In follow-up studies, patients in the community with "chronic pain", as defined above, had a spontaneous remission rate of 32.5% after an interval of 8 years. The frequency of subjects with chronic pain was slightly more than twice that found in the previous survey. In this follow-up using logistic regression analysis, the odds ratio for patients with depression to develop pain 8 years later was 2.14, while the odds ratio for patients with pain to develop depression 8 years later was 2.85. Thus pain preceded depression and depression preceded pain in different cases. These results were highly significant statistically ($p < 0.001$), although the effect was relatively small. The high significance depended upon the large numbers of subjects in the study (Magni et al. 1994). A necessary connection has not been established between the predictive and outcome variables, but the evidence supports both the view that depression promotes pain and that pain promotes depression, and the latter effect is a little more powerful than the former. In Magni's study, the low quantitative effect may be related to the long interval of follow-up. At first we thought that a long interval would be an excellent opportunity to test the interaction between these two variables in a prospective fashion. On further consideration, it seems that a short follow-up interval – say, 18 months to 3 years – might be more effective in telling us about the closeness of the relationship between the two variables in either direction.

In most pain clinics, the frequency of depression or psychological problems appears to be about 30% (Pilowsky et al. 1977; Large 1980; France et al. 1985; Merskey et al. 1987).

7 Behavioural Concepts

Another approach towards pain treats it as a behavioural phenomenon (Fordyce et al. 1968; Fordyce 1976). According to this approach, pain behaviour is augmented by favourable contingencies, i.e. causes, inducements, stimuli or events which favour its presentation and diminished by events which reduce the benefits to the organism of complaining of pain or acting as if in pain. It has long been recognized that exercise helps to reduce pain, and behavioural theory invokes this link. Stiffness produced by increased activity may be reduced by more activity after a day or two if deconditioning is overcome. However, some patients get worse because their pain is increased each time they are active and does not diminish on

subsequent occasions. In this instance, we might think that there is an obdurate cause for increased pain with activity and that this cause is not responsive to improved muscle conditioning. It can be difficult to know who will benefit from exercise and who will be made worse. Patients with acute inflammation and acute injuries may still do better to rest. In chronic pain, exercise programmes appear to have great success with relatively early cases, but give rise to a good deal of discontent in patients who are pushed to exercise and in whom the pain is exacerbated.

Current books or articles on pain frequently indicate a behavioural element in programmes for the treatment of pain (e.g. Gatchel and Turk 1996). The critics of operant behavioural treatment particularly question the view that behavioural methods in pain treatment programmes claiming to treat excess disability and expressions of suffering are also treating pain. They doubt this on logical grounds and also suspect that the clinician will not always be as skillful as is necessary in defining "excess disability and expressions of suffering". Anyone who gets this wrong is going to be pushing patients repeatedly to do things which are increasingly difficult and painful. This follows from the fundamental position which Fordyce (1976) has stated, namely, that the subjective state of the patient is not a matter of concern to him or her provided behaviour can change. Schmidt (1988) demonstrated that the operant approach confused pain and ratings of pain by the sufferer. No matter how much denial there is on this topic, it seems that the notion of treating pain behaviour involves some rejection of the patient's experience. A more moderate approach recognizes that behavioural management of patients can help patients to overcome difficulties in activity which they thought were insuperable and can discourage maladaptive behaviour.

Another grave problem with the behavioural approach is that it has become extremely popular in circumstances where the practitioner appears to have a profound conflict of interest. In the United States especially, the treatment of a considerable proportion of patients in pain clinics is paid for by insurance companies. The interest of an insurance company is to get the insured person back to health and strength, but also to establish that he or she will receive treatment directed to his employability. These aims are in the interest of the insured as well, but patients are more interested than insurance companies in relieving pain. In order to get paid, clinics may have to provide programmes which offer to remove *disability* rather than pain. One aim may be sacrificed for the sake of another. This is rarely discussed in the United States in the technical literature, but behaviour therapists claim that they are "rescuing" patients from disability which would otherwise be interminable. Such an approach is particularly noteworthy in a recent report by a Task Force of the IASP (Fordyce 1995), which takes the view that back pain is so much subject to psychosocial influences that, after the exclusion of surgically correctable lesions and investigation over a period of 6 weeks, individuals with chronic "non-specific back pain" should not receive further medical benefits. Both medical care and disability benefits should be denied and the individuals declared "activity intolerant". Such individuals may be candidates for rehabilitation and further benefits on those grounds, but not otherwise medically, and would need to be compensated through unemployment insurance programmes. This approach has given rise to considerable opposition.

Cognitive measures do not share these objections of principle. Cognitive therapy for depression is now well established, at least for mild and moderate cases, and does not necessarily compete with pharmacotherapy. Flor and Turk (1988) showed that cognitive variables in rheumatoid arthritis accounted for between 32% and 60% of the variance in pain and disability and did so more effectively than physical measures. The patient's awareness of disability and distress in other situations also tends to predict outcome better than the physician's estimate of physical status in a number of instances. This does not prove that the disability is of psychological origin. Patients' awareness effectively takes into account both their physical state and their psychological condition, the latter being based at least in part upon the former. Hence the subjective measure is likely to be the more comprehensive one.

Anderson et al. (1988) have shown that psychological variables do not necessarily independently predict pain behaviour in rheumatoid arthritis. Pain behaviour such as guarding, bracing, grimacing, sighing, rigidity, passive rubbing and active rubbing most closely related to physical illness. This is in accordance with expectation, since the model of pain behaviour was developed out of the model of physical disease. Pain behaviour is thought to be "psychological" or anomalous only when it is not matched by physical disease. In many cases of pain for which X-ray measurements and even computed tomographic scan (CT) and magnetic resonance imaging (MRI) do not contribute much extra information, it is often thought that pain behaviour which is not supported by these measures, or by neurological or orthopaedic findings, must be psychological in origin. This is an important fallacy, and *psychiatric illness in patients with pain should only be diagnosed on its own grounds.* Pain cannot be attributed to psychological illness if an adequate psychiatric diagnosis cannot be made, and a psychiatric diagnosis should not be made simply because the patient complains a lot and organic evidence is insufficient.

Provided one takes a broad view, the identification of pain behaviour and treatment by exercise may be

part of a useful comprehensive treatment of chronic pain. It is generally agreed that it is important to have contact with family members and to work through them to discourage undue dependence at home. With chronic low back pain, in particular, it can help to discuss the patient's abilities and difficulties with family members and to see that they are not unduly solicitous but give patients every opportunity to do things for themselves to the extent possible. However, in dealing with patients' relatives, caution still applies with respect to behavioural interpretations.

8 Psychological and Physiological Mechanisms of Pain

When pain occurs as a result of a psychological process, several mechanisms may apply. Hallucinations can produce pain but do so very rarely. It is hardly ever a clinical problem with schizophrenia. A chronic mono-symptomatic complaint of pain without any other evidence of psychiatric illness or physical cause may be the precursor of schizophrenia, but the diagnosis can only be made when the illness becomes apparent on other grounds. Depression can cause pain as a delusional symptom, but as a rule that only happens in severe endogenous depression and usually it responds very quickly to suitable treatment. Interestingly, somatic hallucinations in schizophrenia are much more often related to passivity experiences and are not painful, although various forms of change may be described in the body (Watson et al. 1981).

Pain associated with depression and anxiety could be due to muscle contraction. This is not nearly as common as has been supposed, or at least it is hard to prove that it is common. Excess muscle contraction in the presence of ischaemia will lead to pain (Lewis et al. 1931). Repeated contraction of the muscles of a limb while blood inflow is restricted by a tourniquet quickly leads to pain, which is presumed to be due to a failure to carry away the waste products of metabolism. Chronic headache is likewise presumed to be due to over-contraction of muscles and a similar possible effect. Some evidence exists in favour of this point of view. The difficulty is that attempts to measure muscle contraction and to quantify it have not generally been in proportion either to the anxiety from which the patient suffers or the extent of the pain. The International Headache Society only describes "tension-type headache", recognizing the poor relationship between demonstrated muscle contraction and chronic headache. It seems that at the present time there is no firm explanation of headache of psychological origin, except that tension-type headache and episodes of migraine increase with anxiety or with depression.

The view that some pain is hysterical is perhaps best reinforced by the example of the Couvade syndrome, in which the husbands of pregnant women develop abdominal pains and even abdominal "contractions". There is no reason to expect physical disorder in such cases and no plausible pathophysiological explanation, even if air swallowing may cause some gastrointestinal distention. While the diagnosis of hysterical pain should be accepted on the basis of this and cognate evidence cited above, its frequency is also rare – or at least it is extremely hard to demonstrate – as we shall discuss subsequently.

One more mechanism of the production of pain deserves consideration. Anxiety may, in some fashion, alter activity in the spinal cord and in the mid-brain in a way which enhances input from noxious stimulation or inhibits suppressor mechanisms. Thus an effect might be transmitted from the limbic system through descending pathways to the spinal cord, which would increase a current abnormal activity. Ascending and descending activity in cerebro-spinal pathways has been repeatedly demonstrated experimentally and provides a potential mechanism, linked in principle to the pattern theory approach of Melzack and Wall (1965). This evolution of the "gate theory" of pain allows for the increase and decrease of pain from a physical illness in accordance with the presence or absence of emotional arousal and also takes account of various types of input and mechanisms of control within the nervous system. While it is not feasible to apply these theories to individual cases, they give a credible reason for believing in the occurrence of some chronic pain as a consequence of pathophysiological dysfunction within the nervous system.

The origins of this pathophysiological dysfunction may well be more organic than psychological. Important changes take place in the spinal cord in response to noxious stimulation and have ramifications at several levels of functioning of the central nervous system. This knowledge arises from developments in appreciation of the plasticity of nervous activity within the spinal cord and brain stem. The most strong focus has to do with regional pain syndromes.

It has been common to date to suppose that regional effects were signs of an emotional state in the individual. Loss of use or spread of pain in one region such as an upper limb or a lower limb fits ideally with a thought in the mind of a patient. Hence regional symptoms have often been categorized as hysterical or likely to be hysterical and as produced by thought processes, but plasticity offers an alternative explanation.

Wall (1984) described abundant evidence that the receptive fields of afferent neurons in the dorsal horn

of the spinal cord can change and extend. In the rat, 3 or 4 days after de-afferentation, cells that formerly responded to stimulation within the usual anatomical area begin to respond to stimuli from other areas. We can compare this in humans to cells in the area of the spinal cord usually related to the little finger only responding to local stimulation at first, but beginning after some time to respond to stimulation in the thumb or the radial side of the arm. Such effects can result from causing a punctate burn in one part of a limb (McMahon and Wall 1984). The presence of the burn in one area permits excitation of cells throughout the whole region. Cook et al. (1987) showed that electrical conditioning stimuli at 1 Hz for 20 s to C-fibre afferents from the gastrocnemius muscle of the rat would more than triple the receptive field of a cutaneous afferent neuron, whether it responded originally to a firm mechanical stimulus or to pinch. Moreover, neurons that originally responded only to pinch would begin to respond to touch about 5 min after the stimulation. Thus mechanisms exist in the spinal cord that allow regional pain to develop from a localized disturbance, including subcutaneous changes.

Woolf and Wall (1986) made the following observation:

> Because brief afferent inputs from deep tissue have even more pronounced effects than cutaneous inputs, this may explain the more widespread sensory disturbances that accompany deep injury. The varied pattern of post injury pain hypersensitivity resulting from injury to different tissues may be the consequence therefore of the activation of different afferents with different central actions. The presence of widespread tenderness (allodynia) with this sort of movement is frequently the most disturbing symptom in patients in chronic pain.

This work demonstrates that mechanisms exist in the spinal cord that allow regional pain to develop from a localized disturbance, including subcutaneous changes. In these circumstances, non-anatomical pain cannot automatically reflect the presence of hysteria. Hyposensitivity and patchy sensory loss in the presence of pain are also unreliable. Traditional explanations of cases of pain of this type as hysterical are unsound.

Other features which have also traditionally been taken to reflect the presence of hysteria or psychological motivation in chronic pain are likewise unreliable. Give-way weakness may be due to the patient not wishing to use an arm which hurts. Signs that have been thought to be typically hysterical – namely, a history of hypochondriasis, potential secondary gain, belle indifférence, non-anatomical patchy sensory loss, change in boundaries or hypoalgesia, sensory loss that splits at the mid-line on pin-prick or vibratory stimulation, and give-way weakness – have all been examined by Gould et al. (1986). In 30 patients with acute central nervous system damage, these authors showed that 29 had at least one feature of a supposedly non-physiologic nature, and the mean number of supposedly hysterical items per patient was 3.4. These authors conclude that hysteria is easily misdiagnosed if the above signs or items of history are accepted as pathognomonic and that the tests which are said to provide absolute evidence of hysteria lack validity.

Other reasons for not diagnosing chronic pain as psychological in origin include the finding that many patients whose pain was supposed to be due to accidents or injuries and dependent upon their search for compensation continue to have pain long after the legal issues have ceased to figure in their circumstances (Mendelson 1982). The psychological implications of accidents and injury, however, deserve some consideration.

9 Compensation and Motive

As just mentioned, many injured patients lack physical signs, but appear to have so-called "soft-tissue pain" and continue to suffer from pain long after their claims for compensation have been judged and either accepted or rejected. Nevertheless, controversy still exists in many countries about the part played by accidents in promoting chronic pain. Two particular sites of injury, the neck and the back, are most involved in this argument. Cervical sprain injuries are a common consequence of rear-end collisions by motor vehicles. Typical cervical sprain injuries ("whiplash") occur at speeds varying from 8 to 30 kmh. A passenger wearing a seat belt will be held to the seat while the vehicle is propelled forward. When this takes place, the head moves backwards and may be restrained somewhat by a head-rest, but nevertheless can undergo an excessive degree of excursion. The organs that take the strain of hyperextension of the head are the muscles of the neck, which may be torn and bleed. This has been demonstrated experimentally in monkeys by MacNab (1973). Information has accumulated which suggests that a variety of physical lesions in the neck may account for these phenomena. While not all individuals suffer from this disorder after a rear-end motor vehicle accident, perhaps as many as one in seven develop some pain.

Follow-up studies and retrospective examinations of material lead to the conclusion that two factors determine the likelihood of chronic pain after rear-end collisions and somewhat similar sideways collisions with respect to the neck. The first is the prior

history of the individual, i.e. whether he or she has had previous headaches or neck pain or injury. The second is the severity of the pain at the time of impact. Psychosocial circumstances and personality factors have no bearing on the outcome at 6 months (Radanov et al. 1991), but the amount of initial pain influences the occurrence of continuing pain at 6 months after the injury as well as difficulties in concentration and the occurrence of secondary effects such as depression. Of course, anyone may develop a painful syndrome after a relatively minor injury on the basis of hypochondriasis, but the majority of those who suffer chronic pain after cervical sprain injury are likely to have a valid physical explanation for their pain.

This view has been reinforced by the work of Bogduk and his colleagues (Lord et al. 1993), who have demonstrated that anaesthetization of the small medial ramus of the dorsal branch of the cervical afferent nerves as well as the descending branch of the first cervical nerve root will anaesthetize very specifically the zygapophysial joint which it supplies (actually, upper and lower rami have to be anaesthetized for each joint). The zygapophysial (facet) joints are highly likely to be injured in a rear-end collision in which they are strained as the head is thrust backwards on the neck. Bogduk has demonstrated in double-blind controlled trials that patients with chronic pain are highly likely to be able to distinguish long-acting injections from short-acting ones, thus demonstrating that they are not having a placebo response. (The investigators had doubts about the ethics of saline injection alone as a control). Not less than 56% and up to 75% of cervical sprain victims were thus found in their series to have pain from those joints and to be rid of their pain temporarily by this investigation.

