethiazole should not be used in patients with multiple trauma because of the risk of respiratory depression associated with intravenous administration and of pneumonia as a result of the increased bronchial secretions. Such patients are therefore managed in intensive care settings with high doses of benzodiazepines, clonidine and haloperidol. In a delirium induced by medication, the responsible pharmacological agents should be stopped immediately. In cases where anticholinergics have caused the delirium, physostigmine is occasionally recommended as an antidote if stopping the medication is not sufficient on its own. The risk of serious side-effects such as cardiac dysrhythmias, bronchial asthma or seizures must always be considered.

In addition to these specific therapeutic approaches, there are a number of general measures which should be taken regardless of whether an underlying physical disorder is identified. Firstly, adequate nutrition and hydration should be provided with prophylaxis against embolisms and secondary infections. If necessary, there should be regular turning and early mobilisation as well as monitoring of vital parameters. Any electrolyte disturbances should be corrected.

In addition, the environment should be arranged such as to facilitate the patients' orientation. This might include placing a large clock, legible signs and

a calendar in their room and ensuring good lighting and a window for daylight. Irritation from loud and sudden noises and a lack of environmental stimuli should be avoided. As far as possible, it is desirable to have constancy of carers and nursing staff as well as regular contact with relatives. Emotional care should be reliable and language simple and not open to misunderstandings. Staff should be aware of the importance of avoiding the mismanagement of delirious patients.

The pharmacological treatment of delirium depends on the symptoms. A patient with a quiet, hypoactive delirium does not require any pharmacological intervention. However, in cases of intermittent or persistent psychomotor agitation, it may be necessary to sedate the patient. In order to do this, a medication should be chosen which does not compromise respiration, blood pressure or consciousness.

The high-potency butyrophenone neuroleptic haloperidol comes closest to meeting these requirements. A low dose (1 mg orally) should be chosen that can be administered several times a day if necessary. In cases of very high arousal, higher doses may also be administered, intravenously if necessary. However, the extrapyramidal side-effects then have to be dealt with, and these limit the use of haloperidol. Nevertheless, antimuscarinic agents should not automatically be administered, as they may exacerbate the delirium. Alternatively, benzodiazepines may be considered as they have advantages over the medium- and low-potency neuroleptics.

3 Amnesic Syndrome

3.1 Symptomatology

The key feature of the amnesic syndrome is the acquired impairment of the ability to store and retrieve new information in memory in clear consciousness. The ICD-10 clinical diagnostic guidelines define an organic amnesic syndrome as follows:

a syndrome of prominent impairment of recent and remote memory. While immediate recall is preserved, the ability to learn new material is markedly reduced and this results in anterograde amnesia and disorientation in time. Retrograde amnesia of varying intensity is also present but its extent may lessen over time if the underlying lesion or pathological process has a tendency to recover. Confabulation may be a marked feature but is not invariably present. Perception and other cognitive functions, including the intellect, are usually intact and provide a background against which the memory disturbance appears as particularly striking. The prognosis depends on the course of the underlying lesion (which typically affects the hypothalamic-diencephalic system or the hippocampal region); almost complete recovery is, in principle, possible (World Health Organisation 1992, p. 56).

DSM-IV uses the term amnestic disorder to refer to the same syndrome. It is defined as follows:

individuals with an amnestic disorder are impaired in their ability to learn new information or are unable to recall previously learned information (Diagnostic criterion A). The memory disorder must be sufficiently severe to cause marked impairment in social or occupational functioning and must represent a significant decline from a previous level of functioning (Diagnostic criterion B). The memory disturbance must not occur exclusively during the course of a delirium or dementia (Diagnostic criterion C) (American Psychiatric Association 1994, p. 156).

Criterion D states that there must be evidence from the history, physical examination or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition (including physical trauma) for a diagnosis of amnestic disorder due to a general medical condition, or the persisting effects of a substance (e.g. a drug of abuse or a medication) for a diagnosis of substance-induced persisting amnestic disorder.

The DSM IV system then allows the amnestic disorder to be subclassified as transient if the memory disorder lasts for no more than 1 month or chronic if it lasts longer than 1 month.

3.2 Epidemiology

Amnesic syndromes are so rare that there are no reliable data to determine their point or lifetime prevalence. One recent study indicated that transient global amnesia may have an incidence of 5.2 cases per 100,000 population per year (Caine et al. 1995). It has been estimated that the Wernicke-Korsakoff syndrome accounts for 3% of all alcohol-related disorders (Franklin and Francis 1992).

3.3 Background: Learning and Memory

In order to facilitate the understanding of memory disorders, the function and organisation of normal memory must be described (Lezak 1995; Kandel et al. 1996; Squire and Alvarez 1995; Hodges and McCarthy 1995). According to current understanding, primary

memory is distinguished from secondary memory (see also Chap. 13, Vol. 1, Part 1).

Primary memory is also known as short-term memory and holds material for short time periods. It is also referred to as working memory, as it processes information cognitively. It is thought to consist of a central executive and of specialised verbal and visuospatial subsystems, in which the contents remain directly accessible in the conscious mind. Thus it enables problems to be solved and decisions to be reached about future behaviour. However, the capacity of primary memory is limited.

Secondary memory is the long-term memory. It is, in principle, unlimited in its capacity and can be further subdivided into explicit and implicit memory.

Explicit or declarative memory stores information about an individual's life in so-called episodic memory and about general knowledge in so-called semantic memory. The acquisition of these memory contents are dependent on their relating to primary memory. This enables cognitive processing such as conscious intake of information, evaluation, comparison and making inferences to occur. Next, incoming information is registered in the sensory store (in a matter of milliseconds). These processes are not yet the expression of actual memory function. Instead, they are related to those structures which process complex sensations. From here the information is taken into the working memory, where, depending on arousal, it is actively stored within seconds (immediate memory) and is associated with additional data in the relevant verbal or visuospatial subsystem within minutes. This storage is strengthened by rehearsal. These functions are associated with medial temporal lobes structures, including the hippocampus, entorhinal cortex (which communicates the majority of the incoming signals to the hippocampus), the subiculum (into which the majority of hippocampal projections project) and finally the parahippocampal cortical areas. Lesions in these areas disrupt the storage or coding of new information. The hippocampus is above all the area where contents are stored in the short term prior to transfer into long-term memory. The transfer of information to other brain areas, probably in the cortex, for long-term storage is known as consolidation. Impairment of these processes form the basis for anterograde amnesia. A particular neuronal representation in the inferotemporal cortex is responsible for the representation of faces. Lesions are associated with prosopagnosia. The contents of explicit memory are retrieved into consciousness by the conscious act of remembering something (retrieval, recall, decoding). If memory contents that were stored prior to brain damage can no longer be retrieved, this is known as a retrograde amnesia. This disorder is particularly associated with damage to the temporal neocortex. Recent PET imaging studies have shown that the right hippocampus is preferentially activated in particular priming processes, whereas the frontal lobes are activated in recall processes (Squire et al. 1992; Tulving et al. 1994).

Both the acquisition of memories into and retrieval of memories from so-called implicit (procedural) memory are more instinctual and automatic in nature. Neither are necessarily associated with conscious awareness or cognitive processes. This form of memory is built up slowly by many repetitions and is outwardly manifest by improved ability to perform different tasks. These include particular unconscious perceptual abilities ("priming"), motor skills and the learning of particular rules and ways of behaving, such as grammar. Implicit memory is built up by classical conditioning. The contents of implicit memory (such as learned vocabulary) can later be recalled automatically without requiring any particular effort. The implicit memory required for the solving of particular problems is tied to the sensory and motor systems involved in learning that task. Accordingly, the memory contents are stored within these functional systems. Implicit memory is not linked to the hippocampus. Instead, it is related to the cerebellum, amygdala and, in the case of very simple forms of learning, to the specific sensory and motor systems associated with the learning exercise. These memory functions are usually spared in patients with amnesia.

A few specific functional pathways relating to more complex forms of learning are understood, especially in relation to explicit memory (Kandel et al. 1996). A unique trisynaptic circuit in the hippocampus is activated by learning tasks in which storage is mediated largely by the phenomenon of long-term potentiation. This neuronal strengthening mechanism is excitatory in nature and based on glutaminergic transmission (via NMDA receptors) and the influx of calcium ions. It forms the basis for structural changes to the synapses and changes to neuronal gene expression. It can be postulated that long-term memory is based on the development of new synaptic connections (synaptic plasticity) and the biosynthesis of new proteins. These processes are thought to happen particularly during rapid eye movement (REM) or slow-wave sleep as part of consolidation. The molecular mechanisms underlying learning and memory are now being investigated with the aid of transgenic animals. In this way, it can be shown that the switching off of particular genes (gene knockout) leads to loss of long-term potentiation and disorders of spatial learning ability. It cannot yet be predicted whether drugs which modulate cholinergic functions and glutaminergic mechanisms will play an important role in the management of amnesic syndromes (Aigner 1995).

3.4 Clinical Examination

For clinical purposes, memory disorders are divided arbitrarily into immediate memory (i.e. ultrashort-term memory), recent memory and remote memory (Leszak 1995; Heilman and Valenstein 1993).

Immediate memory is activated when patients are asked to reproduce material consisting of about seven (plus or minus two) items. The digit span is an example of such an exercise. This falls within the patient's attention span and is therefore connected with registration. Performance in visual and verbal tasks of this sort may be differentially affected according to the disorder.

Recent memory is tested by asking patients to take in newly learnt material and repeat it after about 5–7 min of having their attention diverted by distracting stimuli. Anterograde amnesia is manifest as a disturbance of this type of memory whose processing occurred after the beginning of the illness.

Patients with amnesic syndromes are significantly disabled in their everyday functioning. Their learning and memory disorders can be observed in many ways. They cannot remember the names of staff or patients on the unit. They appear disoriented because they cannot memorise the area they are in or a particular route. However, there is often nothing remarkable about them intellectually during initial conversations or social interactions. The memory disorder only becomes evident when they are required to remember recent events. The impairment is also apparent when the patient is asked to repeat three words immediately to rule out perceptual or comprehension problems and is then unable or inadequately able to reproduce the three words after 5–7 min of intervening conversation.

When considering performance in everyday tasks, it appears to be particularly important to test ability to freely recall text that has been heard once. Patients who have difficulties in this task are subject to many limitations, e.g. in conversation, listening to the radio or watching television. The short-term ability to retain individual information can also be tested through free recall or recognition of complex geometrical patterns.

In addition to deficits of recent memory, amnesic patients often have disorders of remote memory. Remote memory is manifest as the ability to recall information from a long time ago, the storage of which preceded the onset of the illness causing the memory disorder. In this respect, so-called semantic memory includes knowledge related to language and so-called episodic memory includes autobiographical information.

In order to assess a retrograde amnesia, we can either ask about autobiographical details or about information in the public domain, such as historical events or political figures, e.g. former heads of state. Alternatively, patients can be presented with pictures of famous figures (Famous Faces Test) and asked for their names.

According to the Hodges and McCarthy (1995) cognitive model of memory, autobiographical memory is structured hierarchically. Planning processes are under frontal control. They relate to subordinate so-called thematic memory stores that are activated via thalamofrontal pathways. The corresponding verbal material from semantic memory is probably represented in the temporal and inferior parietal cortices. On the other hand, individual pieces of autobiographical information are stored in sensory and motor areas.

Three particular patterns of retrograde amnesia are recognised:

1. Time-limited disorders such as those seen in depressed patients treated with electroconvulsive therapy. These are restricted to one particular period of time.
2. Extensive disorders which extend beyond time-limited retrograde amnesia and affect contents that were acquired many years previously and had long been consolidated. Korsakoff's syndrome is an example of this type.
3. Global disorders which involve practically a complete loss of all memory contents, such as those seen in patients who have survived herpes encephalitis or who have advanced Huntington's disease. In these cases, extensive lesions have been found, in particular within the limbic system, but also in temporal, frontal, parietal and occipital cortical areas (Damasio and van Hoesen 1985; Heilman and Valenstein 1993).

Standardised tests allow a detailed assessment of the type and severity of the disorder. This can, however, only be achieved in the context of a comprehensive neuropsychological examination which assesses overall intellectual ability, language function, visuospatial skills, and motor and frontal "executive" functions, including self-assessment.

Patients with classical amnesia do not exhibit any gross deficits in the commonly used intelligence tests, such as the Wechsler Adult Intelligence Scale, or tests of concentration, as long as the information can be held within their actual attention span. On the other hand, amnesic patients can be identified using the Wechsler Memory Scale (WMS, with seven subtests; Wechsler 1945). The global memory quotient (MQ) that was derived from the subtests has been much criticised. However, the revised Wechsler Memory Scale (WMS-R) allows a differential diagnostic approach. For clinical purposes and in order to monitor the effectiveness of rehabilitative measures, it is

necessary to test the ability of patients to learn new material. Verbal learning tests are used to this end in which information is repeatedly presented and the improvement in learning after each stage is assessed. Examples of such tests include association tests using pairs of words or pairs of names and faces. The ability to learn and retain visual information, including simple and complex figures, can be assessed using the Benton Test (Benton 1968) or the *Diagnosticum für Cerebralschädigung* (Diagnosis for Cerebral Damage) (DCS; Weidlich and Lamberti 1980). Further details about neuropsychological assessment instruments and their uses can be found (in German) in von Cramon and Zihl (1988).

3.5 Aetiology

Amnesic syndromes are generally the consequences of pathological processes affecting, in particular, diencephalic structures (the thalamus and mamillary bodies), medial temporal lobe structures (the hippocampus and amygdala), the fornix, the basal forebrain and the prefrontal cortex.

Lesions are frequently bilateral, but one-sided lesions can also lead to deficits. Causes to consider include head trauma (blunt injuries and penetrating gunshot wounds), localised tumours, neurosurgical operations, infarcts in the area perfused by the posterior cerebral artery, hypoxia and encephalitis (especially due to herpes simplex).

Chronic alcohol misuse with associated thiamine deficiency is among the most common causes of amnesic syndromes. When amnesic syndromes are transient, they are usually attributable to cerebrovascular disease with changes in blood flow in the vertebro-basilar system, hypoxia (e.g. following cardiac arrest, resuscitation or suicide attempts), acute intoxication (e.g. during alcoholic blackouts, following ingestion of benzodiazepines, especially high-affinity substances such as triazolam, Van der Kroeff syndrome), poisoning (with carbon monoxide, isoniazid, lead and arsenic), cerebral convulsions (post-ictally or after electroconvulsive therapy) or other disorders which occur episodically.

3.6 Clinical Presentation

The inability to learn and reproduce new information (anterograde amnesia) or to remember past events that occurred before the onset of the brain damage (retrograde amnesia) is a central feature of an amnesic syndrome. Depending on the location of the lesion, the memory disorder may relate either to verbal or visual material. Patients are able to learn new motor skills without problem but are later unable to remember having done so. Transient and persistent disorders are distinguished from one another. However, there is some overlap. Retrograde amnesia following head trauma may abate with increasing recovery of the patient.

Transient global amnesia is a disorder with a sudden onset in which patients are unable to take in or reproduce any new information. Such patients are noticeable because, in the course of a normal conversation, they forget all information conveyed to them within a few minutes. In these circumstances, they repeat questions put to them. They appear to be aware of the disorder and present as baffled. As a result of typical questions such as " How did I get here?" and "What am I doing?", they can erroneously create the impression that they are suffering from an acute confusional state and are disoriented. However, communication and knowledge of personal identity remain unaffected, and more severe behavioural disturbances are not seen. The episode lasts for a period of hours, not longer than 1 day, and subsides suddenly. Afterwards, there are no detectable cognitive abnormalities other than the amnesic gap for the period of the episode. There is no specific single aetiology for the syndrome. Aetiological factors that have been described include epilepsy, emotional stress and migraine-related vasospasm. Transient disturbances of bilateral temporal blood flow to diencephalic and medio-temporal structures are the most likely cause. The syndrome typically occurs in later life (over 50). Episodes can re-occur.

Korsakoff's syndrome usually occurs as a consequence of many years of alcohol abuse in combination with nutritional deficits, in this case thiamine. It is occasionally seen in association with malabsorption syndromes. Often the syndrome starts with symptoms of delirium such as confusion and disorientation that may progress to stupor and coma. Typically, this is accompanied by eye movement disorders, ranging from nystagmus to complete ophthalmoplegia, as well as ataxia, particularly affecting the trunk. This clinical picture is called Wernicke's encephalopathy and it can develop into Korsakoff's syndrome. However, the onset of Korsakoff's syndrome can sometimes be insidious. The key characteristics of Korsakoff's syndrome are a persisting anterograde amnesia, often with severe disturbance of ability to remember things, a retrograde amnesia, in which the more recent the memory the greater the extent to which it is affected, a tendency to confabulate, particularly in the early stages and, in severe cases, disorientation. Not uncommonly, there are indications of frontal lobe involvement, such as apathy, poor judgement and a tendency to

perseverate, as well as of other functional disorders associated with neurotoxicity of the cerebellum or peripheral nervous system.

Amnesia following head trauma is characterised by the fact that the greatest functional deficits, both retrograde and anterograde, occur immediately after the trauma. Memory function can recover. Improvement is occasionally seen as long as 2 years after the trauma. Most commonly, some residual impairment persists in cases of severe injury.

Amnesia caused by cerebrovascular disorders usually presents suddenly, e.g. as a cerebrovascular accident, and can be attributed to occlusion of blood vessels in the area perfused by the posterior cerebral artery and branches to thalamic areas. Amnesia associated with disorders of the basal forebrain is usually caused by bleeding aneurysms of the anterior communicating artery or by surgical interventions in this area. Amnesic syndromes may also be caused by other cerebral processes, such as hypoxia, herpes simplex encephalitis and electroconvulsive therapy, as well as by limbic processes.

3.7 Neurobiological Background

Neuropathological research into Korsakoff's syndrome has demonstrated that both the memory disorder and disturbance of consciousness can be attributed to the damage observed to diencephalic structures, in particular of the ventral and lateral nuclei and the pulvinar of the thalamus, the mamillary bodies, the end of the fornix, the reticular activating system and the periaqueductal grey matter (Victor et al. 1971). In addition, there is diffuse cerebral damage (Lishman 1987). Such damage to the frontal lobes may account for the tendency to confabulate and the impaired judgement. Following herpes simplex encephalitis, hypoxia, abscesses or trauma, there are often extensive lesions to limbic and cortical structures.

The biochemical changes in amnesic disorder are thought to occur predominantly within the cholinergic system, as the synthesis of acetylcholine is particularly sensitive to hypoxia. Chronic toxic disorders of the noradrenergic and GABAergic systems have also been postulated. It is likely that disorders of the GABAergic system in the hippocampus occur as a result of the acute effect of certain high-affinity benzodiazepines such as triazolam. Where malnutrition also occurs, disorders of thiamine metabolism may be associated with genetically determined alterations in the activity of transketolase.

Neuroimaging techniques such as CT and MRI are able to demonstrate lesions in the medial temporal region, i.e. dilatation of the third ventricle and of the temporal horn of the lateral ventricle. Evidence can also be seen of cortical and subcortical atrophy. Angiography studies seldom provide evidence of disorders of perfusion, as these usually elude detection. SPECT studies have found evidence of reduced regional blood flow bilaterally in the temporal lobes and in the left thalamus and frontal cortex during transient global amnesia. EEG changes are usually not detectable even during a transient global amnesia.

3.8 Differential Diagnosis

The key features of amnesic syndromes, namely impairment of memory and learning, can occur to varying degrees and in varying contexts. Cognitive deficits are common in mild cognitive disorders such as in benign senescent forgetfulness or age-related cognitive decline. However, they are not severe impairments and are difficult to detect using quantitative measures (see Chap. 10, Vol. 2, Part 2). On the other hand, symptoms of amnesia can occur in the context of a number of other neuropsychiatric disorders, in particular dementia and delirium. When they present in association with impairment of consciousness and attention, the diagnosis is likely to be that of delirium.

Immediate memory is impaired in delirium but not in the amnesic syndrome. However, it can be difficult to distinguish the two, as the deficits in recent memory seen in patients with amnesia can make patients appear confused and disoriented. When amnesic symptoms present simultaneously with other neuropsychological symptoms such as aphasia, apraxia or agnosia, the diagnosis is likely to be that of dementia.

Many degenerative disorders, such as Pick's disease, Parkinson's disease and Huntington's disease, are associated with memory impairment. Patients with Alzheimer's disease are particularly likely to present initially with amnesic symptoms. Confabulation may be a feature of dementing disorders, delirium and amnesic syndromes. Because of the potential therapeutic benefit of an acute dose of thiamine in patients with Wernicke's encephalopathy, this diagnosis should always be considered. In patients with transient amnesic syndromes, the underlying cerebral processes should be investigated. If there is no evidence of a physical disorder, the possibility of a psychogenic origin should be considered.

Learning capacity and the reproduction of actual memory contents are usually not impaired in psychogenic amnesia. Instead, patients report that they cannot remember recently stored information or periods of their life. Such symptoms occur within the context of simulated amnesia of so-called multiple

personality disorder or in dissociative disorders, in which psychological trauma, intense affect and a particular excitement play a large role. Psychogenic amnesia may last days or weeks but seldom years. Episodes commonly end abruptly, usually in relation to experiences connected with the triggering event. Patients with psychogenic amnesia describe their memory difficulties in a very detailed and expressive manner. In the absence of any other severe cognitive deficits, the isolated forgetting of one's own name, occupation or address is only ever seen in psychogenic disorders.

3.9 Treatment

Where the underlying pathological cause of an amnesic syndrome is known or suspected, specific treatment of the pathology should be investigated without delay. This might include treatments such as thiamine, antiviral medication or aspirin.

There are currently no treatment measures that are reliably effective in reversing the memory deficits. Historically, a number of different rehabilitative approaches have developed using memory training in an effort to support patients in coping with everyday activities. However, these approaches have arisen from a pragmatic rather than a theoretical perspective (Heilmann and Valenstein 1993). Such methods include the repetitive exercising of memory with the help of games and simple exercises in the context of everyday clinical activity. However, there is nowadays scepticism about the likelihood of achieving a general improvement in memory functioning using this method.

On the other hand, internal memory aids are based on the use of mnemonic strategies. Such therapeutic approaches are based on the inclusion of mental imagery in memory training. The imagery serves to increase the memory capacity by linking verbal memory contents with visual engrams. The process has to be specially adapted, often with great effort, for each patient. This method appears to have proved useful in individual cases. However, further studies of its effectiveness are needed. Moreover, it is difficult to assess the extent to which learning is transferred from the laboratory to everyday situations. An alternative has been tried which consists of enabling patients who are sometimes able to learn particular procedural or sensorimotor skills to acquire a computer vocabulary with the help of a computer. In this way, successful learning can be quantified. Once again, the transfer to daily living is very limited.

External memory aids such as appointment diaries, shopping lists, individually programmable electronic notebooks have uses in appropriate cases (von Cramon and Zihl 1988). Finally, amnesic patients are often dependent on appropriate accommodation and comprehensive care from either relatives or medical staff.

4 Other Cognitive Disorders

Terms such as dementia, delirium or amnesia are often used categorically to describe illnesses. However, cognitive disorders are frequently observed in patients who do not fit the diagnostic criteria for dementia, delirium or amnesia. These cases are more easily conceptualised using a dimensional perspective of gradually decreasing cognitive function, as is seen in mild cognitive disorders (see Chap. 10, Vol. 2, Part 2). These disorders are grouped together in DSM-IV under the heading "cognitive disorders not otherwise specified".

Organic Personality Changes

Translator: E. Taub

1 Development of Terminology

The traditional concept of "organic personality change" implies a lasting and irreversible change of personality structure, behavior, and affect in consequence of changes in the brain of whatever origin. In its clinical application, the term "organic" in this context refers to psychopathological manifestations produced by a morbid disturbance of brain function. Kraepelin (1909) and other authors validated this concept largely in the context of a single construct, that of the so-called epileptic personality change. According to the classical understanding, the epileptic personality change is characterized by (among other features) viscous, perseverative, circumstantial, and diffuse thinking; loss of initiative; certain affective abnormalities; and a dedifferentiation, or leveling out, of premorbid personality traits.

In Anglo-American psychiatry, much attention was paid to organic personality changes in the late nineteenth and early twentieth centuries in connection with research on the end stage of neurosyphilis, the epidemic of encephalitis in 1918, and the many traumatic brain injuries sustained in the course of the First World War (Popkin 1986). Many authors writing in German, including Huber, Scheid, Bleuler, von Baeyer, and Häfner, contributed to the conceptualization of this group of disorders, mainly through qualitative research methods.

Thus Huber (1972) divided the organic psychoses into acute forms (exogenous reaction types), transitional syndromes, and syndromes of chronic, irreversible form. He further subdivided the latter category into pseudoneurasthenic syndromes (without major impairment of intellect or memory, but with "irritable weakness") and "encephalopathies" (with "formal preservation of personality"). Huber denoted disturbances of these types as "organic personality changes" and stated that they are characterized by alterations of the dynamic components of personality (affective responsiveness and baseline affect, psychomotor speed, adaptive ability, formal volitional structure) without any change in the substance of the patient's character. In his conception, the impairment of brain functioning characteristic of dementia is absent in these disorders. In his later works, Huber (1976) stressed that brain damage incurred in early childhood is followed most frequently not by cerebral palsy or feeble-mindedness, but by so-called pseudopsychopathic syndromes, which manifest themselves in the affective rather than the intellectual sphere. This "exogenous psychosyndrome of early childhood," to use Harbauer's term, could then set the stage for neurotic developmental abnormalities.

According to Bleuler (1966), the local cerebral psychosyndrome is a "special form of an isolated organic personality change" that is associated with "episodic or persistent changes of mood, motivation, and individual vital drives." Local cerebral psychosyndromes arising on the basis of mild, diffuse brain atrophy are difficult to classify into frontal, diencephalic, and temporal psychosyndromes. Characteristic, but nonetheless nonspecific, psychopathologic features of these subtypes may be made out only in particularly marked individual cases, such as the "lack of spontaneity with preserved responsiveness to external stimuli" seen in frontal abulia.

Scheid (1980) described three types of "irreversible defect syndrome." One of these types was early childhood brain injury associated with a deficiency of personality and intelligence. With reference to Kurt Schneider's concept of "organic personality change," he further described a syndrome of deterioration of the personality and mental abilities, which he divided into two forms, mild (reduction of spontaneity, vitality, and initiative, or a tapering off of the personality) and severe (leveling off of the personality).

Although the construct of organic personality change, as described above, figures importantly in the European literature, particularly in works written in German, empirical studies have been rather rare, and those that have been performed have been fraught with a number of serious methodological problems. The predominant objects of study were clinical populations, which are inherently laden with a high prevalence of personality disorders or accentuations. The diagnostic problem of distinguishing personality disorders from organic personality changes remains largely unsolved, and the prominent position given to organic personality changes in the more recent classification systems – a throwback to the classical diagnostic rules – therefore has in fact no empirical justification.

There are as yet no large prospective studies on the effect of brain damage in early childhood on the later occurrence of personality disorders. Nevertheless, many authors stress its importance as a risk factor. Similarly, little empirical clarity exists concerning the relevance of the stage of cerebral development at the time the lesion is produced, e.g. after brain trauma in early childhood.

Research on organic personality changes has been performed almost exclusively in retrospective, cross-sectional studies employing instruments of assessment that, in part, fail to satisfy minimal test-theoretical requirements. Empirical longitudinal studies are almost entirely lacking. In the particular case of epileptic personality change, the type that has been most

thoroughly studied by far, the findings to date have been partly inconsistent, as will be shown below.

Despite these limitations regarding both content and method, the authors of both the ICD-10 (Dilling et al. 1994) and the DSM-IV (APA 1994) decided to incorporate some of the categories just discussed into their operational diagnostic manuals, not least because of the clinical obviousness of organic personality changes.

2 Symptomatology and Terminology in Recent Classification Systems

As Lauter (1988) pointed out, proper use of the current terminology, as employed in the recent classification systems, requires attention not only to the psychopathological state at the time of assessment, but also to a number of other important features. These include, among others, the course and prognosis of disease, the localization of injury, the degree of severity, the age of onset, and underlying physical conditions.

With regard to disease course, it should be emphasized that personality changes, encephalopathies, and so-called pseudoneurasthenic syndromes may all occur without dementia, in the sense of a deficiency of cerebral function. As for prognosis, dementias, organic personality changes, and pseudoneurasthenic syndromes were considered irreversible and were thereby held to be distinct from reversible organic psychoses, at least in the German-speaking countries. Although these prognostic principles worked out by Scheid and Wieck, among others, still possess a certain validity today, they must increasingly be modified in the light of new concepts of neural plasticity and neuronal regeneration (Spitzer and Casas 1997).

As for the localization of injury, Bleuler recognized that it bears little relevance to the type and severity of the clinical syndrome, at least in milder disturbances. Localization becomes significant only when the disturbance is massive, in which case certain marked neuropsychological syndromes also appear (e.g. the syndromes of the frontal, parietal, and temporal lobes). Previous classifications of organic psychic disorders often considered the degree of severity of cognitive functional impairment an important element of differential diagnosis, so that the diagnosis of dementia, for example, was reserved for particularly severe and irreversible forms. Today, however, the concept of dementia is broader. Furthermore, with regard to the age of onset of disease, it appears to be important whether an injury, of whatever type it may be, takes place in a developing or a mature brain. Concepts such as that of the exogenous psychosyndrome of early childhood, or of minimal cerebral dysfunction, are partly subsumed today under the developmental disorders, even though their significance as predisposing factors for the later development of (for example) complex, primarily nonorganic personality disorders, mainly of antisocial type, seems to be beyond doubt (Herpertz and Sass 1997). Much more research is required in this area if the organic contribution to the etiology of these disturbances is to be clarified.

As for the relevance of underlying physical conditions, Lauter (1988) and others have emphasized that the term "organic" does not imply that the psychopathological manifestations are determined exclusively by organic factors; rather, they may also be influenced by other moderating variables.