There is pathological evidence that pain from cervical sprain injuries may be due to lesions in which the posterior ligament in particular is torn and separated from the disk, or there may be partial lesions of disks with clefts where the ingrowth of small aberrant vessels and nerves will give rise to chronic pain in the neck. This brief sample of the available information may serve to indicate that there is a strong potential physical basis for an illness which has frequently been described as being due to economic or psychological motives.

One study has emerged to challenge these findings scientifically. Schrader et al. (1996) followed up 202 individuals who had suffered rear-end collisions in Lithuania and matched them with a very similar number of controls who had not had such collisions. At the end of between 1 and 3 years of follow-up, they found no difference between the two groups and concluded that the cervical sprain injury "loses its validity". Unfortunately, 80% of the subjects were men, which is unusual in the West, where 60% of individuals with cervical sprain injuries are women. Secondly, the study was retrospective and relied upon asking individuals at least 1 year, and sometimes 3 years later, whether they had had pain 1–3 years previously. Thirdly, and most importantly, it appears that only 31 individuals out of 202 (i.e. 15%) acknowledged any pain at the time of the first injury. About one in seven of individuals who are involved in rear-end collisions actually experience pain from the accident (Bjørgen 1996), while many individuals who are involved in such collisions do not and thus never come to medical notice. Follow-up studies in Australia, Britain, Canada and the United States tend to put the frequency of persistent symptoms at between 10% and 45% in patients seen at hospital emergency departments following motor vehicle accidents. Only a selected sample of individuals in developed countries experience pain in the neck sufficiently badly to attend hospital. The main weakness of the Norwegian/Lithuanian study is that it lacked the power to make the necessary discrimination and it handled its statistics incorrectly (Merskey 1997).

Similar problems of interpretation beset low back pain, which may also follow motor vehicle accidents but is more common after industrial injuries. An extensive study (Bigos et al. 1991) of Boeing factory workers demonstrated that, in a follow-up of a sample of industrial workers, not liking one's job and having a previous accident both contributed towards time off work. The findings were based upon acute absence. It is commonplace that if one does not like one's boss or one's employment, a minor illness will be treated with more concern than if one is keen to get back to work. This has little bearing on the frequency of pain from physical injuries which may cause chronic disability. While there is evidence according to the IASP Task Force (Fordyce 1995) that cases of disability from back pain are rising and this may present a financial burden to a number of countries, the direct evidence that the pain is due to psychosocial factors is weak (Teasell and Merskey 1997). None of the arguments that have been brought forward about the increase in back pain have faced the possibility that this may be due to significant organic processes of the type discussed here. Likewise, they have not taken into account the weakness of the diagnosis of psychological causes in most current clinical cases with chronic pain.

10 Patients with Pain

Who are the patients who complain of pain? A few major groups of patients with chronic pain can be delineated from the experience of pain clinics. The

easiest to identify are those with clear nerve lesions, such as causalgia, a nerve entrapment syndrome, post-herpetic neuralgia, trigeminal neuralgia, etc. These forms of chronic pain attract attention and receive treatment readily from most practitioners. The largest group of patients with chronic pain are those with non-malignant causes of musculoskeletal pain, usually cervical sprain injury or a low back sprain. Patients with chronic pain from disk lesions are rare, except for the few who post-operatively develop complications such as arachnoiditis or the rather larger numbers who have additional musculoskeletal discomforts associated with their disk lesions. These have often been categorized as having "mechanical back pain" or myofascial pain, the latter being identified by the occurrence of taut muscle bands (which are not always reliably found), a tender location over the band or in the muscle and radiation of pain from the site of pressure.

Some patients develop generalized pain affecting both the upper and lower parts of the body and the right and left sides as well as the spinal region. Many such patients, who have no other particular cause for widespread pain, appear to develop it as a result of the existence of chronic pain in one or more areas previously, such pain often following from trauma. In such instances, it is quite common to find that the patient has developed fibromyalgia (FM), defined as diffuse pain with the above characteristics, accompanied by at least 11 out of 18 specific tender points. The significance of this illness has been much disputed, but is becoming clearer. First, diffuse pain and specific tender points may be associated with several types of physical disorder that precipitate the condition. These include rheumatoid arthritis, auto-immune disease and prior chronic pain. When it is present, a sleep disorder consisting of the appearance of alpha-type rhythms in deep sleep (alpha/delta pattern) can be found in a significant proportion of patients (Moldofsky et al. 1975). This sleep pattern is not specific, but is found in many patients with FM and is associated with waking and not feeling refreshed. In addition to the specific tender points, there is usually a widespread lowering of the threshold for pain on noxious stimulation such as pressure. Thus the illness appears to be one of diffuse pain accompanied by disruptions of sleep and the presence of widespread aching in the musculature. In addition, it appears to be associated more often than by chance with auto-immune disease, as already mentioned, migraine, Raynaud's syndrome and the irritable bowel syndrome.

In FM, increases in substance P in the cerebro-spinal fluid (CSF) to a level of two or three times the normal level have been demonstrated in patients and controls in three independent studies (Vaerøy et al. 1988; Russell et al. 1994; Bradley et al. 1996). FM is also associated with a somewhat increased rate of psychological disturbance, but not sufficient to establish that psychological factors are always a cause. Thus, in some studies, the amount of psychological illness has been found to be comparable to that in control patients with rheumatoid arthritis, and in others it has been rather more, but not affecting 100% of patients. It would not be surprising if emotional stress were to exacerbate a physical condition of this type, presumably by way of an effect upon spinal cord dysfunction.

Other musculoskeletal conditions such as rheumatoid arthritis have to be taken into account as causes of chronic pain. Patients with cancer pain comprise a large separate group who are commonly treated by a number of methods, both psychological and physical.

There are four types or groups of patients of psychiatric interest:

1. Minor lesion: emotional exacerbation (very common)
2. Hysterical emulation of pain complaints or factitious simulation (rare)
3. Primary psychiatric illness, e.g. depressive disorder, anxiety state (common in psychiatric practice, less common in pain clinics)
4. Major physical illness: secondary depression or other psychological response (very common)

In the first group, there is a definite physical lesion, e.g. mild post-herpetic neuralgia, which becomes worse if the patient is under stress or in emotional difficulties, depressed or perhaps gaining benefit from the symptom. Next, it is always possible, despite the case made above for organic explanations, that individuals who do not have physical illness may mimic, either deliberately or unintentionally, the experience and complaints of pain of others who do have a physical basis for them. This group does not appear to be large. In the third group of patients who have chronic pain, some will have other independent psychological illness, such as chronic depression, or sub-acute depression, anxiety states, hypochondriasis or "somatization disorder", etc.

The worst problems probably comprise the fourth group, i.e. patients with physical illness that is sufficient to cause disability who develop psychological complications. These patients with severe pain develop depression at about 6 months after the onset of their pain, when several measures have been tried and relief is inadequate. They see themselves losing their income, perhaps losing their houses, unable to support their families, unable to maintain normal sexual and other relationships with their spouse and suffering from broken sleep, difficulty in concentration and a general handicap in running their life. This handicap is poorly recognized by others and often rejected by insurance

companies, workers' compensation boards, etc. The recent tendency is clearly negative in North America towards these patients. In the province of Quebec, in Canada, for example, individuals who have cervical sprain injuries usually cease to receive benefits after they have been paid for 27 days.

The most common association of pain with psychiatric conditions is between a physical illness which has disabled and distressed the patient and the onset of depression. Patients with independent psychiatric illness such as depression from bereavement who receive appropriate psychiatric treatment commonly recover. This is not so for the patients with chronic pain causing psychiatric illness and, indeed, is another reason for supposing that their illnesses are not independent psychiatric conditions and may have a more intractable peripheral somatic basis.

11 Management and Treatment

11.1 Evaluation

Psychiatric management in chronic pain begins with the review of the physical state. Whether a psychiatrist works alone or within the team of a comprehensive pain clinic, he or she should be ready to contribute actively to the evaluation of all types of case. This includes diagnosis, although his or her colleagues in a pain clinic are more likely to be looking particularly for advice on issues of management such as how to respond to the presence of anxiety or depression, what techniques of psychological care should be used and whether supportive interviews, cognitive formulations, assistance with job issues or family matters are required, and of course they may seek information on the use of psychotropic drugs.

It is important to note the pain of which the patient complains and to discuss it as well as the patient's ideas and beliefs about its physical origin. The psychiatrist must also determine whether the physical evaluation is adequate. The fact that there is "nothing neurological" or "no bones broken, no nerve injury, no reflex impairment or nothing more than a so-called soft tissue injury" does not prove psychological causation. "Soft tissue disorder" might include physical damage to small joints, latent damage to larger joints or disks which has not been seen and perhaps also some fibrosis in muscles and around nerves subsequent to the rupture of muscles and bleeding into them. If the psychiatrist accepts the patient as "psychiatric", he or she will have some obligation to produce a cure – which may be much more available for some potential psychiatric causes than for the organic ones at this stage. Psychiatrists must therefore be very cautious in accepting these types of cases for psychiatric care, and if they recognize a physical state on which they can make some useful comments, they should be prepared to do so, without claiming authority in the diagnostic field of another discipline. Further, one should be able to provide a psychiatric perspective which will assist in encouraging treatment of complicating psychological factors in an "organic" case or in minimizing their relevance where psychological factors are perhaps being over-emphasized.

Among physical conditions which I have seen, and which were being misdiagnosed as "neurosis", there are many cases of cervical sprain syndrome, a number of cases of the thoracic outlet syndrome, paroxysmal hemicrania, cluster headache, peripheral neuropathy and the syndrome of painful legs and moving toes. Whether or not there is a physical state which can be recognized, the psychiatrist must be careful and thorough in deciding whether the evidence for psychiatric change in terms of a recognizable psychiatric diagnosis matches the symptoms. There may be some evidence of separate disturbances in a person's life, stress at work, marital problems or failure to achieve adequate relationships at work or in other interpersonal relationships. That may not be enough to match or account for the symptoms for which the individual complains. Whatever the psychiatric diagnosis, it should be reached through standard procedures and treated without prejudice to the possibility of a physical illness being present as well.

Patients who have had chronic pain prior to the onset of depression are likely to have a primary physical problem, and patients who have depression first and then chronic pain may have some or much of their pain as a result of the depression. This is most likely in the case of headache and least likely in the case of unilateral or focal symptoms.

In investigating patients with chronic pain, it is important to take the complaint of pain seriously, to suspend judgement on aetiology until adequate grounds exist for giving the patient information and, if there are no grounds for a firm diagnosis, to say so.

Psychiatrists may also be involved in the management of patients with cancer pain and palliative care. In these settings, psychiatrists often function in three ways. First, there may be patients with formal psychological illnesses which, although recognized by family practitioners and others, seem to need extra help, particularly with the treatment of depression. This will most often be achieved by extending the amount of psychological support and assistance to the patient to adapt psychologically to a changing physical state. Help may also be needed sometimes from the psychiatrist in regard to particular applications of

psychotropic medications, such as phenothiazines for analgesia or a choice of a second or third alternative among anti-depressants. Thirdly, the help of a psychiatrist may be sought in some clinics (perhaps many) in providing support for the professional staff in their continuing exposure to patients with great distress and tragic conditions. This help from professional staff is likely to be in terms of psychological discussion as well as help with particular patients.

11.2 General Management

In a comprehensive pain clinic, a psychiatrist will join his or her colleagues in determining the application of the different measures of treatment that may be employed. Some of these will clearly be specific, and specific diagnoses will lead to appropriate specific treatments. Few of these are psychiatric in nature, except for some types of major depressive illness, but psychotropic drugs or other drugs acting on the central nervous system may often be used. Trigeminal neuralgia can be treated with carbamazepine or other anti-convulsants which have an effect upon it. Cluster headache responds to lithium carbonate among other prophylactic measures, but most perhaps to the withdrawal of nicotine. Chronic paroxysmal hemicrania, a rather rare variant, almost always found in women, can be controlled specifically by indomethacin. Anaesthetists may provide nerve blocks for defined syndromes in particular regions, and repeated nerve blocks, with or without steroids in the injection, can help to produce abatement of pain and enable the patient to progress in physiotherapy. Transcutaneous electrical nerve stimulation (TENS) may be useful and is essentially harmless.

Patients with pain, especially when it is chronic, need support and tolerance. They should be encouraged where possible to undertake specific exercises related to any musculoskeletal area that causes trouble and to improve their general physical state. Management by a physiotherapist for these purposes is often desirable in severe cases. A psychiatrist will be likely to offer additional guidance within pain clinics in the choice of techniques of psychological value.

11.3 Medication

Several tricyclic anti-depressants, including clomipramine, doxepin, imipramine, maprotiline and nortriptyline, have analgesic effects. However, amitriptyline is the tricyclic drug which has the most evidence of proven analgesic actions that are independent of the presence of depression. It is particularly useful in restoring sleep impaired by pain. Its main disadvantage is the tendency it has to promote weight gain. This may be counteracted by skilled psychopharmacotherapy, either with the use of fluoxetine (adjusting the dose because of the interaction of fluoxetine with tricyclics via the P450 cytochrome system) or by the administration of fluvoxamine, citalopram or sertraline to assist in night sedation. Each of these four specific serotonin re-uptake inhibitors, and also venlafaxine and bupropion can be helpful in promoting weight loss in some patients, but none of them has any particular effect on pain, so far as is known, unless the pain itself is due to a depressive illness. Amitriptyline, or a similar tricyclic, is therefore still necessary for many patients despite the side-effects and problems. Neuroleptics, e.g. methotrimeprazine, also appear to have direct analgesic effects in some patients.

Treatment should be comprehensive. The patient's life situation should be looked at as well as the prescription of pharmacotherapy. Some non-psychotropic analgesics may be prescribed by psychiatrists and others. Non-steroidal anti-inflammatory drugs such as naproxen or indomethacin or paracetamol (acetaminophen) should be avoided if possible. All these drugs, even including acetaminophen (paracetamol), are liable to give rise to chronic gastrointestinal problems, most often dyspepsia or ulceration, but not infrequently diarrhoea. The best available non-steroidal anti-inflammatory drugs in North America are the Cox-2 inhibitors, because they have less effect on the stomach than other drugs as they do not inhibit prostaglandins in the stomach wall, but inhibit prostaglandins elsewhere. Drugs which produce muscle relaxation, including baclofen (a γ-aminobutyric acid antagonist), cyclobenzaprine (closely similar in structure to amitriptyline), carisoprodol or hydroxyzine, are used in many countries as adjuvant treatments in patients with chronic pain. Baclofen can cause depression or confusion, while carisoprodol breaks down to meprobamate, and those using these drugs should be aware of these problems.

Most patients coming to the psychiatrist for the treatment of pain have already had a number of these measures, but it pays to review them and to see how carefully they have been employed and whether some small benefits may be obtained by giving the amitriptyline earlier in the evening so that the patient falls asleep when intended and so that the amitriptyline, with its long half-life, does not last too long when he or she is ready to wake up.

Narcotics, including sustained-release preparations of oxycodone or of morphine, are also recommended for chronic non-malignant pain. Acceptance of this is not universal. Patients receiving these drugs should

have had extensive alternative treatment and, ideally, no history of substance abuse.

11.4 Relaxation

Among general measures, relaxation is the foremost. Progressive relaxation was introduced originally by Jacobson (1929). Biofeedback has been widely used, but it seems to be no more effective than relaxation (Jessup et al. 1979; Turk et al. 1979; Nuechterlein and Holroyd 1980). Specific efforts with biofeedback occasionally produce reports of extra benefit, but none seems to have established wide reliability.