If we return to a consideration of the recent classification systems, it becomes quite clear that many of the traditional concepts of German-speaking authors, in particular, have been abandoned and replaced by social measures of assessment and internationally acceptable demands for reliability and validity. Nonetheless, even the categorical constructs chosen in these systems do not do justice to the dimensional character of personality changes. Furthermore, they largely neglect the possibility of variation of personality.

Both ICD-10 and DSM-IV posit the following basic requirements for the diagnosis of an organic personality disorder:

- Objective evidence or historical documentation of a cerebral illness, injury, or functional disturbance
- No impairment of consciousness and absence of a severe memory deficit
- Exclusion of other premorbid mental illnesses, including personality disturbances, as possible causes of the disorder

According to the Clinical Diagnostic Guidelines and Research Criteria of ICD-10, organic personality disorder (F07.0, Appendix A) is characterized by a major change from the patient's premorbid behavior, with especially marked involvement of the expression of affect, needs, and impulses. Cognitive functions may be impaired mainly with regard to the planning of activities and the anticipation of their individual and social consequences, as in the so-called frontal lobe syndrome. The Guidelines and the Research Criteria require the fulfillment of two or three diagnostic criteria, respectively, from a list of criteria involving the areas of endurance and gratification of needs, affectivity, impulse control, cognitive disturbances, language and speech, and sexual behavior (see Appendix A).

Furthermore, the post-encephalitic syndrome (F07.1) and the organic psychosyndrome after traumatic

brain injury (F07.2) are listed as further specific disorders to be classified under the organic behavioral changes. The post-encephalitic syndrome is said to be distinguished from organic personality change by being largely reversible, although no corresponding temporal intervals or other specific diagnostic criteria are given here (Appendix B). Similarly, a number of rather non-specific criteria are given for the organic psychosyndrome after traumatic brain injury (see Appendix B).

DSM-IV rejects a differentiation of this type and subsumes organic personality change under category 310.1, personality change because of a medical disease factor (Appendix C). Aside from characteristics appearing in the catalogue of criteria that have to do with etiology (criterion B) and with the diagnostic differentiation from other entities (criteria C and D), DSM-IV places emphasis on the personality disturbance (criterion A) and on the limitation of psychosocial functioning (criterion E). In a manner almost analogous to the ICD-10 criteria, the personality change is characterized by affective instability, inadequate impulse control, sudden, inappropriate outbursts of aggression or rage, apathy, suspiciousness, and paranoid ideation. Unlike ICD-10, DSM-IV provides a subclassification based on the most prominent clinical manifestations, which can then be considered in the context of the type and localization of the underlying pathological processes.

3 Epidemiology

Reliable epidemiological data on organic personality changes derived from representative population samples are not available. Published clinical studies do, however, contain estimates of the frequency of organic personality changes associated with certain underlying illnesses. Thus, depending on the population sampled, 8%–60% of patients with long-standing epilepsy will develop personality changes, and patients with temporal lobe epilepsy seem to be at highest risk (Taylor 1987; Mendez 1988, 1995). Motomura et al. (1988) report, in a study employing the DSM-III-R criteria, that approximately 33% of a consecutive series of patients whom they studied with right hemispheric injury later developed secondary organic personality changes. The occurrence of personality changes in this study, as in others, had a more than random association with neglect syndromes, anosognosia, extinction phenomena, constructive apraxia, and motor disturbances. The extent of the clinical manifestations of post-traumatic personality changes was correlated with the severity of the causative brain trauma (Levin et al. 1979).

A similar dependence of basic epidemiological data on the degree of severity of disease, in addition to considerable interindividual variation in disease course, complicates the provision of exact prevalence figures for organic personality disorder in the context of a number of other relevant illnesses, including human immunodeficiency virus (HIV) infection and other infectious diseases that affect the cerebrovascular system, endocrine diseases, and autoimmune diseases (Perkins et al. 1993; Popkin and Tucker 1994). In these diseases, clinical neurological findings, or other findings made with additional laboratory tests, are often not associated with the presence or the degree of severity of personality changes. Furthermore, questions of comorbidity, e.g. with disorders brought about by substance abuse, have been studied inadequately or not at all.

4 Techniques of Assessment

Organic personality disorders are difficult to diagnose, principally because they are complex disturbances of regulatory or integrative functions that may also be viewed as partial impairments of performance in the area of higher cognitive functioning. Beyond the characterization of syndromes and etiological and pathogenetic considerations, the diagnostic process must also make use of different sources of information as well as of longitudinal observation.

Alongside the determination of psychopathological findings and neurological and psychiatric diagnosis, the observation of behavior plays a particularly important role in clinical assessment, because the deficiencies of the patient's personality can often be diagnosed only in the context of a complex interaction. Some of the most important features of organic personality change, such as a disturbance of impulse control, an inability to plan one's activities in a goal-directed fashion, and inappropriate behavior in social relationships, may often be recognizable only in the framework of complex behavioral processes, while disturbances of affectivity and of the form and content of the patient's thinking are subjects for psychiatric exploration.

Furthermore, in order to render the diagnosis more certain, historical data should be obtained from informants other than the patient, so that it can be documented that the patient's problem indeed represents a change from an intact premorbid personality. Characterization of the personality change as persistent is possible only with an adequate historical or prospective period of observation; these means provide the otherwise lacking longitudinal perspective.

Structured or standardized diagnostic instruments may be very useful in this process. To be sure, there are no specific instruments for the diagnosis of organic personality changes at present, but a number of screening questionnaires and diagnostic interviews have been developed and empirically tested in the area of personality changes of nonorganic etiology, and these can be used to advantage in the provision of a diagnosis. With regard to screening questionnaires, the Personality Diagnostic Questionnaire (PDQ-R) deserves mention as a self-assessment scale of comparatively high specificity, but low sensitivity. As for structured diagnostic interview techniques, the International Personality Disorder Examination (IPDE; World Health Organization 1994), which is designed for the diagnosis of all personality disorders according to ICD-10 and DSM-IV, is most useful. A further interview technique, the Structured Clinical Interview for DSM-IV Personality Disorders (SCID-II), has been developed for DSM-IV (for a brief description, see Stieglitz and Baumann 1994).

Many mostly Anglo-American studies on the diagnosis of organic personality changes have made use of the Minnesota Multiphasic Personality Inventory (MMPI), which, however, has been repeatedly criticized on test-theoretical grounds. An instrument similar to the MMPI, the Bear-Fedio-Inventory (Bear and Fedio 1977), was developed to assess personality changes in the context of epilepsy. This instrument has not been sufficiently studied from the test-theoretical viewpoint.

The so-called frontal lobe tests in current use (Wisconsin Card Sorting Tests, Continuous Performance Tests, N-Back Tests) have no established role in routine psychiatric diagnosis.

An etiological diagnosis is provided on the basis of the primary medical condition that led to the organic personality change. Laboratory studies and imaging techniques, in the widest sense of term, may be used for this purpose. Electroencephalography (EEG) may reveal generalized abnormalities, focal signs, and epileptiform abnormalities, which, generally speaking, may be due to more than one type of underlying illness. Computed tomography (CT) may reveal acute hemorrhages and their residua as well as other structural defects, while magnetic resonance imaging (MRI) more sensitively detects pathological processes in the gray and white matter of the brain, particularly in the frontal area, which is of special relevance to personality disorders.

The assessment of cerebral perfusion with single photon emission computed tomography (SPECT) and of cerebral metabolism with positron emission tomography (PET) has found application mainly in scientific research; SPECT, in particular, may yield valuable diagnostic information about regional hypoperfusion, most often in the frontal lobes. The sensitivity of these techniques needs to be improved if they are to provide a more precise understanding of the "organically damaged background" than we have from the techniques available today (for a further discussion, see Chap. 11, Vol. 1, Part 1).

5 Etiology

Organic personality changes should be considered in the context of the primary medical conditions that cause them. We shall discuss a number of especially important conditions in this section.

5.1 Epileptic Personality Change

The construct of a characteristic epileptic personality change is a subject of controversy in the literature (Hermann and Whitman 1984; Popkin and Tucker 1994). Taylor (1987) and Mendez (1988, 1995) found that complex partial seizures and temporal lobe epilepsy, at least, are statistically significantly associated with signs of an organic personality change. Mendez et al. (1993) compared 42 epileptic patients who suffered from personality changes with epileptic controls who did not suffer from them and found that the group with personality changes had auras significantly more frequently, and generalized seizures significantly less frequently. No personality profile typical of epileptic patients has yet been revealed by psychological testing (Mendez 1995).

Borderline personality disorders or accentuations, whose characteristic features are instability of identity and impulsiveness, seem to occur most frequently in epileptic patients and are not uncommonly considered in the context of dissociative phenomena that may be traced back to an actual trauma in childhood. It must also be pointed out in this connection that antiepileptic pharmacotherapy, which is often continued for many years, may lead to functional impairment, particularly in the realm of cognition (Lang and Stefan 1990); thus an additional variable affecting the course of disease must be kept in mind.

In a number of studies, right-sided epileptic foci were found to be more strongly associated with affective thought disorders, extraversion, and positive self-esteem, while left-sided foci were more strongly associated with paranoid thought disorders and socially withdrawn behavior. Cummings (1985) found increased interest in religious and philosophical matters, graphomania, lessened sexual responsiveness, circumstantiality, and perseverative thinking.

5.2 Traumatic Brain Injury

A personality accentuation with features of a depressive syndrome, among which apathy and reduced emotional variability are the most prominent, has been repeatedly described in the context of traumatic brain injuries, particularly those involving the dorsomedial portion of the frontal lobe (Capruso and Levin 1995). Personality accentuations of a rather more pseudopsychopathic type, including egocentricity, disinhibition, and sexual deviance, are often attributed to lesions of the orbital frontal lobe. In the view of most authors, the likelihood of later development of an organic personality change rises in nearly linear fashion with the severity of the traumatic brain injury. Personality changes after traumatic brain injury must be distinguished from the anxiety disorders and depressive disorders that also occur more frequently in this group of patients (Starkstein et al. 1990).

Eames (1997) adds that traumatic brain injuries, and especially the so-called minor head injuries, which probably occur frequently in young adults, may be mistaken for organic disorders and then given a different diagnostic label (post-traumatic stress disorder, hypomanic or manic episodes, obsessive–compulsive disorder).

5.3 Frontal Lobe Injury and Frontal Lobe Lesions

Benson (1984) and Lishman (1987) emphasize in their review articles that frontal lobe injuries or lesions may be associated with personality changes, manifesting themselves primarily as changes in initiative and disturbances of the cognitive control of affective reactions. Moreover, disturbances of impulse control have a statistically significant association with frontal lobe lesions.

Three types of frontal lobe disorder may be distinguished on the basis of the location of injury (Cummings 1993):

1. The dorsolateral prefrontal brain syndrome is characterized by disturbance of conceptual recognition, lack of cognitive flexibility, inadequate cognitive planning, and disturbance of initiative.
2. The orbital frontal brain syndrome is characterized by loss of distance, indifference, lack of social control, attention deficit, and a tendency toward imitative behavior.
3. The anterior cingulate syndrome ranges from apathy, indifference, and perseveration to akinetic mutism.

Furthermore, the affective sequelae of frontal lobe lesions vary depending on the side of the injury. While left frontal lesions have a more than random association with depressive manifestations, right frontal injuries are more frequently associated with manic syndromes (Starkstein and Robinson 1991). Frontopolar lesions are associated with marked personality changes, even though there is frequently no cognitive deficit; personality changes may be absent when the lesion is more posterior (Eslinger and Dimasio 1985).

Sciutella and Feinberg (1997) refer to the close association of frontal lobe disturbances with impulsive behavior, which, in a number of studies, was found to be related to psychopathological features of obsessive–compulsive disorder and of aggressive and violent behavior. Herpertz and Sass (1997) discuss frontal lobe lesions as a predisposing factor for various disorders, particularly antisocial personality disorder.

5.4 Right and Left Hemispheric Brain Damage

Motomura et al. (1988), in the article cited above, reported a statistically significant association of organic personality changes with right brain damage, but these findings were not confirmed by longitudinal studies. An association with residual neurologic abnormalities was also revealed in numerous studies of affective changes after right and left brain damage (see, e.g. Starkstein and Robinson 1989), but methodologically adequate comorbidity studies are not yet available. The literature to date unequivocally shows that from 20% to 60% of clinically treated brain-damaged patients develop depressive disorders or, somewhat less frequently, anxiety disorders, in the postacute phase. In the setting of the cognitive deficits that are also present, these disorders may be clinically indistinguishable from organic personality changes (Castillo and Robinson 1994). Well over 50% of these disorders are no longer demonstrable on follow-up 1 year after injury (Steller and Schultz-Venrath 1995). Patients with right brain damage seem to suffer from depressive syndromes, in the broadest sense, approximately as often as patients with left brain damage, while manic syndromes have been observed to date only after right brain lesions (House et al. 1990).

5.5 Personality Changes as Early Manifestations of Dementing Disease

Many authors state emphatically that personality changes may appear as early manifestations of a dementing illness. Thus Heston and White (1983)

consider very mild personality changes as being among the early manifestations of Alzheimer's disease. Unlike the frontal brain degenerations, however, Alzheimer's disease is rarely accompanied by personality changes that impair psychosocial functioning (Cummings and Benson 1992). The course of illness is characterized by complex thought disturbances and, on the behavioral level, first by apathy and agitation, and later by depressed mood, irritability, and psychomotor restlessness (Mega et al. 1996).

In contrast to the situation in Alzheimer's disease, personality changes play an extremely important role in the focal brain degenerations, of which the most important type is frontotemporal degeneration (so-called frontal lobe dementia), which also includes Pick's disease. The characteristic findings here are said to include disinhibition, diminution of social adaptive ability and self-criticism, quarrelsomeness, impulsiveness, and a tendency toward neglect (Miller et al. 1991). This syndrome is contrasted in the literature with an apathetic form corresponding more closely to the dorsolateral prefrontal brain syndrome or to the anterior cingulate syndrome and is characterized by social isolation, loss of interests, and self-neglect (see Cummings and Benson 1992). A form of frontotemporal degeneration that spreads to involve the amygdala and surrounding cortex on both sides is clinically manifested as the Klüver–Bucy syndrome, which may also appear in the setting of herpes simplex encephalitis or after bilateral medial temporal infarction (Poeck 1985). Patients are emotionally indifferent and lacking in initiative, and they tend to put objects of practically any kind in their mouths; they also display hypersexual behavior, react immediately to external stimuli, and have visual agnosia.

Marotta and Perry (1989) showed that HIV-positive patients develop personality changes long before dementia becomes manifest. Perkins et al. (1993) showed, in a study of patients and HIV-negative controls, that HIV-positive homosexual men suffer from personality disorders more often than would be expected by chance. In view of the high degree of comorbidity of various forms of dementia and depressive disorders in this group of patients, further longitudinal studies of personality changes are clearly needed.

Patients suffering from a parkinsonian syndrome have approximately a twofold risk of developing dementia compared to healthy persons of the same age (Marder et al. 1995). Even in the early stage of Parkinson's disease, the patients have disturbances of executive functioning with impairment of the ability to plan and act and of initiative; these disturbances, if they persist, create the impression of personality changes (Levin et al. 1989). In other diseases associated with the development of dementia, such as Steele–Richardson–Olszewski syndrome and Huntington's disease, marked personality changes are seen before dementia becomes manifest (Cummings and Benson 1992).

6 Therapeutic Interventions

Therapeutic interventions must be directed, above all, against the underlying medical condition, as long as the brain has not been permanently damaged. Next in order of priority are attempts at psychopharmacological treatment, based on the predominant clinical manifestations. A few studies have shown a highly beneficial effect of lithium or carbamazepine, in the usual doses, on disturbances of impulse control. No specific cognitive training programs have been developed for the organic personality disorders.

Appendix A. Inclusion Criteria for Category F07 and Criteria for Organic Personality Disorder (Category F07.0) in ICD-10 (World Health Organization 1993)

Disorders of Personality and Behavior Caused by a Disease, Injury, or Functional Disturbance of the Brain (F07)

G1 Objective demonstration, by means of physical, neurological, and laboratory examination and/or history, of a cerebral disease, injury, or functional disturbance

G2 Absence of impairment of consciousness or severe memory disturbance

G3 No adequate and convincing documentation of another cause of the disorder of personality and behavior, which would justify classification in Chapter F6

Organic Personality Disorder (F07.0)

At least three of the following features must be present for a duration of 6 or more months:

1. Persistently reduced ability to carry out goal-directed activities, particularly over long periods of time and when gratification is delayed
2. One or more of the following affective changes:
   a) Emotional lability (uncontrolled, inconstant, and fluctuating expression of emotion)
   b) Euphoria and superficial, inappropriate facetiousness
   c) Irritability and/or outbreaks of anger and aggression

d) Apathy
3. Uninhibited expression of needs or impulses without regard for consequences or for social conventions; affected individuals may engage in antisocial activity such as stealing, inappropriate sexual advances, gluttonous eating, or extreme neglect of bodily hygiene
4. Cognitive disturbances, typically in the form of:
   a) Extreme suspiciousness and paranoid ideas
   b) Excessive preoccupation with a single topic, such as religion, or the strict classification of the behavior of others as "right" and "wrong"
5. Marked changes in language production and the flow of speech, including circumstantiality, vagueness, viscous thinking, and graphomania
6. Altered sexual behavior (hyposexuality or change of sexual preference)

Appendix B. Criteria for the Post-encephalitic Syndrome (F07.1) and the Organic Psychosyndrome After Traumatic Brain Injury (F07.2) in ICD-10 (World Health Organization 1993)

Post-encephalitic Syndrome (F07.1)

A. At least one of the following residual neurological deficits:
   1. Paralysis
   2. Deafness
   3. Aphasia
   4. Constructive apraxia
   5. Acalculia
B. The syndrome is reversible and rarely lasts more than 24 months.

Residual symptoms and behavioral changes after viral or bacterial encephalitis are nonspecific and do not justify the clinical diagnosis. These include a general feeling of illness, apathy or irritability, certain impairments of cognitive function (learning disabilities), disturbances of the sleep–wake cycle, and altered sexual behavior.

Organic Psychosyndrome After Traumatic Brain Injury (F07.2)

A. History of a traumatic brain injury with loss of consciousness, preceding the onset of clinical manifestations by no more than 4 weeks (there may be no objective evidence for brain injury on electroencephalography, imaging studies, and oculonystagmography)
B. At least three of the following features:
   1. Complaints of unpleasant sensations and pains such as headache, lightheadedness (usually without the typical features of vertigo), a general feeling of illness, severe exhaustion or sensitivity to noise
   2. Affective changes such as irritability and emotional lability, both easily provoked by emotional arousal and stress, depression and/or anxiety of a certain degree of severity
   3. Subjective complaints or difficulties in concentrating and in cognitive performance, and memory disturbances, without clear, objective demonstration of unequivocal impairment (e.g. by means of psychological tests)
   4. Sleep disturbances
   5. Reduced alcohol tolerance
   6. Preoccupation with the above symptoms and fear of permanent brain injury, rising to the level of hypochondria, and assumption of the role of an ill person

Appendix C. Criteria for Personality Change Caused by a Medical Disease Factor According to DSM-IV (Category 310.1) (see American Psychiatric Association 1994)

A. A persistent personality disturbance representing a change from the previously characteristic individual personality pattern. (In children, the disorder consists of a significant deviation from normal development or a significant change from the usual behavior pattern of the child lasting at least 1 year.)
B. There is evidence from the patient's history, physical examination, or laboratory tests that the disturbance is the direct physical consequence of a medical disease factor.
C. The disturbance cannot be better explained by another mental disorder (including another mental disorder caused by a medical disease factor).
D. The disturbance does not occur exclusively in the course of a delirium and does not fulfill the criteria for dementia.
E. The disturbance causes, to a clinically significant extent, suffering or impairments in social, professional, or other functional areas.

Subtypes:
- Labile type (affective lability)
- Disinhibited type (reduced impulse control)
- Aggressive type (aggressive behavior)
- Apathetic type (apathy and indifference)
- Paranoidtype (suspiciousness and paranoid ideas)
- Other type
- Combined type
- Nonspecific type

Mental Disorders and Internal Medicine

Translator: E. Taub

1 Prevalence of Medical Comorbidity Among the Mentally Ill

Many studies have shown that a considerable percentage of the mentally ill suffer from concomitant physical illnesses.[1] According to a meta-analysis of published results, this percentage is approximately 50% (Felker et al. 1996); this figure refers to all accompanying illnesses, regardless of whether they bear a causal relationship to the mental disorder or are random, coincidental occurrences. The fact that such illnesses often go undiagnosed is of considerable importance to clinical practice. It has been estimated in several studies that up to half of all comorbid somatic illnesses are undiagnosed at the time of referral to a psychiatric institution (Koranyi and Potoczny 1992; Koranyi 1979).

It is not uncommon for patients with previously unrecognized physical illnesses to present with psychopathological phenomena (Marsh 1997). It has also been shown that, among patients obtaining care in psychiatric institutions, a high percentage of comorbid illnesses are not diagnosed, and previously diagnosed illnesses are often neglected; one or the other of these was the case in 47% of comorbid medical illnesses in 529 mentally ill patients in California, most of them less than 40 years old, who were investigated in a methodologically very careful study (Koran et al. 1989).

The reported percentages of mentally ill patients with comorbid physical illnesses are usually global and do not differentiate the illnesses according to medical specialty. These figures, therefore, should not be equated with the frequency of comorbid disorders in the field of internal medicine, although there is no doubt that they are by far the most common type represented (Felker et al. 1996). For example, disorders in the domain of internal medicine accounted for approximately two thirds of all physical illnesses in a study of a representative sample of patients undergoing acute inpatient treatment (Hewer et al. 1991).

As might be expected, physical comorbidity is particularly common among mentally ill patients of advanced age. Studies of psychogeriatric patients undergoing inpatient treatment have shown that they suffer from an average of two to five accompanying illnesses, of which approximately two thirds are within the domain of internal medicine. Cardiovascular disorders were most common, followed in order of frequency by metabolic and endocrine disorders, respiratory disorders, and gastrointestinal disorders (Hewer and Förstl 1998; Zubenko et al. 1997). The high prevalence of physical illnesses and disabilities among psychogeriatric patients was also demonstrated specifically for patients with dementia (Fichter et al. 1995) and depression (Lyness et al. 1996).

In the Berlin Old Age Study, the prevalence of depression among subjects with unequivocal evidence for significant physical impairment (e.g. multiple physical illnesses, immobility) was found to be two- to threefold higher than that among patients without such impairment, of whom 14.1% were depressed (Linden et al. 1998). It should be mentioned in this connection that chronic physical illnesses typically associated with persistent pain are not uncommonly a determinant of suicidal behavior in elderly patients; according to Summa (1988), this is the case in approximately 40% of patients admitted to hospitals because of attempted suicide.

A number of methodological problems complicate the simultaneous determination of physical and psychiatric morbidity. One such problem is that such studies are supposed to encompass the entire diagnostic spectrum of (internal) medicine, and it is quite difficult to find a satisfactory method for doing this. Furthermore, the question of psychiatric–medical comorbidity is inevitably fraught with the difficulty of deciding whether particular disease manifestations should be attributed to medical or to psychiatric causes; this gives rise to considerable diagnostic imprecision (Linden et al. 1998). In addition, the majority of studies in this field to date have failed to employ satisfactory methods of psychiatric and medical data collection, such as those used in the Berlin Old Age Study cited above (Linden et al. 1995).

Although a number of questions must remain open because of the methodological difficulties just mentioned, the available data, taken as a whole, suggest

[1] A remark on nomenclature: terms such as "medical comorbidity," "physical illness," "somatic illness," or "medical illness" are used synonymously in this chapter to refer to illness(es) in the domain of any medical specialty other than psychiatry or psychotherapy. These terms are approximately equivalent to "general medical condition," as used in DSM-IV (American Psychiatric Association 1994). The use of terms of this kind is not meant to imply that mental illnesses lack physical causes or correlates or that psychiatry and psychotherapy are not medical specialties.
When we use the terms mentioned above, especially "medical illness/disorder/condition" (mainly in the singular), we are referring – with regard to the topic of this chapter – in particular to comorbid physical disorders in the field of internal medicine. Beyond that, these terms may also, in certain contexts, relate to comorbid physical disorders in general, namely for two reasons: first, because it is often difficult to differentiate between diseases within the frame of internal medicine and those "belonging" to other medical specialties; second, because many of the interactions between medical and mental illness discussed below are not confined to internal medicine, but may also be found in relation to other medical branches, such as orthopedics and urology (see Chap. 24, Vol. 3, Part 2).

that mentally ill patients have a degree of physical impairment that, on average, is higher than that of the general population, at least for certain patient groups. Further evidence for a global link between psychiatric and physical morbidity was provided by a Danish epidemiological study of the frequency of hospital admission. Inpatient hospitalizations in general hospital and psychiatric wards were strongly correlated with each other: individuals requiring inpatient treatment in a general hospital at some point in the 8-year period of the study were four times more likely than others to require psychiatric hospitalization (Fink 1990).

In this context, we would like to refer to the numerous studies of the prevalence of psychiatric morbidity among general medical patients, especially those treated in hospital. Presently available information indicates that psychiatric disorders can be diagnosed in 30%–50% of these patients (Arolt et al. 1995; Saupe and Diefenbacher 1999).

Lastly, numerous studies have very consistently shown a significant elevation of mortality among the mentally ill, not only because of suicide, accidents etc., but also because of a higher rate of death from natural causes. According to the recent, extensive literature review by Harris and Barraclough (1998), approximately half of the excess mortality of patients suffering from affective disorders, for example, is due to a higher incidence of death from natural causes. For schizophrenic patients, the corresponding figure is approximately two thirds. Moreover, by evaluating the clinical course of more than 50,000 patients, these authors arrived at the conclusion that the mentally ill in general have a mortality rate that is twice as high as that of the general population.

2 Interactions Between Medical Illness and Mental Disorders

The observations in the previous section concerning the frequency of medical comorbidity are of importance primarily because physical and mental disorders interact with each other in many different ways. In the present section, various medical–psychiatric interactions will be discussed in a simplified manner, as these interactions are often extremely complex, as was shown by Linden et al. (1998) for interactions between medical morbidity and depressive illnesses in advanced age. It should also be noted that "medical" and "psychiatric" factors are differentiated from each other purely from a didactic viewpoint, and no particular philosophical stance toward the mind–body problem is thereby implied.

2.1 Medical Illness as the Immediate Cause of Mental Disorders

Many medical illnesses may lead to cerebral pathology or to brain dysfunction and thereby cause psychopathological syndromes of variable phenomenology in a physiologically explicable manner. The most important pathogenetic mechanisms are the following:

- Disturbances of brain function as a consequence of inadequate supply of oxygen and/or substrate (caused by a focal or generalized disturbance of cerebral perfusion, or a reduction of the oxygen or substrate content of the blood, e.g. in hypoxia or hypoglycemia)
- Disturbances of brain function by means of metabolic–endocrine or toxic processes or other humoral factors (e.g. renal or hepatic failure, disturbances of fluid and electrolyte balance, nutritional disorders, paraneoplastic processes, and infectious or other inflammatory diseases)

Examples of mental disorders as direct physiological consequences of medical illness will be given mainly in Sects. 3.1–3.5 of this chapter, in which dementia, delirium, and other mental disorders resulting from general medical conditions will be discussed from the point of view of internal medicine.

Further typical examples are provided by those medical disorders that may produce an organic amnestic syndrome. It is well known that the Wernicke-Korsakoff syndrome, which is caused by thiamine deficiency, occurs not only in alcoholics, but also (more rarely) in patients suffering from malnutrition, diseases of the upper gastrointestinal tract (such as gastric carcinoma), or protracted vomiting (as in hyperemesis gravidarum), when these entities cause a severe restriction of nutrient intake or absorption. Furthermore, post-anoxic states (such as that seen after cardiopulmonary resuscitation) and recurrent severe hypoglycemia may cause an amnestic syndrome. The particular vulnerability of the hippocampus to hypoxia and hypoglycemia seems to be the most important pathogenetic factor in this process (Förstl 1999).

2.2 Medical Illness as a Factor Influencing the Occurrence and Course of Mental Disorders

Medical illness may be an important risk factor for mental disorders; vascular dementia syndromes are an example. The available data imply that arterial hypertension is the most important treatable risk factor for

vascular dementia. Further risk factors include diabetes mellitus, disturbances of lipid metabolism, smoking, the presence of potential sources of cardiogenic emboli, intermittent hypotension, and syncopal events (Kloss et al. 1994).

Medical illness may also have unfavorable effects on the course of mental disorders. Several empirical lines of evidence indicate that the appearance of resistance to drug treatment in elderly, depressed patients may be influenced by an increased prevalence of comorbid medical disorders, among other factors (Bonner and Howard 1995).

Medical conditions may influence the occurrence and course of mental disorders by a variety of mechanisms. They may have various secondary effects on cerebral function, as is true of arterial hypertension (Lis and Gaviria 1997) and diabetes mellitus (Mooradian 1997). On the other hand, severe, chronic physical illness may also lead to various psychosocial problems, e.g. early retirement and loss of social support, which in turn render the patient more susceptible to related psychiatric disorders, such as adjustment disorders and depression (Ormel et al. 1997).

Finally, the treatment of medical illness may also cause mental disorders. Many primarily non-psychotropic drugs may have unwanted psychiatric effects. Even if such an association remains unproved for some agents, many drugs used in internal medicine have been shown empirically to have undesired psychotropic effects (Kasper and Jung 1995). Propranolol and reserpine, for example, can cause depression, while a broad spectrum of substances can produce delirium (see Sect. 3.2). Such undesired effects may also be produced by nonpharmacological therapeutic measures: mental disorders are found in association with the postoperative phase (Huber 1988), treatment in intensive care units, and organ transplantation (see Chap. 17, Vol. 2, Part 2).