Likewise, hypnosis, which used to be a focus of attention and hope in the treatment of chronic pain, has long been found to be extremely sporadic in its effects and generally not worthwhile. Hypnosis also produces little more benefit, if any, than systematic procedures for relaxation. There are those who claim occasional dramatic responses, but results with hypnosis remain unpredictable and unreliable, and occasional cases of apparent great success never seem to be followed through or maintained with other workers. Some current opinion holds that hypnosis amounts only to cooperative role-playing on the part of both patient and physician (Merskey 1995). Used in a non-committal way, hypnosis may be encouraging and helpful to some patients, provided it is not employed for interpretative purposes, regression, memory recall or some of the other activities which have lately made it notorious (Merskey 1996).

11.5 Cognitive Treatments

Cognitive therapy is often linked currently with encouragement of coping mechanisms and behavioural treatment, as already indicated. More pure cognitive therapy without emphasis on deconditioning focuses upon the patient's ideas about himself or herself being insufficiently able to master pain. Controlled studies have given validation to the idea that cognitive treatment is an effective method of assisting patients with pain. It seems unlikely that it can help patients with severe pain as much as those with mild or moderate chronic pain. It is as appropriate to try it in patients who have a physical cause for pain as in those who do not. Misconceptions about pain deserve attention, and fears about pain may be resolved during cognitive therapy which becomes, in that case, virtually identical with the practice of supportive therapy. The aim of cognitive therapy includes encouragement to patients to believe that they are not helpless and that they have some resources and ability to function regardless of pain. This clearly overlaps with support for coping mechanisms and the standard type of sympathetic tolerance, encouragement, guidance and re-orientation which many psychiatrists have long employed. The methods used in these approaches also include emphasis on self-efficacy in the sense of control over aversive stimulation. It is to be expected that they will be helpful and also that they will only assist in adjustment within limits. Support for the patient should also be provided through interviews with other members of the family and consistent recognition that the patient is affected by a disabling and difficult problem.

11.6 Psychological Techniques Overall

Psychological treatment or psychotherapy will attend to the various problems of patients with depression and anxiety on conventional lines. It may be repetitive to say that this will include supportive psychotherapy of the cognitive and interpretive type with attention to social issues and marital counselling and other forms of psychological treatment, whether these approaches are needed because of a physical illness or because the pain appears to be giving rise to significant emotional change. Some influence may be exerted on behaviour by the selection of topics and goals – more often than by providing a formal cognitive or behavioural programme. In my experience, a behavioural technique such as deconditioning is often more appropriate to patients who have associated fear of motor vehicles (where they suffered the injuries which have given rise to their pain) and of driving than in the direct reduction of "pain behaviour", which is, in any case, a concept that is too readily misapplied.

The psychiatrist would obviously participate here in the assessment and provision of rehabilitation plans and in their encouragement. He or she may also look at other issues which occur in patients with chronic pain. For example, many individuals in mid-adult life – particularly those below the age of 55 – form a very gloomy view about their future because they anticipate that their chronic pain will only get worse as they get older. It often helps with patients with chronic musculoskeletal pain related to the spinal axis to explain that these types of pain may not decline dramatically, but that they do decline somewhat over decades. The patient may be more stiff and less mobile, a little more bent in stature, but will not have quite as much pain as currently. This advice is frequently received with a good deal of relief on the part of patients who have anticipated that because most

physical conditions seem to get worse with age, so their chronic pain will inevitably be worse likewise. Other aspects of adaptation to alterations in life will also be needed for patients with chronic pain, and psychiatrists as well as family practitioners and other specialists will be able to add their particular quota to the general support and psychological assistance which should always be offered with medical care of patients with chronic disorders.

Part 1
Schizophrenic, Affective and Related Disorders

CHAPTER 1

A. Jablensky

Symptoms of Schizophrenia

1
Definition of Schizophrenia by Its Symptoms

1.1
Diagnosis

1.1.1 Clinical Diagnosis

A century since the delineation of the diagnostic entity of *dementia praecox*, schizophrenia is still an "epigenetic puzzle" (Gottesman and Shields 1982). It can only be diagnosed by a painstaking analysis of the subjective experience reported by patients, the history and course of symptoms, the observation of behaviour and (to a lesser extent) by evaluation of the pre-morbid development, personality traits and family background. Recent research has highlighted "candidate" biological markers, such as neurocognitive deficits, peculiarities in brain morphology and neurochemical abnormalities, yet none of these variables possesses at present the sensitivity and specificity required of a diagnostic test. Schizophrenia remains, essentially, a clinical entity defined by its symptoms and their course. The existence of a specific disease (or diseases) underlying the clinical entity is a working hypothesis for which definitive proof or refutation is yet to be produced, although the link of schizophrenia to brain disorder is no longer disputed.

1.1.2 Polymorphism of Schizophrenic Symptoms

The symptoms of schizophrenia span the entire range of psychopathology and display an extraordinary amount of inter-individual variation. The diagnostic concept of schizophrenia is an omnibus term for clinical pictures as disparate as the insidious development of the "clinical poverty syndrome" (Wing and Brown 1970) and the expansive delusional preoccupation with themes of cosmic significance. The polymorphism of the manifestations of schizophrenia (incorrectly referred to as "heterogeneity") is an essential feature of the disorder and a persisting irritant to any theories about its unitary nature.

1.1.3 Symptoms as Diagnostic Criteria

The introduction of explicit diagnostic criteria in psychiatry, with their latest versions incorporated in ICD-10 (WHO 1992) and DSM-IV (American Psychiatric Association 1994), was a major advance which reduced semantic variation and the effect of bias due to selective emphasis on particular manifestations of schizophrenia by different "schools of thought".

The diagnostic criteria for schizophrenia proposed since Feighner et al. (1972) have strived to achieve at least three different, not fully compatible goals: (1) to identify groups of patients with similar prognosis (e.g. poor outcome), (2) to define a "heritable" diagnostic category and (3) to enable early diagnosis and treatment. "Narrow" definitions, such as those in the Research Diagnostic Criteria (RDC; Spitzer et al. 1978), DSM-III (American Psychiatric Association 1980) and DSM-IIIR (American Psychiatric Association 1987), were successful in achieving the first goal, simply because they included previous chronicity as one of the diagnostic criteria. As regards the second goal, the evidence is conflicting: the "narrow" DSM-III definition has been associated with a higher heritability in twin studies but not in adoptive, family or linkage studies where higher heritability estimates are obtained with a broader definition. As regards the third goal, the evidence available does not allow us to determine whether the choice of "narrow" versus "broad" criteria, and of the corresponding ratio of false-positive to false-negative diagnoses, is associated with better or worse outcome of early intervention in incipient psychotic illness.

It is now generally accepted that no single symptom is absolutely necessary for diagnosing schizophrenia, and that any subset of symptoms from an agreed list can be sufficient for the diagnosis (this method of classifying is called "polythetic", as opposed to the "monothetic" method, which requires the presence of at least one "strong" indicant; Sokal 1974). In practice, the polythetic definition of the symptomatology of schizophrenia means that patients can be allocated to the diagnostic category without having a single symptom in common. The symptom checklists contained in current diagnostic criteria for schizophrenia (Table 1) treat symptoms as interchangeable, so that the presence of any one, or any two, would suffice for the criterion to be met. As a consequence, the agreement between different operational definitions of schizophrenia in current use is less than perfect. The proportion of patients that are concordantly identified as schizophrenic by the different diagnostic systems can be disappointingly low, not only between different diagnostic systems but also within the same system because different subsets of symptoms can be used for the diagnosis (McGorry et al. 1992). The "polydiagnostic" approach proposed by Berner and Katschnig (1984), in which alternative sets of diagnostic criteria are applied to the same patients in order to identify a "core" group meeting all criteria, is still of uncertain practical value.

Table 1. Symptoms as part of diagnostic criteria for schizophrenia

Diagnostic criteria	Delusions	Hallucinations	First-rank symptoms	Thought and speech disorders	Negative symptoms	Other symptoms
Research Diagnostic Criteria, RDC (Spitzer et al. 1978)	Delusions of being controlled or influenced; bizarre or multiple delusions Somatic, grandiose, religious, nihilistic, or other, lasting for longer than 1 week Any type, if accompanied by hallucinations for longer than 1 week	Non-affective verbal, spoken to the subject Any type throughout the day for several days or intermittently for longer than 1 month	Thought broadcasting, insertion or withdrawal A voice keeps up a running commentary on the subject's behaviours or thoughts Two or more voices converse	Marked formal thought disorder accompanied by either blunted or inappropriate affect, delusions or hallucinations of any type, or grossly disorganised behaviour		
DSM-III-R (American Psychiatric Association 1987)	Delusions Bizarre (totally implausible) delusions for longer than 1 week	Prominent (throughout the day for several days or several times a week for several weeks) Voice having no apparent relation to depression or elation	Voice keeping up a running commentary on the person's behaviour or thoughts Two or more voices conversing	Incoherence or marked loosening of associations	Flat or grossly inappropriate affect	Catatonic behaviour
DSM-IV (American Psychiatric Association 1994)	Delusions present for a significant portion of time during a 1-month period (or less if treated) One delusional symptom required, if bizarre	Hallucinations	Voice keeping up a running commentary on the person's behaviour or thoughts Two or more voices conversing	Disorganised speech Frequent derailment or incoherence	Affective flattening Alogia Avolition	Grossly disorganised or catatonic behaviour
ICD-10 (WHO 1993)	Delusions of control, influence or passivity, referred to body or limb movements or specific thoughts, actions or sensations Persistent delusions of other kind	Persistent hallucinations, any modality, occurring every day for more than 1 month, accompanied by delusions without affective content or by persistent over-valued ideas	Thought echo, insertion, withdrawal or broadcasting Delusional perception	Neologisms, breaks or interpolations in the train of thought Incoherence Irrelevant speech	Apathy Paucity of speech Blunting or incongruity of emotional response	Catatonic behaviour: excitement, posturing or waxy flexibility, negativism, mutism, stupor

1.2 Is Schizophrenia a Disease Entity?

1.2.1 Critique of the Concept

The proposition that clinical pictures as disparate as hebephrenia, catatonia and paranoid psychosis could have anything in common has provoked vigorous debate since its inception. Hoche (1912) compared Kraepelin's theory to the chasing of a phantom. Towards the end of his career, Kraepelin himself changed his point of view and admitted that, rather than being a disease, schizophrenia could be seen as "a common reaction of mankind to the most varied forms of noxious events" (Kraepelin 1920). The protean nature of the symptoms and behaviours embraced by the diagnosis of schizophrenia continues to be the focus of critique.

Modern critics of the concept of schizophrenia advance three main arguments.

1. The concept lacks coherence because of the polymorphism of its attributes – a point which no one at present seems to dispute.
2. A diagnosis of schizophrenia does not predict other attributes (behavioural or biological) of the individuals given that label.
3. No genetic base specific to schizophrenia has been demonstrated to exist, and the findings of family studies (including twin and adoptive data), as well as those of genetic linkage studies, are fully compatible with alternative models.

The solutions proposed by critics are (a) to split schizophrenia into smaller, narrowly defined syndromes which may have discrete genetic and pathophysiological bases, (b) to replace the current nosology with a rehashed "unitary psychosis" concept, or (c) to discard the concept altogether since it is no more than a "social construction" (Sarbin 1990) or a "scientific delusion" (Boyle 1990).

1.2.2 Relevance of the Concept

Whereas each of the critical arguments above has a point, it is hard to see demonstrable advantages stemming from any one of the proposed alternatives. Both "splitting" and "lumping" strategies have been tried before, e.g. by the Kleist–Leonhard school (Leonhard 1995) and the psychobiology school tradition (Meyer 1958), respectively, without substantial advances in the scientific understanding of schizophrenia. Radical calls to dismantle the concept have so far failed to propose a plausible alternative model that would account for the subjective experiences and behaviours we designate as schizophrenic, nor for the consistent observation that about 1% of the population develop such disorders in their lifetime.

Perhaps the strongest evidence that schizophrenia is not an artifactual construct comes from the relative invariance of its clinical presentation and incidence across different populations and over time. Field research carried out by the World Health Organization (WHO) has shown that patients matching the diagnostic concept can be reliably identified in over 20 different populations and cultures and that the incidence of such disorders is within the range of 1.8–4.2 per 10,000 population at risk per year (WHO 1973, 1979; Jablensky et al. 1992). Comparative studies based on hospital archives and on a re-analysis of Kraepelin's own case records (Jablensky et al. 1993; Jablensky and Woodbury 1995) have led to the conclusion that the psychopathological pictures classified as dementia praecox at the turn of the century, and as schizophrenia today, are essentially similar. The ubiquitous occurrence and striking constancy of the manifestations of schizophrenia amid general human diversity has led to the conjecture that they are related in some direct fashion to the "speciation characteristics" of *homo sapiens* (Crow 1997).

1.2.3 Is There a "Basic" Disturbance?

There have been many attempts to define a common denominator for the bewildering variety of the manifestations of schizophrenia. The fundamental disturbance has been sought in "a weakening of the mainsprings of volition" and the "loss of inner unity of mental activities" (Kraepelin 1919), a "structural loosening of associations" (Wernicke 1900; E. Bleuler 1911), a "weakness in consciousness" (Berze 1914), "intrapsychic ataxia" (Stransky 1904) and a "loss of vital contact with reality" (Minkowski 1927). While intuitively appealing, such formulations simply replace one level of description with another.

More recent attempts at reduction involve theoretical models which allow testable predictions to be made. Such models assume that schizophrenia is essentially a cognitive disorder resulting from a "neurointegrative defect" (Meehl 1990), a neurocognitive "vulnerability" (Zubin and Spring 1977; Nuechterlein et al. 1990) or a "misconnection disorder" involving the multimodal association cortices and the basal ganglia (Frith 1992; Hemsley 1994). The predictions that can be derived from such theoretical models are currently generating a substantial body of empirical research.

It remains an open question whether a single basic disturbance or a *causa prima* of the symptoms of

schizophrenia will ever be found. It is possible that the primary genetic, physiological and cognitive deficits are multiple and only loosely related, although they manifest a "common final pathway". It is also possible that the primary deficits are not intrinsically pathological but represent extreme normal variants of structure and function. Their interaction, either additive or non-linear, could produce the diagnostic symptoms, but subclinical manifestations would be detectable in otherwise healthy individuals. There is a fairly convincing evidence of a preliminary nature to support the emerging research agenda along such lines, with "candidate" markers of pathogenetic processes in attention and memory dysfunction, brain morphology and physiology.

To sum up the argument, we do not know whether schizophrenia is a single process with pleiotropic manifestations at the level of cerebral organisation or a collection of aetiologically unrelated but interacting processes. Its manifestations in toto do not fit neatly into any of the current disease models, including the multifactorial ones usually associated with cancer, ischaemic heart disease or diabetes. For the time being, the validity of the clinical construct of schizophrenia is based on a polythetic logic in the sense that we designate as schizophrenia any co-occurring subset of manifestations in the following domains:

- Characteristic symptoms
- Characteristic patterns of course and outcome
- Characteristic brain morphology and neurochemistry
- Characteristic neurocognitive performance
- Characteristic genetic associations

The key word "characteristic" refers to internal consistency and discriminant power vis-à-vis abnormalities associated with other disorders or clinical constructs.