2.3 Mental Disorders as Immediate Causes of Medical Illness

The physical harm resulting from abuse of, and dependence on, psychotropic substances is by far the most common problem in this category (Cherubin and Sapira 1993; Seitz et al. 1995). Further examples include the diverse medical complications of catatonia (Fricchione et al. 1997) and, lastly, the many medical problems brought about by self-destructive behavior, regardless of possible suicidal intent. Special problems are posed in this regard by the factitious disorders and the diagnostic uncertainties typically associated with them, which directly result from the characteristic behavior of the affected patients (Kapfhammer et al. 1998).

2.4 Mental Disorders as Factors Influencing the Occurrence and Course of Medical Illness

The presence of mental illness can negatively affect the patient's physical health in many ways. Empirical evidence suggests that mental disorders may be an important risk factor for the occurrence of medical illness. Impressive support for this concept comes from a longitudinal study by Vaillant (1998), in which the possible relation between psychopathological variables and the subjects' physical health was studied prospectively over a period of several decades. There are also indications that the risk of developing ischemic heart disease is elevated by the presence of depression. It has been shown, in relation to the same paradigm of ischemic heart disease and depression, that mental disorders can negatively affect the course of medical illness (see Chap. 14, Vol. 2, Part 2).

Negative effects on the course of medical illness are also to be expected because many mentally ill patients have a limited ability to cooperate with their medical treatment ("noncompliance"; Häfner and Bickel 1989; see also Sect. 6).

Dementia and *schizophrenia* are the most important examples of mental disorders that put the patient's physical health at increased risk:

- As *dementing illnesses* progress, the affected patients are increasingly subject to bronchopulmonary infections and to disturbances of nutritional and fluid balance. Furthermore, these patients' ability to express physical complaints is often limited, and major diagnostic difficulties may result (Hewer and Förstl 1998).
- Several behavioral features characteristic of patients with *schizophrenia* may have unfavorable effects on the occurrence and course of comorbid somatic illnesses (Adler and Griffith 1991; Vieweg et al. 1995). An alteration of pain perception is not uncommon; this may be due in part to antipsychotic treatment, but it was observed even in the preneuroleptic era (Jakubaschk and Böker 1991). Furthermore, the consequences of drastically elevated nicotine consumption, widespread abuse of psychotropic substances, and (less frequently) polydipsia must be kept in mind in this group of patients (Jeste et al. 1996). Furthermore, schizophrenic patients, like those suffering from dementia, carry an increased risk of bolus aspiration (Schmitt and Hewer 1993).

It should be remarked, for the sake of completeness, that the literature contains several reports of possible protective effects of physical illness on the patients' mental health. These effects, however, seem to be

rather less significant than the unfavorable effects discussed above (Häfner and Bickel 1989). For example, it has been observed in individual cases that severely depressed patients suffering from acutely life-threatening medical illness may obtain significant improvement of their psychopathological condition (Deahl 1990).

Psychotropic drugs are, of course, an important cause of medical problems. They are known to have negative effects on the functioning of many different organ systems (Kane and Lieberman 1992; Tueth 1994); nonetheless, according to the findings of a large study on the safety of medications used in psychiatry (the AMÜP Study, a drug surveillance program carried out in selected university departments of psychiatry in Germany; Grohmann et al. 1994), acute, severe medical problems appear to be relatively rare when these drugs are given in accordance with recommended practice and under appropriate supervision. Long-term use of psychotropic drugs has not been shown to be associated with elevated mortality (Brown 1997; Weeke 1987). It must not be forgotten, however, that most of the currently used drugs can cause weight gain with the well-known associated risks to the patients' health (Fritze et al. 1992).

2.5 Other Constellations

Coexistent medical and psychiatric illness may have a common etiology, as in certain hereditary metabolic disorders (e.g. metachromatic leukodystrophy, Fabry's disease), in which an inborn enzyme deficiency causes both systemic pathology and brain damage with resulting psychiatric disturbance (for a review, see Huber 1988).

Finally, it must be mentioned that a medical illness and a mental disorder may occur in the same patient by random coincidence. Statistical considerations lead us to expect this constellation to occur mainly with relatively common illnesses. As we will discuss further in Sect. 6, medical problems should not be neglected within the framework of psychiatric care even in these cases.

2.6 Frequency with Which Medical Disorders Induce or Aggravate Mental Disorders

Difficult methodological problems, as discussed in part in Sects. 1 and 3 of this chapter, complicate any attempt to answer the question of how often medical conditions induce or aggravate mental disorders (Popkin 1995). The major problem is that the judgment of whether a particular medical illness is a cause of, or exacerbating factor in, a mental disorder is nearly inevitably influenced by the subjective experiences and attitudes of the evaluator (Koran et al. 1989). Thus all reported figures on this topic must be interpreted with an appropriate degree of caution.

Nonetheless, in view of the clinical and scientific importance of the question, one figure will be cited: Felker et al. (1996), in their review article, conclude that medical disorders are a cause of or exacerbating factor in mental illness in approximately 20% of patients treated in psychiatric institutions.

When interpreting this figure, it should be borne in mind that it refers not only to the direct physiological consequences of somatic conditions, but also to indirect effects mediated by the patients' altered psychosocial situation. In other words, types of illness that would be classified as "nonorganic" according to ICD-10 are included in this figure, as long as evidence suggests that they are subject to significant influence from comorbid medical disorders.

3 Mental Disorders Resulting from General Medical Conditions

This section concerns the major types of psychopathology resulting from medical disorders with reference to the internationally accepted systems of classification, particularly ICD-10 (WHO 1992), but also to some extent the diagnostic criteria for mental disorders formulated in DSM-IV (American Psychiatric Association 1994). The organic mental disorders[2] that may arise in connection with medical conditions are listed in the Appendix.

The first three syndromes named in the Appendix differ from the others in that they involve a disturbance of consciousness and/or an impairment of higher cognitive function as a pathognomonic feature and are thereby clearly linked to an organic cause. The syndromes of dementia, amnesia, and delirium can therefore be designated as "psycho-organic syndromes of the first rank" (*psychoorganische Syndrome ersten Ranges*, Lauter 1988), or – in the nomenclature of DSM-IV – as cognitive disorders (American Psychiat-

[2]The use of the term "organic" in the sense of ICD-10 does not imply that "nonorganic disorders" have no cerebral substrate. "Organic mental disorders" according to ICD-10 correspond largely to the "mental disorders due to a general medical condition" as defined by DSM-IV (with the exception that mental disorders caused by nonpsychotropic medications are classified as "organic mental disorders" in ICD-10, while they are included under the heading "substance induced disorder" in DSM-IV.

ric Association 1994) (see also Chaps. 1, 2, 8–11, Vol. 2, Part 2).

The assignment of the attribute "organic" to the syndromes listed in the Appendix, which are coded under F06 in ICD-10, implies that they are "causally related to brain dysfunction" (WHO 1992). ICD-10 names four features that it considers to be prerequisites for the assignment of a clinical condition to one of these categories, which essentially correspond to the criteria formulated earlier by Kurt Schneider (1967):

1. Evidence of a potentially causative cerebral or systemic disease
2. Temporal relationship between the development of the underlying disease and the onset of the mental disorder
3. Recovery from the mental disorder following remission or improvement of the underlying disease
4. No evidence of an alternative cause of the psychiatric symptomatology (such as a strong family history or precipitating stress)

Conditions classified under F06 whose phenomenology resembles, or may even be identical to, that of nonorganic syndromes may be designated as "psycho-organic syndromes of the second rank" (*psychoorganische Syndrome zweiten Ranges*, Lauter 1988). Nevertheless, for a number of reasons that have been discussed in DSM-IV and elsewhere, it may be difficult or impossible to verify the "organic" origin of these syndromes in the individual case. The possibility, already mentioned above, that a mental disorder and a physical illness can occur together by chance must first be considered. Furthermore, certain syndromes accompanying serious physical illnesses – particularly depressive and anxious states – require differentiation from adjustment disorders that have similar manifestations; this may pose a difficult problem in the individual case (Lieb et al. 1997).

Mental disorders due to a general medical condition manifest themselves only by a limited spectrum of syndromes, as compared with a considerably greater variety of possible underlying illnesses (Table 1). It may therefore be asked what factors influence the occurrence and the manner of presentation of a mental disorder in the individual patient. In this context, it is useful to remember the principle of nonspecificity formulated by Bonhoeffer, according to which different medical illnesses may lead to identical psychopathological manifestations, just as a single underlying illness may lead to different types of organic mental disorder (Gross and Huber 1993). The psychopathological manifestations appearing in the individual case are determined not only by the causative disease process, but also by several other unrelated or only indirectly related factors (Gross and Huber 1993),

Table 1. Medical conditions that may be associated with organic mental disorders

Disease group	Examples
Infectious diseases	Syphilis, HIV infection
Neoplastic diseases	Paraneoplastic syndromes, e.g., limbic encephalitis in bronchial carcinoma
Endocrine disorders	Hyperthyroidism, hypothyroidism
Nutritional and metabolic disorders	Malnutrition, vitamin deficiencies, acute intermittent porphyria
Hematological diseases	Severe anemia
Cardiovascular diseases	Congestive heart failure, cardiac dysrhythmias
Respiratory diseases	Chronic obstructive pulmonary disease
Diseases of the gastrointestinal tract, the hepatobiliary system, and the pancreas	Malabsorption syndrome, severe hepatic diseases, acute pancreatitis
Diseases of the kidneys and urinary tract	Advanced renal failure
Rheumatic and autoimmune diseases	Systemic lupus erythematosus
Toxic disorders	Psychotropic effects of nonpsychotropic drugs, heavy metal poisoning

HIV, human immunodeficiency virus.

including those designated by Lauter (1988) as "secondary factors" (e.g. limitation of mobility and social activity because of disease) and "vulnerability factors" (e.g. biological predisposition, premorbid personality).

An illustration of these concepts is furnished by the systemic autoimmune diseases, some of which are relatively frequently associated with organic mental disorders (Table 2). The following conditions are more commonly seen:

- Paranoid–hallucinatory syndromes
- Affective disorders (especially depressive syndromes)
- Cognitive deficit syndromes (of variable degrees of severity, up to the level of dementia)
- Other disorders, e.g. organic personality and behavioral disorders, organic anxiety disorder

In systemic lupus erythematosus, for example, psychopathological abnormalities of these types are observed in approximately 20%–60% of patients (Lieb et al. 1997; Shannon and Goetz 1995). In the case of the systemic autoimmune diseases, the principle remains valid that each of the organic mental syndromes listed

Table 2. Frequency of organic mental disorders in systemic autoimmune diseases (after Lieb et al. 1997)

Disease	Associated mental disorders
Systemic lupus erythematosus	Common
Sjögren's syndrome	Common
Scleroderma	Very rare
Mixed collagenosis	Very rare
Primary CNS angiitis	Rare
Takayasu's arteritis	Rare
Temporal arteritis	Rare
Churg-Strauss syndrome	Rare
Wegener's granulomatosis	Rare
Polyarteritis nodosa	Rare
Microscopic polyangiitis	Rare
Antiphospholipid syndrome	Less common
Sneddon's syndrome	Common
Behçet's disease	Less common

CNS, central nervous system.

above can be associated with any underlying illness in this group, just as any underlying illness can give rise to any of these organic mental syndromes. A similar nonspecificity of psychopathological syndromes is associated with several other classes of illness, e.g. the endocrinopathies (see Sect. 4); the presence of a particular type of psychopathological manifestation cannot therefore be taken as a reliable clue to the underlying etiopathogenetic process.

Nonetheless, the principle of nonspecificity is not universally applicable. Taking up the example of systemic autoimmune diseases once again, we find that, even though diagnostic precision cannot be obtained in the individual case, there are nonetheless clear correlations between the type of underlying illness and the frequency of certain psychopathological syndromes. For instance, affective and paranoid–hallucinatory syndromes are most common in systemic lupus erythematosus and Sjögren's syndrome, while dementia is more characteristic of angiitis, antiphospholipid syndrome, and Sneddon's syndrome (Lieb et al. 1997). Furthermore, the nonspecificity paradigm has been criticized on the grounds that the manner in which psychopathological features and syndromes have been described to date may still be too undifferentiated to enable more specific correlations of the desired type (Lauter 1988). In view of the rapid progress now being made in the neurobiological understanding of mental illness, it is conceivable that future research will establish clearer correlations between disease processes in the field of internal medicine and the types of psychopathological manifestation that they cause.

Because limitations of space preclude a discussion of all of the conditions listed in the Appendix in relation to all possible causes in the field of internal medicine, the following subsections will deal with only a few of the more frequently occurring organic mental syndromes.

3.1 Dementia

A great variety of medical conditions may underlie a dementing process, including the following (Mumenthaler 1987; Lang 1994):

1. Cardiovascular and pulmonary diseases:
   - Arteriosclerotic and degenerative angiopathies
   - Arteritides (e.g. systemic lupus erythematosus, giant cell arteritis)
   - Major heart diseases (e.g. congestive heart failure, valvular heart disease, cardiac dysrhythmias)
   - Recurrent cerebral emboli
   - Chronic respiratory failure
   - Sleep apnea syndrome
2. Infectious diseases:
   - Human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS)
   - Lyme disease
   - Brucellosis
   - Whipple's disease
   - Malaria
3. Metabolic and endocrine diseases:
   - Endocrine disorders (e.g. hypothyroidism, hypoparathyrodism, hyperparathyroidism, hypoglycemia)
   - B_{12} and other vitamin deficiencies
   - Uremic encephalopathy, dialysis dementia, hyponatremia
   - Hepatic failure
   - Metabolic diseases (e.g. disorders of lipid metabolism, porphyria)
   - Malabsorption syndromes
4. Miscellaneous diseases:
   - Hematological diseases (e.g. polycythemia vera, paraproteinemias, coagulopathies)
   - Sarcoidosis
   - Paraneoplastic limbic encephalitis

It is important to establish the particular disease underlying dementia in the individual case because of the potential implications for treatment. It is estimated that 13%–15% of demented patients have a potentially reversible underlying illness, and 10%–12% an actually reversible one (Clarfield 1988; Weytingh et al. 1995).

Among possible types of treatable underlying illness, diseases within the domain of internal medicine (most importantly metabolic–endocrine disorders) are third in order of frequency. Approximately 2% of demented patients have an underlying medical problem whose directed treatment will result in an improvement of the cognitive deficits. Complete remission of dementia can be obtained in no more than one third of such patients, while dementia regresses partially in the remaining patients (Clarfield 1988; Weytingh et al. 1995).

Vascular processes are the second most frequent cause of dementia after Alzheimer's disease. Vascular dementia is generally caused by arteriosclerotic and degenerative changes of the extra- and intracranial cerebral vasculature, of both macro- and microangiopathic types; the latter type is currently thought to be of particular pathogenetic importance (Poeck and Hacke 1998). Rarer causes of vascular dementia include cardioembolic events, inflammatory angiopathies, and coagulopathies (Geldmacher and Whitehouse 1996; see also Chap. 8, Vol. 2, Part 2).

The diagnostic assessment of dementia must, therefore, always include a basic general medical assessment, whose findings may then necessitate further investigation (Hewer and Förstl 1998). From the therapeutic viewpoint, a question that frequently arises in clinical practice is whether a dementia syndrome caused by arteriosclerotic–degenerative vascular disease can be influenced by treatment. The therapeutic prospects become worse with increasing duration and severity of the clinical manifestations; the medical risk factors named in Sect. 2 should thus be treated at an early stage, if possible even before the appearance of dementia. The management of high blood pressure is particularly important. An abrupt decrease of blood pressure leading to hypotension must be avoided, however, as this may promote further progression of the cerebral parenchymal insult (Dettmers et al. 1997).

3.2 Delirium

Since Bonhoeffer originally described the "acute exogenous reaction" at the beginning of the twentieth century, it has become clear that a very wide variety of medical disorders can cause this syndrome, in addition to primary brain disorders and the use of psychotropic substances (Lipowski 1990). The occurrence of delirium can be understood as a threshold phenomenon (Jacobson 1997): the more intense a delirogenic factor is and the more such factors are involved, the more likely delirium is to develop. In a typical constellation, for example, acutely or subacutely emerging medical disorders, superimposed on a preexisting cerebral insult, may precipitate delirium. When the preexisting insult is severe, even relatively mild medical problems, such as an uncomplicated urinary tract infection, may lead to delirium.

The following are the more important medical conditions that may cause delirium (Jacobson 1997):

- Infections (e.g. pneumonia, urinary tract infection)
- Disturbances of fluid and electrolyte homeostasis (e.g. hypovolemia, acid–base disturbances, and disorders of sodium, potassium, calcium, and magnesium balance)
- Metabolic and endocrine disturbances (e.g. hypoglycemia, renal or hepatic failure, vitamin deficiencies, thyroid or parathyroid dysfunction)
- Cardiopulmonary diseases (e.g. myocardial infarction, congestive heart failure, cardiac dysrhythmias, pulmonary embolism, respiratory failure, hypertensive encephalopathy, shock)
- Severe anemia
- Undesired effects of medications used in internal medicine (e.g. antiarrhythmics, antibiotics, antirheumatic agents, corticosteroids, cytostatic agents)

Delirium may occur in conjunction with medical illnesses at any age, but in the industrial countries it tends to affect mainly the elderly, because they are most subject to multimorbidity, including neurodegenerative processes. It is estimated that at least 20% of elderly patients admitted to general hospitals are in a state of delirium at the time of admission or at some point in their hospital course; prevalence may even be higher for patient subgroups at particular risk (Inouye 1998).

The major prognostic significance of delirium becomes clear if we consider that there is a mortality rate of roughly 25% within 6 months; this may be explained by the fact that many of the diseases causing or precipitating delirium are life-threatening (Trzepacz 1996). Furthermore, the occurrence of delirium, at least in the elderly, is correlated with other prognostically unfavorable features (American Psychiatric Association 1999), such as prolonged hospital stays, frequent nursing-home admissions, and certain complications (e.g. falls, decubitus ulcers); this remains so even after appropriate statistical control for potential confounding variables, e.g. age and severity of illness (O'Keeffe and Lavan 1997).

Even though delirium is often associated with a negative overall prognosis, it generally responds to therapy, and there is a good chance that the patient's mental state can be restored to what it was before the appearance of the acute psychopathological disturbance. Early and specific treatment of the causative or contributing physical illnesses is therefore essential.

In view of the etiological and pathogenetic relationships discussed above, the diagnosis and treatment of states of delirium clearly require an interdisciplinary process involving both internal medicine and neuropsychiatry. The treatment of delirium includes not only the treatment of the underlying illness, but also all medical and nursing measures promoting physiological homeostasis (e.g. nutrition, fluid balance, mobility). Moreover, certain principles of therapeutic interaction with patients should be adhered to, including the provision of aids to orientation, the avoidance of excessive stimulation, and the greatest possible constancy of treating personnel (Förstl 1999; Rabins 1991). The indication for symptomatic psychopharmacological treatment should be reviewed in each case (Trzepacz 1996). It should be recalled that many medications have delirogenic effects (Inouye 1998), including a number that are frequently used in internal medicine and do not have primary psychotropic effects (Tune et al. 1992).

3.3 Mild Cognitive Disorder

According to the ICD-10 Research Criteria (WHO 1993), the essential, feature of mild cognitive disorder is an impairment of cognitive abilities (e.g. memory, attention, concentration) to a lesser degree than in dementia, delirium, or various other conditions. A duration of symptomatology of at least 2 weeks is also required (see also Chap. 10, Vol. 2, Part 2). As discussed in DSM-IV (research criteria for mild neurocognitive disorder), the cognitive deficit takes a variable course, depending on the dynamics of the underlying process. Stable, fluctuating, or remitting courses may be observed; the deficits may also progress and eventually rise to the level of dementia.

The position occupied by mild cognitive disorder among the other cognitive deficit syndromes is still a matter of discussion (Caine et al. 1995; WHO 1993). According to present conceptions, the following medical disorders may be considered as possible causes of mild cognitive disorder (American Psychiatric Association 1994; Egberts 1993; Elias 1998; Stern and Prange 1995; Strachan et al. 1997):

- Arterial hypertension
- Diabetes mellitus
- Endocrine disorders
- Milder forms of hepatic encephalopathy
- Severe metabolic imbalances
- HIV infection and other infectious diseases
- Hypoxic states

Various other medical disorders might also be responsible for this presumably fairly common disorder.

3.4 Organic Depressive Disorder

Depressive syndromes caused by medical disorders are classified in ICD-10 as organic depressive disorder (F06.32). As discussed in Sect. 2, above, a prerequisite for this diagnosis is that the depressive manifestations are caused by physiological processes associated with the underlying illness, rather than by the patient's emotional reaction to the knowledge that he or she has a serious illness. The spectrum of medical disorders that may cause organic depressive disorder includes the following, among others (Caine et al. 1995; Popkin 1995):

- Endocrine disorders (e.g. hormonal excess or deficiency states of the thyroid or parathyroid glands)
- Metabolic disorders (e.g. vitamin B_{12} deficiency and certain electrolyte disorders, such as hyper- and hypocalcemia)
- Cardiopulmonary diseases (e.g. congestive heart failure, respiratory failure)
- Hepatic or renal failure
- Systemic autoimmune diseases (e.g. systemic lupus erythematosus, temporal arteritis, rheumatoid arthritis)
- Cancer (e.g. pancreatic carcinoma)
- Infectious disease (e.g. infectious mononucleosis, hepatitis, influenza, HIV infection, syphilis)
- Medications (e.g. reserpine, propranolol, clonidine, glucocorticoids, nonsteroidal anti-inflammatory agents, H_2 inhibitors)

As discussed in Sect. 3, it may be difficult to determine in the individual case whether an organic depressive disorder is present or whether there is an alternative explanation, such as an adjustment disorder or the presence of depression as a second, independent disease. Comorbid medical illness as a precipitating factor in patients with preexisting vulnerability to depression is a further possibility to consider (Tölle 1990). Such an explanation is currently being discussed for the frequent observation, in earlier decades, of depression in patients under treatment with reserpine (Akiskal 1995).

3.5 Organic Delusional Disorder

Organic delusional or schizophrenia-like psychoses may be produced by the following medical conditions, among others (or by the undesired effects of medications used in internal medicine) (Davison and Bagley 1969; American Psychiatric Association 1994; Huber

1994; Lieb et al. 1997; Marsh 1997; Pearlson and Petty 1994):

- Endocrine diseases (hyper- or hypothyroidism, hyper- or hypocortisolism, hypoparathyroidism, hypopituitarism)
- Metabolic disorders (Vitamin B_{12}, folic acid, or thiamine deficiency, acute intermittent porphyria, Wilson's disease, hyponatremia, renal and hepatic insufficiency, hypoglycemia)
- Systemic autoimmune diseases (systemic lupus erythematosus, Sjögren's syndrome, Churg-Strauss syndrome)
- Infections (syphilis, HIV infection, malaria, subacute bacterial endocarditis)
- Miscellaneous disorders (cerebral anoxia, hypercapnia, carbon monoxide poisoning, sarcoidosis, polycythemia, thalassemia)
- Undesired effects of medications used in internal medicine (e.g. digitalis, certain antiarrhythmics, propranolol, β-sympathomimetic agents, cephalosporine and other antimicrobial agents, nonsteroidal anti-inflammatory agents, corticosteroids, anticholinergics, cimetidine)

Schizophreniform states are only rarely produced by medical illness, but the possibility is clinically important because of its therapeutic implications. For that reason, the guidelines for the treatment of schizophrenia recently issued by the German Psychiatric Association (Deutsche Gesellschaft für Psychiatrie, Psychotherapie und Nervenheilkunde 1998) contain explicit recommendations for basic medical assessment in schizophrenic conditions. In addition to its clinical importance, the occurrence of schizophreniform syndromes in certain medical illnesses is of basic scientific interest for the understanding of the neurobiology of schizophrenia.

4
Medical Illness Associated with Mental Disorders: Examples from Endocrinology

As can be seen from Table 1, a broad spectrum of medical illness may be associated with mental disorders. A number of the disease groups listed in Table 1 form the subject of individual chapters in Part 2 of this volume (Chaps. 14–17) and will therefore not be dealt with in detail here.

The major endocrine diseases will be discussed in the remainder of this section, in view of their common occurrence and frequent interactions with mental disorders. Although the principle of nonspecificity remains operative, as M. Bleuler (1954) pointed out, the individual endocrine diseases nonetheless have particular features that are worthy of consideration from a psychiatric point of view. In endocrinopathies, like other medical disorders, psychopathological manifestations may be the presenting symptoms (Heuser 1993); this fact should make clear once again that psychiatric diagnosis requires a background of experience in general medicine.

4.1
Disorders of Glucose Metabolism

Diabetes mellitus is the most common endocrine disease; its prevalence in the German population, for example, is approximately 5% (Hauner 1998). Patients with both insulin-dependent (IDDM) and non-insulin dependent diabetes (NIDDM) have a markedly elevated risk of developing depressive syndromes (Eiber et al. 1997; Gavard et al. 1993). IDDM patients also have an elevated prevalence of anxiety disorders (Eiber et al. 1997). Whether these mental disorders occur more frequently in diabetics because of a direct causative effect of the metabolic abnormality in diabetes or primarily because of nonspecific effects related to the presence of a chronic illness remains uncertain (Eiber et al. 1997). Their clinical importance results not only from the suffering they cause, but also from the unfavorable effect they may have on blood sugar control (Kovacs et al. 1996).

Diabetes mellitus is a major risk factor for vascular dementia in the elderly (Skoog 1998). As discussed in Sect. 3.3, multiple studies have shown that certain neuropsychological deficits, including memory impairment and cognitive slowing, occur more frequently in patients with NIDDM (Strachan et al. 1997); it remains unknown to what extent these deficits may be precursors of frank cognitive deficit syndromes that will develop later. Recent findings also suggest a possible association of diabetes mellitus with dementing processes of the Alzheimer type (Ott et al. 1996).

Hypoglycemia is most commonly caused by antidiabetic treatment with insulin or oral antidiabetic agents. Other causes of severe hypoglycemia, such as insulinoma, end-stage liver diseases, or severe malnutrition, are much rarer. Acute hypoglycenia may be accompanied by psychopathological manifestations of many different kinds, of which the most common are clouding of consciousness, psychomotor agitation, and anxiety (Lishman 1998). The characteristic vegetative signs of hypoglycemia – tremor, tachycardia, and severe hyperhidrosis – are not always seen (Cryer 1997). It follows that the possibility of hypoglycemia must always be considered in the differential diagnosis of acute psychopathological changes of unknown

origin. Chronic, recurrent hypoglycemia of any degree of severity may lead to irreversible cerebral damage, including dementia. This risk is especially prominent in cases of insulinoma that go unrecognized for years (Lishman 1998), but cases of cognitive deficit syndromes arising in diabetics as a consequence of severe hypoglycemia have also been reported (Langan et al. 1991).

4.2 Disorders of Thyroid Function

Disorders of thyroid function occupy a special position among all types of endocrine disease in the differential diagnosis of mental disorders, because they are common and may give rise to highly varied psychopathological manifestations. Alongside patients with known thyroid dysfunction who may require psychiatric treatment, there are also more than a few cases of thyroid dysfunction that are first diagnosed in psychiatric institutions. The proportion of patients with previously undiagnosed thyroid dysfunction among those undergoing acute psychiatric treatment is reported to be on the order of 1%–2% (White and Barraclough 1989; Lederbogen et al., in preparation).

Typical psychopathological phenomena produced by hyperthyroidism are emotional lability, psychomotor agitation, and anxious and depressive states (Heuser 1993). It is noteworthy that elderly patients with hyperthyroidism may also manifest apathetic–depressive syndromes while simultaneously losing weight; this constellation may bring a neoplastic process to mind. In other cases, manifestations resembling those of organic or schizophreniform psychosis may be produced (Lishman 1998). Interestingly, psychotic syndromes also seem to be precipitated by the treatment of hyperthyroidism in rare cases (Irwin et al. 1997); a rapid decline in hormone production or a transient hypothyroid state has been suggested as the explanation (Lishman 1998).

Affective abnormalities are often prominent in the clinical picture of hypothyroidism. Depressive mood alteration, with prominent apathetic–lethargic manifestations, is typical (Lishman 1998), while agitated depression may also be observed (Heuser 1993). Psychoses of variable phenomenology may occur, just as in hyperthyroidism (Lishman 1998). Acquired hypothyroidism is, lastly, one of the more important causes of potentially reversible dementia (Mumenthaler 1987), just as congenital hypothyroidism leads to an impairment of intelligence whose severity depends on the duration and severity of the hormone deficiency (Postellon and Abdallah 1986).

Under modern conditions of medical care in industrial countries, massive psychopathological abnormalities (such as psychosis) due to thyroid dysfunction are only rarely seen, presumably because thyroid hormone substitution or antithyroid therapy is generally initiated while the disease is still at a relatively early stage (Baumgartner 1993). With regard to the psychopathological effects of subclinical hyper- and hypothyroidism, varying opinions can be found in the literature. While some authors maintain that these disturbances can, in principle, evoke manifestations similar to, but less pronounced than, those of frank hyper- and hypothyroidism (Haggerty et al. 1993), others state that no association of this type has been conclusively demonstrated (Baumgartner 1993). There are also no generally accepted recommendations for the treatment of subclinical disorders of thyroid function (Stern and Prange 1995).

4.3 Disorders of Parathyroid Function

Psychopathological manifestations of hyper- and hypoparathyroidism are largely similar (Heuser 1993). Both conditions are frequently associated either with depressive mood disturbances, typically accompanied by fatigue and lack of initiative (Heuser 1993), or with cognitive deficit syndromes. The latter may be severe enough to qualify as dementia or delirium (Lishman 1998). Mental disorders are commonly seen in association with disorders of parathyroid function: Petersen (1967) showed, in a study of 54 patients suffering from hyperparathyroidism, that mild mental abnormalities were present in approximately one third, and severe mental abnormalities in a further third of the patient group.

It is presumed that the psychopathological manifestations of parathyroid dysfunction are directly caused not by the abnormally high or low peripheral concentration of parathyroid hormone, but rather by the resulting hyper- or hypocalcemia. The psychopathological manifestations of hyper- and hypocalcemia are largely independent of etiology, and their severity is significantly correlated with the magnitude of the deviation of the serum calcium concentration from the normal range (Petersen 1967).

Now that the determination of serum calcium concentration has become part of clinical routine, and an assay for intact parathyroid hormone is available, milder cases of hormone deficiency and excess are being diagnosed much more commonly than before. Because of this, the number of diagnosed

cases of primary hyperparathyroidism, in particular, has increased (Raue 1996). The serum calcium concentration is often only mildly or moderately elevated (i.e. less than 3 mmol/l). It has not yet been established whether milder degrees of parathyroid dysfunction can produce cause psychopathological abnormalities; the authors of a recent review of the literature conclude that they can (Okamoto et al. 1997).

4.4 Disorders of Adrenal Cortical Function

Mental disturbances are observed in 40% or more of patients with Cushing's disease, which is caused by excessive endogenous secretion of steroid hormone by the adrenal cortex (Heuser 1993; Stern and Prange 1995). Depressive syndromes are the type most commonly encountered (Kelly 1996). Affective disorders are also the most common psychopathological side effects of the therapeutic administration of glucocorticoids; in this situation, hypomanic syndromes with euphoria seem to be more common than in Cushing's disease (Kershner and Wang-Cheng 1989; Naber et al. 1996).

In principle, however, hypercortisolism of whatever etiology may produce psychopathological manifestations of any kind. The same is true of hypocortisolism, a condition characterized by fatigue, marked physical weakness, and marked hypotension (Heuser 1993).

4.5 Pheochromocytoma

Pheochromocytoma is a usually benign secretory tumor of the chromaffin cells of the sympathetic nervous system, located, in 90% of patients, in the adrenal medulla. Paroxysmal hypertension is the hallmark of the disease. More than 60% of patients have baseline hypertension, upon which paroxysms of still higher blood pressure are superimposed (Bornstein 1996). The massively elevated concentration of circulating catecholamines produces the typical psychopathological manifestations of pheochromocytoma: anxiety and the associated characteristic vegetative phenomena.

When due attention is paid to the patient's blood pressure, it is generally not difficult to differentiate cases of pheochromocytoma from the primary anxiety disorders (Rubin and King 1995). It should also be noted that there is a possibility of hypertensive encephalopathy in pheochromocytoma, which may be caused by the dramatically elevated blood pressure, with resulting clouding of consciousness and cognitive deficit syndromes (Lishman 1998).

5 Diagnostic Problems

As discussed in Sect. 1, a considerable percentage of the mentally ill suffer from undiagnosed somatic illnesses. This is so because of various problems that typically arise in the context of medical and psychiatric comorbidity and that may impede the recognition of medical illness. One such problem is that of mental disorders limiting the patient's capacity to perceive and communicate the presence of physical symptoms, as discussed in Sect. 2. Another is the occurrence, in many mental disorders, of diverse physical complaints that may lead treating physicians to suspect medical illness where there is none or, conversely, reinforce a pattern of behavior on the physicians' part in which physical symptoms are primarily regarded as expressions of mental illness (Thiel et al. 1998). Furthermore, the diagnosis of medical disorders in the mentally ill may be hindered by factors such as a lack of competence in internal medicine on the part of the psychiatrist, insufficient experience in dealing with the mentally ill on the part of the internist, or the unavailability of necessary diagnostic technology in psychiatric institutions (Vieweg et al. 1995).

Because many manifestations of illness are nonspecific, it is often difficult to determine whether they are the result of a medical or a psychiatric disorder. There may be difficulty not only with the diagnosis of medical illness in the mentally ill, but also with the diagnosis of psychiatric illness in the medically ill. An example of the latter situation is the frequently missed diagnosis of depression in medical patients (Popkin 1995). One of the reasons for this may be that certain manifestations of depression (e.g. weight loss, lack of initiative) may also be manifestations of medical illness, and their attribution to disorders of one or the other type is highly variable among physicians of different specialties (Linden et al. 1995).

6 Therapeutic Problems

6.1 Treatment of Medical Illness

A number of factors that may complicate the treatment of medical illness in the mentally ill are discussed in

the literature. Certain constellations of psychopathological symptomatology are commonly associated with noncompliance (Adler and Griffith 1991), while, conversely, a lack of acceptance of psychiatric patients on the part of medical institutions may also be observed (Vieweg et al. 1995). Furthermore, the mentally ill may be less able to make use of available medical resources (Felker et al. 1996), problems may arise in the multidisciplinary collaboration of internists and psychiatrists, and, as mentioned in Sect. 5, there may be a lack of expertise in internal medicine within psychiatric institutions.

The indication for medical treatment may result from the presence of a mental disturbance if a medical illness is found to be the underlying etiology. If, as discussed in Sect. 3, the etiology cannot be reliably established, this is usually only of limited relevance for the therapeutic approach. Largely regardless of whether it is assumed that there is an organic mental disorder associated with medical illness or whether a "nonorganic" disorder is diagnosed, the same principles of syndrome-related therapy are applied, as are the therapeutic measures indicated for each particular medical condition.

Problems may arise when the decision about whether a particular mental disorder is due to a general medical condition determines whether potentially harmful treatments are indicated. For example, the decision to treat systemic autoimmune disorders with corticosteroids (Lieb et al. 1997), or primary hyperparathyroidism with parathyroidectomy (White et al. 1996), may largely depend on whether the medical illness is considered the essential etiological factor for the concomitant psychopathological syndrome, or whether the latter is thought to be a causally unrelated "nonorganic" mental disorder. There are no generally applicable rules for such decisions, which may be very difficult. Close cooperation between the psychiatrist and the medical specialist is required in all such cases.

6.2
Treatment of Psychiatric Illness

Concomitant medical illness may have implications for the treatment of psychiatric illness, and these implications must always be taken into account, even when the medical and psychiatric illness are causally unrelated. Physical limitations with respect to mobility or sensory perception, for instance, may make it difficult or impossible to carry out certain behavioral treatment measures that would otherwise be indicated.

The administration of psychotropic medication to medically ill patients is particularly problematic. The numerous special considerations involved in the use of antidepressants by such patients are well known, particularly the effect of tricyclic antidepressants on the cardiovascular system (Glassman et al. 1993). The clinician faces a dilemma: patients with cardiovascular disease are at increased risk for depression (see Chap. 14, this volume), but the available antidepressants often are known to be contraindicated in such patients (tricyclic agents) or have been insufficiently studied in this regard (non-tricyclic antidepressants; Kapfhammer 1998). Recent findings suggest, however, that the serotonin reuptake inhibitors have a more favorable risk–benefit ratio than the tricyclic agents in this group of patients, although it is too early for definite conclusions to be drawn (Roose et al. 1998). Furthermore, the results of studies demonstrating the effectiveness of certain agents in medically healthy depressed patients are not necessarily applicable to patients with accompanying medical illness (Popkin 1995).

7
Conclusions and Future Prospects

Nearly half of all mentally ill patients suffer from comorbid physical illnesses, among which roughly two thirds are within the domain of internal medicine. Medical and psychiatric disturbances interact with each other in many ways, not all of which have been adequately studied to date, and each type of disturbance may, on occasion, be a cause of the other. It is common for medical illnesses to complicate mental disorders, and vice versa. The mentally ill require a considerable amount of general medical care, but the care that they receive is apparently inadequate in many respects (Felker et al. 1996; Jeste et al. 1996). This discrepancy is explained by aspects of the patients' behavior that are the consequence of mental illness as well as physician-related factors and certain shortcomings of psychiatric and medical institutions (Thiel et al. 1998).

The foregoing discussion should make it clear that steps must be taken to improve the general medical care of the mentally ill. These will involve not just ensuring that the required level of basic medical competence is available in psychiatric institutions, but also improving interdisciplinary cooperation between psychiatrists and other medical specialists and among the various services involved in the care of the mentally ill. An important prerequisite for achieving these goals should be the position of psychiatry and psychotherapy as an integral component of general medicine, which might even be reinforced in the future (Kathol et al. 1997).

Appendix. Classification of Organic Mental Disorders According to ICD-10[3]

F00–F03 Dementia
F04 Organic amnestic syndrome
F05 Delirium
F06 Other mental disorders due to brain damage or dysfunction and to physical disease
- F06.0 Organic hallucinosis
- F06.1 Organic catatonic disorder
- F06.2 Organic delusional (schizophrenia-like) disorder
- F06.3 Organic mood (affective) disorders
- F06.4 Organic anxiety disorder
- F06.5 Organic dissociative disorder
- F06.6 Organic emotionally labile (asthenic) disorder
- F06.7 Mild cognitive disorder
- F06.8/6.9 Other disorders, unspecified disorder

F07 Personality and behavioral disorders due to brain disease, damage and dysfunction
F09 Not otherwise specified organic or symptomatic mental disorders

A.H. Glassman, E.G.V. Giardina

An Examination of the Linkage Between Ischemic Heart Disease and Depression

This work was supported in part by the Suzanne C. Murphy Foundation, Grant RR-00645 from the Research Resources Administration, Bethesda, Maryland, and a grant from Linda and Peter Nisselson. Parts of the material in this manuscript appeared in an article by Professor Glassman in the American Journal of Psychiatry in January 1998.

1 Introduction

Both literature and folklore have long acknowledged a relationship between depression and mortality. Even our language refers to the relationship between grief and the heart – in speech, poem, and song we describe people dying of a broken heart. However, in spite of this widespread common recognition, scientific evidence supporting these relationships has come only recently.

2 Depression and Mortality

The first scientific report of the relation between emotion and mortality did not occur until the early 1930s. At that time, Malzberg examined the mortality rate of involutional melancholic patients in the New York State civil hospital system and compared it with the mortality of an age-matched sample of the general population (Malzberg 1937). Not surprisingly, the rate was significantly elevated; however, Malzberg's findings did not receive widespread acceptance. The problem with Malzberg's data was that they confused the diagnosis of depression with being an inmate of the New York State asylums. It was not possible to tell which condition was responsible for the observed increase in mortality.

Further scientific inquiry into this question was delayed by the onset of the Second World War. After the war, attention focused not so much on diagnostic categories as on personality. In the United States, two cardiologists developed the concept of the "type A" personality (Rosenman et al. 1964). Early evidence supported the usefulness of this category of "time urgent" personality, and most of American psychological medicine pursued this concept. It was not until the late 1970s that investigators returned to examining the diagnostic concept of depression and its relationship to mortality. A Danish epidemiologist by the name of Weeke surveyed the extensive Danish National Registries. She compared the mortality of all patients admitted to the Danish mental health care system who received a diagnosis of either major depression or manic depressive disease between 1974 and 1978 with the mortality of the general population (Weeke 1979). This approach eliminated the scepticism that had haunted Malzberg's institutional study, because in the Weeke data the vast majority of the patients under observation were outpatients and resided at home. Although the risk of dying was not elevated to the same degree as in Malzberg's data, cardiovascular mortality was increased 50% above the general population.

The major criticism raised about the Weeke data and a number of similar studies is that, in the 40 years since Malzberg's observations, a number of antidepressant drugs had come into widespread use and it was possible that these pharmacological treatments rather than the diagnosis of depression were responsible for increased mortality. Weeke attempted to deal with these concerns in a second study published in 1987 (Weeke et al. 1987). Cardiovascular mortality among depressed patients before and after the introduction of either antidepressant drugs or lithium was compared. Cardiovascular mortality was elevated during both periods; however, the risk was actually higher during the predrug period.

In addition to the two studies by Weeke, seven other investigators examined the relative mortality among patients with major depression and/or bipolar disease and compared that mortality to the general population (Black et al. 1985; Norton and Whalley 1984; Rabins et al. 1985; Sharma and Markar 1994; Tsuang et al. 1980; Vestergaard and Aagaard 1991; Zilber et al. 1989). Eight of the nine studies found evidence of a significantly increased cardiovascular mortality rate. Only a single Israeli study that collected patients and compared their mortality to a nonpatient population failed to find an increased cardiac mortality rate (Zilber et al. 1989). That study by Zilber also found an increased mortality rate, but the increase was primarily from infectious, not cardiovascular, disease.

All nine of these studies collected patient samples from individuals in treatment at the time they were identified. As a result, the relationship that was observed between depression and cardiovascular mortality could not really be extended beyond patients with relatively serious depression who came to those treatment settings. These studies did not address the question of whether milder cases of depression would also be associated with any increased mortality. In addition, although neither the second study by Weeke nor any other available data set (Muller-Oerlinghausen et al. 1992; Avery and Winokur 1976) gave any evidence that antidepressant treatment accounted for the increased mortality rate, it was not possible to eliminate entirely this consideration. By going out into the community and collecting epidemiological, rather than clinical samples, research workers were able to resolve both of these issues.

In the late 1980s and early 1990s, data from two such epidemiological studies became available. Murphy examined the Sterling County data (Murphy et al. 1987). This data set followed 1000 individuals for 16 years, and specific causes of death were available. A diagnosis of depression was explicitly associated with cardiovascular mortality. In the second study of this

type, Bruce used the New Haven data set that had followed 3500 individuals for 9 years (Bruce et al. 1994). She also found that a diagnosis of depression was associated with an increase in natural deaths; however, no information was available as to the specific cause of these excess deaths.

Thus, in the 15 years between the late 1970s and the early 1990s, all 11 studies that had looked for an association between a diagnosis of depression and mortality had found a significantly increased risk of death. In nine of the 11 studies, the increased mortality rate was specifically demonstrated to be cardiovascular in nature. This increased risk had been seen in both unipolar and bipolar patients and in cases that would seem to be both mild and severe. It did not appear in any way to be related to treatment. At that point in time, this relationship appeared to be real. However, in the late 1980s, a serious potential confound became apparent. At that time, the powerful relationship between depression and cigarette smoking began to become apparent (Glassman et al. 1988, 1990). This relationship might readily explain the apparent association between depression and cardiovascular mortality. It could easily be that depression was associated with cigarette smoking and that smoking caused the increased risk of death. None of the 11 studies that had searched for a relationship between depression and cardiovascular disease had in any way attempted to control for smoking.

3
Depression and Heart Disease Controlled for Smoking

One of the early replications of the initial observation linking depression to smoking and to smoking cessation failure came from the Communicable Disease Center (CDC) of the United States Department of Health (Anda et al. 1990). Anda and coworkers realized that a second CDC data set actually contained information that would allow for an analysis of the association between depression and cause-specific mortality while controlling for smoking. The Medical Illness Follow-Up Study contained information on 2832 individuals over the age of 45 who were found to be free of any physical disease after initial physical and laboratory examinations (Anda et al. 1993). These individuals were then followed for a minimum of 12.5 years. In order to preclude the possibility that subjects may have had some awareness of symptomatology that prompted their depression even though it was not revealed by their history, physical, or laboratory examination, patients who died in the first 2.5 years of follow-up were excluded. Nevertheless, after controlling for known cardiovascular risk factors (gender, weight, physical activity, blood pressure, and cholesterol level), including cigarette smoking, apparently healthy individuals that had an elevated depression rating were more likely both to develop and to die of ischemic heart disease (IHD). This study by Anda and colleagues was the first to show that the association between depression and cardiovascular disease persisted even after controlling for smoking and the first to identify the dual risk of both developing and dying of ischemic disease.

In the last few years, six more epidemiological studies have taken a similar approach to different data sets. All studies controlled for smoking, and five of the six studies found a relationship between depression and cardiovascular disease. Ford reported on 1198 former Johns Hopkins medical students followed for a median of 35 years. Men with depression had a higher relative risk of myocardial infarction (MI) (RR, 1.68; 95% CI, 1.03–2.74) than men free of depression (Ford et al. 1994). On average, the first report of depression preceded the first report of cardiovascular disease by 10 years. Aromaa et al. (1994) reported on the Mini-Finland Health Survey follow-up of individuals 40–64 years of age. The study was based on 5355 individuals who had both medical and psychiatric evaluation at baseline and who were followed for an average of 6.6 years. The risks of both developing and dying of IHD were significantly elevated among depressed individuals after controlling for age, education, and traditional IHD risk factors, including smoking.

The Kuoppio Ischemic Heart Disease Study followed a separate sample of 2428 Finnish men over a 6-year period (Everson et al. 1996). Here, very much like the data obtained by Anda and colleagues in the United States, men without any prior history of angina or MI who had higher levels of depression were more likely to experience their first infarction even after controlling for a wide array of biological, behavioral, and social risk factors. There was again an elevated risk of cardiovascular mortality among men with higher depression scores, and again the investigators controlled for traditional cardiac risk factors, including smoking.

Another recently published long-term study that also controlled for smoking is the Glostrup cohort (Barefoot and Schroll 1996). This is a study of 730 individuals born in Glostrup, Denmark in 1915. They had both physical and psychological examinations in 1964 and again in 1974 and were followed for an average of 27 years. After controlling for both smoking and physical health, like the CDC and Finnish data, individuals with elevated depression scores were 65% more likely to develop IHD. Elevated depression scores were also associated with a significant increase in all natural causes of mortality; however, the question of

whether this increased mortality rate was specifically cardiovascular in nature was not addressed.

The most recently published data come from a 13-year follow-up of the Baltimore cohort of the Epidemiological Catchment Area Study (Pratt et al. 1996). Among the 1551 respondents apparently free of medical illness at baseline, a diagnosis of major depression increased the risk of MI more than fourfold after controlling for both medical risk factors and other psychiatric diagnoses. This study is interesting because it used a DSM-III diagnosis of depression, is the only study to control for other psychiatric diagnoses, and included the category of dysphoria in the same population. Individuals that were dysphoric but never met lifetime criteria for major depression were intermediate in their risk for MI compared to patients with DSM-III major depression and individuals totally free of depression.

Only one study that started with healthy individuals and controlled for all the usual medical risk factors failed to find a relation between depression and new IHD and/or cardiovascular mortality, and that is the 15-year follow-up of 2573 members of the Northwest region of Kaiser Permanente (Vogt et al. 1994). Only 1399 of these individuals were over the age of 45. Even here, the authors refer to a "possible" relationship between mortality and depression among men.

Thus, since 1993, six of the seven studies that started with healthy individuals and controlled for cardiovascular risk factors, including smoking, found an association between increasing levels of depression and the onset of new IHD and/or cardiovascular death. In addition to these seven studies that either started with healthy individuals or controlled for existing medical risks, there are also two studies with patients who were in treatment for hypertension. Wassertheil-Smoller and coworkers (1996) followed 4367 otherwise healthy hypertensive patients for 5 years, while Simonsick et al. (1995) observed 3561 hypertensive individuals for 6 years. Both groups were controlled for smoking. The depressed individuals in both studies were found to be at increased risk for cardiovascular death. Wassertheil-Smoller and colleagues also found an excess risk for both stroke and MI. Thus, since the need to control for cardiovascular risk factors, including smoking, became apparent in the early 1990s, eight of nine epidemiological studies have found a significant association between depression and cardiovascular disease or death.

4 Known Cardiovascular Disease and Depression

In 1988, Carney, working at Washington University in St. Louis, adopted a somewhat different strategy. He started not with individuals that were healthy or essentially healthy, but deliberately began with patients who had documented IHD (Carney et al. 1988). He performed structured psychiatric examinations on consecutive patients undergoing coronary angiography. Of the 52 patients whose studies confirmed the presence of coronary artery disease, just less than 20% met criteria for major depression. This depressed population was two and a half times more likely to develop a serious adverse cardiac complication over the next 12 months. Although Carney's sample size was too small to adequately control for other risk factors, this was corrected in subsequent studies using this strategy.

Ahern obtained baseline ratings of anxiety, anger, and depression in 350 patients with ventricular arrhythmia following a heart attack (Ahern et al. 1990). Those postinfarction patients who survived the first year had lower baseline depression scores than nonsurvivors after controlling for the usual medical and social risk factors. Neither anger nor anxiety scores were associated with survival. Several other investigators evaluating post-MI patients also found a higher mortality rate associated with depression (Frasure-Smith et al. 1993; Frasure-Smith 1991; Ladwig et al. 1991). The most convincing of these studies was by Frasure-Smith et al. (1993).

Frasure-Smith and Lesperance obtained a structured psychiatric examination in 222 patients 5–15 days after an MI and contacted them 6, 12, and 18 months after discharge from the hospital. Sixteen percent showed evidence of major depression while hospitalized for their index MI. This is consistent with other surveys that regularly show 15%–20% of postinfarction patients developing major depression (Hance et al. 1996; Schleifer et al. 1989). At 6 months, approximately 17% of the depressed patients had died compared to 3% of the nondepressed patients (Frasure-Smith et al. 1993). Controlling for other independent predictors of risk, the relative hazard for depressed patients was almost three and a half times greater. The strongest predictor of mortality after an infarct is generally heart failure, and similarly it is associated with a three and a half times greater mortality rate.

Although concern has been expressed about the reliability of a psychiatric diagnosis made in a medically ill patient, and especially in one who is post-MI, only 25% of the patients Frasure-Smith and Lesperance identified as depressed were free of major depression at both the 6- and 12-month follow-up interviews (Lesperance et al. 1996). This compares with 81% of those patients who had not originally received a diagnosis of depression remaining free of depression. Similarly, Hance et al. (1996) found that half the patients diagnosed with major depression in the immediate post-MI period either remained depressed or relapsed within 12 months.

In addition to a diagnosis of major depression, Frasure-Smith also measured symptomatic depression using the Beck Depression Inventory (Beck et al. 1961). At 6 months after MI, patients with elevated Beck scores but free of major depression had mortality rates much like those of patients free of any depression. However, by 12 months, patients with Beck scores above 10 were dying at a significantly higher rate than patients free of depression, and by 18 months their mortality rate was not much less than those with major depression (Frasure-Smith et al. 1995a). It is not clear whether increased mortality is really associated with lesser degrees of depression or whether high Beck scores are merely identifying a group at high risk for major depression. In the study by Hance and coworkers, 42% of patients with minor depression developed major depression over the subsequent 12 months (Hance et al. 1996).

Recently, Barefoot and coworkers at Duke University in Durham, North Carolina, published a 17-year follow-up of patients admitted to the cardiology service with a diagnosis of coronary artery disease. This study combines the strategy of using a high-risk population and long-term follow-up. Once again, depression was associated with diminished survival in patients with preexisting cardiovascular disease (Barefoot et al. 1996).

5
Anxiety and Cardiovascular Disease

Taken together, the studies described above constitute compelling evidence linking depression to an increased risk of IHD. However, a number of issues need to be clarified. One of these issues is whether the association between depression and cardiovascular disease is unique to depression or whether similar associations exist with all negative affective states. Although there is more information available about depression than any other negative affect, there are extensive data concerning anxiety. In thinking about the impact of any affective state, it is important to realize that the short-term effect of mood states, i.e. over hours or days, could be different from its effect over months or years. There are three long-term epidemiological studies that have examined the effects of anxiety (Kawachi et al. 1994a,b; Haines et al. 1987). However, all anxiety states may not have the same consequences, and all authors do not define anxiety in the same way. Examining the available data would suggest that, over the long term, being an anxious person or having a nonspecific anxiety diagnosis does not increase the likelihood of developing or dying of IHD. However, phobic anxiety or panic states do over the long term seem to be associated with an increased risk of death, particularly sudden death (Kawachi et al. 1994a; Haines et al. 1987). Over the short term, much fewer data are available. Frasure-Smith has examined the impact on survival of high anxiety scores following infarction over the subsequent 6–18 months. She found that high scores were associated with an increased likelihood of developing cardiac complications. However, in a meta-analysis of multiple "type A" personality studies following infarction, anxiety played a very minor role if it played any role at all (Booth-Kewley and Friedman 1987).

6
Anger and Cardiovascular Disease

The influence of anger in distinction to symptoms of anxiety or depression has been examined in a number of studies. Many of these studies suggest that increased anger ratings are associated with more rapid progression of IHD (Booth-Kewley and Friedman 1987; Kawachi et al. 1996; Julkunen et al. 1994). The problem is that almost none of the studies that carefully measured anger also obtained reliable measures of depression. This is particularly troublesome because anger and depression frequently coexist and measures of depression are so consistently associated with cardiovascular disease. To establish that anger is independently associated with either a more malignant course or an increased mortality rate in IHD would necessitate that both mood states be measured. Two studies that did measure both failed to find any independent contribution of anger; however, both of these studies specifically studied post-infarction patients and both followed patients for approximately 1 year (Frasure-Smith et al. 1995b; Ahern et al. 1990).

7
What Is It About Depression that Carries the Risk

Another unresolved issue is precisely what it is that carries the risk. In phenomenological terms, the studies that have been mentioned up to this point have identified populations at increased risk using either a diagnosis of major depression, various scales that measure symptoms of depression, or the hopelessness item of the Well-Being Scale (Dupuy 1974). The obvious question is whether the increased risk travels specifically with the diagnosis of major depression, whether it varies with the severity or chronicity of a depressive state, or whether it can be associated with symptoms of depression in the absence of a diagnosis.

There are only very limited data available to address these distinctions. In the short term following a heart attack, Lesperance et al. (1996) found that the risk of death is strongly associated with recurrent major depression, but that a single episode of major depression occurring for the first time after an MI was not associated with any increased risk of mortality. Because of the manner in which Frasure-Smith and Lesperance collected their follow-up data, it is not possible to say whether the excess deaths occurred among those patients who were persistently depressed after infarction, whether those who died had their depression return prior to their death, or whether the mere occurrence of depression after infarction in those with a history of prior depression marked a group at higher risk of death whether or not they continued to be depressed. In the long-term studies carried out by Anda et al. (1993), Everson et al. (1996), and Barefoot and Schroll (1996), it was found that the higher the symptom scores at baseline, the higher the risk both to develop IHD and to die of it. However, it is again not clear whether this increased risk is the result of these individuals merely having more severe symptoms of depression. Alternatively, these higher symptom scores may have identified individuals who were more likely to develop major depression and the risk is concentrated in those individuals who developed major depressive episodes. Everson et al. (1996) assert that hopelessness is a state that can be separated from depression and that this state confers a risk independent of depression. In general, these remain open issues.

In addition to the studies that have been described up to this point, a series of studies from the Netherlands have examined a condition described as "vital exhaustion." This state is characterized by a lack of energy, increased irritability, and feelings of demoralization (Appels et al. 1987). Vital exhaustion sounds similar to depression and seems to demonstrate a similar association with cardiovascular disease. In long-term prospective studies, it was associated with an increased relative risk of initial MI (Appels and Mulder 1988), and it is associated with an increase in adverse cardiac events in the year and a half following angioplasty (Appels et al. 1995). It would seem very likely that recurrent major depression and vital exhaustion tap the same underlying process, but the data available do not allow us to test that hypothesis.

Ultimately, whether these descriptive entities are measuring the same or different processes will be established by identifying the mechanism or mechanisms that lie behind these associations. In the Montreal study (Frasure-Smith et al. 1995a), the excess mortality among the patients with post-MI depression was due almost exclusively to sudden death. Because sudden death is almost always the result of ventricular arrhythmia, Frasure-Smith looked to see whether there was an interaction between depression and post-MI arrhythmia. There was, in fact, a striking increase in the mortality rate among those post-MI patients who had both depression and even mild baseline ventricular arrhythmia (Frasure-Smith et al. 1995a). There is considerable evidence that fluctuations in autonomic tone influence the risk of ventricular fibrillation and sudden death (Schwartz et al. 1992). Changes in autonomic tone have long been considered an integral part of serious depression, and the direction of those changes is such that one would anticipate an increase in sudden death (Carney et al. 1995; Dalack et al. 1992). This could easily explain a good part of the increased mortality associated with depression following infarction. However, it would be an unlikely explanation of the increased rate of new infarction seen in depressed individuals initially free of any cardiac disease.

8
Platelet Studies and Depression

A number of investigators have reported both increases in platelet serotonin ($5\text{-}HT_2$) binding and a decreased platelet 5-HT transporter site density in depressed patients (Nemeroff et al. 1994). These were seen as abnormalities associated with the biology of depression, but not as abnormalities that would influence the clotting function of the platelet. When Anda first noticed that depression was associated not just with cardiac mortality, but also with the onset of new cases of IHD, it occurred to him that these platelet abnormalities might actually have functional significance. As a result of Anda's suggestion, Musselman and colleagues compared platelet function in depressed patients and normal controls. In a particularly sophisticated study, they found that depressed patients had a heightened susceptibility to platelet activation (Musselman et al. 1996).

Musselman compared healthy depressed patients and healthy normal controls. Perhaps more surprisingly, Laghrissi-Thode et al. (1997) found evidence of increased platelet activation in a group of depressed patients comorbid for cardiovascular disease. This abnormality was observed in spite of the fact that many of these patients were already taking aspirin because of a prior MI. Laghrissi-Thode's methodology was not as sophisticated as Musselman's, but taken together their results strongly suggest that depression alters platelet function such that one would expect an increased rate of both heart attacks and strokes. In fact, there is considerable evidence that depression's effect is not limited to cardiovascular disease but

involves all vascular disease, including stroke (Morris et al. 1993a,b; Wassertheil-Smoller et al. 1996).

It would be easy to think that depression in association with cardiovascular disease is nothing more than a natural reaction to a stressful life event. Depressions are certainly common among medically ill patient populations. However, numerous epidemiological studies have shown that the onset of depression precedes cardiovascular disease, and in addition the absolute rate of depression seen in the post-infarction period is far greater than that seen in other medically stressful situations. A number of studies have examined the onset of symptoms of major depression in the first 10 days or so following MI (Hance et al. 1996; Schleifer et al. 1989). This 10-day rate is triple that ordinarily expected in a 6-month incidence rate and double that associated with chronic medical illness. In addition, in follow-up studies of post-MI depression, the depression either becomes recurrent or persists over the next 6 months in at least 50% of patients (Travella et al. 1994; Lesperance et al. 1996).