1.2.4 Why Study Symptoms?

In the absence of an identified "basic disturbance" and validated biological markers, the clinical concept of schizophrenia hangs together on the strength of the empirical evidence that its many facets form a broad syndrome with some internal cohesion and a characteristic evolution over time. The evidence is neither final nor static and needs to be re-examined as new concepts and technologies coming from molecular genetics, cognitive science or brain imaging bring forth new perspectives on disease causation and brain function. The construction of "top-down" models based on cognitive theory must be complemented by a "bottom-up" approach involving a reliable and valid description of its symptoms and signs which are the building blocks of the whole edifice. However, the study of symptoms should no longer be purely descriptive. The mapping of clinical phenomenology on specific brain dysfunction (and vice versa) is becoming feasible, and the resulting "functional psychopathology" (van Praag 1993) may substantially recast the present nosology. The dissection of schizophrenia into clinical phenotypes with specific neurocognitive or neurophysiological underpinnings is beginning to be perceived as a promising approach in psychiatric genetics amid growing doubts that the diagnostic categories of DSM-IV or ICD-10 are coded in the human genome.

1.2.5 How to Capture the "Schizophrenic" in the Symptoms

The symptoms of schizophrenia relate to virtually all domains of psychological function. However, the characteristic that sets them apart from other psychiatric disorders is the pervasive way in which they affect the core perceptions of the self and the external world. Scharfetter (1983) coined the term "ego psychopathology" and proposed to group the key symptoms of schizophrenia into five psychopathological domains of ego dysfunction: vitality, activity, consistency, demarcation and identity.

Generally, the manifestations of schizophrenia fall into two large categories: abnormal subjective experiences and objectively observable disorders of behaviour and performance. The characteristic "schizophrenic" quality of the subjectively experienced symptoms can only be grasped by phenomenological analysis (Jaspers 1948) which relies on patients' self-reports, whether spontaneously produced or elicited by means of clinical interviews such as the Present State Examination (PSE; J.K. Wing et al. 1974, 1990). A common denominator for many of the characteristic subjective symptoms is that they represent "disorders of significance" in which the normal categories of cognitive apperception, i.e. time, space and causality, break down or are replaced by a pervasive delusional awareness of connectedness between objectively unrelated events, persons and intentions ("the patient knows there is a meaning but not what that meaning is"; Gruhle 1915). In one of those symptoms, delusional perception, the individual perceptual components are split from their natural context and acquire different properties from those which they have when the normal context prevails (Matussek 1952). In this example, phenomenological analysis suggests the hypothesis of an underlying neurocognitive dysfunction (inability to hold context in working memory) which is empirically testable.

2 Overview of Symptoms

2.1 Classification and Frequency

2.1.1 Ways of Classifying the Symptoms

Different ways have been proposed of classifying the manifold symptoms and signs in schizophrenia (Cutting 1995). E. Bleuler (1911) introduced the distinction between fundamental and accessory symptoms. The fundamental symptoms (loosening of associations, ambivalence and autism) are present, at least to a minimally discernible degree, in every case of schizophrenia and are therefore necessary for the diagnosis. The accessory symptoms, which include hallucinations, delusions and catatonic signs, are much more conspicuous than the fundamental symptoms but are not necessary for the diagnosis, though in the absence of clearly identifiable fundamental symptoms they may be sufficient for the diagnosis.

Other ways of grouping symptoms involve the "positive/negative" distinction (see below) or their temporal sequence (prodromal, acute and residual). However, neither Bleuler's distinction between fundamental and accessory symptoms, nor the positive/negative or temporal sequence schemes are strict classifications based on explicit principles and rules. In the following overview, symptoms are therefore grouped according to domains of psychopathology, beginning with those that are subjective in the phenomenological sense and then proceeding to those accessible to objective observation and measurement.

2.1.2 Most Frequent Symptoms

Figure 1 provides frequency profiles for 44 psychotic and affective symptoms in 1288 patients with schizophrenia (the majority of them experiencing a first psychotic episode) assessed in the WHO ten-country study (Jablensky et al. 1992). The group profiles of patients in developing countries (India, Nigeria, Colombia) are remarkably similar to those of patients in developed countries (Czech Republic, Denmark, Ireland, Japan, Russia, UK and USA). Table 2 lists the 15 most common symptoms along with their frequency at the index psychotic episode and 2 years later in 811 schizophrenic patients evaluated in the WHO International Pilot Study of Schizophrenia (WHO 1973). In most clinical samples, the relatively non-specific psychotic symptoms such as hallucinations and delusions (i.e. accessory symptoms in Bleuler's sense) and negative symptoms such as flat affect, apathy and slowness tend to predominate. However, they are intermingled with "nuclear" symptoms such as delusional mood and thought alienation for which claims of relative specificity have been made.

2.2 First-Rank Psychotic Symptoms

2.2.1 Definition

Kurt Schneider (1950, 1957) proposed that nine groups of symptoms had a "decisive weight" in the differential diagnosis between schizophrenia and affective psychoses and designated them as "first-rank symptoms" (FRS). These symptom groups are as follows:

- Audible thoughts
- Voices arguing about or discussing the patient
- Voices commenting on the patient's actions
- Experiences of influences on the body (somatic passivity experiences)
- Thought withdrawal and other interference with thought
- Thought broadcast (diffusion of thought)
- Delusional perception
- Any other experiences involving "made" volition, impulses and feelings that are experienced as caused by an outside agency

In acknowledging the empirical derivation of the FRS, Schneider noted that they lacked a common structure (admitting nevertheless that some of them could be described as "loss of the contours of the ego") and had no theoretical implications for the understanding of schizophrenia.

The FRS concept, which had been familiar to German-speaking psychiatrists since the 1940s, became internationally accessible largely through the English translation published in 1959 of the 5th edition of *Klinische Psychopathologie* (Schneider 1950), the work of Fish (1967) and the WHO International Pilot Study of Schizophrenia (WHO 1973). At present, FRS are incorporated, explicitly or implicitly, in the RDC (Spitzer et al. 1978), DSM-III and its successors (American Psychiatric Association 1980, 1987, 1994) and ICD-10 (WHO 1992, 1993). Their international promotion since the 1960s was probably due to the sharpness of their definition and the belief that they could be ascertained reliably.

2.2.2 Versions

There are several modifications in the presentation of FRS (Table 3). Mellor's list (Mellor 1970) includes definitions which correspond closely to those of Schneider and are accompanied by illustrative vignettes. Data are provided on their frequency and

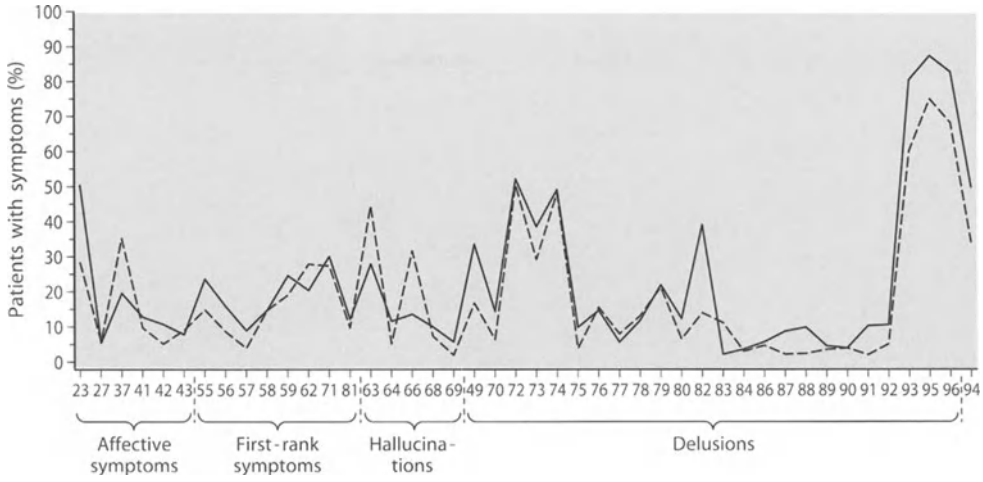

Fig. 1. Frequency of 44 selected symptoms in 551 patients in developing countries (*dashed line*) and 737 patients in developed countries (*solid line*), all meeting ICD/Catego criteria for schizophrenia. *Affective symptoms:* 23, depressed mood; 27, morning depression; 37, early waking; 41, expansive mood; 42, ideomotor pressure; 43, grandiose ideas and actions. *First-rank symptoms:* 55, thought insertion; 56, thought broadcast; 57, thought echo; 58, thought withdrawal; 59, thoughts being read; 49, delusional mood. *Hallucinations:* 62, voices in third person; 63, voices speaking to subject; 64, dissociative hallucinations; 66, visual hallucinations; 68, olfactory hallucinations; 69, delusion of smell; 70, other hallucinations. *Delusions:* 71, control; 72, reference; 73, delusional misinterpretation; 74, persecution; 75, assistance; 76, grandiose abilities; 77, grandiose identity; 78, religious; 79, paranormal; 80, physical forces; 81, alien forces; 82, primary delusions; 83, subcultural beliefs; 84, morbid jealousy; 86, sexual; 87, fantastic; 88, guilt; 89, appearance; 90, depersonalisation; 91, hypochondriacal; 92, catastrophe; 93, systematisation of delusions; 94, evasiveness; 95, preoccupation with delusions or hallucinations; 96, acting out of delusions. Data from the WHO ten-country study on schizophrenia (Jablensky et al. 1992)

Table 2. The 15 most frequent symptoms in a cohort of 811 patients with diagnosis of schizophrenia assessed in the WHO International Pilot Study of Schizophrenia (WHO 1979)

Symptom	Frequency (%) at index psychotic episode	Frequency (%) at 2-year follow-up
Ideas of reference	55.1	18.0
Suspiciousness	60.0	25.2
Delusions of reference	50.3	14.2
Delusions of persecution	48.1	12.7
Auditory hallucinations	43.8	11.6
Verbal auditory hallucinations	37.9	10.7
Voices speak to patient	36.3	9.4
Delusional mood	47.5	10.5
Thought alienation	33.5	7.4
Restricted quantity of speech	17.5	12.9
Flat affect	51.0	27.1
Apathy	30.4	18.8
Lack of insight	82.7	42.5
Inadequate description of symptoms	67.2	25.2

associations in a sample of 173 patients with schizophrenia. The tenth edition of the PSE, incorporated in the WHO Schedules for Clinical Assessment in Neuropsychiatry (SCAN; J.K. Wing et al. 1990) provides a semi-structured clinical interview, a glossary of definitions and rating rules for 11 FRS, but neither the composition of the list nor the glossary definitions are fully identical with those of Mellor.

Table 3. Comparison between three sets of definitions of Schneider's first-rank symptoms (FRS)

Mellor (1970)	Koehler (1979)	SCAN (Wing et al. 1990)
	Delusional continuum	
	Delusional mood	Delusional mood
	Delusional notion linked to, or provoked by, a perception	
Delusional perception	Delusional perception	Delusional perception
Influence on body (somatic passivity)	*Passivity continuum*	
"Made" impulses (drives)	Passivity mood	"Made" impulses
"Made" volitional acts	General experience of influence	Replaced control of actions
Thought insertion	Specific experience of influence	Thought insertion
"Made" feelings	Experience of influenced depersonalisation	Replaced control of affect
	Positive experience of alienation	
Thought withdrawal	Negative-active experience of alienation (includes thought withdrawal)	Thought withdrawal
Thought broadcasting (diffusion)	Negative-passive experience of alienation (includes thought broadcast)	Thought broadcast
	Sense deception continuum	
Voices commenting	Pseudohallucinatory voices (commenting, arguing, audible thoughts)	Voices commenting; loud thoughts; thought echo
Voices arguing	Hallucinatory voices (commenting, arguing,	
Audible thoughts (*écho de la pensée*)	audible thoughts)	Hallucinations of other senses

SCAN, Schedules for Clinical Assessment in Neuropsychiatry.

The PSE Catego (diagnostic categories) algorithm (J.K. Wing et al. 1974), used in the WHO cross-cultural studies, defines a "nuclear" class of schizophrenia (S+) characterised by at least three out of six of Schneider's FRS or, in their absence, by the concurrent presence of other, non-affective hallucinations and delusions.

In reviewing the "boundary criteria" of Schneider's symptoms, Koehler (1979) proposed re-formatting the FRS into three phenomenological continua (delusional, passivity and sense deception). Each symptom can be dichotomised into a "narrow" and a "wide" form. A clinical questionnaire compiled by O'Grady (1990) combines Mellor's set of FRS and the narrow/wide dichotomies.

2.2.3 Critique of the Concept

How well do the FRS perform in clinical practice and research? What is their frequency among schizophrenic patients, and how specific are they for schizophrenia? Critique of the diagnostic utility of FRS has been prompted by exaggerated claims about their "pathognomonicity" (made mainly in the British and American literature; see Andreasen and Flaum 1994) or the lack of adequate evidence (by present-day conventions) in Schneider's own writings to support their reliability and validity (Boyle 1990; Crichton 1996).

2.2.4 Are First-Rank Psychotic Symptoms Pathognomonic?

As regards "pathognomonicity", Schneider's own pronouncements are somewhat inconsistent: within the same chapter they are ascribed both a "strong" role in clinical decision-making ("undisputed precedence when it comes to the allocation of the individual case") and a "weaker" one (as simply having a "special value in helping us to determine the diagnosis"). However, he never referred to them as "pathognomonic" and stated explicitly that FRS may also occur in psychotic states associated with organic brain disease. Their original purpose was pragmatic: "when I find thought withdrawal in a psychosis which has no demonstrable somatic basis, then according to convention I call that psychosis schizophrenia" (Schneider 1957). As regards evidence for their diagnostic utility, the FRS have been more extensively investigated than any other group of symptoms in schizophrenia.

2.2.5 Frequency

The frequency of FRS is not as low as assumed. Allowing for some variation in the inclusion criteria, the prevalence of FRS in clinical populations with schizophrenia is in the range of 35%–68%, i.e. a frequency that is optimal for the use of a likelihood ratio in clinical diagnostic decisions. As Geddes et al.

(1996) point out, the published data suggest a likelihood ratio of about 30. With an a priori probability of schizophrenia in a clinical population of 30%–50%, the ascertainment of FRS would increase the *posterior* probability of a patient meeting RDC criteria for schizophrenia to 85%–95%. With a lower a priori probability of 5%–10%, the posterior probability would still be of the order of 65%–75%.

2.2.6 Specificity

The data available tend to confirm the relative specificity of FRS (Table 4). The positive predictive value (PPV), i.e. the ratio of FRS-positive cases that are "true" schizophrenia (diagnosed according to criteria which do not contain FRS) to all FRS-positive cases is in the range of 0.68–1.00. Allowing for sample size, selection and diagnostic bias, it would still be reasonable to accept that the PPV is no less than 0.80. In other words, the FRS indicate the likely presence of other psychotic symptoms diagnostic of schizophrenia. On the other hand, the absence of FRS (i.e. their negative predictive value, NPV) does not rule out schizophrenia.

2.2.7 Cross-Cultural "Robustness"

FRS are cross-culturally "robust". In clinical studies totalling over 450 cases, FRS have been described in 20%–56% of non-European schizophrenic patients in India (Radhakrishnan et al. 1983), Pakistan (Malik et al. 1990), South Africa (Teggin et al. 1985), Saudi Arabia (Zarrouk 1978) and among immigrants to the United Kingdom (Ndetei and Vadher 1984). In the WHO studies (WHO 1973; Jablensky et al. 1992), the prevalence of FRS (Catego class S+) among patients with ICD schizophrenia ranged from 38% (a rural area in India) to 84% (Nigeria). The subjective reports of patients on such symptoms were strikingly similar.

Moreover, the morbid risk (age, 15–54 years) for Catego S+ schizophrenia in the WHO ten-country study was in the narrow range of 0.27%–0.54%, in contrast to the risk for the "broad" clinical diagnosis, which varied between 0.50% and 1.72%. Thus FRS delineate a subset of cases that would meet criteria for "positive" schizophrenic symptomatology in different populations and cultural settings.