9 Conclusion

What has been presented to the reader is a series of studies that document two associations. First, depression is associated with an increased rate in the onset of new cases of IHD. Furthermore, depression is also associated with a higher rate of cardiac mortality among patients with preexisting IHD, especially those in the postinfarction period. It would be easy to think that depression causes this worsening. Increased platelet aggregation and the decrease in various measures of heart rate variability shown to be a finding in postinfarction death (Dalack et al. 1992) as well as the poor health behavior seen in depression all suggest a causal relationship. However, at this time, what has been proven is still only an association. It is conceivable that a genetic predisposition could put an individual at risk for both depression and arteriosclerotic disease. Evidence that some forms of late-onset depression may be secondary to arteriosclerotic disease in the brain support this view (Krishnan 1993). At this point, these issues need to be resolved. Although we suspect that certain characteristics of chronic depression contribute to the relationship with IHD, that relationship could be a two-way street and the process of arteriosclerosis in the brain could increase the risk for chronic depression.

The other question raised by the relationship between depression and mortality is whether successful treatment of depression would reduce cardiovascular mortality. However, even before we test whether treatment reduces mortality, we need to establish that treatment is safe and effective in a seriously ill cardiac population. While tricyclic antidepressants are not suitable in this patient sample (Glassman et al. 1993), serotonin reuptake inhibitors would seem to be more benign drugs in this population. To date, the data are inadequate to be certain about either their safety or efficacy, and evaluation of safety and efficacy are critical to this issue.

Psychiatric Syndromes in Infectious Diseases

1 Introduction

Infectious diseases of the central nervous system (CNS) are characterized mainly by neurological symptoms and signs. However, in several cases, psychiatric features not only accompany neurological manifestations, but even predominate in the clinical picture, being the early or even the only clinical manifestations of the disease. In this chapter, we will consider those infectious diseases of the CNS in which psychiatric manifestations are prominent.

Infectious agents can reach the CNS either by hematogenous spread from extracranial foci or by retrograde propagation of infected thrombi within emissary veins. Viruses and bacteria can invade different sites in the CNS (brain parenchyma, meninges, spinal cord) and peripheral nerves, producing inflammatory reactions (encephalitis, meningitis, meningoencephalitis, brain abscess) and/or degenerative processes.

The cellular composition of CNS, its sequestration from the rest of the body by the blood–brain barrier, its close confinement within rigid skeletal structures, and the presence of lymphatic system only within the epidural space greatly influence the course of brain infections (Greenlee 1995).

Many viruses, bacteria, and fungi do not present an elective tropism for specific brain regions; hence these agents induce a global impairment of brain functioning, which may be responsible for a nonspecific organic psychiatric syndrome. In contrast, other infectious agents may localize in some brain areas; in these cases, the functional specialization of the involved brain region can produce characteristic psychiatric symptoms. In some cases, the infectious agent appears to consist of proteins and is devoid of functional nucleic acid; such agents are designated as prions (i.e. proteinaceous infectious agents) in order to distinguish them from viruses.

Finally, systemic infectious diseases with no direct localization in the CNS may induce psychiatric manifestations as a consequence.

2 Nonspecific Psychiatric Syndrome Due to Infectious Agents

The generalized psychiatric syndrome which follows some infections of the CNS consists of a nonspecific set of acute symptoms often evolving in two stages (Sheld et al. 1991; Mandell et al. 1995).

The first stage is characterized by insomnia or hypersomnia, irritability, restlessness, forgetfulness, difficulty in thinking, inability to concentrate, and distractibility. These symptoms are frequently accompanied by fever, headache, meningism, and other neurological signs. If the infectious agent is brought under control, this clinical picture subsides in a few days. If the infection persists, the symptomatology evolves into the second stage.

The second stage is characterized by the clinical picture usually referred to as delirium, in which the most important feature is the impairment of consciousness, often varying in intensity through the day and being worse at night. Visual hallucinations and memory deficits frequently coexist and affect registration, retention, and recall. On recovery, there is usually amnesia for most of the illness. Normally, these manifestations disappear if a specific therapy is available and it is possible to control and overcome the infection.

In some cases, several signs can persist as sequelae. Patients can present personality changes, such as irritability, loss of spontaneity, and drive, reduced control of aggressive impulses, and/or persistent cognitive deficits, ranging from slight defects in intellectually demanding activities to a stable residual dementia.

3 Psychiatric Syndromes in Specific Infectious Diseases

Many infections of the CNS can present a more specific symptomatology, related either to the infectious agent and its elective tropism for certain brain areas and/or to the host reaction. They include neurosyphilis, Lyme disease, tuberculous meningitis, encephalitides, subacute sclerosing panencephalitis (SSPE), and brain abscess.

3.1 Neurosyphilis

Syphilis is a systemic infectious disease caused by the spirochete *Treponema pallidum*. It is transmitted by sexual contact, and the percentage of patients with CNS infection has been increasing since the advent of the human immunodeficiency virus (HIV) epidemic (Musher et al. 1990; Kinghorn 1993). The psychiatric signs of syphilis may be present at any time during the evolution of the disease, which evolves in three phases.

During the first phase, psychopathological signs are nonspecific and rare. In fact, depressive and anxious

reactions, and in some cases suicide, are usually due to the patient's awareness of his or her disease (Lukehart et al. 1988).

In the second (or septic) phase, *Treponema pallidum* spreads throughout the whole body. The most common psychiatric symptoms are sleep disturbances, distractibility, irritability, disorientation, confusion, depression, anxiety, and delusional and hypochondrial worries. This phase may also be characterized by periods of elevated mood, confabulation, and auditory and, to a lesser extent, visual hallucinations (Tramont 1995).

The third phase is characterized by the neurologic and psychiatric signs of neurosyphilis, which can assume the clinical presentation of meningovascular syphilis, tabes dorsalis, or general paresis. As a general rule, meningovascular (inflammatory) syndromes occur within a few years of infection, while parenchymatous (degenerative) syndromes such as tabes dorsalis and general paresis may have a latency of decades.

Patients with meningovascular syphilis may show the same symptomatology as in the second phase (e.g. insomnia, depression, anxiety), but the disease is more often characterized by intellectual weakness, followed by a subconfusional or confusional state. Irritability, mood disturbances, and memory impairment are usually present. Sometimes, this state can evolve with the appearance of oneiric, delusional agitation or stupor, which are frequently consequences of ictal events related to cerebral arteritis (Simon 1985; Hook 1991). Very occasionally, it is possible to observe focal neurological signs (hemiplegia, aphasia, epilepsy), amnesia, or a schizophrenic-like state.

Mental disturbances are not usually part of the clinical picture of tabes dorsalis. When they occur, the patients usually show a psychotic state with impairment of consciousness. Sometimes, they may present with dementia or chronic psychosis, with persecutory delusions related to clear sensory disturbances.

General paresis, although rare, is the most important psychiatric complication of neurosyphilis. It usually develops 10–15 years after the infection, and patients present with personality changes, dysphoric or elevated mood, and striking lapses in social functioning. Any other combination of psychiatric symptoms may occur (Rundell and Wise 1985; Emsley et al. 1988; Sirota et al. 1988; Roberts and Emsley 1992). As the disease progresses, it is possible to distinguish three main clinical pictures: (1) a megalomanic syndrome with grandiosity and elation without insight, (2) a depressive syndrome with nihilistic delusions and hypochondrial worries, and (3) a primitive and deep dementia, involving the patient's whole personality. Neurological signs such as paralysis, ataxia, and seizures may be also present. In untreated cases, death normally occurs within 4–5 years.

Although the incidence of all forms of syphilis has decreased in industrialized countries, there is now a rise in the number of cases in the groups at risk for AIDS (Temmerman et al. 1992). It may be predicted that, as the survival of HIV-infected subjects is prolonged by the new treatments that are becoming available, psychiatrists will face a recrudescence of mental complications of neurosyphilis.

3.2 Lyme Disease

Lyme disease is a multisystemic illness, caused by the tick-borne spirochete *Borrelia burgdorferi*. Because of its spirochetal etiology and its course, with early skin localization and rapid invasion of the CNS, Lyme disease has been believed to be similar to syphilis. It has been reported in several countries around the world and throughout the United States, where a dramatic increase in its incidence has recently occurred (Centers for Disease Control 1993).

Typical clinical manifestations of Lyme disease involve an initial erythematous annular rash at the site of the bite of a tick infected with the pathogenic agent. Within a few weeks after the skin reaction, the spirochetes disseminate to the CNS, where they may remain silent for months to years before producing symptoms. In 15%–40% of patients, neurological problems may be the presenting symptoms, involving initial headache, followed by meningitis, motor or sensory radiculitis, and encephalitis with fluctuating disturbances of mood, concentration, memory, and sleep (Reik 1992).

Later-stage illness generally affects the joints, eyes, and skin, and patients may present with an encephalopathy, characterized by subtle to severe cognitive changes, fatigue, sleep disturbance, extreme irritability or mood lability, and spatial disorientation (Fallon et al. 1992). At this stage, a distinction between an organic mood disorder and a concomitant major depression may be quite difficult to make. Severe cases of anxiety, panic, and obsessive-compulsive disorders have also been associated with Lyme disease.

3.3 Central Nervous System Tuberculosis

Tuberculous meningitis is the most common form of tuberculosis in the CNS. The immunosuppression induced by HIV makes more people susceptible to tuberculous infection and, in a West African study, tuberculous meningitis was found to be the cause of death in 11% of HIV-infected patients (Lucas et al.

1993). Less frequent psychiatric manifestations of tuberculosis are a subacute psychosis and a neurasthenic syndrome related to a latent infection.

The clinical picture of tuberculous meningitis is typically heterogeneous, with prodromes lasting from 1 week to several months characterized by irritability, sadness, anxiety, asthenia, thought slowness, and memory impairment. Most frequently, an atypical depression develops, but a delusional and hallucinatory syndrome with possible antisocial reactions can also occur and rapidly subside.

Subacute psychosis is a very rare complication of a developing tuberculosis. It is characterized by subacute mental confusion with either anxiety or euphoria, delusions, and multiple hallucinations. This clinical picture is normally transient, and regression can be obtained more rapidly with specific treatment.

The neurasthenic syndrome related to latent tuberculosis is characterized by asthenia, anergy, difficulty in thinking, inability to concentrate, and distractibility, probably secondary to a generalized toxic, infectious state.

3.4 Encephalitides

Encephalitis may be either the consequence of a primary viral infection of the brain or a complication of bacterial meningitis, general sepsis, or brain abscess. In the acute stage, the above-mentioned nonspecific psychiatric syndrome usually occurs. More relevant for psychiatrists are the complications that follow the acute episode, including dementia, prolonged depressive or anxiety states, and personality changes (Lishman 1987).

Among all the encephalitides, epidemic encephalitis, although nowadays rare and sporadic, deserves special mention because of the frequency of psychiatric manifestations (Gelder et al. 1996). Initially described by Von Economo at the Viennese Psychiatric Clinic in 1917, it has been etiopathogenetically linked to influenza viruses, although this link has never been proved conclusively.

The acute stage is characterized by sleep disturbances, with inversion of the sleep–wake rhythm and predominance of narcolepsy and cataplexy. The patient is unable to perform any movement during the waking or the sleep phase; hallucinations, anxiety, depersonalization, and depression are also frequent. In some cases, impulsivity and suicidal ideation are present.

The chronic sequelae are of psychiatric interest. Besides parkinsonism and oculogyric crises, severe psychotic syndromes may develop. It is possible to distinguish the following syndromes:

- A delusional–hallucinatory syndrome, with chronic paranoid delusions, hallucinations, and pseudohallucinations
- A hebephrenic–catatonic syndrome with negativism, eccentricity, and stereotypies
- Depressive episodes, either pure or associated with delusions and hallucinations
- A rapidly progressing dementia (rare)
- Personality changes possibly leading to antisocial behavior

3.5 Subacute Sclerosing Panencephalitis

SSPE is a slow viral infection of the CNS, accompanied by degeneration of gray matter and loss of white matter, likely due to the measles virus.

The clinical picture is initially characterized by behavioral and cognitive changes, such as forgetfulness and irritability, while neurologic signs and symptoms predominate as the disease progresses (Jabour et al. 1969). Patients with SSPE often present with a psychosis in the absence of impairment of consciousness, with bizarre behavior, hallucinations, and aphasia, suggesting the temporal lobe as the site of infection (Duncalf et al. 1989).

3.6 Brain Abscess

Clinical signs of brain abscess are caused by the space-occupying mass rather than the infection itself. Headache, papilledema, seizures, and other neurological focal signs may occur (Nielsen et al. 1982).

In some cases, a cerebral abscess may develop insidiously, mimicking a psychiatric syndrome. For example, depressive symptoms accompanied by mild confusion and fever should cause the physician to suspect the presence of a brain abscess. The clinical picture of a frontal lobe abscess is often dominated by drowsiness, distractibility, and a generalized deterioration of mental functioning. Impairment of consciousness, ranging from lethargy to coma, occurs in most patients (Samson and Clark 1973).

The primary focus of the infection is usually outside the brain, in the mastoid, middle ear, or nasal sinuses. Penetrating head injury may be a further cause (Tay and Garland 1987). The anaerobes most commonly encountered in brain abscess include *Bacteroides*, *Prevotella*, *Fusobacterium*, *Clostridiium*, and *Actinomycetes*. In the antibiotic era, abscesses due to *Staphylococci* are decreasing in frequency, whereas those due to Enterobacteriaceae are more prevalent (Dacey and Winn 1983).

4 Prion Diseases

4.1 General Remarks

Prion diseases, sometimes referred to as transmissible spongiform encephalopathies, include human CNS disorders characterized by an aberrant metabolism of the cellular prion protein (PrP^{C}), a normal soluble protein of the cell membrane, which undergoes a conformational change to an insoluble form. This form, denoted PrP^{SC} (prion protein, scrapie, as it was first identified as the agent which causes scrapie in sheep), is poorly metabolized and accumulates in the CNS, causing cell death with spongiform changes (Prusiner and Hsiao 1994).

Prion diseases are therefore quite different from typical infectious diseases which require genetic material to be transferred. Furthermore, in these diseases, incubation usually takes months or years, leading to the concept of "slow infection" of the CNS.

Classical prion diseases in humans comprise Creutzfeldt-Jakob disease (CJD), Kuru, Gerstmann-Straussler-Scheinker syndrome, fatal familial insomnia, and the recently described new variant of CJD. Here, we focus on CJD and its new variant.

4.2 Creutzfeldt-Jakob Disease

CJD is a subacute prion disease with spongiform encephalopathy. Although its prevalence and incidence is only 1 per million of the population worldwide, hereditary, infectious, and sporadic types can be distinguished, with the latter accounting for 85%–95% of cases.

In the majority of patients, CJD begins in the late 50s with mental deterioration, rapidly progressing to a severe dementia accompanied by behavioral disturbances. The presence of myoclonus is another almost invariant feature of the disease. Frequently, visual, cerebellar, and extrapyramidal signs also occur. Characteristic triphasic complexes are found on electroencephalography (EEG) in about 80% of patients. The average duration of the illness from onset of symptoms to death is 7–9 months.

Recently, an apparently new variant of CJD has been identified in United Kingdom (Will 1996), with a single case also found in France (Zeidler et al. 1997). In contrast to typical CJD, onset of the new variant of CJD occurs at an unusually young age (with most patients being in their 20s), and psychiatric symptoms are present at initial presentation, with anxiety, depression, transient delusions, and auditory or visual hallucinations being the most prominent clinical features. Cognitive impairment and neurological signs, including ataxia and involuntary movements, generally occur relatively late.

This apparently new variant of CJD has attracted worldwide interest because of the possibility that it is causally linked to bovine spongiform encephalopathy (BSE) and thus possibly transmitted to humans through "infected" cow meat.

5 Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) is a disorder of unknown etiology, characterized by debilitating fatigue associated with fever, myalgia, arthralgia, lymphoadenopathy, and headache. Photophobia, transient scotomata, forgetfulness, difficulty in thinking, inability to concentrate, excessive irritability, sleep disturbances (insomnia or hypersomnia), confusion, and depressed mood may also occur (Krupp et al. 1991).

A striking feature of CFS is its sudden onset following an acute infectious illness and the subsequent recurrent "flu-like" symptoms. Infectious agents, including the human herpes virus, *Candida albicans*, human spumavirus, enterovirus, Epstein-Barr Virus, and brucella, have been involved. CFS is also common after recovery from hepatitis A and B (Landay et al. 1991). In addition to infectious agents, metabolic factors have also been implicated. Although an infectious dysregulation of the immune system has been postulated in the pathogenesis of CFS, the mechanisms responsible for this syndrome are still unclear.

6 Management

The management of psychiatric syndromes due to infectious agents consists, for the most part, in the management of the specific infection. The pharmacologic treatment of psychiatric symptoms is similar to that for other acute or chronic organic brain syndromes. In the delirious patient, the general rule is to give as few drugs as possible and to avoid any that may increase impairment of consciousness. General measures, such as reducing disorientation and avoiding too much or too little sensory stimulation, are necessary to relieve distress and to prevent

behaviors potentially dangerous to the patient or to other people.

Apart from adequate nursing care, the patient should be given repeated explanations of his or her condition. Preservation of a familiar environment is important, although not always easy to achieve, mainly in those infectious diseases that necessitate isolation. If possible, relatives and friends should visit the patient frequently. It is good practice to advice them about how they may contribute to reassuring and orientating the patient.

M. Maj, A. Tortorella

Mental Health Problems and Psychiatric Disorders in Subjects with Human Immunodeficiency Virus Infection

1 Introduction

According to the most recent estimates by the United Nations and the World Health Organization (UNAIDS 1996), there are currently approximately 22 million individuals with human immunodeficiency virus (HIV) living in the different areas of the world (about 21 million adults and almost 1 million children). More than 90% of them live in developing countries, and almost two thirds live in sub-Saharan Africa.

Heterosexual intercourse accounts for more than 70% of all adult infections to date, being the predominant mode of transmission in Africa, Asia, and the Caribbean; male homosexual intercourse accounts for 5%–10% of cases and remains the predominant mode of transmission in North America; sharing of contaminated needles by i.v. drug users accounts for a further 5%–10% of cases and is the predominant mode of transmission in some European countries; finally, transfusion of contaminated blood or blood products accounts for 3%–5% of adult infections to date.

Mother-to-child transmission of the infection occurs during pregnancy or delivery or through breast-feeding in 25%–35% of infants born to HIV-infected women. Over 85% of all infections in children have occurred up to now in sub-Saharan Africa.

In industrialized countries, about 60% of adults progress to acquired immunodeficiency syndrome (AIDS) within 12–13 years of becoming infected with HIV (UNAIDS 1996). Although no long-term cohort study has been completed, progression to AIDS may be more rapid in developing countries. The average survival time after the onset of AIDS is at present about 3 years in industrialized countries and is estimated to be less than 1 year in developing countries. The majority of AIDS cases occur before the age of 35, and over 90% of all AIDS deaths occur in individuals under the age of 50.

An epidemic of this proportion and with these characteristics can be expected to have profound mental health implications at several levels: (a) those directly affected by the infection, (b) groups at risk for the infection, including homosexual/bisexual men, i.v. drug users, people with multiple sex partners, and patients with serious psychiatric disorders, (c) partners, relatives, and friends of those with HIV infection, (d) health care providers, and (e) the general population. In this chapter, we will focus on the first of these levels. For information on the impact of the epidemic at the other levels, the reader is referred to the reviews by Maj (1991), Knox et al. (1994), and Coverdale (1996).

2 Mental Health Problems

HIV infection is often accompanied by significant mental health problems, for the following reasons:

- It produces a devastating physical illness, the psychological impact of which is comparable to that of cancer.
- In contrast to cancer, it elicits adverse social reactions (fear, stigma, rejection).
- It involves the brain, not only by inducing secondary infections or neoplasms, but also by producing a primary encephalopathy.
- In industrialized countries, it predominantly affects groups (homosexuals, i.v. drug users) who are already highly vulnerable to mental health problems.

Most people with HIV infection can be expected to experience mental health problems, although only a minority of them will suffer from proper psychiatric disorders.

The mental health problems most commonly reported by persons with HIV infection can be subdivided into the following groups: (a) distressing emotions, (b) cognitive disturbances, (c) relationship difficulties, (d) instrumental problems, and (e) suicidal ideation and/or attempts (Pakenham et al. 1996).

Distressing emotions most frequently experienced by those with HIV infection include the following: fear (of death, illness, pain, disability, disfigurement, abandonment, dependency, of infecting others, of others discovering their status, of the unknown), anger (directed at the partner or partners, family, friends, health staff, medical profession, institutions, fate, themselves), sadness, anxiety (frequently associated with overattentiveness to bodily changes), despair, guilt (about their lifestyle), uncertainty, and numbness. These emotions peak after the notification of serostatus, remain in the background or fluctuate during the asymptomatic stage of the infection, and then peak again after the appearance of physical symptoms, the start of antiretroviral treatment, the diagnosis of AIDS, and any worsening of physical status or exacerbation of HIV-related relationship and instrumental problems. For further information on emotional reactions to the notification of seropositivity and on pre- and post-test counseling, the reader is referred to Miller (1987).

Cognitive disturbances most frequently experienced by individuals with HIV infection include forgetfulness, poor concentration, slowness of thought, and speech difficulties. These disturbances are reported by 15%–25% of those with symptomatic HIV infection

(Maj et al. 1994b) and reflect, at least in a proportion of the cases, the initial involvement of the brain, as demonstrated by the concomitant impaired performance in some neuropsychological tests, in particular timed motor tasks with a cognitive component. Cognitive disturbances are relatively rare in the asymptomatic stage of the infection. For an overview of the data currently available on neuropsychological performance in physically asymptomatic HIV-seropositive subjects, the reader is referred to Newman et al. (1995).

Relationship difficulties most frequently experienced by individuals with HIV infection include the following: sexual problems (sexual frustration, detachment during sexual activity, difficulties in effecting appropriate changes in sexual behavior, problems in being open about their homosexuality), discrimination and/or rejection (by coworkers, neighbors, friends, family, or partner), dependence/independence conflicts and other problems related to caregiving, problems in establishing new relationships (in particular, dating problems), exacerbation of long-standing relationship problems (due to the underlying tension induced by having to cope with HIV infection), and isolation (as a consequence of rejection, self-inflicted, or due to physical disability). Problems in establishing and maintaining relationships predominate during the asymptomatic phase, whereas relationship difficulties reported by those with symptomatic infection tend to center around caregiving issues.

Instrumental problems most frequently encountered by those with HIV infection include employment, financial, and daily living difficulties and problems concerning access to health care services. These difficulties become prominent in the late stages of the infection, when physical health deteriorates.

Suicide is contemplated, at least transiently, by several individuals with HIV infection, especially in the symptomatic stages, although reliable prevalence rates of suicidal ideation are at present unavailable. In patients with AIDS, the suicide rate has been found to be seven to 36 times greater than in the age- and sex-matched population in the same geographic area (Marzuk et al. 1988; Wedler 1991; Coté et al. 1992; Pugh et al. 1993), whereas reliable estimates of the suicide risk in all individuals with HIV infection in a given area are currently lacking.

According to the currently available empirical research (for a review, see Catalàn et al. 1995), the factors which can affect the intensity of mental health problems in those with HIV infection and/or predispose them to or protect them from the development of proper psychiatric disorders include the following: (a) past psychiatric history (mental health problems and proper psychiatric disorders have been found to be more frequent in HIV-seropositive persons with a history of inpatient or outpatient psychiatric care), (b) social support (emotional, practical, and particularly informational support has been found to buffer HIV-related mental health problems and to affect the incidence of clinical depression), (c) concomitant life events (in particular, the AIDS-related death of one or more partners or friends has been found to affect the intensity of mental health problems and to influence the prevalence of clinical depression), (d) demographic factors (in particular age, since older persons are at higher risk for HIV encephalopathy), and (e) coping strategies (on which we will focus now briefly).

The coping strategies most frequently adopted by those with HIV infection can be classified as follows (Namir et al. 1990): (a) active and expressive/information seeking ("talked with others in the same situation," "tried to find out more about my illness"), (b) active and relying on others ("went to a friend or a professional to help me feel better"), (c) active and behavioral ("got involved in political activities related to my illness," "took more vitamins and ate healthy foods"), (d) active and cognitive ("prayed hard for a good outcome to the situation," "thought more about the meaning of life"), (e) passive and cognitive/ruminative ("daydreamed about better times," "thought about how I could have done things differently"), (f) passive and resigned ("tried to keep others from knowing how I was feeling"), (g) avoidant ("refused to think about it"), and (h) looking for distraction ("bought or did something special for myself"). Of these coping strategies, the "active and behavioral" and, to a lesser degree, the "active and expressive" and the "active and relying on others" have been found to be associated with lower anxiety and mood disturbance, whereas the avoidant strategy has been reported to be associated with higher levels of mood disturbance, including an increased prevalence of clinical depression (Namir et al. 1990; Folkman et al. 1993; Commerford et al. 1994).

3 Psychiatric Disorders

Virtually all psychiatric disorders have been described in individuals with HIV infection (for reviews, see Maj et al. 1993; Lyketsos and Federman 1995; Rabkin 1996). Some of them, such as psychotic disorders, mania, and anxiety disorders, do not seem to be more frequent in HIV-seropositive individuals than in matched seronegative control groups, while others, such as personality disorders and drug and alcohol abuse, are indeed more frequent, but only because they predispose subjects to the infection itself. The concept of adjustment disorder is of questionable value in those with HIV infection, in whom distressing

emotions are almost the rule, and looking for a boundary between normal and abnormal emotional reactions to the stress of the infection is merely a waste of time. We are therefore left with only two psychiatric disorders – dementia and delirium – whose prevalence is clearly increased in the symptomatic stages of the infection, and with another one – major depression – whose prevalence may be increased among symptomatic HIV-seropositive subjects in particular contexts. We will focus now on these three disorders.

3.1 Dementia

3.1.1 Clinical Picture

The onset of HIV-associated dementia is usually insidious. Early cognitive symptoms include forgetfulness, loss of concentration, mental slowing, and reduced performance in sequential mental activities of some complexity (the subject misses appointments or needs lists to recall ordinary duties; loses track of conversations or his or her own train of thought; and needs additional time and effort to organize thoughts and to complete daily tasks). Early behavioral symptoms include apathy, reduced spontaneity and emotional responsiveness, and social withdrawal (the subject becomes indifferent to his or her personal and professional responsibilities; his or her work production decreases, as does the frequency of his or her social interactions; and he or she complains of early fatigability, malaise, and loss of sexual drive). Depression, irritability, or emotional instability, agitation, and psychotic symptoms may also occur. Early motor symptoms include loss of balance and coordination, clumsiness, and leg weakness (the subject is less precise in normal hand activities, such as writing and eating; drops things more frequently than usual; trips and falls more frequently than usual; and feels the need to exercise more care in walking; Navia et al. 1986; Maj 1990).

Routine mental status tests, in this early stage, may be normal or show only slowing in verbal or motor responses and/or difficulty in recalling a series of objects after 5 or more minutes. Neurological examination may show tremor (best seen when the patient sustains a posture, such as holding the arms and fingers outstretched), hyperreflexia (particularly of the lower extremities), ataxia (usually seen only on rapid turns or tandem gait), slowing of rapid alternating movements (of the fingers, wrists, or feet), frontal release signs (snout reflex, palmar grasp), and dysarthria. Tests of ocular motility may show interruption of smooth pursuits and slowing or inaccuracy of saccades.

In the late stages of the disease, there is usually an overall deterioration of cognitive functions and severe psychomotor retardation. Speech is slow and monotonous, with word-finding difficulties and possible progression to mutism. Patients become unable to walk, due to paraparesis, and usually lie in bed, indifferent to their illness and their surroundings. Bladder and bowel incontinence are common. Myoclonus and seizures may occur. Pedal paresthesiae and hypersensitivity may appear, due to concurrent sensory neuropathy. The level of consciousness is usually preserved, except for occasional hypersomnolence.

It has been repeatedly maintained that, in HIV-associated dementia, higher cortical functions are spared, so that the picture is that of a "subcortical dementia" (Navia et al. 1986). This tenet, however, has been challenged by the report of patients showing such aspects as dyspraxia, dysgraphia, dyscalculia, mild paraphasia, and altered language comprehension (Poutiainen et al. 1991).

The course of HIV-associated dementia is variable, and no predictor of the pace of progression is currently available. The syndrome often progresses rapidly to severe deterioration and death, especially in patients with advanced systemic disease, but it may also have prolonged stable phases or may fluctuate, with reversible deterioration occurring in concomitance with opportunistic infections, such as *Pneumocystis carinii* pneumonia (World Health Organization 1990). Death usually occurs as a result of inanition, aspiration pneumonia, or systemic opportunistic infections.

3.1.2 Neuropsychological Picture

Formal neuropsychological examination of patients with HIV-associated dementia usually shows the most prominent impairment on tests of fine motor control (finger tapping, grooved pegboard), rapid sequential problem solving (trail making A and B, digit symbol), visuospatial problem solving (block design), spontaneity (verbal fluency), and visual memory (visual reproduction). In contrast, naming and vocabulary skills are largely preserved even in the most advanced cases. This pattern has been regarded as consistent with the clinical picture of a subcortical dementia.

3.1.3 Neuroradiological, Electroencephalographic and Laboratory Findings

The predominant neuroradiological finding in HIV-associated dementia is cerebral atrophy: both computed tomography (CT) and magnetic resonance imaging (MRI) demonstrate widened cortical sulci and, less

commonly, enlarged ventricles. Furthermore, MRI frequently shows high-intensity signal abnormalities on the T_2-weighted image (diffuse widespread involvement, patchy localized involvement, focal distinct areas of involvement, or punctuate white matter hyperdensities). These lesions are without mass effect and are most commonly located in the periventricular white matter and the semioval center (less frequently in the basal ganglia or in the thalamus).

The assessment of the regional cerebral metabolic rate for glucose by positron emission tomography (PET) has been reported to show a relative subcortical (thalamus and basal ganglia) hypermetabolism in the early stages and cortical and subcortical gray matter hypometabolism in the late stages of the disease (Rottenberg et al. 1987). The electroencephalogram (EEG) may be normal or show diffuse slowing, especially in late stages.

The most frequent cerebrospinal fluid (CSF) findings in HIV-associated dementia are an increase in total proteins (typically in the order of 50–100 mg/100 ml) and in the immunoglobulin (Ig) G fraction and index. Oligoclonal bands, either specific to HIV or not, may be present. A mononuclear pleocytosis (four to 50 cells/mm^3) may occur, and the ratio between the T-lymphocyte subsets (CD4 to CD8) may be reversed. The presence of the HIV core antigen p24 can be detected; although this finding is possible also in neurologically normal subjects, it does appear to reflect viral replication and may be useful in establishing the diagnosis and possibly in monitoring response to treatment (Price et al. 1988). A CSF to plasma ratio higher than 1 for neopterin and β_2-microglobulin has been reported and, in the absence of a correlation to the blood–brain barrier status, has been ascribed to an intrathecal synthesis of the two substances (Fuchs et al. 1989). CSF β_2-microglobulin levels have been found to correlate with the stage of dementia (Brew et al. 1989).

3.1.4 Neuropathology

Gross neuropathological examination of brains from patients with HIV-associated dementia usually reveals cerebral atrophy with sulcal widening and ventricular dilatation and occasionally meningeal fibrosis.

Microscopic abnormalities are most prominent in central white matter and deep gray structures. The two major lesion patterns are HIV encephalitis (multifocal and inflammatory) and HIV leukoencephalopathy (diffuse and noninflammatory), but it is recognized that overlapping and transition between these patterns may occur (Budka 1991).

The term *HIV encephalitis* corresponds to multifocal giant cell encephalitis, multinucleated cell encephalitis, and subacute encephalitis with multinucleated cells. This pattern is characterized by multiple disseminated microgranulomatous foci composed of microglia, macrophages, and macrophage-derived multinucleated giant cells, all or most of which show intense production of HIV antigens. Although the white matter, basal ganglia, and brain stem are preferentially involved, these foci are not rare in the cerebral cortex. In larger foci, central coagulative necrosis may develop. Damage to parenchyma in the foci is either inconspicuous or involves sponginess and myelin loss, whereas neurons and axons are usually perfectly preserved. Small vessels within a focus may show fibrinoid extravasation.

The term *HIV leukoencephalopathy* refers to progressive diffuse leukoencephalopathy. This picture consists of a diffuse damage to white matter, including myelin loss ("pallor"), astrogliosis, and infiltration by mono- and multinucleated microglia and macrophages. The white matter of the cerebral hemispheres is mainly affected, usually in a symmetric fashion, but cerebellar white matter may also be involved. Mono- or multinucleated macrophages, usually in a perivascular position, may incorporate myelin debris. Vacuolar swelling of myelin may be prominent in some cases.

A third histopathological pattern is that of *diffuse poliodystrophy*, defined as a diffuse reactive astrogliosis and microglial activation in the gray matter (basal ganglia, brain stem nuclei, and cerebral cortex). Neuronal dropout may be suspected, but remains to be verified by morphometry. This pattern has been proposed as a possible substrate of the cerebral atrophy which is frequently seen in neuroimaging studies and at autopsy. There are rare cases which exhibit prominent cortical diffuse poliodystrophy as the only correlate of severe progressive dementia.

The correlation between clinical and pathological aspects is reported to be poor in about one third of patients with HIV-associated dementia. In the majority of patients, however, more severe clinical manifestations tend to correspond to more severe neuropathology (Price et al. 1988).

3.1.5 Epidemiology

Data on the epidemiology of HIV-associated dementia are still preliminary. A recent prospective study, carried out on a cohort of homosexual men in the United States, found that the diagnosis was made concurrently with that of the initial AIDS-defining illness in 3% of patients and that the incidence of the dementia syndrome during the first 2 years after the diagnosis of AIDS was 7% per year (McArthur et al. 1994).

3.1.6 Pathogenesis

The pathogenesis of HIV-associated dementia is at present incompletely understood. Productive infection is almost exclusively restricted to macrophages and microglia, whereas neurons are not infected. Neuronal injury is currently believed to be produced by toxic products released directly by HIV-infected macrophages and microglia or by activated astrocytes. Some of these factors have been identified (Price and Perry 1994); they include platelet-activating factor, quinolinic acid, nitric oxide, and some metabolites of arachidonic acid, which are neurotoxic, and tumor necrosis factor-α, which is toxic for oligodendrocytes and can cause demyelination.

The strains of HIV which are isolated from the brain have in common the characteristic of infecting macrophages but not lymphocytes. This macrophage tropism corresponds to what was initially regarded as neurotropism. Macrophage tropism is related to a mutation in a specific region of gp120, the external glycoprotein of the virus. In the late stages of the infection, when active replication of the virus generates more mutants and the compromised immune system permits the escape of these mutants, the development of macrophage-trophic strains is more likely to occur, and this probably represents the limiting step for the occurrence of HIV encephalopathy and dementia.

3.1.7 Management

A beneficial effect of the antiretroviral agent zidovudine (AZT) on several cognitive measures in patients with HIV-associated dementia has been demonstrated in some studies (Yarchoan et al. 1987; Schmitt et al. 1988). One of the main disadvantages of this drug is the bone marrow suppression it causes.

An improvement of cognitive performance in AIDS patients has been also obtained using psychostimulants, such as methylphenidate and dextroamphetamine (Fernandez et al. 1988). Other drugs or nutritional factors that have been suggested for use in patients with HIV-associated dementia include peptide T, nimodipine, pyridoxin, and vitamin B_{12} (Maj et al. 1993).

Psychosocial interventions suggested for patients with HIV-associated dementia include maintenance of a structured daily schedule, titration of external stimuli, restriction to familiar environments, frequent orienting interactions with significant others, and monitoring of personal and financial affairs. Specific psychoeducation of HIV-infected subjects and their relatives before dementia develops has been recommended.

The care of patients with HIV-associated dementia will make increasing demands on health services as well as on volunteer and community support systems. It is uncertain, at present, whether such care is best provided in specialized units (e.g. inpatient AIDS units) or within general psychiatric or medical services. Special management problems may arise when the behavioral disturbance (e.g. poor impulse control, inappropriate sexual behavior) is such as to constitute a risk for other patients or staff members. Placement of patients in the terminal stage of the disease may also represent a problem; the lack of appropriate options in the community may obstruct their timely and humane discharge from the hospital.

3.2 Delirium

Delirium is a relatively frequent complication of the late stages of symptomatic HIV infection, although it often remains undetected or is misdiagnosed as psychosis or mania.

The factors which can lead to the development of a delirious state in symptomatic HIV infection include the following: central nervous system (CNS) opportunistic infections (in particular, cryptococcal meningitis, cerebral toxoplasmosis, and cytomegalovirus encephalitis), opportunistic infections of other organs (in particular, *Pneumocystis carinii* pneumonia), systemic opportunistic infections (such as staphylococcal bacteremia), opportunistic neoplasms of the brain (CNS lymphoma, Kaposi's sarcoma with CNS involvement), other space-occupying lesions of the brain (e.g. brain abscesses due to toxoplasmosis), metabolic derangements (disorders of fluid, electrolyte, or acid–base balance), nutritional deficits (e.g. of vitamin B_{12}), hepatic and renal dysfunction, surgical interventions, substance abuse or withdrawal, use of psychotropic drugs (in particular tricyclic antidepressants, due to their anticholinergic activity), and use of antiretroviral drugs (including AZT).

The clinical picture of HIV-associated delirium does not present specific features. No reliable estimate of the prevalence and incidence of this syndrome in patients with symptomatic HIV infection is currently available.

Medical management of delirium in HIV-infected subjects consists in treating the underlying cause (when possible), maintaining fluid and electrolyte balance and nutrition, and providing sedation and correction of disturbances of sleep–wake cycle. Low-dose neuroleptics (e.g. 1.75 mg haloperidol/day, 80 mg chlorpromazine/day) are frequently effective and safe in the treatment of agitation in AIDS patients with delirium. Haloperidol has been administered orally, intramuscularly, and even intravenously, alone or in

combination with lorazepam. The use of low-dose neuroleptics should prevent the development of the severe extrapyramidal reactions and the neuroleptic malignant syndrome reported in delirious AIDS patients treated with standard neuroleptic doses.

Environmental intervention and nursing care have been found to be very important. The former consists of the following: (a) provision of a well-lit, quiet room with a dimmed light at night and with a clock and a calendar to facilitate orientation, (b) restriction of the number of visitors and staff, while a trusted relative or friend may be allowed to stay with the patient outside of routine visiting hours (he or she will be instructed to talk calmly about matters of interest for the patient, stating frequently the date and the names of the hospital and of the doctors and nurses in attendance), and (c) provision of reassurance and explanation to the patient and significant others about the nature of delirium, its usual causes, and expected degree of reversibility. Nursing care includes careful observation, timely reporting of behavioral change, emotional support, and reorientation.

3.3 Major Depression

The ascertainment of major depression in patients with HIV infection is difficult for the following reasons: (a) the possible confounding effect of the physical symptoms of the infection (fatigue, diminished appetite and sleep, and loss of weight may be physical symptoms of HIV infection as well as depressive symptoms), (b) the possible confounding effect of the cognitive impairment related to HIV infection of the brain (psychomotor slowing, forgetfulness, and difficulties in concentration may be early symptoms of this impairment), and (c) the frequent occurrence of transient emotional and behavioral reactions in coincidence with the key points in the course of the infection (losing interest in human contact, feeling guilty about previous high-risk behaviors, and thinking of death may all be part of these reactions).

In order to diagnose major depression, the psychiatrist should ascertain that a depressive syndrome has persisted for at least 2 weeks, most of the day, nearly every day, including symptoms such as prominent depressive mood, markedly reduced interest or pleasure in all or almost all activities, true sense of worthlessness, and persistent suicidal ideation. Whether depression is understandable or not on the basis of the current situation of the subject should not influence the diagnostic decision. The clinical significance of symptoms such as psychomotor retardation or diminished ability to think or concentrate should be considered equivocal, unless detailed neuropsychological assessment demonstrates the absence of neurocognitive impairment. Similarly, the clinical significance of manifestations such as reduced weight or appetite, fatigue or loss of energy, and insomnia should be regarded as uncertain if the subject has reached the symptomatic stages of the infection.

The prevalence of major depression has been consistently found not to be increased in the typical samples of well-educated, middle class, mostly white homosexual/bisexual HIV-seropositive men studied in Western countries (Atkinson et al. 1988; Perry et al. 1990; Williams et al. 1991; Rosenberger et al. 1993), but may be increased in symptomatic HIV-seropositive subjects with different sociodemographic characteristics. In the WHO Neuropsychiatric AIDS Study, which we conducted in the early 1990s, we found a significant increase in the current prevalence of major depression in symptomatic seropositive i.v. drug users enrolled in Bangkok (Maj et al. 1994a). A similar finding has been subsequently reported in the United States in a sample predominantly composed of Afro-American i.v. drug users (Lipsitz et al. 1994). Current unemployment, history of prior depression, and the presence of AIDS-related symptoms have been found to predict the development of syndromal depression among subjects with symptomatic HIV infection in a recent longitudinal study (Lyketsos et al. 1996).

Major depression in individuals with HIV infection often remains undetected and untreated. In the WHO Neuropsychiatric AIDS Study, only 9% of those fulfilling the DSM III-R criteria for major depression (American Psychiatric Association 1987) were receiving antidepressant treatment.

The presence of depressive symptoms has been found to predict shorter longevity in AIDS patients after controlling for physical symptoms and $CD4^+$ cell count. The most likely interpretation of this finding is that depression may limit the motivation of individuals to continue treatment or to provide self-care in the presence of severe pain and disability (Patterson et al. 1996).

When major depression is present, drug treatment is, at the current state of knowledge, the first therapeutic option. Both tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) have been found to be effective and well tolerated in patients with major depression associated with HIV infection (Rabkin et al. 1994a,b). Some trials suggest that SSRIs may be better tolerated than tricyclics (except in subjects with chronic diarrhea), but systematic studies involving direct comparisons are presently lacking. Psychostimulants have been suggested to improve depressed mood and lethargy in AIDS patients by some case reports and studies conducted on small patients samples (Fernandez et al. 1995).

A few systematic studies have shown the efficacy of individual interpersonal psychotherapy (Markowitz et al. 1995) and of cognitive/behavioral group interventions (Kelly et al. 1993) in samples of mainly asymptomatic depressed HIV-seropositive subjects.

4 Conclusions

HIV infection has a clear, direct impact both on brain functioning and on psychological homeostasis and psychosocial adjustment. This impact occurs in most individuals at some point of the natural history of the infection, although only a minority of them actually develop a proper psychiatric disorder. The development of proper psychiatric disorders is conditioned by predisposing or protective factors, some of which operate at the level of the cerebral "hardware" (e.g. ageing), some at the level of the psychological/psychosocial "software" (e.g. coping strategies, social support, concomitant life events), and others at a level that remains unspecified (e.g. past psychiatric history).

Mental health teams should be equipped to deal not only with proper psychiatric disorders (most commonly dementia, delirium, and major depression in the symptomatic stages of the infection), but also with the much more common mental health problems of HIV-seropositive individuals (distressing emotions, cognitive disturbances, relationship and instrumental problems, and suicidal ideation and/or attempts). Moreover, they should be able to address the mental health problems of groups at risk, the loved ones and caregivers of affected individuals, and the general population. Of course, such an undertaking is only possible if adequate resources are made available in terms of personnel, training, and facilities, and the availability of these resources depends very much on the degree of recognition, by policy makers and public opinion, of the importance of the mental health component in the care of those with HIV infection. This recognition, however, requires opinion leaders in the field of mental health care themselves to become fully aware of the magnitude of the problem and motivated to face it.

Psychiatric Problems Related to Intensive Care and Organ Transplantation

1 Psychiatric Care in the Intensive Care Unit

1.1 Introduction

Affective, cognitive, and behavioral changes are all seen quite frequently in the intensive care unit (ICU) (Cassem 1995). All of these states may be associated with agitation, putting the patient at risk due to inability to maintain important intravenous and arterial lines, pacing wires, and other modern technologies such as the intra-aortic balloon pump.

1.2 Differential Diagnosis

In the ICU, the psychiatric differential diagnosis for abnormal mental states is a large one. Certain emergency conditions must be recognized rapidly. These include Wernicke's encephalopathy, hypoxia, hypoglycemia, hypertensive encephalopathy, intracerebral hemorrhage, meningitis/encephalitis (including human immunodeficiency virus), and poisoning (iatrogenic or exogenous). Although less urgent, several other conditions need rapid assessment, including subdural hematoma, septicemia, subacute bacterial endocarditis, hepatic and/or renal failure, thyrotoxicosis, myxedema, delirium tremens, anticholinergic psychosis, and complex partial seizures, particularly complex partial status epilepticus.

When reasonably assured that the above acute illnesses are not present, the psychiatric consultant will have time to eliminate other basic causes of altered mental status using a systematic approach such as that proposed by Ludwig (1980) (see Table 1).

1.3 Evaluation and Management

The treatment plan often involves diagnostic suggestions, including the organic workup, which is often comprised of thyroid-stimulating hormone level, vitamin B12 and folate levels, the venereal disease research laboratory (VDRL) or rapid plasma reagin (RPR) tests for syphilis, neuroimaging, and electroencephalogram. Cerebral spinal fluid analysis is also requested on occasion as part of this diagnostic evaluation. Recommended psychopharmacologic intervention might

Table 1. Differential diagnosis of brain dysfunction in critical care patients: Ludwig's differential diagnosis of the confusion–delirium–dementia–coma complex[a]

General etiology	Specific etiologies
Vascular	Hypertensive encephalopathy; cerebral arteriosclerosis; intracranial hemorrhage or thromboses; circulatory collapse (shock); systemic lupus erythematosus; polyarteritis nodosa; thrombotic thrombocytopenic purpura
Infectious	Encephalitis; meningitis, general paresis
Neoplastic	Space-occupying lesions such as gliomas, meningiomas, abscesses
Degenerative	Senile and presenile dementias such as Alzheimer's or Pick's dementia; Huntington's chorea
Intoxication	Chronic intoxication or withdrawal, effect of sedative-hypnotic drugs such as bromides, opiates, tranquilizers, anticholinergics, dissociative anesthetics, anticonvulsants
Congenital	Epilepsy; postictal states; aneurysm
Traumatic	Subdural and epidural hematomas, contusion; laceration; postoperative trauma; heat stroke
Intraventricular	Normal pressure hydrocephalus
Vitamin	Deficiencies of thiamine (Wernicke-Korsakoff syndrome), niacin (pellagra), B_{12} (pernicious anemia)
Endocrine/metabolic	Diabetic coma and shock; uremia; myxedema; hyperthyroidism, parathyroid dysfunction; hypoglycemia; hepatic failure; porphyria; severe electrolyte or acid base disturbances; remote side effects of carcinoma; Cushing's syndrome
Metals	Heavy metals (lead, manganese, mercury); carbon monoxide; toxins
Anoxia	Hypoxia and anoxia secondary to pulmonary or cardiac failure, anesthesia, anemia
Depression/other	Depressive pseudodementia; hysteria; catatonia

[a]From Ludwig (1980).

include antidepressants, antipsychotics, anxiolytics, and stimulants. Behavioral/psychosocial approaches may also be recommended, and family intervention is often required. Psychotherapy is most often within the realm of support and education. The psychiatry consultant guarantees regular follow-up for as long as indicated and helps in establishing goals for the patient in future treatment.

Review of current and past medications is very important. Many pharmacologic agents have central nervous system (CNS) effects and can therefore produce neuropsychiatric symptomatology. This may occur when these drugs have reached toxic level or when certain addictive medications are withdrawn (barbiturates, narcotics, benzodiazepines, and meprobamate). It should also be noted that steroids, anticonvulsants, methylphenidate and dextroamphetamine, beta blockers, and clonodine are also associated with withdrawal symptoms in some patients (Adler et al. 1982).

Of importance is the fact that acute reactive psychosis in the ICU is very rare, and thus the phrase "ICU psychosis," while popular with nonpsychiatric physicians, is a barren term. Most patients diagnosed as having ICU psychosis actually have delirium of unknown origin. Pharmacologic agents are probably the most frequent causes of delirium in the ICU. Table 2 lists some medications in clinical use that have been associated with delirium, although this list is by no means exhaustive. Drug–drug interaction merely complicates the issue. The usual management is to discontinue or reduce the dose of the drug; however, sometimes this is not feasible. One example involves patients with malignant ventricular arrhythmias who require lidocaine at a high infusion rate to maintain ventricular stability. In such patients, intravenous haloperidol is used to offset the agitating effects of the lidocaine delirium.

Another frequent occurrence is anticholinergic delirium. This delirium can be reversed by the use of intravenous physostigmine. Doses of 0.5–2 mg can be administered intravenously; however, the physician must be cautious given the potential for profound bradycardiac and hypotensive effects. Glycopyrrolate has been used prophylactically with an intravenous injection of 0.2 mg to protect against the cholinergic side effects of physostigmine, as glycopyrrolate does not pass the blood–brain barrier and therefore will not add to anticholinergicity.

If removal of the factors known to cause CNS impairment fails to lead to improvement in the delirium, the treatment of choice is treatment for nonspecific delirium. Psychosocial and behavioral approaches are usually not effective. The usual treatment includes the administration of antipsychotic

Table 2. Drugs associated with delirium and other psychiatric symptoms

Drug type	Drugs
Antiarrhythmics	Dilisopropamide Lidocaine Mexiletine Procainamide Tocainide
Antibiotics	Aminoglycosides Amphotericin Cephalosporins Chloramphenicol Chloroquine Ethambutol Gentamicin Isoniazid Rifampin Sulfonamides Tetracyclines Ticarcillin Vancomycin
Anticholinergics	Atropine Scopolamine Tricyclic antidepressants, amitriptyline, protriptyline, imipramine, desipramine, nortriptyline, trimipramine, maprotiline Trihexyphenidyl Benztropine Diphenhydramine Thioridazine Eye and nose drops
Anticonvulsants	Phenytoin
Antihypertensives	Captopril Clonidine Methyldopa Reserpine
Antineoplastic agents	Procarbazine L-Asparaginase Methotrexate (high dose) 5-Azacytidine Cytosine arabinoside (high dose) Vincristine Vinblastine 5-Fluorouracil Hexamethylmelamine Dacarbazine Aminoglutehthimide Tamoxifen
Antiviral agents	Acyclovir Gancyclovir Interferon
Barbituates	
Beta blockers	Propranolol Timolol
Cimetidine, rantidine	

Table 2 (Continued)

Drug type	Drugs
Digitalis preparations	
Disulfiram, metronidazole	
Dopamine agonists (central)	Amantadine Levodopa
Ergotamine	
GABA agonists	Benzodiazepines Baclofen
Immunosuppressives	ACTH Cyclosporine Steroids
Lithium	
Monomine oxidase inhibitors	Phenelzine Procarbazine
Narcotic analgesics	Meperidine (normeperidine) Pentazocine
Nonsteroidal anti-inflammatory drugs	Ibuprofen Indomethacin Naproxen Sulindac
Podophyllin (topical)	
Sympathomimetics	Amphetamine Cocaine Ephedrine Phenylephrine Phenylpropanolamine Aminophyline Theophyline

medications with or without benzodiazepines. If these medications are not sufficiently successful in controlling agitation and behavioral lack of control, even when physical restraints are in place, paralytics are sometimes used. Paralytic drugs such as pancuroninum bromide require the use of mechanical ventilation, which carries a clear risk in postoperative patients and also requires concurrent sedation.

Occasionally, the cause of agitation in a patient with delirium is pain, and in such situations morphine sulfate, Dilaudid (hydromorphone hydrochloride), or fentanyl are used to manage this aspect of agitation. Respiratory depression and hypotension are potential side effects, although the short-acting profile of fentanyl has led to increased safety and increased use in the ICU. Occasionally, patients whose agitation is being managed with fentanyl find it difficult to reach steady state tranquilization because of the short-acting nature of the drug. Intravenous haloperidol is the mainstay in the management of delirious agitation (Shapiro et al. 1995). In Europe, haloperidol is used intravenously to treat delirium tremens and acute psychosis and to premedicate electroconvulsive therapy patients. The effects of haloperidol on blood pressure, pulmonary artery pressure, heart rate, and respiration are milder than those of the benzodiazepines. This makes it a treatment of choice for severely ill patients with impaired cardiorespiratory status (Sos and Cassem 1980). Intravenous use of haloperidol is preferable to intramuscular administration for several reasons. Drug absorption may be poor in distal muscles if a patient's delirium is associated with hemodynamic instability. In addition, the agitated patient is usually quite paranoid, and intramuscular injections that are painful may worsen his or her paranoia. Interpretations of muscle enzyme reports may be erroneous if intramuscular injections are used frequently. Moreover, haloperidol used intravenously is less likely to produce extrapyramidal syndromes than intramuscular or even oral haloperidol (Menza et al. 1987). Intravenous haloperidol has a mean distribution time of 11 min; however, in critically ill patients and in the elderly, this may take even longer and thus observable tranquilizing effects may take 15–20 min. The mean half-life of intravenous haloperidol is approximately 14 h. In comparison, the mean half-life of intramuscular haloperidol (oral formula) is 24 h. Intravenous haloperidol is twice as potent as the oral form.

The intravenous line should be flushed with 2 ml normal saline prior to the use of haloperidol. Phenytoin precipitates haloperidol, and the two should therefore not be given in the same intravenous line. Haloperidol may also precipitate heparin, and since all lines in the ICU are usually heparinized, a 2-ml flush is advised. Haloperidol is usually given in 2- to 2.5-mg doses for mild agitation, 5-mg doses for moderate agitation, and 7.5- to 10-mg doses for severe agitation. Doses can be repeated every 30 min until the patient is calm. If the patient becomes agitated again after a calm state has been achieved, a repeat dose can be given. The dose of haloperidol on the second day should, if clinically feasible, be less than that given on the first day. If the sensorium and behavior improve, the patient will often only require haloperidol in the evening to protect against "sundowning" agitation. In this case, often only small, 1- to 5-mg doses of haloperidol will be required and can often be given by mouth. The psychiatric consultant tries to break the agitation rapidly as is done with delirium tremens. Partial control of agitation can sometime prolong the delirium behavior. Obviously, in the elderly delirious patient, doses should be approximately one third of what is usually used.

Maximum daily doses have not been established for intravenous haloperidol, although at the Massachusetts General Hospital over 1000 mg haloperidol per day has been used with safety (Tesar et al. 1985). Hypotension

may occasionally follow the use of intravenous haloperidol. It is often caused by a low-volume state; therefore, if patients have pulmonary artery catheters allowing for close monitoring, as is often the case in the ICU, volume replacement can be used to offset hypotension before administering further doses of haloperidol. Haloperidol may lower the seizure threshold, although it is one of the safest neuroleptics in this respect. It is a safe medication for patients with chronic obstructive pulmonary disease and is thus often used to reduce severe anxiety and agitation in patients who are having difficulty being weaned from the ventilator. Intravenous haloperidol does not block dopamine-related increase in renal blood flow. On occasion, it has been found to cause ventricular arrhythmia, sometimes in a torsades des pointes configuration, so electrocardiographic monitoring is important, especially in susceptible populations such as those with a prolonged corrected QT interval (Metzger and Freidman 1993).

Intravenous droperidol can also be used to manage delirious agitation; however, this agent is more potent at the α^1-adrenergic receptor as an antagonist and is thus more likely to cause problems with hypotension. It can also be more of a respiratory depressant. Intravenous benzodiazepines are often used alone or in combination with haloperidol for the treatment of agitation due to delirium, especially if patients have stable respiration while on mechanical ventilation. It may be beneficial to add intravenous lorazepam (1–2 mg IV every 2–4 h) to intravenous haloperidol in the management of severely agitated patients in the ICU setting, because intravenous lorazepam may reduce the dosage requirement for intravenous haloperidol as it adds a sedative effect. It may also reduce the extrapyramidal side effects of haloperidol, especially neuroleptic-induced catatonia and possibly the neuroleptic malignant syndrome. Lorazepam has also been found to successfully treat catatonic withdrawal states (Fricchione et al. 1997). Of course, it is also a good antiepileptic drug as well. Lorazepam can be used as an infusion at a rate of 1–3 mg per h, if necessary, to calm patients being ventilated. Intravenous lorazepam has a half-life of about 12–14 h and its sedating effect may therefore accumulate. This is an important factor when patients are about to be weaned from the ventilator. To avoid respiratory depression, lorazepam will occasionally need to be tapered before weaning can proceed.

Nevertheless, of the benzodiazepines, lorazepam is one of the least likely to cause respiratory depression. Along with oxazepam, it is safest for patients with hepatic insufficiency due to the fact that it does not require oxidative metabolism. Fentanyl can also be used to manage agitation in inpatients who are being mechanically ventilated, and propofol is another available sedating medication with which anesthesiologists are very familiar. Phenobarbital has been useful occasionally for severely burned patients who require prolonged sedation for burn care. Of course, phenobarbital and propofol are medications that are very depressing to respiratory drive, and therefore extreme caution must be applied, even in the ICU on the ventilator. Other parenteral neuroleptic drugs have also been used for treatment of agitation, including thiothixene, perphenazine (a medication often used intravenously for the nausea and vomiting associated with chemotherapeutic agents), and chlorpromazine, an extremely effective medication which can cause hypotension and a fall in cardiac output because of its very potent α_1-adrenergic antagonism. Chlorpromazine is also relatively anticholinergic and lowers the seizure threshold. In smaller doses, e.g. 10 mg, it can be both safe and effective.

1.4 Intensive Care Unit-Specific Problems and Their Management

1.4.1 Specific Unit Issues

In 1971, Cassem and Hackett reviewed the frequency of reasons for psychiatry consultation requests in various intensive care unit settings.

In the coronary care unit (CCU), in order of frequency, psychiatrists will be called to help with anxiety, depression, and behavioral problems such as signing out against medical advice and dependency/independency conflicts with the staff, hostility, and delirium psychosis.

In the surgical ICU, delirium, depression, and ventilator weaning anxiety are the most frequent reasons for consultation. In the respiratory ICU, depression, ventilator weaning anxiety, and dependency conflicts are the most frequent reasons for psychiatric consultation.

In the medical ICU, psychiatrists often see patients who have attempted suicide by overdose. They also see those with depression, character disorder, delirium, substance or alcohol abuse, and anxiety.

As an example of reactions to critical illness requiring intensive care, myocardial infarction serves as a good model. At the start of their illness, these patients exhibit fear and anxiety; then, as cardiac treatment stabilizes the patient and reduces symptomatology such as anginal pain, the patient may succumb to a resurgency of denial, which can often lead to maladaptive behavior, e.g. insisting on signing out of the hospital against medical advice. Through their presence and advocacy, the family may be able to encourage the patient to accept continued treatment. If

the ministrations of the physician and the family are successful and the patient remains in the hospital, he or she should be calmed by the prompt use of medication, usually haloperidol or lorazepam. The patient may go on to feel a sense of demoralization and vulnerability, culminating in depressed mood and affect. If the patient remains in the hospital for a prolonged period, certain personality problems may arise, such as passive/aggressive behavior or independency/dependency conflicts. Patients who, during the first days of adaptation to the crisis of critical illness, experience fear and anxiety should be treated with anxiolytic medications, with one priority being maintenance of sleep at night in the unit.