2.2.8 Common Pathophysiology

The cross-cultural "robustness" of the FRS suggests that they may have a common pathophysiological basis, e.g. in a temporo-limbic dysfunction. FRS occur in psychoses associated with temporal lobe epilepsy (Trimble 1990). Catego S+ patients in the WHO study (Jablensky et al. 1992) had an increased probability (relative risk, RR $\geqslant$ 2) of a history of seizures when compared to non-S+ patients. Another possible lead is provided by evidence that FRS may be markers of postsynaptic dopaminergic supersensitivity, as suggested by the significantly increased growth hormone response to apomorphine in Catego S+ patients compared to non-S+ patients (Whalley et al. 1984).

2.3 Prodromal and Residual "Basic" Symptoms

2.3.1 Definition

The basic deficits or basic symptoms (BS; Huber 1983; Süllwold and Huber 1986; Gross and Huber 1995) are conceptually related to Schneider's FRS. They are described as subjective experiences which precede or follow episodes of florid psychotic symptoms in schizophrenia and schizoaffective disorder. As "sentinel" symptoms or prodromes, they may be the earliest precursors of psychosis; and as postpsychotic "pure defects", they are presumed to express aspects of the biological vulnerability to schizophrenia, e.g. subtle impairments in information processing.

2.3.2 Precursors of Psychosis

The BS are not negative symptoms; they have been described as "microproductive" symptoms or as "positive symptoms *in statu nascendi*". As such, they are claimed to be "the real primary symptoms of schizophrenia and the basis of the fluctuating productive psychotic symptomatology", especially the FRS (Huber and Gross 1989). Patients have at least partial insight into them and may develop coping strategies. They can remain compensated in a favourable environment.

2.3.3 Assessment and Measurement

The BS are rated on a continuum ranging from the least specific (level 1) to the most specific or "typical schizophrenic phenomena", which include FRS (level 3). The Bonn Scale for Assessment of Basic Symptoms (BSABS; Gross et al. 1987) contains 98 BS items divided into five groups:

1. Direct minus symptoms (fatiguability, diminished "psychic tolerance", reduced energy)

Table 4. Frequency, positive predictive value (PPV) and negative predictive value (NPV) of Schneider's first-rank symptoms (FRS) calculated from data reported in six studies

Author(s)	Total study population (*n*)	Patients with schizophrenia (*n*)	FRS definition	Proportion of schizophrenia patients with one or more FRS	PPV	NPV
WHO IPSS (1973)	1131[a]	809[g]	CATEGO S (PSE-8)	0.68	0.91	0.51
Carpenter et al. (1973)	165[b]	103[h]	8 FRS (PSE-8)	0.51	0.85	0.50
Radhakrishnan et al. (1983)	266[c]	88[i]	PSE-8	0.35	0.68	0.74
Tandon and Greden (1987)	294[d]	81[j]	SADS	0.51	0.82	0.83
O'Grady (1990)	99[e]	21[k]	Mellor's "narrow" definition	0.62	1.00	0.90
Jablensky et al. (1992)	1288[f]	1087[l]	CATEGO S+ (PSE-9)	0.58	0.87	0.19

[l]ICD-9.

2. Indirect minus symptoms (heightened impressionability, obsessions, depersonalisation phenomena, phobic avoidance)
3. Subjective cognitive disorders, involving (a) thought, speech and memory (lowering of "thought energy", diminished ability for "re-visualisation", impaired ability to comprehend symbols, impaired, false or overinclusive recall of biographical memories, poverty of content of speech), (b) sensory distortions (e.g. acoasms, micro- and macropsies, visual perception of "pseudomovement" or distorted outlines of objects, "aroused state of perceptual awareness", captivation by detail, seeing own face in mirror as changed), (c) motor phenomena (transient motor automatisms, freezing or blockage, loss of normal automated routines)
4. Coenesthesias or alterations of general sensibility (paroxysmal numbing or pains, migrating sensations, "electric" or thermal sensations, sensations of body enlargement or shrinkage, levitation, "dysaesthetic crises" similar to panic attacks, occurring mainly at night)
5. Autonomic symptoms (pupillary abnormalities, hyperhidrosis, vasomotor disturbances, nycturia and polyuria, paroxysmal tachycardia, systolic hypertension)

The description of BS suggests a substantial overlap with symptomatology that is usually classified under the rubrics of anxiety, obsessive-compulsive, somatoform or other neurotic manifestations.

2.3.4 Predictive Value

The clinical epidemiology of BS has been less well studied than that of FRS. The hypothesis that early presence of BS is predictive of later schizophrenia has been tested in an 8-year follow-up of 96 patients with provisional diagnoses of neurotic, mood or personality disorders, of whom 78 had BS on initial examination (Klosterkötter et al. 1997). On follow-up, 58% had either developed Schneider's FRS or otherwise met the DSM-III-R criteria for schizophrenia. All of the patients who made a transition to schizophrenia had had BS at the initial examination, and none of the patients who remained non-psychotic on follow-up had had BS at the initial examination. As screening criteria, the BS performed at the perfect level of 1.0 sensitivity but with low specificity (0.45), which resulted in 23% of the cases being misclassified (false positive for schizophrenia). The predictive value of BS was explained mainly by the subjective cognitive symptoms, such as thought interference and sensory distortions. One cannot, therefore, exclude the possibility that in this study psychotic symptoms had been present but masked by other symptomatology at index examination. Further evaluation of the clinical utility of BS is required.

2.4 Thought, Language and Communication Disorders

2.4.1 Earlier Studies

Kraepelin (1919) paid close attention to thought and speech disorders. Based on his previous research in Wilhelm Wundt's psychological laboratory, he introduced the word association test in the study of dementia praecox. Under the rubrics of disorders of self-expression, internal speech and the train of thought, he described poverty of thought (the "cessation of the need to express oneself"), incoherence, rhyming and word play, stereotypies, derailments, paraphasias and neologisms in ways anticipating present-day concepts. E. Bleuler (1911) regarded the "loosening of associations" as pathognomonic and detectable "in every case and at every period of the illness". Various other facets of thought disorder were described as "alogia" and "paralogia" (Kleist 1930), "overinclusiveness" (Cameron 1939), "concretism" (K. Goldstein 1944) and "cognitive slippage" (Meehl 1990).

2.4.2 Terminology and Classification

Despite the wealth of clinical description, the terminology and classification in this area of psychopathology have been inconsistent. Andreasen (1982) proposed designating this group of disturbances as "thought, language and communication disorders" and, using linguistic principles, divided them into disorders of the following:

- Morphology (word approximations, neologisms, clanging, paraphasias)
- Syntaxis (incoherence)
- Textual discourse (derailment, loss of goal)
- Pragmatics (poverty of speech, poverty of content, pressure of speech, distractible speech)

2.4.3 Measures and Scales

This classification underlies the Thought, Language and Communication (TLC) scales (Andreasen 1979) and the Communication Disturbance Index (CDI; Docherty et al. 1996). The latter is focused specifically on communication pragmatics and includes items such as vague, confused or ambiguous references, missing information and lack of structural clarity.

The Thought Disorder Index (TDI; Johnston and Holzman 1979) is derived from transcripts of subjects' verbatim responses to Rorschach cards, which are rated according to 20 categories.

2.4.4 Linguistic Perspective

It is hard to see whether the different scales measure a common construct. In this respect, psychopathological and neurocognitive research can benefit from a reference standard provided by linguistics. Chaika (1974, 1990) performed linguistic analysis of speech transcripts from patients diagnosed with schizophrenia. She concluded that, from a linguist's point of view, the speech of schizophrenic patients was as rule based and analysable as "normal" discourse. However, it manifested several regularly appearing peculiarities, such as a sporadic disruption in the ability to match semantic features with actual lexical items in the language, production of sentences according to phonological or semantic features of previously uttered words (rather than according to topic) and a failure to self-monitor. None of these features would qualify a "schizophrenic" speaker as linguistically incompetent. Together, the abnormalities seem to point to memory and information-processing deficits rather than to a primary defect in linguistic competence.

2.4.5 Neurocognitive Studies

Neuropsychological research using error detection and semantic priming paradigms provides some insight into the nature of these underlying deficits. Leudar et al. (1994) reported experimental support for the notion of deficient self-monitoring (the internal error detection rate in a sample of patients with schizophrenia was about 50% lower than in the control subjects). Vinogradov et al. (1992) investigated semantic memory in schizophrenic patients using a semantic priming paradigm. Their results suggested an intact semantic memory network and a normal priming effect (reflecting the spread of activation in the network) when "automatic" processing was involved, e.g. in a word pronunciation task. However, no significant priming effects were observed in lexical decision tasks (deciding whether a string of letters is a word or a non-word) which involve "controlled" or post-lexical information processing. Studies of acutely thought-disordered schizophrenic patients suggest the presence of other abnormalities which may be related to their state. "Hyperpriming" was described in such patients by Manschreck et al. (1988), and Spitzer (1997) found an increased indirect semantic priming effect (i.e. an excess of low-probability, unusual or remote responses to primed stimulus words). These findings are consistent with an inhibitory deficit causing hyperactivation in semantic association networks and a consequent lowering of the signal-to-noise ratio.

Drawing on analogies from primate research, Goldman-Rakic (1994) proposed that both types of findings may be related to a primary working memory defect manifesting as an impaired ability to maintain relevant semantic contexts "on line".

2.4.6 Are Thought, Language and Communication Disorders Specific to Schizophrenia?

Such impairments may not be specific to schizophrenia. Studies comparing the speech of patients with different psychotic disorders have failed to produce a clear separation of the schizophrenic patients from the rest, and some of the linguistic features displayed by "schizophrenic" speakers are shared by patients with manic disorder (Docherty et al. 1996). It seems, therefore, that contrary to E. Bleuler (1911), thought and language disorders may be neither fundamental nor pathognomonic for schizophrenia but a secondary expression of a more widespread neurophysiological deficit involving the mechanisms of memory.

2.5 Movement Disorders: Catatonic Phenomena

2.5.1 Definition

Catatonic phenomena, first identified as a clinical cluster by Kahlbaum (1874), comprise disorders of movement, speech and autonomic function. The motor disturbances consist of hyperkinesias (excitement), hypokinesias (inhibition and slowness) and dys- or parakinesias (abnormal postures, loss of the "fluidity" of spontaneous movements, mannerisms, grimacing, staring, stereotypies, iterations). These disturbances are usually intertwined with phenomena described as disorders of volition (negativism, excessive or automatic compliance, echo-phenomena, impulsivity). Catatonic speech disorders include perseveration, verbigeration, echo- or palilalia, aprosody and mutism. Characteristic autonomic signs are dilatation of pupils or anisoconia, seborrhoea, sweating, oedema and acrocyanosis and alterations in muscle tone (rigidity, hypotonia).

2.5.2 Clinical Rating Scales

Two rating scales, the 17-item Modified Rogers Scale (Lund et al. 1991) and the 23-item Bush-Francis

Catatonia Rating Scale (Bush et al. 1996), have been shown to be reliable. A checklist of catatonic signs and glossary definitions is included in the WHO SCAN (J.K. Wing et al. 1990).

2.5.3 Leonhard's Typology of Catatonia

Catatonic signs tend to be underdiagnosed and underreported in clinical populations. In this context, the differentiated typology of catatonic phenomena proposed by Leonhard (1957, 1995) merits a wider clinical use. Within the group of systematic schizophrenias, Leonhard distinguished six types of catatonia:

1. Parakinetic (grotesque distortions or fragmentation of movements and speech which are reactive to external stimuli)
2. Manneristic (predominance of odd stereotyped or stylised movements suggestive of special meaning or purpose)
3. Proskinetic (automatic or impulsive motions triggered by external stimuli)
4. Negativistic (predominance of "contrariness" or resistance to interference)
5. Speech-prompt (disordered speech production provoked by questions)
6. Speech-sluggish (slowing and poverty of speech to the extent of mutism)

It is doubtful that these types constitute independent entities, but their description should help to differentiate catatonic phenomena from other movement disorders such as parkinsonism, tardive dyskinesia or akinetic mutism.

2.5.4 Frequency of Catatonic Phenomena

The evidence suggests that, on proper examination, catatonic signs can be detected in at least 7%–14% of consecutive admissions with diagnosis of schizophrenia (Bush et al. 1996). Such signs were present in as many of 23% of the patients of the pre-neuroleptic era admitted during the 1950s (Fenton et al. 1997). This is comparable with the frequency of 19.5% referred to by Kraepelin (1919). In the WHO ten-country study (Jablensky et al. 1992), the catatonic subtype of schizophrenia was diagnosed in 5.2% among 1151 first-contact patients, but the proportion varied markedly from 10.3% in the developing countries to 1.2% in the developed countries.

2.5.5 Specificity in Schizophrenia

There is a widespread belief that catatonic phenomena are diagnostically non-specific and that schizophrenia is one of the many conditions in which such disorders may occur. Catatonic signs have been described in depression (20% of elderly depressives, according to Starkstein et al. 1996), mania and organic brain disease (a catatonic type was listed as one of the "exogenous reaction types" by Bonhoeffer 1912). However, the published evidence is not fully consistent with this view. In a retrospective cohort of 273 neuroleptic-naïve patients rated for movement disorders, Fenton et al. (1997) found that the only statistically significant association of "spontaneous dyskinesias" was with a diagnosis of schizophrenia, although dyskinesias were also present in 14.3% of the bipolar affective cases. It is possible that the catatonic syndrome includes components which occur predominantly in the context of schizophrenia and autistic spectrum disorders (L. Wing 1996), while other components are shared with motor disturbances in affective disorder (e.g. melancholic stupor) or organic brain disorder such as parkinsonism.

2.5.6 Pathophysiological Basis

The pathophysiological basis of catatonia remains quite elusive. There is a tendency to subsume catatonic phenomena under the extrapyramidal disorders (Rogers 1991), but surprisingly little evidence has been produced that they are "organic" in the neurological sense or that they are strictly involuntary. Catatonic disorders are peculiarly responsive to the environment, as evidenced by patients' subjective reports (Strömgren 1992). Indirect evidence for an environmental effect is provided by the decline in the incidence of the catatonic subtype in "modern" sociocultural settings and its relative persistence in traditional rural communities. Despite their "neurological" appearance, catatonic phenomena may in fact be more closely related to the dissociative disorders. Their designation by E. Bleuler (1911) as "disorders of the will" may therefore be quite appropriate.

2.6 Disorders of Affect and Mood

2.6.1 Fundamental Affective Disturbances

Disturbances of affect are one of Bleuler's "fundamental" disorders in schizophrenia (E. Bleuler 1911). Certainly, abnormalities of affect, emotional response and mood are also among its most visible manifestations, since they are readily elicited in any social situation and permeate the patients' psychomotor behaviour and expression. The profound disturbance

of emotional rapport or of "affective exchange", perceived by a clinically trained interviewer interacting with a patient with schizophrenia, was designated by Rümke (1941) as "praecox feeling" and was considered to be pathognomonic for the disorder. The fundamental affective disturbances that can be described as deficits or negative symptoms include the following:

- Blunted, or flat, affect, including a general diminution of emotional response (flatness) and indifference to events or topics that normally evoke such response
- Incongruity of affect (affect not in keeping with, or not understandable in, its ideational context), also referred to as parathymia when it is a marked and persistent characteristic
- Restricted affect or affective rigidity (lack of modulation of affect)
- Anhedonia (a pervasive and refractory reduction in the capacity to experience pleasure)

2.6.2 Perplexity

Another characteristic symptom, perplexity, or "the oppressive awareness of being unable to maintain a consistent grasp of reality" (Störring 1939) is a mood state with a strong cognitive component.