Short-acting benzodiazepines such as oxazepam, lorazepam, or alprazolam should be given as a standing dose to patients in the CCU unless there is some contraindication. Midazolam can be used intravenously if patients are not taking medications orally. It is short acting with a half-life of 1–12 h, whereas oxazepam and lorazepam have half-lives of 5–15 h and 10–20 h, respectively. Diazepam and chlordiazepoxide are moderately long acting benzodiazepines, and clonazepam is a longer-acting benzodiazepine. Clonazepam and alprazolam are often best for patients with panic-like anxiety, and clonazepam is often a useful agent in patients who are anxious and agitated with reactions to certain medications such as steroids and in managing manic symptomatology. Zolpidem is a sleeping agent with some non-benzodiazepine-like properties at the respiratory center level, thus making it perhaps a safer sleeping agent associated with slightly less respiratory depression. Buspirone is a non-benzodiazepine anxiolytic alternative. In the medically ill, it is occasionally a very worthwhile medication in the management of anxiety, having few side effects. This medication has been used with success particularly in patients in the respiratory ICU, as it is a respiratory stimulant and not a respiratory depressive. It can also be an adjuvant in patients with depression already on antidepressants and has been used to help manage agitation in patients with organic brain syndrome. A neuroleptic agent is often used if anxiety and fear become so severe that they approach psychotic agitation. Patients who are panicked to this degree are usually out of control. The preferred neuroleptic is haloperidol.

Psychiatrists can also aid patients with fear and anxiety through clarification, explanation, and reassurance. Behavioral relaxational therapies can also be used, although often relaxation breathing instructions may need to be altered. Correction of false myths is often fruitful, since these incorrect misconceptions can add to anxiety. Stressing the positive is appropriate. With a cardiac patient, this may mean telling the patient that normal activities can be resumed after an exercise program has been completed. In patients whose prognosis is poor, restatement of plans, goals, and treatments can go a long way in reducing fear and anxiety. Reassurance can be given by assuring the maintenance of comfort during the crisis. False reassurances regarding cure are not appropriate, as a physician needs to maintain credibility. The physician's equanimity may have the most therapeutic effect on patients, as long as the physician can express his or her empathy in the bargain.

The psychiatrist may become involved in consultation regarding capacity to make medical decisions such as signing out. Such a psychiatric evaluation will require a detailed mental status examination with a special focus on insight and judgment (Applebaum and Grisso 1988; see also Vol. 2, Chaps. 16 and 18).

While anxiety represents the fear of loss of health, of life, and of role as "spouse, parent, and citizen," depression represents a sense of having lost already. With any critical illness, the patient's mind may be said to have suffered an ego infarction. This can lead to psychological damage that can be referred to as despondency. This can be distinguished from major depressive disorder, which is a clinical illness. Recovery of psychological well-being often requires 2–3 months. Feeling more like one's self is the best treatment for illness in acute despondency. Before this occurs, patients should be encouraged to express concerns about what they feel the illness has done to their self-esteem and functioning, and it is important to let patients know that such concerns are normal emotional responses to physical illness and that they will disappear once the patient begins to feel healthy again.

If the patient has loss of energy and is unable to be mobilized, a psychostimulant such as methylphenidate in doses of 2.5–20 mg or dextroamphetamine in this same dose range may be safe choices for treatment. Patients should be checked in terms of their vital signs and response to the psychostimulant about 1 h after a dose. In patients with physiologically significant tachycardia, e.g. patients with atrial fibrillation with rapid ventricular rate, caution must be exercised with psychostimulants that can increase heart rate. These medications should not be given after 1–2 p.m. in the afternoon, as they can cause insomnia. On the other hand, they do not appear to cause anorexia in the medically ill, and in fact they may improve appetite. The serotonin reuptake-inhibiting medications (SSRI) sertraline, paroxetine, and fluoxetine are good alternatives to begin the treatment of major depression in the medically ill in the ICU. They are well tolerated in terms of respiration and cardiac functioning, but they may cause gastrointestinal dysfunction and restlessness. Because of their effects on certain cytochrome systems, drug–drug interactions may be a limiting factor in their use. Buproprion is also an excellent

choice in the management of depression in these patients and has been shown to be a very safe medication in the cardiac population. While it has been associated with seizures, when used in doses of less than 450 mg a day and with single doses of no more than 150 mg, it is safe in this regard.

The tricyclic antidepressants have four major problems associated with them:

1. Orthostatic hypotension (nortriptyline is the least likely to cause this)
2. Significant anticholinergic effects (desipramine has the least such effects of the tricyclics)
3. Conduction defects and increased risk of complete heart block especially in those patients with bifascicular block and second-degree heart block
4. Possible increase in the risk of ventricular arrhythmias (because they will increase a QTc interval)

1.4.2 Anxiety Caused by Weaning from the Ventilator

Patients with anxiety caused by weaning from the ventilator are often a great challenge for psychiatric consultants in the respiratory ICU. Patients will often be treated with a benzodiazepine such as lorazepam, which can be given prior to the weaning periods, or with a neuroleptic such as haloperidol if the patient's anxiety approaches the extremes of fear or agitation. Behavioral exercises can also be used, including hypnosis or relaxation techniques. It is always important to ask the patients themselves which medicine has been most effective. In some cases, for instance, the use of diphenhydramine has provided the calmness required for ventilator weaning.

1.4.3 Patients Exhibiting Maladaptive Behaviors

In the face of a crisis, some patients will regress to maladaptive behaviors, including noncompliance with the treatment regimen. These patients are usually thrust back into their own struggles with dependency and independency issues. They will sometimes become overdependent, refusing to get out of bed or to participate in physical therapy or refusing to eat unless spoon fed, etc. On the other hand, patients will occasionally become hyperindependent. These are patients who, instead of merely dangling their feet by the side of the bed at that stage of their recovery, will be found jogging on the spot or doing push-ups at the bedside. The physician should try to reestablish compliance in these individuals without becoming embroiled in battles over control. This will sometimes involve stressing to patients that they deserve the best treatment possible and that in order to get it they need to become partners in their own care.

Patients with narcissistic demanding traits must be informed repeatedly, in an appeal to their entitlement, that, when they comply, they are doing so in their own best interest. The use of humor, when indicated, can often diffuse some of the tension involved in these dependency/independency conflicts. When patients become hostile, angry, and aggressive, the physician can try a hearing-out process, avoiding the tactical error of saying "I understand." Reestablishing the common enemy – the disease itself – is often helpful. There are some patients who are not merely regressed in the context of a severe illness. Instead, they may have severe personality disorders that are premorbid in nature. Borderline personalities may be so difficult that the help of a psychiatrist is required. Occasionally, these patients are manipulative, help-rejecting complainers. They can stir up staff conflicts through the use of primitive defense mechanisms such as splitting, idealization–devaluation, projection, and pathological denial. While limit setting is often important, it is also important to acknowledge the real stressors in the patient's situation. Breaking down necessary defenses such as avoidance and idealization–devaluation should be avoided. The physician should also minimize overstimulation of the patient's wish for closeness while at the same time minimizing overstimulation of the patient's rage. Again, the physician can utilize patients' narcissistic entitlement by highlighting that they deserve the best treatment possible, which requires their cooperation.

1.4.4 Intensive Care Unit Transfer

Patients leaving the ICU environment experience both a loss and a gain. They may become increasingly anxious, because moving to a stepdown unit or to a ward environment is reflected in decreased staffing coverage and observation. On the other hand, this move is symbolic of the fact that their condition has improved to the point where they no longer require ICU care. Patients should be given educational information about the transfer at least 24 h in advance. They will then be able to anticipate less frequent checks and fewer nurses. At the same time, they can be assured that they are now healthy enough to no longer require intensive care and that, as a reward for their improvement, they are moving to a healthier environment.

1.5 Conclusions

The psychiatric consultant can be valuable in the recovery of critically ill patients by helping to relieve symptoms of behavioral, cognitive, and affective dysfunction that are related to the medical problems at hand. The psychiatrist accomplishes this through a careful examination and evaluation of the patient and the family, through an extensive differential diagnosis, and through the process of discovering etiologies and addressing them via a therapeutic multimodal approach that is closely integrated with the patient's critical care regimen.

Over the past 30 years, there has been an unprecedented increase in the pace of development of technology. The benefit of this technology in the majority of cases outweighs the risk. Nevertheless, significant psychiatric morbidity is associated with the use of medical technological innovations. Working at the interface between medicine and surgery, psychiatrists are perhaps most frequently confronted with the risk of psychiatric morbidity not only in the ICU setting but also in the area of organ transplantation.

2 Psychiatric Problems Related to Organ Transplantation

2.1 Introduction

The pioneering efforts in bone marrow and solid organ transplantation have begun to bear fruit during the last 20 years. At an early stage, surgical therapies and immunotherapy were relatively crude, with complicated postoperative courses and minimal psychosocial care available. Recently, in the setting of generally improved survival, more interest has been paid to the psychosocial and psychiatric care needs of transplant patients. This may stem from the fact that teams have lost patients after successful transplantations due to their severe psychiatric disorders in the form of suicide or drug abuse or noncompliance with postoperative immunosuppressive therapies.

2.2 Psychiatric Assessment of Organ Transplant Candidates

Transplantation assessment usually involves screening carried out by internists and surgeons who are specialized in the organ system being considered for transplantation. Nursing coordinators become involved in the formal assessment phase of potential transplant recipients and also take part in the education and support of patients and their families. There is usually also a social evaluation of the patient's home milieu and the quality of the support network. Considerations include the quality of the marital support available, support of others, including family and friends, financial resources, and geographic factors (Strouse et al. 1996).

By virtue of their education and training, transplantation psychiatrists are in a good position to direct the psychosocial evaluation of potential transplant donors and recipients (Levenson and Olbrisch 1996). They must be proficient in the examination of character and its effect on present and future compliance and will also have the expertise to evaluate and manage not only primary psychiatric disorders, but also secondary disorders pathophysiologically caused by the physical compromise organ failure and various treatments create. The psychiatrist will also need to be skilled at designing and co-managing a treatment regimen for each specific patient (Strouse et al. 1996).

Lowry and Martin (1992) have written about the ethical aspects of transplantation selection committees. Psychosocial evaluation must be done in a equitable manner, insuring equal access while avoiding the danger of harm to the patient. They urge that there should be informed consent for prospective transplant recipients, informing them of the psychosocial information used by the selection committee. Strouse and colleagues (1996) have summarized criteria for psychosocial screening. Absolute contraindications include:

1. Ongoing substance abuse
2. Psychosis which hinders informed consent or compliance in a significant way
3. Transplant refusal
4. Active suicidality
5. Physical symptoms without any pathophysiological basis (factitious disorder)

Relative contraindications include:

1. Dementia or static encephalopathy
   a) Inadequate psychosocial resources to maintain compliance
   b) Association of the brain disorder with a high incidence of post-transplantation neuropsychiatric morbidity, e.g. frontal lobe dementias
2. Psychiatric disorder such as a potentially lethal mood disorder, schizophrenia, or character disorder that has been refractory to treatment
3. A history of noncompliance with the transplant program, including refusal to take part in obligatory psychiatric or psychosocial treatments

Orentlicher (1996) has recently written about the use of psychosocial criteria to assess candidates for organ

transplantation in light of the American Disabilities Act (ADA). The ADA does not allow discrimination on the basis of any disability. However, it accepts that a person's mental health must be considered when organ allocation is being decided, as this involves a bonafide social interest, especially since a person's mental disability may reduce the benefit that he or she will receive from a transplant. Orentlicher therefore believes that the ADA will be interpreted by the courts to permit organ denial or lower waiting list priority for those with intractable psychiatric disorders as long as these diminished benefit forecasts are based on scientific criteria with good validity. They will also likely require that the assessment of candidates be individualized and not solely based on predictors that are generalizable and that transplant programs should involve a program of psychiatric care to help to improve the organ transplant candidate's mental disability.

2.3 Psychiatric Assessment of Living Donors

Psychiatrists specializing in organ transplantation also become involved in assessing living relatives and other living donors.

Strouse et al. (1996) recommend that potential organ donors be assessed for informed consent in essentially the same way as in any other presurgical condition. There are special considerations, however, including the following:

1. Assessment of family systems, focusing on coercion in the donation process and the concept of recipient obligation in response to the gift of an organ
2. Investigating the "black sheep" phenomenon in which a donor may have unrealistic beliefs that he or she will wipe clean any past indiscretions or problematic behavior by the organ donation
3. Investigating whether there are any individual, cultural, or religious apprehensions about the donation of an organ
4. Investigating the possible worsening of a donor's psychopathology secondary to biopsychosocial strain of organ donation

Studies in kidney donation appear to show that most kidney donors feel a sense of satisfaction and would repeat their donation if the opportunity arose again. A recent study of partial liver segment donors, which mostly involves parents of children requiring liver transplant, found that the donors tended to do well psychiatrically after the transplant, with increased self-esteem and satisfaction gains. This coincides with the findings on kidney donors (Fellner and Marshall 1968; Goldman 1993).

2.4 Preacceptance Phase

There are two rating scales which are used for the assessment of psychosocial variables in transplant candidates. These are the Psychosocial Assessment of Candidates for Transplant Scale (PACT) and the Transplantation Evaluation Rating Scale (TERS). The former was developed by Olbrisch et al. (1989), while the latter was developed by Twillman and colleagues (1993). They are both weighted scales with various psychiatric and behavioral categories. The TERS appears to have good interrater reliability, which is also true of the PACT, but the former may also have better predictive power in terms of post-transplant clinical outcomes. While reliability of psychosocial assessments has been established within some programs, Olbrisch and Levenson (1995) conclude that more validation studies are necessary with particular attention paid to patient and family outcomes in addition to patient survival.

In a recent study, the statistical relationship between psychiatric diagnosis, psychosocial adjustment, and health status was examined in organ transplant candidates. The authors interviewed and carried out psychometric testing on 311 heart, kidney, lung, and liver transplant candidates (Chacko et al. 1996). They found that more than 60% met criteria for DSM-IIIR axis I diagnoses and almost 32% met criteria for axis II diagnoses. The axis I disorders were associated with reduced psychosocial adjustment and health status. In patients with both axis I and axis II pathology, which comprised about 25% of the sample, the poorest premorbid coping and the worst degree of marital harmony was found. These patients were at particular risk for poor outcome. The most common axis I disorders found were adjustment disorders, with depression and anxiety. The authors conclude that psychiatric evaluation and management may be important in the maintenance of good health in transplant patients and believe that their findings underscore the importance of psychiatry consultation-liaison participation in the evaluation of transplant candidates.

Lucey and colleagues have developed an assessment of alcoholic transplant candidates (Lucey and Beresford 1992; Lucey et al. 1992). In what is called the Beresford Algorithm, alcoholic patients seeking transplantation require:

1. Accurate diagnosis
2. Understanding by both the family and the patient of the nature of alcoholism as a disease
3. Evaluation of social stability of the patient and family

4. Assessment of the patient's ability to maintain commonly accepted predictors of long-term abstinence

In a recent survey study of academic liver transplant team selection practices for alcohol-dependent applicants, Snyder and colleagues (1996) found certain consistencies between the centers. There was agreement that many alcoholic patients are suitable applicants for transplantation. None of the centers would reject out of hand an alcohol-dependent patient who had been abstinent for longer than 6 months, but some centers do reject applicants with less than 6 months of sobriety. The patients that most concern centers appear to be those with current alcoholism or with abstinence of less than 1 month. The centers are also most concerned about patients requiring a second transplantation after an alcoholic relapse and about those with comorbid antisocial personalities, schizophrenia, or mental retardation. Most centers do not proceed with outright rejection, with the majority preferring to require alcohol rehabilitation or observation. Of course, there are high degrees of mortality during the period in which alcoholics wait to complete an abstinence requirement.

In 1996, Kumar and colleagues presented an analysis of data concerning alcoholic liver transplant patients. They found drinking relapses in 11.5% of 73 alcoholic patients after liver transplantation. Most of these were said to be drinking socially. However, the majority of centers in the survey carried out by Snyder et al. (1996) (12 out of 14) had had experience with alcoholic patients who returned to alcohol intake after the transplantation. There were alcohol-related cases of graft failure in seven centers and of death in four centers. Nevertheless, Starzl and colleagues (1988) have found that survival of alcoholic patients after liver transplants is comparable to that of adult patients with other hepatic diseases.

Other substance abuse is highly correlated with noncompliance with medical and surgical postoperative management and with subsequent graft loss (Gastfriend et al. 1989). Another problem is that patients exposing themselves to drugs of abuse while they are in an immunosuppressed state as transplant recipients will be more susceptible to medical complications. Chang and colleagues (1997) recently found a significant reduction in survival for patients with substance abuse who had undergone bone marrow transplantation. Alcohol, marijuana, and opiates were identified as the principle forms of substance abuse.

The literature on the use of transplantation in patients with chronic psychotic disorder such as schizophrenia is scarce. While there have been reports of post-transplant outcomes such as suicide or psychotically induced noncompliance leading to transplant rejection, there is hope that more effective treatments for psychosis may improve the chances of these patients becoming transplant recipients. In terms of mental retardation and dementia, Strouse et al. (1996) recommend an approach which entails recognition of potential compliance difficulty, characterization of current psychosocial functioning and the patients' ability to care for themselves after transplantation, and organization of the network of support that will be necessary for post-transplantation care and compliance. These authors believe that exclusion out of hand of patients with dementia or mental retardation is an unfair policy given the fact that there may be few other risk factors for premature death other than organ failure.

In patients with severe treatment-refractory personality disorders, especially when comorbid mood or substance abuse disorder exists, the possibility of post-transplant noncompliance and acting-out behavior must be carefully scrutinized. Some researchers have found this group of patients to have postoperative surgical and psychiatric complications.

While self-destructive or lethal behaviors such as suicidality or refusal to accept transplant are grounds for not accepting a patient, some of these patients will have occult mood disorders related to their organ failure. Occasionally, management of the mood disorder will result in clearance of the suicidal ideation and in transplant acceptance. A situation in which organ failure is secondary to severe suicide attempts requires high-level ethical and clinical consideration (Strouse et al. 1996).

2.5 Pretransplant Phase

Once patients have been accepted onto a transplant waiting list, a new set of psychological challenges has to be faced, especially in areas such as heart transplantation, in which nonurgent transplants are becoming less rare. Potential transplant recipients must face mortality and increasing morbidity, which could eventually make transplantation impossible. It is not surprising that anxiety is therefore a common feature in patients awaiting transplantation. Physicians working with transplantation patients must recognize the anxiety and intervene promptly with referral for psychiatric evaluation and management. It is also important to realize that the risk of suicide is increased with anxiety and depression in the group awaiting a transplant.

Potential transplant recipients often have to wait for their procedure in the hospital because of the risk of increasing medical morbidity. Delirium is not uncom-

mon in these patients and will require psychiatric help with diagnosis and management. These patients also must deal with discouragement, demoralization, and depression, especially when comorbid medical conditions or complications put them at risk for coming off the transplantation list. These occurrences can be destabilizing not only for the patient but also for the family and loved ones. It is also important to take note of personality changes in the waiting period. Increased dependency or independency may be seen, and ambivalence toward transplantation may become pathological, leading to noncompliance. This requires periodic reexamination and support for compliance behavior.

2.5.1 Psychiatric Disorders

Patients Awaiting Renal Transplantation
Patients awaiting renal transplant usually do so while on dialysis. Major depressive disorder is often diagnosed in this population. There are also cognitive disorders, including dialysis dementia and organicity associated with end-stage renal disease. The transplant may improve these cognitive disorders.

Patients Awaiting Heart Transplantation
Patients who are potential heart transplant recipients often suffer from anxiety disorder. Cardiac diseases such as cardiomyopathy and congestive heart failure as well as valvular disease and arrhythmia are often associated with panic-like anxiety and depressive adjustment disorder. There are also patients with long-standing dysthymic disorder. This population will also be subject to cognitive disorder and other organicities with hypoxia and hyperfusion among the many etiologies. In addition, medications such as antiarrhythmics and digoxin used to stabilize these patients will often lead to delirium. In view of the shortage of organs available, patients awaiting a heart transplant will now sometimes require left ventricular assist devices (LVAD). Shapiro and his colleagues (1996) at Columbia Presbyterian have written about the psychosocial aspects of LVAD. While these mechanical marvels are successful in maintaining hemodynamic stability over a period of weeks to months, serving as a bridge to heart transplantation, they are associated with significant psychiatric and psychosocial sequelae. The same can be said for automatic implantable cardioverter defibrillators (AICD) used for ventricular arrhythmias (Fricchione et al. 1994). Panic/phobic and post-traumatic stress anxiety may be problematic in these patients, especially those with frequent device firings.

In the Shapiro group's LVAD experience, consultation was most often requested for family strain, major depressive disorder, organic mental syndromes, and significant adjustment problems. Cerebrovascular disease was a risk factor for depression and encephalopathy. Strokes were a risk of LVAD implantation, and the authors recommend treating major depression vigorously with antidepressants (serotonin reuptake inhibitors and stimulants) and psychotherapy. They feel that the treatment of both mood disorder and encephalopathy was a key factor in giving patients improved function and improved quality of life during the use of the LVAD.

Patients Awaiting Lung Transplantation
Patients awaiting single or double lung transplantation have a high incidence of anxiety disorder and depressed mood. Patients with chronic pulmonary disease are often dyspneic, and the level of their dyspnea seems to coincide with the degree of their mood dysfunction.

In addition to the anxiety problems including secondary panic-like episodes and major depression, dysthymia, and adjustment disorder depression, chronic lung disease patients often have a history of alcohol or other substance abuse and of encephalopathy.

Patients Awaiting Liver Transplantation
Because of the occurrence of hepatic encephalopathy in patients with liver failure, delirium is a frequent finding both in patients awaiting liver transplantation and in those who have undergone a transplantation. While patients may have improvement in neuropsychiatric functioning after a liver transplantation, postoperative delirium is frequent. In some cases, this delirium will lead to a dementing illness. In addition to these organic brain disorders, patients awaiting liver transplant will also suffer from adjustment reactions and major depression. Trzepacz and colleagues (1989) found that 9% of patients awaiting liver transplant have alcohol abuse or dependence, while 2% have abuse of other substances.

Patients Awaiting Bone Marrow Transplantation
Patients who have accepted bone marrow transplantation can become depressed during preparation and immunosuppression in the pretransplant stage. Anticipation of isolation while battling against cancer plays a role in mood changes. Total body irradiation which includes the brain can sometimes lead to acute radiation encephalopathy with cognitive changes (Jenkins et al. 1991).

2.5.2 Psychiatric Management

Surman and colleagues (1987) have discussed treatment in patients awaiting transplantation. They recommend symptom-directed behavioral intervention,

relaxation techniques, supportive psychotherapy, and psychopharmacologic interventions. Psychopharmacologic interventions include the SSRI and bupropion for depression in patients with end-stage organ diseases. Psychostimulants such as methylphenidate, dextroamphetamine, or pemoline can also be used, particularly for patients who are depressed with psychomotor retardation and fatigue. Anxiety reactions and panic-like states can be treated acutely with benzodiazepines such as lorazepam and oxazepam, which have no active metabolites and undergo simple glucuronidation in the liver. This is not to say that they cannot cause further confusion in patients who are encephalopathic, for example. Buspirone is a very well tolerated medication for anxiety disorders which avoids the benzodiazepine side effect profile, including respiratory depression. It has been used particularly in patients with lung disease. As noted, haloperidol can also be helpful in managing a high degree of anxiety and agitation states associated with delirium or psychosis.

2.6 Post-transplant Phase

2.6.1 Postoperative Considerations

Strouse et al. (1996) have outlined the factors predictive of psychiatric complications after transplantation surgery. They include the nature of the procedure performed, length of the surgery, intraoperative complications, metabolic derangements, physiologic stability, and medications given. Other issues must be attended to in the postoperative environment. These include the adaptation of those patients who require strict isolation to the sense of feeling alone and abandoned. They also include the questions the patient may raise about who the donor was. Some programs allow for very circumscribed information about the donor, such as a demographic description. In general, donors remain anonymous. Patients must also become acclimated to a new level of medical care. They must pay strict attention to their medication regimen and to the cataloguing of information such as weight and vital signs. The post-transplant patient should also be prepared to be vigilant in regard to the signs and symptoms of infection and rejection. Of course, the price to pay for this vigilance is often an elevation in anxiety level, leading to stress and adjustment reactions. If an organ is rejected, the patient will undergo a grief reaction, culminating in withdrawal and self-isolation and at times severe depression. These patients are often at elevated suicide risk. There are a variety of ways in which patients will deal with the potential for retransplantation once rejection takes hold. Since the decision for transplantation is often made in the context of a major depression or an anxiety reaction related to the graft rejection, it is often very important that psychiatry be an integral part of the treatment team.

2.6.2 Postoperative Neuropsychiatric Disorders

Delirium is not uncommon in patients who have had liver transplants. It is also a frequent occurrence in patients after lung transplantation. Patients undergoing heart and renal transplants also develop delirium, although not as often. Delirium in patients after transplantation will be caused by the added strain of major surgery and general anesthesia in patients who have end-stage organ disease. Metabolic derangements, intraoperative complications, postoperative use of CNS-active medications (including opiates, chemotherapeutic agents, and immunosuppressives such as cyclosporine, corticosteroids, and OKT3), early graft rejections, infections (including opportunistic ones), and residual effects of substance abuse (including withdrawal states) can all cause delirium. In bone marrow transplant recipients, brain irradiation may lead to acute, early-delayed, and late-delayed encephalopathies (Pollard and Young 1997). Encephalopathy is more likely if methotrexate is given during or after cranial irradiation. Cyclosporine is not only associated with delirium after transplantation, but also can result in neurotoxicity (Strouse et al. 1996). Cyclosporine neurotoxicity is associated with diffuse white matter lesions on magnetic residence imaging (MRI). It is well known that corticosteroids can also result in delirium as well as secondary affective syndromes. In terms of the management of post-transplant delirium, haloperidol has become a standard treatment to control agitation.

Seizures, both generalized tonic-clonic and complex partial ones, are not uncommon complications of transplantation. Those patients who have received liver transplants also can develop CNS lesions, including small vessel disease, leukoencephalopathy, and central pontine myelinolysis. Cyclosporine is a risk factor for the induction of seizures after transplantation. Strouse et al. (1996) point out that a cyclosporine holiday involving brief periods off the drug is sometimes required in order to manage seizures especially since anticonvulsants are occasionally unsuccessful in preventing them. There are frequent secondary organic mood disorders in patients after transplantation. Patients may become depressed and/or manic in this setting. Of course, medication side effects play a large role in the production of these affective changes. Even the antiviral agents acyclovir and gancyclovir can produce mood changes as well as delirium, panic, and isolated visual hallucinations.

Levenson and Olbrisch (1993) have reviewed the treatment of heart transplant recipients with psychopharmacological agents. They discourage the use of tricyclic antidepressants because of the hypotensive effects of these agents and the risk of precipitating ventricular arrhythmias and conduction defects. They sanction the use of newer antidepressants, including the SSRI and buproprion, although they acknowledge that very little has been published on this particular group of patients. They suggest using low starting doses with close monitoring, especially in regard to cytochrome effects in the liver. They also point out that fluoxetine, in addition to having a very long half-life, can elevate the serum levels of both cyclosporine and some antiarrhythmic medications. Our experience has been that SSRI and buproprion are well tolerated in transplant patients; as buproprion neither inhibits nor stimulates cytochrome, it is a particularly good choice in patients after liver transplantation, although vigilance for seizure activity needs to be maintained. Levenson and Olbrisch (1993) point out that electroconvulsive therapy (ECT) has been used safely in patients after transplantation.

Lithium can be hard to manage in patients with severe heart failure due to changes in cardiac output which affect the attainment of a steady state lithium level. Medications used in heart failure, including diuretics, salt restriction, angiotensin-converting enzyme inhibitors, and calcium channel blockers, may also affect lithium levels. Because of major fluid compartment shifts and electrolyte imbalances, lithium is occasionally even harder to manage in the immediate post-transplant period. When post-transplant stability returns, lithium can be used, but cyclosporine drug–drug interaction may pose its own difficulties, since cyclosporine has a tendency to elevate serum lithium levels. In addition, both agents cause tremor. Levenson and Olbrisch (1993) recommend the acute use of neuroleptics for mania in the post-transplant period. They do not feel that carbamazepine should be used because of its tendency to worsen congestive heart failure, potentiate hypotension, and produce arrhythmias and conduction defects. They do feel that valproic acid and clonazepam are reasonable agents in heart transplant recipients who are suffering from a manic episode. These agents can also be used with caution in patients who have had a renal or a lung transplant. Special caution must be used in liver transplant patients given the potential for hepatic toxicity. Cyclosporine, OKT3, and FK506 are all implicated in tremor. Attention must be paid to medications that increase cyclosporine levels, including methylprednisolone, ketoconazole, fluoconazole, cimetidine, verapamil, erythromycin, fluoxetine, and sertraline.

Strouse et al. (1996) report that central pontine myelinolysis in patients after liver transplantation is linked to cyclosporine use, perhaps due to cytochrome enzymes in the donor liver which increase cyclosporine levels. Patients may also complain of loss of taste, changes in hearing, incontinence, and sexual dysfunction after transplantation. Cognitive dysfunction may persist along with a fatigue syndrome after transplantation. It is difficult to distinguish the contribution of end-stage organ disease plus post-transplantation status and changes complicated by immunosuppressive and other medications. The use of psychostimulants and certain antidepressants with activating properties may be helpful in this condition. DiMartini (1996) has recently reviewed the case of a liver transplant recipient who had Wernicke-Korsakoff syndrome. She points out that transplantations may produce a propensity to Wernicke-Korsakoff syndrome secondary to factors such as gastrointestinal distress, chronic vomiting, and nutritional deficiencies brought on by conditions such as cytomegalovirus gastritis and nutritional depletion secondary to end-stage organ disease.