2.6.3 Dissociation Between Experience and Expression

Although affective symptoms are common and persistent (see Table 2), they have attracted less research than the other negative or positive symptoms in schizophrenia. Some recent research findings on emotions in schizophrenia seem to challenge the conventional clinical view on affective disturbances as a manifestation of inner emotional impoverishment. Thus, while patients exposed to emotion-arousing video segments were rated as significantly less facially expressive of both positive and negative emotions than control subjects, they reported experiencing as much positive and negative emotions as the controls (Kring et al. 1993). Further, the "anhedonia" hypothesis that schizophrenic subjects may be selectively impaired in experiencing positive emotions while not differing from normal individuals in the experience of negative emotions was not supported. This suggests a dissociation between the inner emotional experience, which may be relatively intact, and the outward display of emotion, which is grossly disturbed in schizophrenia.

2.6.4 Frequency of Depressive Mood Disorder

Depressive symptoms are extremely common in schizophrenia and may appear at any stage of the disorder. In the prodromal phase, or in the first psychotic episode, depressed mood can be found in over 40% of the patients (Leff et al. 1988; Bustamante et al. 1994). In the WHO ten-country study (Jablensky et al. 1992), depressed mood was present on initial examination in 50% of the patients in the developed countries and in 30% of the patients in developing countries. Patients with Schneider's FRS tended to have a higher prevalence of depressive symptoms (over 60%) than patients without FRS. During a 5-year follow-up, 15% of the schizophrenia patients developed purely affective episodes (Leff et al. 1992). In the stabilisation phase of schizophrenia, the point prevalence of depressive symptoms is of the order of 30% (Birchwood et al. 1993). The suicide risk is correspondingly high (13%–15% of schizophrenic patients eventually kill themselves; Caldwell and Gottesman 1990) and represents a central problem in the long-term management of patients with schizophrenia.

2.6.5 Heterogeneity of Depressive States

Depression in schizophrenia is heterogeneous. Firstly, depressed mood needs to be distinguished from anhedonia, which is a primary deficit, and from akinetic parkinsonism, which may be a side-effect of neuroleptic treatment. Secondly, when correctly diagnosed, depression may be one of the following:

- A feature of the disease process itself
- A psychological response to the schizophrenic illness as a traumatic life situation (Birchwood et al. 1993)
- A true co-morbid disorder

2.6.6 Schizoaffective Disorder

The high frequency of depressive symptoms in schizophrenia and their temporal relationship to the psychotic phenomena raise doubts about the validity of establishing a separate clinical entity for schizoaffective disorder. The same reservation applies to the diagnostic rules in ICD-10 and DSM-IV, which give precedence to a diagnosis of schizoaffective or mood disorder if characteristic symptoms of schizophrenia or other mood-incongruent psychotic symptoms follow, or co-occur with, a major depressive syndrome. Considering that genes predisposing to mood disor-

ders must be very common, and that they may interact with other common genes associated with the risk of schizophrenia, a phenotypic co-occurrence of schizophrenic and affective symptoms could be expected to be the rule rather than an exception.

2.7 Negative Symptoms and Deficits

2.7.1 Origin of the Concept

A general "weakening" of mental processes resulting in a "defect" was the cornerstone of the construction of dementia praecox out of the previously unrelated syndromes of hebephrenia, catatonia and paranoid dementia. Kraepelin (1919) suggested that precursors of the "defect" could be detected at the earliest stages of the process, co-existing with "productive" or "florid" symptoms. Since the 1970s, the terms "negative symptoms" and "positive symptoms" have virtually replaced "defect" and "productive" symptoms in the literature on schizophrenia. According to Berrios (1985), the terms "negative" and "positive" symptoms were first mentioned by Reynolds in 1858. However, their current usage derives from Hughling Jackson's doctrine of the dissolution of higher nervous functions (Jackson 1887). In the 1960s, J.K. Wing (1961) proposed a symptom profile of schizophrenia consisting of four measures: flatness of affect, poverty of quantity or content of speech, incoherence of speech and coherently expressed delusions and hallucinations. Snezhnevskij (1975) in Russia developed a syndromal scale, based on Jackson's evolutionary concepts, with nine levels of positive syndromes and ten levels of negative syndromes of schizophrenia.

2.7.2 "Type I" and "Type II" Schizophrenia

The present popularity of the terms owes much to an influential paper by Crow (1980), who proposed to simplify the description of schizophrenia by grouping its symptoms and signs as either positive or negative. "Type I" (positive) schizophrenia was characterised by hallucinations, delusions and formal thought disorder, with a presumed underlying dopaminergic dysfunction, as evidenced by the good response of these symptoms to neuroleptics. "Type II" (negative) schizophrenia displayed the "clinical poverty syndrome" (Wing and Brown 1970) with social withdrawal, loss of volition, affective flattening and poverty of speech and thought content. Its response to neuroleptics was poor, and the presumed pathophysiology was associated with structural brain abnormalities, as evidenced in enlarged ventricles and an attenuated inter-hemispheric asymmetry. This typology can be clinically misleading, since it implies that the two clusters or "types" are mutually exclusive, which is certainly not the case (see also Eaton et al. 1995, p. 28).

2.7.3 Assessment

The scales for assessment of negative and positive symptoms (SANS and SAPS) were developed by Andreasen and Olsen (1982) on the basis of factor analysis indicating that the two groups of symptoms loaded on a single bipolar factor and that their extreme forms, similar to Crow's type I and type II, occupied the two ends of a continuum. The claim that the symptoms of schizophrenia could be reduced to a single bipolar factor was subsequently retracted, and the Type I/Type II dichotomy was replaced by three- or four-factor models. However, the SANS and SAPS continue to be widely used in schizophrenia research, providing a "shortcut" to the evaluation of mental state. That such "shortcut" methods are not without a price is illustrated by the findings of Bell et al. (1994), who applied a latent trait logistic model (item-response analysis) to the SANS/SAPS ratings obtained in 149 patients. They demonstrated a high proportion (85%) of threshold order errors inherent in the scales themselves. It is likely that similar scaling problems are common to many of the other instruments offering simple, aggregate measures of psychotic symptomatology.

2.7.4 Are the Terms "Negative" and "Positive" Misnomers?

The negative/positive typology may be contributing to a loosening of the concepts in the clinical description of schizophrenia. In their current usage, the terms are misnomers insofar as they imply a reference to Jackson's concept of hierarchical dissolution of functions (Jackson 1887). According to the latter, negative signs indicate a loss or "suspension" of a higher brain function due to a lesion. A positive sign cannot be caused by a lesion but results from the release of lower-level functions through the removal of inhibitory processes. Negative symptoms, therefore, precede, and could be said to cause, the positive symptoms. Although Jackson's dissolution theory, which was explicitly espoused by Kraepelin (1920), may still have some relevance for the understanding of the symptoms of schizophrenia, the actual usage of the terms negative and positive symptoms is "atheoretical" and purely descriptive. Since no theory-based rule exists for classifying a symptom of schizophrenia as either negative or positive, the placement of symptoms in these categories is by and large arbitrary. In reviewing

the literature, Walker and Lewine (1988) came to the conclusion that only six symptoms were both consistently classified as either negative or positive and included in the widely used clinical scales; a further 19 symptoms were consistently classified but not included, and seven symptoms (including Bleuler's "loosening of associations") were neither consistently classified nor included in rating scales. In many instances, it is hard to see what considerations might help to decide whether a symptom is negative or positive. Thought and speech disorders, as well as catatonic phenomena, which are difficult to place in either group, illustrate the ambiguity of the negative/positive classification. The expectation that the statistical processing of symptoms by factor analysis or other techniques would result in a "natural" classification of schizophrenic symptoms is unwarranted unless the raw data used as input to such an analysis are exhaustive or representative, unbiased by selection and phenomenologically sound.

2.7.5 Primary Deficits

The proposal by Carpenter et al. (1988) to distinguish between primary and secondary negative symptoms is an attempt to refine the classification of negative symptoms. The primary deficit symptoms are "enduring traits" which may precede the initial psychotic episode, are present both during and between episodes, are not accounted for by depression, anxiety or drug side-effects and do not respond to conventional anti-psychotic medication or its withdrawal. They include anhedonia, flat or restricted affect, poverty of content of speech, lack of a sense of purpose and diminished social drive. In the Schedule for Deficit Syndrome (SDS; Kirkpatrick et al. 1989), the presence of any two such symptoms is required for the diagnosis of a "deficit syndrome". In contrast, non-deficit negative symptoms, such as psychomotor slowness, anergia or social withdrawal, lack persistence, fluctuate in severity and show a temporal association with mood states or side-effects of medication. Samples of patients identified by deficit syndrome criteria have been shown to have higher rates of poor pre-morbid adjustment and neurological impairment, as well as lower depression scores and lower rates of alcohol abuse (Buchanan et al. 1990; Kirkpatrick et al. 1996a,b).

2.7.6 A Discrete Syndrome or a Dimension?

Notwithstanding the advantage of defining a core primary deficit, the validity of designating a discrete deficit syndrome, as opposed to a continuous dimension of primary deficits, is open to question. It is conceivable that the primary deficits seen in schizophrenic patients represent the severe end of a continuum which extends to borderline states and to normal temperament and character trait variation. The designing of neurobehavioural probes and psychometric measures capable of capturing such continuous variation could be a promising avenue for research.

2.8 Other Symptoms

2.8.1 Neurological Signs

Neurological abnormalities (both "hard" and "soft" signs) have repeatedly been shown to occur more frequently in schizophrenic patients than in normal control subjects. The difference between schizophrenic patients and controls persists after controlling for effects of medication. The deviations are widespread, but those most commonly ascertained include the following:

- Motor coordination deficits (e.g. dysdiadochokinesia, ataxia)
- Involuntary movements (e.g. choreiform movements)
- Integrative sensory functions (e.g. astereognosis, right–left discrimination)
- Primitive reflexes (e.g. snout reflex)

Patients with neurological abnormalities tend to perform poorly on neurocognitive tasks when compared to patients without such abnormalities and control subjects (Flashman et al. 1996). Perhaps more importantly, neurological deficits appear to be familial, with non-psychotic siblings of patients scoring intermediate between probands and healthy controls (Ismail et al. 1998). It is possible, therefore, that the diffuse neurological abnormalities represent the mildest expression of the genetic vulnerability underlying schizophrenia.

2.8.2 Minor Physical Anomalies

Dysmorphic or dysplastic signs have been described in patients with psychoses since the nineteenth century. Lombroso (1887) took systematically anthropometric measures in institutional populations in Italy and Switzerland and reported an excess of anomalies (especially craniofacial) among the inmates of psychiatric asylums, of whom many were undoubtedly schizophrenic. Using the Waldrop scale (Waldrop

and Halverson 1971), Gualtieri et al. (1982) compared schizophrenic patients with other psychiatric patients and with controls and found higher scores for minor physical anomalies in the schizophrenia group. The majority of the subsequent studies have confirmed the higher incidence among schizophrenic patients, compared to controls, of minor abnormalities including the following:

- High palate, abnormal palate ridges
- Bifid tongue
- Epicanthus
- Protruding ears
- Transverse palmar crease and a decreased total a–b (palmar) ridge count

These abnormalities are not specific to schizophrenia and do not appear to be strongly associated with any of the clinical features or known risk factors (McGrath et al. 1995). Using a refined measurement scale, Lane et al. (1997) identified 12 craniofacial anomalies which reliably distinguished schizophrenic patients from controls. These signs were normally distributed in both patients and controls, with a distribution around a higher mean score for the patient group. It is generally accepted that minor physical anomalies are signs of a "developmental instability", but the exact contribution of genetic and environmental factors, such as obstetric events between 8 and 22 weeks of gestation, is not known (see also Chaps. 4 and 6, Vol. 3, Part 1).

3
Reducing Variation: Grouping and Ordering

3.1
Grouping on the Basis of Clinical Concepts

3.1.1 Bleuler's Fundamental and Accessory Symptoms

Great clinicians are able to grasp "meaningful connections" (Jaspers 1948) – a performance which computers and statistical analysis can only imperfectly emulate but are able to test. There is no scarcity of attempts at reducing the complexity of schizophrenia to simple "laws" on the basis of clinical observation and analysis. One simplification which has not only survived but profoundly influenced present-day thinking about schizophrenia is Bleuler's distinction between fundamental and accessory symptoms (E. Bleuler 1911).

Bleuler's fundamental "four A's" include the following:

1. Loosening of associations (formal thought disorder)
2. Affective disturbances (blunting, flattening, incongruity)
3. Ambivalence (disturbance of volition and behaviour)
4. Autism (withdrawal from reality)

Any of these disorders can vary from minimum intensity (as in "latent" schizophrenia) to maximum intensity (as in schizophrenic psychosis), but they are persistent, never absent and impart on the clinical presentation the specific quality that allows the experienced clinician to diagnose schizophrenia. They take precedence over any other symptoms (e.g. mood disorder) that may be present concurrently and are decisive for the diagnosis. The accessory symptoms, on the other hand, are far more conspicuous and usually dominate the clinical picture without being either specific or necessary for the diagnosis:

- Perceptual disorders (hallucinations and illusions)
- Delusions
- Disorders of memory
- Changes in verbal expression (speech and writing)
- Personality change
- Catatonic signs
- Somatic signs
- Acute states (depressive, manic, catatonic)

The distinction between fundamental and accessory symptoms is purely clinical and should not be confused with Bleuler's less successful attempt to identify aetiologically "primary" and "secondary" symptoms.

3.1.2 Kraepelin's "Registers"

In one of his last journal articles, Kraepelin (1920) questioned and virtually rejected the existence of discrete disease entities in psychiatry (which he himself had promoted) and proposed instead a model based on Jackson's evolutionary concepts. In this model, the major psychopathological syndromes formed an hierarchical continuum ranging from "encephalopathic" mental states associated with organic brain damage to syndromes expressing pre-formed, heritable forms of reaction to noxious events. The psychopathological syndromes were compared with "the different registers of an organ, any of which may be brought into play according to the severity and extent of the pathological changes involved". Kraepelin distinguished three main "registers" of mental disorder:

1. Affective, paranoid and hysterical forms
2. The schizophrenic form
3. Encephalopathic and paroxysmal forms

Pathological processes operating at the encephalopathic or paroxysmal level of disorder usually recruit functions belonging to the higher levels and can therefore manifest schizophrenic, affective and hysterical features. The reverse is not the case: a primary affective or hysterical mechanism of reaction has no means of involving the lower levels. The intermediate position of the schizophrenic "register", on the other hand, implies that its manifestations can combine with either, or both, of the other two levels.

This model is, of course, an over-simplification, but a productive one. It has modern repercussions in the "continuum of psychosis" hypothesis (Crow 1995) and can provide an organising framework for many current genetic and neurophysiological concepts.

3.2 Grouping by Statistical Methods

3.2.1 Need for Data Reduction

Considering the variation in schizophrenic symptomatology, there is a need for data reduction to simplify the description of patient samples and increase the statistical power of clinical and biological studies. Factor analysis has been applied to psychiatric rating scales since the 1960s (Lorr et al. 1963; WHO 1973). A renewed interest in its application to the symptoms of schizophrenia has emerged recently with the availability of desktop computing statistical packages.

3.2.2 Factor Analysis

Essentially, factor analysis and related methods reduce the co-variation of the primary data matrix to a small number of latent variables or "factors" which account for the interrelationships among the primary variables and explain a proportion of their observed variance. By explicating relationships that might remain hidden from inspection or univariate analysis, exploratory factor analysis (EFA) generates hypotheses about dimensions which require replication by confirmatory factor analysis (CFA) and validation against external criteria (which should not be of the original data matrix).

Results of factor-analytical studies of symptoms of schizophrenia are strongly dependent on input. For example, studies using the SANS and SAPS generate factors that are different from those produced by studies using the Positive and Negative Syndrome Scale for Schizophrenia (PANSS) or other instruments.

3.2.3 Three-Factor Model

Based on a relatively small number of input variables (such as SANS/SAPS scores), a three-factor structure has been described by Liddle (1987) and replicated by other investigators (Brown and White 1992; Johnstone and Frith 1996). In this model, the negative symptoms of schizophrenia load on a single factor or dimension ("psychomotor poverty"), while the positive symptoms tend to split into a delusions and hallucinations factor ("reality distortion") and a thought and speech disorder factor ("disorganisation"). However, in comparing Liddle's and several other factorial models based on SANS and SAPS in terms of goodness-of-fit, Peralta et al. (1994) concluded that a four-factor model accorded best with the original data. The fourth factor proposed has been labelled "relational impairment" and involves the SANS items "anhedonia-asociality" (Peralta et al. 1994; Toomey et al. 1997).

3.2.4 How Many Factors?

Generally, the number of factors required to explain the variance is greater when a wider range of symptoms is used as input. For example, the use of the 50 SANS/SAPS items rather than the ten SANS/SAPS global ratings, or of alternative instruments such as the 30-item PANSS (Kay 1990) or the 27-item Comprehensive Psychopathological Rating Scale (CPRS; Åsberg et al. 1978), results in different factor solutions, which include a depressive factor (Kay and Sevy 1990; White et al. 1997; Arora et al. 1997; Salokangas 1997), a cognitive factor (Lindenmayer et al. 1995), a general neurotic factor (Rey et al. 1994) and a pre-morbid social impairment factor (Lenzenweger and Dworkin 1996). Using 21 items of the OPCRIT (Operational Criteria for Diagnosis) symptom checklist, rated on 102 patients with schizophrenia, Cardno et al. (1996) obtained negative, disorganisation and three positive symptom factors (paranoid delusions, FRS subjective thought disorder and FRS hallucinations). Factor solutions therefore are not unique, and the question of how many factors can parsimoniously describe the symptomatology of schizophrenia can only be answered in the context of a particular selection of symptoms and measurement method.

3.2.5 Stability of Factors

Most factor analytical studies have been cross-sectional, based on clinical populations of varying length of illness. One study (Arndt et al. 1995) of recent-onset patients examined the three-factor model based on

SANS/SAPS scores longitudinally over 2 years and found the three factors to vary independently of one another. The negative factor was identifiable at initial examination and was stable over 2 years. In another longitudinal study of recent-onset patients (Salokangas 1997), both the negative symptoms factor and a delusional factor were stable over 5 years. However, factor stability may be eroded over longer follow-up periods.

A prospective follow-up of 90 patients in Madras, India (Eaton et al. 1995), who were rated monthly for PSE symptoms over a 10-year period indicated that the initial two-factor structure of negative and positive symptoms faded in the course of time, evolving into a single factor loaded by both negative and positive symptoms.

3.2.6 Limitations of Factor Analysis

Results of factor-analytical studies of schizophrenia should be interpreted with caution, considering the diversity of clinical populations investigated (in terms of sample size, age, length of illness and diagnostic criteria employed) and the limitations of the instruments used to generate the input data. Measurement errors are bound to result in inconsistencies or in method-related co-variation in the primary correlation matrix of factor analysis which will ultimately affect its output. It is premature, therefore, to refer to the factor output of studies based on measures that may be psychometrically and phenomenologically flawed as established "dimensions" or "syndromes" of schizophrenia.

3.2.7 Cluster Analysis

Whereas factor analysis groups variables, cluster analysis groups individuals on the basis of maximum shared characteristics. Farmer et al. (1983) identified four clusters into which patients with schizophrenia could be grouped according to symptoms. A combination of cluster analysis and multidimensional scaling using SANS/SAPS ratings (Minas et al. 1992) produced four groups of symptoms (negative, thought disorder, hallucinations and delusions and persecutory delusions). In a more recent study (Dollfus et al. 1996), a sample of 138 patients with schizophrenia assessed with the PANSS also yielded four clusters, including one characterised by negative symptoms, one mainly psychotic, one mixed and one oligosymptomatic. The psychotic cluster could be split further into one group with conceptual disorganisation and another with delusions and hallucinations.

Cluster analysis is as dependent on the selection of input variables as factor analysis. Its advantage of grouping individuals, rather than variables, makes it suitable for epidemiological purposes but less so for clinical research focused on disease constructs.

3.2.8 Grade of Membership

A statistical approach which combines the features of factor analysis and cluster analysis is the grade of membership model (GoM), in which psychiatric disorders are represented as "fuzzy sets" (Woodbury et al. 1994; Manton et al. 1994a), allowing individuals to be members of more than one set. The method is computationally complex and was designed to analyse large data sets and to handle categorical variables and missing values. The GoM model simultaneously extracts from the data matrix a number of "pure types" (corresponding to factors in a general sense) and assigns scores describing the degree to which an individual belongs to a pure type. GoM analysis was applied to 1065 patients from the WHO International Pilot Study of Schizophrenia, with ratings on 170 symptoms used as input (Manton et al. 1994a). A statistically optimal solution (maximum likelihood) for schizophrenia was obtained with five pure types, each characterised by a unique set of symptoms. There were two clearly affective pure types (one depressive and one manic) and a "negative" pure type characterised by apathy and restricted speech. The positive symptoms of schizophrenia formed two pure types: one with marked FRS and another characterised by multiple perceptual disorders, depersonalisation–derealisation phenomena and bizarre delusions. When the pure types were correlated with the 5-year course and outcome, the pure type characterised by perceptual disorders, depersonalisation–derealisation and bizarre delusions had the worst prognosis. The potential of GoM to handle complexity in data sets makes it well suited to the study of schizophrenic symptomatology, but its actual applications are still in an initial stage.

3.2.9 General Remarks on Data Reduction

By applying statistical modelling and data analytic techniques to large, clinically well characterised samples, it should be possible to tease out specific dimensions or syndromes within the broad spectrum of schizophrenic symptomatology. This would represent a considerable advance for clinical and biological research, which at present relies mainly on a global diagnosis of the phenotype. However, this goal may not be easy to achieve in schizophrenia. A serious constraint which reduces the power of this strategy to

discover a "natural classification" within schizophrenia is the narrow information base on symptoms due to small or biased samples, selective measurement and the lack of validation criteria.

3.3 Grouping on the Basis of Familial Clustering

3.3.1 Schizophrenia Spectrum

The application of the methods of molecular genetics to the study of the aetiology of schizophrenia in groups of related individuals (entire families, siblings, twins) presupposes an ability to distinguish between "affected" and "unaffected" or "undiagnosed" subjects. Since the results of genetic linkage methods are very sensitive to false-positive identification of individuals as "affected", it would be safe to designate as "affected" only probands who meet restrictive ("narrow") diagnostic criteria, such as DSM-III-R schizophrenia. However, the rarity of families with multiple cases of schizophrenia among first-degree relatives means that samples would be small and the statistical power to detect linkage low. To overcome this limitation, use can be made of epidemiological and family study data which suggest that the genetic influence on the liability to schizophrenia in families is shared with liability to other disorders or syndromes, i.e. that schizophrenia is part of a spectrum of conditions which may have a common genetic basis (Kendler and Diehl 1993). The main criterion for deciding whether a given disorder can be admitted to membership in the schizophrenia spectrum is its relative risk ratio, which compares its prevalence among the first-degree relatives of schizophrenic probands with its prevalence among the relatives of probands with other psychiatric diagnoses or with its population rate.

A number of disorders and syndromes meet this criterion to a varying degree and have been included in the schizophrenia spectrum:

- "Typical" schizophrenia (core member of the spectrum)
- Schizotypal and paranoid personality disorders
- Schizoaffective disorder (depressed type)
- Other non-affective psychotic disorders (schizophreniform and delusional disorders, atypical psychosis)
- Affective disorders with psychotic features

The shared liability to these five disorders, in terms of a correlation coefficient, has been estimated at 0.36 on the basis of an epidemiologically based family study (Kendler et al. 1995). However, while the evidence is strong that "typical" schizophrenia and affective disorders with psychotic features are the two ends of the spectrum, the relative positions of the schizophrenia-like personality disorders, schizoaffective disorder and the mixed group of "other non-affective" psychotic disorders within the spectrum remain ambiguous. Some investigators treat schizophrenia, together with schizotypal personality disorder (SPD), as "hard" spectrum, in contrast to a "soft" spectrum which includes the remaining three and sometimes even further conditions. In all its variations, however, the spectrum concept depends critically on the validity of the concept of SPD.

3.3.2 Schizotypal Personality Disorder

The origin of the concept of SPD, which is the cornerstone of the schizophrenia spectrum theory, is in Bleuler's belief that "there also exist, beyond doubt, latent schizophrenias which never become manifest" (E. Bleuler 1920). "Latent schizophrenia" was listed as a subtype of schizophrenia in ICD-8 and ICD-9. The term "schizotypy" was introduced by Rado (1956) and subsequently adopted by Meehl (1990) to describe a personality type characterised by anhedonia, ambivalence, "interpersonal aversiveness", body image distortion, perceptual anomalies and sensory, kinaesthetic and vestibular aberrations. Along similar lines, Chapman et al. (1982) developed scales to measure perceptual aberrations and "magical ideation" as traits predicting "psychosis proneness". These two constructs were amalgamated with clinical descriptions from the Danish–U.S. adoptive study into a diagnostic category (Kety et al. 1978), which was used to explain the excess prevalence of oddities of personality and behaviour among the biological relatives of adopted children who developed schizophrenia as adults. The diagnostic category was incorporated, with some modifications, into DSM-III and its successors and into ICD-10. The criteria emphasise the following:

- Pervasive social and interpersonal deficits
- Constricted affect
- Odd speech
- Cognitive or perceptual distortions
- Odd beliefs or magical thinking
- Occasional, brief quasi-psychotic episodes

The relatively frequent occurrence of SPD among the first-degree relatives of probands with schizophrenia has been replicated by the majority (though not by all) of the family studies (Kendler and Walsh 1995). There is also some evidence that individuals sampled for presence of SPD features are more likely to have relatives with clinical schizophrenia than control subjects without SPD (Thaker et al. 1993). Overall, however, the evidence that SPD is a well-defined and coherent cluster of traits is not overwhelming. No

population prevalence data are yet available, and the reliability of the diagnosis based on self-report measures has been questioned (Kendler et al. 1996). Twin data suggest that the current SPD criteria may be heterogeneous and that its manifestations fall into a "negative" cluster (odd speech and behaviour, inappropriate affect and social anxiety) that is more common among the relatives of schizophrenic probands and a "positive" cluster (magical ideation, brief quasi-psychotic episodes) that may be related to major affective disorder (Torgersen et al. 1993).

4 Course of Symptoms

The systematic investigation of the course of schizophrenic symptoms was initiated by Kraepelin, who believed that, in the absence of demonstrable brain pathology and identifiable causes, careful observation of the natural history could establish the validity of the disease entity: "The complexity of the conditions which we observe in the domain of dementia praecox is very great, so that their inner connection is at first recognizable only by their occurring one after the other in the course of the same disease" (Kraepelin 1919).

4.1 Adult Schizophrenia

Towards the end of his career, Kraepelin revised his earlier claim that the prognosis of dementia praecox was invariably poor and acknowledged that "permanent cures" had occurred in about 15% of his patients. Many subsequent longitudinal studies have highlighted the wide variability of the course of schizophrenia, which seems to be the most salient characteristic of its natural history. Manfred Bleuler's observations on 208 patients followed up intensively for 22 years or until death (M. Bleuler 1972; M. Bleuler et al. 1976) are worth retaining as an important record of the pre-neuroleptic prognosis of schizophrenia (although some of the patients were medicated at later stages of the follow-up):

- Lasting recovery ("complete cure") in 20%–26%, severe chronic states in 14%–24%
- No further deterioration after the fifth year since onset and development of a clinically stable state in 50%–75% of the patients
- Remitting course characterised by multiple episodes and full remissions in 22%
- Catastrophic course (rapid onset of chronic deterioration) in 4%
- 20-year suicide rate of 14%–22%

4.1.1 Recent Course and Outcome Studies

More recent studies tend to corroborate the pattern of outcomes outlined by the earlier studies. The reported rates of improvement without relapse range from 21% (Bland and Orn 1978) to 30% (Scottish Schizophrenia Research Group 1992), and poor outcome in terms of continuous psychotic symptoms and/or increasing social disability from 24% to 43% (Shepherd et al. 1989).

The prospective WHO studies (WHO 1973, 1979; Leff et al. 1992; Jablensky et al. 1992) provided a cross-cultural database on the course and outcome of schizophrenia which comprises initial and follow-up information on a total of 2736 patients diagnosed as schizophrenic according to strict criteria. The general conclusions of the WHO studies are as follows:

- A wide continuum of outcomes can be observed in patients with similar initial symptom characteristics, ranging from stable recovery after a single psychotic episode to a chronic unremitting psychosis
- The relapse rate for psychotic symptoms tends to increase over time, but their average duration tends to remain stable or to decrease
- Only a minority of patients (22% in the WHO cohorts) experience unremitting psychotic symptoms
- The level of social impairment associated with negative symptoms at 2 years changes little during a 5-year follow-up; most of the clinical change occurs between the 2-year follow-up and the 5-year follow-up and is in the direction of improvement

The recent resurgence of interest in the early detection and treatment of first episodes of psychosis, driven by theoretical considerations and clinical concerns, is supported by empirical evidence suggesting that the pre-onset period is marked by a characteristic sequence of sub-stages (Häfner et al. 1995; Hambrecht et al. 1994) that can be described in finer detail. Plausible clinical considerations have been proposed in support of the view that the first episode of psychosis represents a critical developmental transition that may impact the subsequent course of schizophrenia. Thus clinical research bridging the gap between statistical investigations of risk factors or antecedents of disease and individual pathways to psychotic illness may have an important role to play in understanding and, ultimately, influencing the development and course of schizophrenia.

4.1.2 Stability of Clinical Syndromes

Longitudinal studies suggest that the symptomatology of schizophrenia "breeds true" in the sense that few patients are eventually reclassified into other disease categories following a firm initial diagnosis of a schizophrenic illness. In the 2-year follow-up of the International Pilot Study of Schizophrenia (WHO 1979), 75% of the patients with an initial diagnosis of schizophrenia who experienced relapses of any type had schizophrenic symptoms only, and another 3% had both schizophrenic and other types of episodes. On 5-year follow-up, these proportions were 59% and 17%, respectively, i.e. there was some increase in the number of patients who in the course of time developed other symptoms (mainly affective) in addition to persisting or episodic schizophrenic symptoms. Patients with FRS on initial examination had a relative risk of 2.7 of experiencing the same symptoms at later stages of the disorder compared to patients with no initial FRS (Jablensky et al. 1992).

The most common non-psychotic symptoms developing in the course of schizophrenia are depressive. In the course of 2 years, 17% of the patients in the International Pilot Study of Schizophrenia with a diagnosis of schizophrenia who remitted and relapsed had clear-cut depressive episodes (Sheldrick et al. 1977). This proportion remained unchanged at 15% at the end of the 5-year follow-up (Leff et al. 1992). Similarly, the frequency of major depressive episodes was 24% during the 2–12 years of follow-up in the National Institute of Mental Health (NIMH) study (Breier et al. 1991). These data suggest that depression is part of the clinical spectrum of schizophrenia.