2.7 Long-Term Adjustment to Transplant

Craven (1990) outlined the coping challenges patients face after transplantation. These include readjusting to roles both in the family and in the workplace, adapting to a changed body image, coming to terms with rejection and infection fear, remaining compliant with immunosuppressants despite side effects, adapting to a new level of patienthood by meeting the expectations of the transplantation team, and realizing that the transplantation is not a cure and that even after the transplantation the physical hardships of chronic illness still have to be dealt with. In terms of quality of life following transplantation, a recent study looked at survivors of heart, liver, and lung transplantation procedures (Littlefield et al. 1996). The study included responses from 55 heart, 149 liver, and 59 lung transplant recipients and showed that those who had undergone successful lung transplants reported better functioning than heart or liver transplant patients in the three domains of physical, psychological, and social functioning. While lung patients reported levels of functioning equal to or better than published norms, heart and liver patients reported impairment in the areas of physical and social functioning. The heart patients felt that their new life style was intruded upon by their illness management, and they experienced more difficulty complying with it. Nevertheless, in all three groups, the majority of patients reported that life had improved in terms of health, energy, activity level,

and overall quality of life. Approximately 25% of the total subject group reported employment (full- or part-time). Others have found better employment and activity statistics, particularly in lung transplant survivors, although hepatic and renal transplant patients also have a high rehabilitation rate (Strouse et al. 1996). Altmaier and colleagues (1991) looked at the 2-year adjustment of bone marrow transplant survivors and found that they experienced greater vocational and sexual dysfunction than did a comparison sample of maintenance chemotherapy patients. However, the transplant survivors saw themselves as equally healthy and with low levels of psychological distress.

2.8 Conclusions

Stress and staff burnout are not uncommon in transplantation medicine. The organ transplant psychiatrist may be able to help members of the team through supportive relationships, referral to other psychiatrists or therapists when needed, and through group meetings of the staff, particularly at times of loss or disruption on the unit. Inviting the chaplain can sometimes help to reduce stress as well. The future of organ transplantation will involve certain built-in limits, particularly in the area of solid organ transplantation. These limits will include growing numbers of patients on waiting lists and longer waiting times due to the stagnant donor organ availability. This situation has led to more research on bridging technologies, including left and right ventricular assist devices and even a bile artificial liver (Coffman et al. 1996). However, as with all advances in medical technology, there will be secondary neurologic and psychiatric conditions. Psychiatrists working in cooperation with their transplantation team colleagues will need to employ the methods outlined above to insure that the cognitive and emotional quality of prolonged life is optimized.

Psycho-oncology

1 Introduction

The field of psycho-oncology is a recently developed subspeciality within oncology which reflects the increased interest in the behavioral, psychological, and social factors in cancer prevention and in the quality of life of patients with cancer at all stages. It addresses the two psychological dimensions of cancer: (1) the impact of cancer on the psychological function of the patient, the patient's family, and staff (the psychosocial dimension) and (2) the role that psychological and behavioral variables may have in cancer risk and survival (the psychobiological dimension) (Holland 1998).

This subspeciality is comprised of health professionals from several disciplines and medical specialties who contribute to the wide breadth of clinical and research expertise in psycho-oncology. Psychiatry, psychology, social work, and nursing, in particular, have contributed significantly to clinical care, research, and training in psycho-oncology. Pastoral counselors increasingly bring in the spiritual and religious dimension, and cancer survivors, acting as advocates, also bring their own expertise based on their own unique personal experiences and insights.

The main objectives of the field of psycho-oncology are the following:

1. To foster concern for the integration of psychological care into the total care of cancer patients and their families by all health professionals in oncology
2. To foster the education and training of clinicians and investigators in the subspeciality of psycho-oncology
3. To develop a training curriculum in psycho-oncology which is comprised of a common body of knowledge relevant to professionals from all backgrounds, but with specific modules added to meet the educational needs of each particular oncologic discipline
4. To promote the study of psychological, social and behavioral factors in cancer prevention and detection and to study the effect of psychological, social, and behavioral factors on survival
5. To promote cross-cultural research that attempts to define the universal stresses of cancer and brings an understanding of the influences of cultural factors on adaptation
6. To encourage controlled trials of psychotherapeutic, behavioral, and psychopharmacological interventions to control the distress experienced by cancer patients
7. To increase the awareness of the psychological and social problems and their management that are relevant to cancer patients at all stages of illness
8. To include quality of life as an outcome variable in clinical trials research in order to aid patients in making treatment decisions
9. To incorporate quality of life and well-being as part of the treatment goals and to aim to obtain a disease-free state which includes patients regaining maximal functional outcome in the major domains of living
10. To promote policies at the local, community, state, national, and international levels, aimed at reducing cancer risk and fostering optimal rehabilitation and survival.

The areas reviewed in this chapter address the variables that influence the adjustment of patients to cancer, the range of psychological problems related to patients' adaptation to illness, and the behavioral and psychosocial variables in cancer morbidity and mortality.

2 Adaptation to Illness

Learning that one has cancer, or that a close relative has cancer, is always a frightening event. Thoughts of death, disability, disfigurement, dependence, and disruption of relationships are inevitably linked to a cancer diagnosis. While the initial response to such a diagnosis is fairly universal, individuals vary in how well they ultimately adapt to the disease. It is thus important to identify the factors that predict good or poor adjustment.

Three categories of factors contribute to adaptation to cancer: those contributed by the society, those derived from the patients, and those which are the consequence of the disease itself (Spencer et al. 1998).

1. *Society-based factors.* These are the social attitudes and beliefs held by a society about cancer. They deeply influence the patient's own beliefs and reactions and those of the people around them. The stigma that cancer carries and the long silence in telling patients their diagnoses both stem from long-held beliefs that "cancer equals death." While this is no longer true, attitudes change slowly.
2. *Patient-based factors.* The individual's developmental stage at the time of diagnosis and the life cycle events with which it interferes (e.g. marriage, fertility), the personality, the emotional level of maturity, and coping style, and the interpersonal resources of family and friends and social support

available to the individual are important resources that contribute to adaptation. Predictors associated with poor coping are social isolation, low socioeconomic status, alcohol or drug abuse, prior psychiatric history, prior experience with cancer (e.g. death of a relative), recent bereavement, rigidity of coping strategies, having a pessimistic philosophy of life, absence of a supportive belief/value system which allows the person to find meaning in the experience, and multiple stressors (such as financial or family obligations) (Spencer et al. 1998).

3. *Cancer-based factors.* The disease itself presents certain "givens" which determine the symptoms and disabilities with which the person has to cope, i.e. the stage and site of illness (e.g. colon, breast) and the symptoms (especially pain) and prognosis to which each patient must adapt. Important here as well is the critical role of the doctor–patient relationship and of the health care team, which can either be a strong positive or a troubling negative factor.

These three factors interact and determine the adaptation of each patient at any given point in time. This explains why each person's adaptation is unique to the particular situation and why universals about coping strategies are apt to be more helpful in the understanding of aggregate responses rather than in the application to a single person.

3 Normal Psychological Reactions

When individuals deal with serious illness, responses of fear, worry, and sadness are normal. These are the "normal" forms of distress which all patients manifest to a greater or lesser degree. The distress varies in relation to the challenges presented by the illness at a particular time and the issues to which the person has to adapt. Four areas can be identified that require different coping strategies and types of psychosocial interventions in order to achieve maximum quality of life. They are:

1. Adaptation to active treatment, which may be curative
2. Adaptation to palliative and terminal care
3. Adaptation to being a survivor
4. Adaptation to the knowledge of a high genetic risk and as yet asymptomatic cancer.

In individuals undergoing active and possibly curative treatment, the goal of psychosocial care is to support the patient's coping with the stresses of treatment and its side effects. Behavioral and psychopharmacological interventions, counseling, and self-help groups are all useful techniques to increase adherence to treatment by controlling symptoms of anxiety and depression and side effects of treatment such as nausea, vomiting, and alopecia.

For individuals at the time of transition from treatment with cure as a goal to care with palliation as the goal, there is usually a period of great distress as the new reality becomes clear. However, this is followed by an adaptation to the altered therapeutic goal of control of the disease. Psychosocial intervention should help patients and families with decisions about treatment and care and should be directed toward the control of anxiety and depression. Troublesome physical symptoms, particularly pain, commonly associated with advanced and terminal stages of illness, must also be controlled, and this often results in opiate-related encephalopathy (Breitbart and Payne 1998) and delirium, which require treatment.

In individuals who have successfully completed active treatment and who consider themselves survivors, there is often greater appreciation of life and a need to reexamine values and goals. On the negative side, however, there is a strong fear of recurrence, anxiety, and a sense of enhanced vulnerability to illness and death. Anxiety may dissipate over time, but it is exacerbated at the time of a medical checkup and when minor symptoms occur, which are rationally recognized not to be related to cancer, but are irrationally assumed to be due to cancer. Self-esteem is often lower, and problems with insurance and employment do occur (Cella et al. 1991). Reminders of treatment serve as stimuli for conditional responses of nausea, vomiting, and anxiety after chemotherapy (Cella et al. 1986). Studies have found that 15% of bone marrow transplant survivors experience the complete symptom cluster of a post-traumatic stress disorder, while 10% of them have nightmares, hypervigilence, and flashbacks. Up to 30% of mothers of children with transplants also have similar symptoms of distress (Pelcovitz et al. 1998).

In individuals who are at high genetic risk for cancers, there is an increasing awareness of their family history and a concern about whether genetic testing is wise to obtain. The anxiety about risk is handled differently; whereas some people use denial and refuse to come in, even for routine screening such as mammograms, others repeatedly check their bodies for signs of cancer and present to doctors frequently for evaluation and screening procedures. Regardless of their coping style, these individuals are vulnerable to high psychological distress, and support groups have proved valuable.

4
Psychiatric Disorders

When transient negative emotional reactions exceed normal limits, begin to pervade a person's life, and interfere with treatment and overall quality of life, these symptoms need to be evaluated for the presence of a psychiatric disorder (Roth et al. 1998). The most common psychiatric disorders seen in patients with cancer are adjustment disorders (with anxiety, depression, or both), anxiety disorders, depressive disorders, and delirium related to metabolic problems or medication side effects.

4.1
Anxiety Disorders

Symptoms of anxiety range from normal fears to incapacitating anxiety disorders. Three common sources of anxiety have been identified among cancer patients:

1. Situational anxiety may be related to the disease itself (the initial diagnosis, the anticipation of a new procedure, or, later on, the fear of recurrence). This is usually an adjustment disorder with anxious mood. Anxiety can be related to medical problems, such as poorly controlled pain, abnormal metabolic states, treatment side effects, drugs which produce anxiety or withdrawal symptoms (e.g. narcotic analgesics), hormone-secreting tumors, and paraneoplastic symptoms (Noyes et al. 1998).
2. Anxiety related to the treatment process, such as the fear of painful or frightening procedures (e.g. magnetic resonance imaging, MRI) and anticipatory anxiety prior to chemotherapy (Andrykowsky and Redd 1997; Redd et al. 1987).
3. A preexisting anxiety disorder that may be exacerbated in the context of cancer and its treatment. Examples occur with phobias stimulated by the need to deal with hospitals, needles, blood, or claustrophobia. Traumatic memories that are triggered by the medical setting may also resurface during the stress of cancer as a delayed posttraumatic stress disorder. All are symptoms that must be controlled to ensure patients' ability to tolerate optimal medical treatment.

In terms of treatment, simple situational anxiety can be easily managed by the reassuring and informative words of the treating physician reinforced by the oncology nurse or social worker. When more serious levels of anxiety are present, three means of treatment are appropriate: (1) counseling or formal psychotherapy using a supportive crisis intervention model; (2) behavioral interventions such as relaxation, systematic desensitization, and hypnosis; and (3) psychopharmacological agents (e.g. benzodiazepines, antidepressants, and neuroleptics).

4.2
Depression

Depression is a difficult disorder to diagnose among cancer patients due to the fact that the physical symptoms of depression, such as fatigue, weakness, loss of libido, anhedonia, and poor concentration, are also common symptoms caused by cancer, especially in advanced stages.

Most depressive disorders are reactions to the disease (adjustment disorders), and they occur in about one quarter of outpatients; higher percentages are reported among inpatients who are more physically ill (Bukberg et al. 1984). The symptoms of depression are several: depressed and/or dysphoric mood, restlessness or psychomotor slowing, insomnia, hopelessness and helplessness, guilt, and suicidal ideation. In diagnosing major depression, prior psychiatric and family history of depression and any substance abuse must also be taken into account.

Major risk factors for depression are prior history of depression or suicide attempts, substance abuse, poor social support, or recent bereavement. Risk factors related to the illness itself are advanced disease, poorly controlled pain, presence of another chronic disease or medical complication (such as metabolic, nutritional, endocrine, or neurological conditions), use of certain chemotherapeutic agents (e.g. interferon), and use of medications such as steroids and opiates.

The presence of a depressive disorder is particularly concerning because it is a risk factor for suicide. The incidence of suicide among cancer patients is increased compared to the general population (Bolund 1985, 1986). Recent studies have shown that requests for physician-assisted suicide occur primarily due to depression, not pain (Breitbart and Krivo 1998). Risk factors for suicide are prior history of suicide attempts, prior psychiatric or substance use disorders, depression and hopelessness, recent bereavement, and poorly controlled pain, delirium, advanced disease, debilitation, and exhaustion (Breitbart and Krivo 1998).

An evaluation of a suicide risk should gather information about the disease stage and prognosis, the patient's understanding of his or her symptoms and prognosis, the nature of the suicidal thoughts, the presence of other losses and the past history of psychiatric disorders or of poor adjustment to stressors, and family history of depression.

Depression is first treated by developing a good rapport with the patient and by then offering supportive psychotherapy, cognitive-behavioral treatment, and psychotropic agents.

4.3 Delirium

Medical causes for a change in the mood or behavior of an individual with advanced cancer need to be considered and evaluated for the presence of delirium: metabolic encephalopathy, electrolyte imbalance, treatment side effects (e.g. anticholinergics, chemotherapeutic agents, radiation), infection (e.g. septicemia), and paraneoplastic disorders (Posner 1978; Breitbart and Cohen 1998). Over 75% of hospitalized patients with advanced and terminal illness were found to develop a confusional state prior to death (delirium) (Massie et al. 1983).

Early signs of delirium are changes in sleep patterns, irritability, uncooperativeness, somnolence or agitation, and misinterpretation of sounds and objects. These early symptoms may later be followed by a refusal to cooperate with reasonable requests, anger, verbal abusiveness, illusions, delusions, and hallucinations as the symptoms escalate (Breitbart and Cohen 1998).

In terms of treatment, it is valuable to have a familiar person stay with the patient to provide a known, trusted, reassuring presence. Physical restraints should only be used with caution and checked regularly. Psychopharmacological intervention most commonly consists of administering low-dose haloperidol several times a day to reduce confusion. Lorazepam may be added to reduce agitation.

5 Behavioral and Psychosocial Variables in Cancer Morbidity and Mortality

Behavioral, psychological, and social variables have been found to have an impact on cancer morbidity and mortality. Specifically, lifestyle, poor socioeconomic status and education, early detection and treatment compliance, and the availability of social supports clearly reveal the impact of behavior and social factors on cancer morbidity and mortality (Cella et al. 1991; House et al. 1988). Personality type has not been found to be a significant factor. Bereavement and depression studies have failed to confirm a significant connection to cancer morbidity and mortality. While psychosocial interventions have proven useful in improving patients' well-being and quality of life, it is still unclear as to whether they can have a significant impact on survival (Classen et al. 1998).

6 Conclusion

Psycho-oncology is a new specialty within oncology, reflecting greater interest and concern about the psychological, behavioral, and social factors related to cancer prevention and treatment. The total care of cancer patients today must include concern for their psychological management as one of the basic elements. Research on prevention and detection depends on the social sciences for dealing with ways to change lifestyles and behavior. Theory and practice related to the effects of cancer on psychological function and its prevention depend heavily on the expertise provided by this new speciality. Psychiatry as a medical speciality and psycho-oncology as an oncologic subspeciality have a unique role to play in cancer treatment and prevention.

CHAPTER 19

H. Merskey

Pain and Pain Therapy

1 Definition of Pain

In practice, we often fail to find physical explanations for pain. It sometimes seems to arise from psychological processes, as with the headache of depression or the very rare pain which is an hallucination in schizophrenia. This raises a conceptual problem in the understanding of the word "pain". In normal conversation and in technical speech, pain describes an experience which one person relates by word of mouth to another. Normally, it connotes a type of experience which we associate with damage to the body. Thus the word for pain describes a subjective experience. It is a word for a psychological state and does not describe physical conditions. It tells us nothing about what is happening in the axon of the nerve or in nerve pathways. It has bodily reference so that the experience is tied to some portion of the body, but it is always a private experience and something which can only be inferred about a person, either from his or her report or by observation of behaviour which suggests that the individual has this condition. It requires confirmation by direct enquiry. Thus it cannot be defined by external criteria. Advances in neurophysiology and imaging may tell us one day that reports of pain are consistently associated with particular physiological changes, but to date those observations are limited and are not available for general use.

It is common for the word *pain* to be employed when an individual suffers injury or damage to the body and experiences a particular type of subjective state which is found to be unpleasant. The words used to describe pain commonly imply tissue damage (Devine and Merskey 1965). From this reasoning, it has seemed possible to form a definition of pain which would describe it as an unpleasant experience and which would say that it was one which we primarily associate with tissue damage or describe in terms of such damage. It is that characteristic experience which seems to be common to all mankind, with only very rare exceptions among those who do not withdraw from noxious stimuli and are thought to have a congenital absence of the experience of pain. The International Association for the Study of Pain (IASP) (1979) adopted the following definition: "An unpleasant sensory and emotional experience, associated with actual or potential tissue damage, or described in terms of such damage".

In a sense, this definition is only a semantic trick. It removes preoccupation with whether a noxious stimulus is pain and instead provides a psychological framework. It says that we will not use the word "pain" to describe a noxious stimulus, but we will use it to describe what a person feels. One of the advantages of this definition is that in those relatively few cases where pain seems to have a psychological cause and no other explanation, the patient can correctly use the same word as a patient with a broken limb.

This is a monistic view of pain. Often, we cannot distinguish in experience between pain of psychological origin and pain of physical origin. However, we should be very concerned to find the causes of pain. A given pain may have both physical and psychological causes, and in that sense it has a multiple aetiology.

2 Psychodynamic Hypotheses

"We feel a cut from the surgeon's scalpel more than ten blows of the sword in the heat of battle" (Montaigne 1580). This remark by Montaigne illustrates some aspects of the psychology of pain. Mild or moderate anxiety, which we often see in association with pain in clinical practice, seems to heighten pain. Being placed in a passive situation and unable to escape likewise increases pain. On the other hand, heightened arousal, as in battle, appears to minimize or abolish pain.

Besides anxiety, multiple symptoms, including pains in different parts of the body, have been associated historically with the diagnosis of hysteria. What was previously called hysteria has varied enormously in different periods of time, and it is best understood as a broad term used in the past for depression and for psychological complaints about the body and about mental function, e.g. memory. This approach has also led to the category of somatoform disorders in DSM-III and DSM-IV (American Psychiatric Association 1980, 1994) and its successors, separate from conversion and dissociative symptoms.

The historical tradition that pain could be a conversion symptom was popular in psychoanalytic literature and appeared in at least 31 separate psychoanalytic reports (Merskey and Spear 1967). This literature depended upon the use of the concept of repression, a concept which is now in considerable difficulties, particularly with reference to long-term effects (Holmes 1990). Most of the current difficulties with the concept flow from its over-use in the production of multiple personality disorder and from the development of false memories which have led to a re-appraisal of the theoretical and practical justification for the use and employment of the notion of repression (Merskey 1996). There may still be some place for repression as an acute mechanism in

conversion or dissociative disorders occurring with acute stress, but there is no good evidence to scientifically validate the notion of repression as a long-term mechanism.

Nevertheless, the idea that individual reactions may be determined by childhood experience persists. Schilder (1931) interpreted pains in one of his patients as a defence against sexuality and as a perverse sadomasochistic satisfaction. From this starting point, Engel (1951) described "atypical facial pain" as an hysterical conversion symptom associated with many varieties of self-punitive behaviour. He stressed the frequency in his cases of unnecessary surgery, the presence of other somatic symptoms, the tolerance of physical causes of pain – often with gusto – and remission of the pain at times of misfortune or when there was other cause for suffering, whether physical or mental. Later, he named this type of patient the "pain prone patient", whether the symptoms applied to facial pain or pain elsewhere in the body (Engel 1959).

Engel's work was anecdotal and has only been borne out in limited respects. These include the finding of increased resentment in patients with pain, increased numbers of operations, consultations, painful past illnesses and poor marital adjustment (Merskey 1965a,b). Alternative explanations are also available for many of the findings. Irritability and resentment are common phenomena in all patients with pain, whether of psychological origin or physical origin. In animals, aggression is one of the main responses to occur in the presence of pain from trauma (Ulrich et al. 1965; Ulrich 1966). Pain in humans similarly features hostile responses.

3 Personality Features

Traditionally, it was supposed that hysterical personality or histrionic personality, as it is now termed, would be liable to be associated with such pain as was not based upon organic disease. Work with the Minnesota Multiphasic Personality Inventory (MMPI) favoured the idea that there was a characteristic pattern of abnormality in patients with pain. Typically, the hypochondriasis scale is elevated above the mean, the depression scale is somewhat elevated and the hysteria scale is elevated more than depression but not as much as hypochondriasis. If the patient does not have organic illness, this may be accepted as evidence that the symptoms are hysterical in type. However, many patients with physical illness are liable to have a similar pattern of response on the MMPI. If a patient with physical illness gives positive responses to questions which appear on the hypochondriasis scale and which confirm that he or she has back pain, pain in other joints, headache or a liability to sleep badly, the result will often be interpreted as meaning that he or she is psychologically ill. In addition, half the items on the hysteria scale come from the hypochondriasis scale. Thus, if the hypochondriasis scale is elevated, the hysteria scale will be pulled upwards after it. Moreover, items such as sleeplessness, fatigue and difficulty in concentration, which can all be due to chronic physical causes of pain, are liable to be scored as positive, not only on the hypochondriasis scale, but also on the depression scale. Hence the pattern that has been described as a "conversion V" triad in the MMPI seems usually to be due to physical causes of pain (or other disruptive chronic physical illness). Causalgia (chronic regional pain syndrome type II) or other de-afferentation pain, is as likely a cause of this syndrome as the mind, if not more likely.

The problems of the MMPI limit its use in patients with chronic pain. The same applies to any other test, e.g. the Symptom Checklist-90, which relies upon a category called somatization and is based upon a count of physical symptoms. In patients with chronic pain, psychiatric measures must be free from questions with a somatic weighting. The Hospital Anxiety and Depression Scale (Zigmond and Snaith 1983) was designed specifically with this problem in mind and has particular merit in this field.

4 Selection

Selection influences which patients present with pain or in general medical care. Even very acute potentially serious conditions do not automatically produce an admission to hospital of a normal sample of the population. This is true even in general practice. Patients with migraine may say to themselves: "I have this dreadful headache again. I must see my family doctor about it. Mother always went to see him when she had headaches and vomiting and I should do the same." Or they may say: "Mother always went to see the doctor with her headaches and got no benefit. I will take the day off, take a pain killer and go to work tomorrow." Not surprisingly, patients in specialized migraine clinics tend to be more persistent in seeking relief than those with migraine in the community, and patients in other clinics are often anxious and hypochondriacal. Early studies held that migraine occurred in subjects who were hesitant over positive decisions, insecure, perfectionists and unduly worrying. They were of high intelligence; the women had not had a

successful heterosexual life, and the men had a low sexual drive. The migraine attack was seen as a conflict between the desire to escape from the mother's influence and the compulsion not to leave her. These sorts of descriptions were adopted by the late H.G. Wolff (1937, 1948), who particularly emphasized the presence of a rigid, ambitious, perfectionist personality with headache resulting from a variety of stresses.

Migraine is very common in the population as a whole. A survey by Crisp et al. (1977) in an actual general practice population showed that migraine patients were scarcely any different from a general practice population. There was a statistically significant increase in anxiety in migraine patients, but its quantitative significance was slight. Thus, while anxiety may provoke migraine, and migraine seems to be more common in patients who are going through a phase of anxiety and depression, it does not have an automatic relationship with emotional states. For all types of chronic pain, selection is a natural phenomenon, and the more specialized the clinic, the stronger the selection pattern.

Studies of facial pain lead to similar conclusions. Temporomandibular pain and dysfunction syndrome (TMPDS) is marked by pain in the face, particularly in the maxillary region, clicking of the joints in some patients, tenderness of the muscles of mastication and over the joint and limitation of mouth opening. Thirty-nine per cent of a normal population had clicking, 12% had pain in the face on wide opening of the jaw and 7% had limitation of movement (Agerberg and Carlsson 1972). In addition, facial pain affects about 5% of 25-year-old normal males and 11% of normal female (Heloe and Heloe 1979). In this latter study, 2% of the men and 5% of the women sought treatment. This resulted in a ratio of men to women of 1:6 in the clinic compared with a ratio of 1:2 in the community. In clinical practice, women typically present far more often with a complaint of TMPDS than do men. TMPDS used to be held to result from psychophysiological dysfunction. We found that only 48% of a population with TMPDS could be classified as likely to have psychiatric illness even when we used very liberal cut-off points on the General Health Questionnaire-28, a screening measure for psychological illness (Salter et al. 1983). Speculand et al. (1983) likewise observed that the abnormal illness behaviour patterns of patients with this condition were more like those of general practice patients than of a chronic pain population.

Strong evidence of selection effects has been produced by Crook et al. (1989) with respect to patients with chronic pain. Patients in a pain clinic were more likely to have been injured than those in a community sample and also reported a greater intensity and constancy of pain and had more difficulties with the activities of daily living. They were more depressed and withdrawn socially and showed more long-term consequences due to unemployment, litigation and alcohol and drug abuse. Whereas only 2% of patients in the family practice group were disabled or unemployed, 38% in a pain clinic were in that situation.

5 Clinical Contributions

Many specific painful syndromes have long been recognized. Bonica (1953, 1990) established that both acute and chronic pain were damaging pathophysiologically in and of themselves and provided a method for diagnosis and treatment of the different chronic pain syndromes. His major work, *The Management of Pain*, put together a wealth of knowledge about the neurology of chronic painful syndromes and how to treat them by regional blocks, many of which he himself had pioneered. He established the importance of multi-disciplinary consultation, including the significance of psychiatric and psychological advice, which would be incorporated in a comprehensive pain clinic. Bonica always acknowledged that the development of the comprehensive pain clinic was not only his idea but was also promulgated by the late F.A.D. Alexander (1978). By 1990, Bonica was able to identify 336 pain control facilities worldwide, two thirds of which were in the United States. Forty-nine per cent of clinics were run by anaesthetists, 13% by rehabilitation specialists and 12% by neurosurgeons. Psychiatry and psychology specialists together ran 7%. In general, the primary responsibility for organizing comprehensive pain clinics is in the hands of other disciplines, but psychiatry and psychology play a vital role in many cases. Bonica also described a system of classification for chronic pain syndromes which was adopted by the Task Force on Taxonomy of the IASP and forms the basis for a classification of chronic pain syndromes (Merskey and Bogduk 1994).

It is useful to know the rates of depression in patients with pain and the rates of pain in patients with depression, even if selection is taking place. The incidence of depression in clinics ranges from 10% to 100% (Romano and Turner 1985) in patients with chronic pain. By depression, one means a state which is of the order of severity of a major depressive disorder rather than only a symptom. In surveys of patients in different clinics, we found that the lowest probable incidence of the likely presence of psychiatric disorder appeared in an oral medicine clinic where patients were referred by dentists for consultations on facial pain. The highest rate was in a psychiatric clinic (Merskey et al. 1987). Patients with headache were between these two extremes (Merskey et al. 1985), as

were patients with pain in various regions attending anaesthetist nerve block clinics. In these latter studies, the measure used was the General Health Questionnaire with 28 items (GHQ-28; Goldberg 1978). The values presented were obtained with a cut-off score of 4/5, which tended to maximize the presence of supposed psychiatric conditions.

When a fairly stringent instrument for the diagnosis of depression such as the Levine-Pilowsky Depression Questionnaire was used, the findings tended to be more conservative and produced the low figure of 10% mentioned above. The latter questionnaire was designed to diagnose well-established cases of depression and to show also whether they appeared to have a reactive or an endogenous pattern.

6 Survey Data

Community figures for chronic pain have generally been based upon pain which may only have lasted as long as 1 month. Most survey figures for chronic pain (e.g. Crook et al. 1984) find that about 11% of the population overall has pain present for most of the time over a period of 2 weeks, and another 5% has had some incidental pain in a previous period of 2 weeks. Magni et al. (1990) examined data collected by the United States National Center for Health Statistics. In this data, 14.4% of a representative sample of the United States population between the ages of 25 and 74 suffered from chronic pain related to the joints and musculoskeletal system. The definition of chronic pain in this case was pain present for most of the time during a period of at least 1 month in the preceding 12 months. In addition, 7.4% had some pain of uncertain duration. On the basis of scores on the Depression Scale of the Center for Epidemiologic Studies (CESD), it appeared that 18% of the population with chronic pain were found to have depression, whereas only 8% of the population who did not have chronic pain reached similar scores for depression. There were significantly more women with pain (ratio approximately 6:4) and older people as well as people with a lower income.

These data imply that nearly one in five patients with joint pain present for most of 1 month had clinical depression. In the study, 83% of patients with chronic pain had received some formal medical treatment for their condition. Of those who received treatment, whether from family practitioners or others, the numbers who were depressed at any one time appear to be about two out of nine. Of those who had pain, 7.9% lost between 1 and 30 days of work, while 8.5% lost more than 30 days of work. This figure of 8.5% is approximately 1.2% of the whole population studied. In this group, one would expect to find more depression and of course more frequent attendance for medical care.