4.1.3 Predictors of Course and Outcome

The predictors of course and outcome in schizophrenia fall into six classes:

1. Socio-demographic and family background characteristics
2. Characteristics of the pre-morbid personality and pre-index functioning
3. History of past psychotic episodes and treatments
4. Characteristics of the onset
5. Symptoms of the initial clinical state
6. Mixed findings related to brain morphology, treatment response and habit behaviour

Many of these predictors have been established independently by different investigators, and there is agreement on the general direction of their effects. Their explanatory power varies depending on the setting, sample size, homogeneity of patient groups, number of predictors and dependent variables and measurement error, but generally tends to be low. Generally, male sex, single marital status, pre-morbid social withdrawal, insidious onset and pre-index chronicity emerge as robust predictors of a poor outcome in the short to medium term (2–5 years), while female sex, being married, having social contacts outside the home and acute onset predict a relatively good outcome (Childers and Harding 1990; Angermeyer et al. 1990; Munk-Jørgensen et al. 1991; Jablensky et al. 1992). In the short term, the best predictor of relapse is anti-psychotic drug withdrawal (Dencker et al. 1986). With the exception of negative symptoms, the initial symptoms of schizophrenia have less predictive power than the variables listed above.

4.2 Pathoplastic Influences on Symptom Expression

4.2.1 Age

Of all pathoplastic influences on the manifestations of schizophrenia, age has the most significant impact. Most studies on the psychopathology of schizophrenia have been based on clinical samples of young adults. However, schizophrenic symptoms may have their onset at any age. Recent research has highlighted more systematically than previous studies the clinical profile of the disorder at a very young age and also after the age of 45. The frequency and severity of the different types of schizophrenic symptoms are age dependent and seem to reflect particular domains of vulnerability associated with the developmental stages. However, the precise nature of the relationship is not yet clear. Notably, this age-dependent expression appears to be much more marked in positive symptoms than in negative symptoms. The latter may occur at any age and show little variation across developmental stages.

4.2.2 Childhood Schizophrenia

Childhood schizophrenia is extremely rare (prevalence of less than 0.9% of all psychiatric inpatient admissions of children under 15; Thomsen 1996). Nevertheless, its clinical manifestations can be distinguished from those of other early-onset disorders such as autism or Asperger syndrome. They show similarity to, and continuity with, the symptoms of schizophrenia manifesting at a later age. Several studies of children with schizophrenia beginning before the age of 12 (Russel 1994; Remschmidt et al. 1994; Alaghband-Rad et al. 1997) indicate that hallucinations in all sensory modalities, delusions (often bizarre or involving childhood themes and beliefs), catatonic signs and

negative symptoms are common. Command auditory hallucinations and visual hallucinations are more frequent in childhood than in schizophrenia of later onset. They may occur in the context of an oneiroid (dream-like) state with a strong affective colouring and are difficult to distinguish from dissociative states and vivid imagery. Thought disorder, however, is rare in schizophrenic illnesses beginning before puberty. Its frequency relative to other symptoms increases sharply in adolescence, mainly in the context of the hebephrenic syndrome, which is also characterised by inappropriate or shallow affect and severe conduct disorder.

4.2.3 Childhood Precursors of Symptoms in Adult Schizophrenia

Both the cognitive and psychomotor symptoms of schizophrenia have early developmental precursors. In the Copenhagen prospective follow-up of 207 children born to schizophrenic mothers, early measures of thought disorder ("vague and drifting thinking" and poverty of speech) were found to correlate positively with adult thought disorder, a finding suggesting that "schizophrenic symptomatology develops by gradual accretion" (Parnas and Schulsinger 1986).

4.2.4 Ageing Process and Symptoms

The effect of ageing on the symptoms of schizophrenia concerns two different issues: the clinical manifestations in elderly patients with an onset of the disorder at a younger age, and the symptom picture of schizophrenia with first onset in middle or older age. As regards the ageing schizophrenic patient, the results of follow-up studies suggest that the florid psychotic symptoms tend to recede and that residual, mainly negative symptoms occupy the foreground (Harvey et al. 1996). Cognitive deficits are correlated with the negative symptoms and may be conspicuous, although the negative symptoms themselves show little or no progression with age. Such symptoms may not be totally irreversible, and remarkable symptomatic improvement (in 24% of patients, according to M. Bleuler et al. 1976) has been described in long-term follow-up studies.

4.2.5 Late-Onset Schizophrenia

First onset of schizophrenia after the age of 65 years has been documented in 4% of males and 18% of females in a community prevalence sample of non-affective functional psychoses (Castle and Murray 1993). The terms late-onset schizophrenia (onset after age 45) and late paraphrenia (onset after age 60) are used somewhat inconsistently to denote syndromes which overlap but may be associated with different causal and risk factors (Almeida et al. 1995). Generally, the late-onset schizophrenia-like illnesses may display any of the symptoms of schizophrenia occurring at an earlier age, including FRS, but usually have several characteristic features (Henderson and Kay 1997):

- Rare occurrence of formal thought disorder and catatonic signs
- Preserved affect (absence of restricted, flat or inappropriate affect)
- Predominance of paranoid delusions and auditory hallucinations
- Schizoid or paranoid pre-morbid personality and social isolation
- Frequent finding of visual impairment or hearing loss

The paranoid ideation often takes the form of the so-called permeable walls or partition delusions (people, substances or forces are entering through the walls). Fantastic delusions and delusional memories are also characteristic and may have a basis in deficits in episodic memory and in recognition memory for faces which have been found in elderly psychotic patients (David and Howard 1994).

4.2.6 Sex Differences

Both brain maturation differentials and environmental influences in pre-adolescence could be expected to result in male–female differences in the presentation of psychotic disorders with an onset in early adulthood. The epidemological evidence suggests sex differences in the population incidence of schizophrenia (higher in males) and affective disorders (higher in females) in 16- to 25-year-olds and a tendency to an earlier onset of schizophrenia in males which may be attenuated by environmental factors (Jablensky and Cole 1997). However, the evidence for a strong pathoplastic effect of gender on the symptoms of schizophrenia and their course is far less clear-cut than might be predicted. There is a tendency for women to have a better premorbid social adjustment (Shtasel et al. 1992), a greater admixture of affective symptoms (Copolov et al. 1990) and better long-term outcomes (J.M. Goldstein 1988), but studies with a focus on specific negative, positive and cognitive symptoms have failed to demonstrate sex differences in their frequency and treatment response (Lindström and von Knorring 1994; Fennig et al. 1995; Pinals et al. 1996). Generally, the data do not support the view (Lewine 1981) that fundamental male–female differences exist in symptom expression in schizophrenia.

4.2.7 Effects of Culture and Ethnicity

The WHO cross-cultural studies of schizophrenia (WHO 1973, 1979; Leff et al. 1992; Jablensky et al. 1992) provide consistent and comprehensive evidence that the symptoms and signs associated with the construct of schizophrenia are basically the same in all populations studied and occur with a similar frequency among people presenting for treatment at mental health facilities. Social anthropologists who have commented critically on some of the conclusions of the WHO studies (Hopper 1991; Edgerton and Cohen 1994) have pointed out (correctly) that the methodology of these studies was "etic", i.e. proceeding from a diagnostic construct which has its historic origin in one culture and seeking to replicate and validate the construct in other cultures. It is theoretically possible that other manifestations of "reality distortion" exist in various traditional cultures but remain undetected or unaccounted for in studies using instruments and symptom definitions that are "ethnocentric". This argument is irrefutable, since it is impossible to design a study that would be exhaustive in investigating, without an a priori hypothesis, all possible mental states and behaviours. However, no evidence has been produced up to date of any culture or ethnic group in which schizophrenic disorders meeting the WHO criteria and description simply do not exist. This is not to say that ethnic variation in schizophrenic symptomatology is non-existent. It has not been systematically explored and its extent is practically unknown.

5 Symptoms and Brain Function

5.1 Neurocognitive and Neurobiological Correlates

5.1.1 Differentiated Symptom Measurement

Some of the symptoms of schizophrenia may be windows to neurocognitive and neurobiological abnormalities involved in the pathogenesis of the disorder. Unfortunately, we do not know which symptoms are best suited for this role, because the greater part of biological and cognitive research in schizophrenia has been conducted on clinical samples defined by diagnosis, without a differentiated subtyping by symptoms or syndromes. Potentially relevant findings from those less numerous studies which have targeted neurocognitive and biological correlates of individual symptoms or areas of psychopathology are reviewed below.

5.1.2 Neuropsychological and Neurocognitive Studies (see Chap. 8, Vol. 3, Part 1)

Certain consistent patterns of abnormalities have been linked to negative or deficit symptoms. Impairment of "executive" functions (categorical reasoning, sequencing and use of representations to guide behaviour) and attention deficits (impairments of selective and sustained attention, reduced processing capacity) have been replicated across studies of patients with "psychomotor poverty" (Gold and Weinberger 1995; Buchanan et al. 1997).

Less consistent findings have been elicited with regard to the neurocognitive mechanisms underlying positive symptoms or the "reality distortion" and "disorganisation" factors. Patients with speech and thought disorder tend to exhibit source memory difficulties and to perform poorly on word generation tasks and on tasks demanding suppression of irrelevant responses. Patients with hallucinatory and delusional symptoms have been shown to be deficient in auditory learning and recognition memory and to perform poorly on eye movement tasks (Strauss 1993). The neurocognitive impairments associated with positive symptoms may be part of an overarching dysfunctional organisation of cerebral activity in schizophrenia which involves functional disconnections between frontal lobe structures (initiation of action) and posterior areas (monitoring and perception of the effects of action). Such disconnection may result in an inability to distinguish between external events and self-generated mental activity (Frith 1992, 1996).

5.1.3 Event-Related Potentials (see Chap. 9, Vol. 3, Part 1)

Electrophysiological measures such as event-related brain potentials (ERP) are sensitive to dysfunctions involving the medial temporal lobe and superior temporal gyrus which are thought to underlie positive symptoms. Thus a well-replicated abnormality in the P50 component (which may reflect a failure in the inhibitory mechanism "gating" sensory input) has been found to be strongly associated with positive symptoms but not with negative symptoms (Waldo et al. 1991). Abnormalities in the mismatch negativity (MMN) wave, linked to an auditory sensory memory deficit, have been found to be negatively correlated with SANS scores (Catts et al. 1995). In contrast, the finding of a prolonged latency of the P300 wave (for which a more widely distributed topography involving the prefrontal cortex is assumed) may be an early sign of cognitive impairment and negative symptoms (McCarley et al. 1997).

5.1.4 Structural Brain Imaging (see Chap. 11, Vol. 1, Part 1; Chap. 5, Vol. 3, Part 1)

Anatomical brain imaging studies involving comparisons between schizophrenic and healthy control subjects indicate grey matter and volume reductions in schizophrenia (Johnstone et al. 1989; Frazier et al. 1996). Most consistently, such reductions have been demonstrated to affect the left hemisphere temporal grey matter and the hippocampus (Mozley et al. 1994; Marsh et al. 1997). However, few studies so far have attempted to relate magnetic resonance imaging (MRI) volumetric changes to particular symptom clusters in schizophrenia. The results are not entirely consistent. Thus at least two recent studies (Turetsky et al. 1995; Wibble et al. 1995) report left temporal lobe abnormalities, rather than the predicted frontal lobe abnormalities, in patients with severe negative symptoms. In subjects mainly characterised by marked positive symptoms, Barta et al. (1990) found a reduced temporal gyral volume in patients with prominent auditory hallucinations, and Rossi et al. (1994) described reduced temporal plane asymmetry in patients with thought disorder. In a recent study of 12 schizophrenic patients, Liddle's three factors were used as co-variates for regional grey matter volume differences. Psychomotor poverty was found to be negatively correlated with volume in a large region of the left ventro-medial prefrontal cortex. Disorganisation, however, was significantly associated with relative increases in regional grey matter volume in the medial temporal cortex bilaterally, which included the hippocampus and the parahippocampal gyrus. No significant correlations, positive or negative, were found for reality distortion (Chua et al. 1997). The results of this study suggest that, although schizophrenic patients as a group tend to have volume decreases in several areas compared to healthy subjects, there may be differences within the schizophrenic group that are related to the predominant clinical symptomatology. In this study, the temporal cortex volume reduction characterising the schizophrenic patients as a group was relatively less pronounced in those patients who had marked thought and speech disorders than in the patients without such symptoms.

5.1.5 Functional Imaging Using Positron Emission Tomography and Single Photon Emission Tomography

Several regional cerebral blood flow (rCBF) studies using positron emission tomography (PET) or single photon emission tomography (SPET) have demonstrated in patients with predominantly negative symptoms, as compared to control subjects, a bilaterally decreased regional activation of the prefrontal cortex during performance of executive tasks. The rCBF reduction in the dorsolateral prefrontal cortex has been found to be particularly significant in patients with marked poverty of speech. Convergent evidence has been contributed by ^{31}P magnetic resonance spectroscopy (MRS) showing a decrease in phosphomonoesthers in the left frontal lobe, correlated with poor executive task performance (Deicken et al. 1995). Such evidence has been interpreted as supporting the "hypofrontality" model of the pathophysiology of negative symptoms in schizophrenia (Weinberger et al. 1986). However, the findings are not consistent and several studies have failed to replicate the hypofrontality effect. More recent interpretations of the PET evidence suggest a major role for an abnormal pattern of functional connectivity between frontal and temporal lobes rather than a circumscribed regional abnormality as a possible correlate of negative symptoms (Liddle 1995, 1997).

PET studies of patients characterised by active positive symptoms report a widely distributed pattern of rCBF decreases and increases which involve the left temporal lobe, left parietal lobe, right medial prefrontal cortex, anterior and posterior cingulate, left ventral striatum and thalamus (Kaplan et al. 1993; Sabri et al. 1997). Experiments attempting to detect a PET "signature" of auditory hallucinations in real time have highlighted a pattern of activation which includes the subcortical nuclei (thalamus and striatum), limbic and paralimbic structures and the orbitofrontal complex (involved in the generation of speech). Group experiments combined with a single case study of a patient with both auditory and visual hallucinations (Silbersweig et al. 1995) led to the tentative conclusion that the generation of hallucinations is associated with activity in the deep brain structures, while their specific perceptual content is determined by activity in the neocortical regions. Failure to activate areas suspected to be related to the monitoring of inner speech (rostral supplementary motor area and left middle temporal gyrus) distinguished patients "prone to hallucinations" from other patients with schizophrenia and controls (McGuire et al. 1996).

5.1.6 Functional Magnetic Resonance Imaging

Functional MRI (fMRI) is a new research tool which provides excellent temporal resolution, uses no radioactive tracers and therefore offers a capacity for practically unlimited serial measurements. Although the number of published fMRI studies on schizophrenic patients (reviewed by Kindermann et al. 1997) is small, the potential of the method has been demonstrated by findings of attenuated exogenous

auditory activation in patients experiencing auditory hallucinations. This is interpreted as an indication of a physiological competition for a common neural substrate between exogenous and endogenous (hallucinogenic) activation (David et al. 1996).

5.2 Current Limitations and Future Prospects of Correlational Studies

5.2.1 Current Constraints

The modest progress in the elucidation of specific pathophysiological mechanisms underlying schizophrenic symptoms is due, in part, to the general constraints of sample size, symptom variability and capacity of the research technology. In addition, there are specific constraints related to clinical assessment, limitations of the neurocognitive and neuropsychological paradigms and limitations of the analysis and interpretation.

5.2.2 "Visualising" Studies

With regard to clinical assessment, the majority of imaging studies use aggregate symptom measures or factors which may be too crude and do not provide an adequate differentiation between relevant clinical states. Few studies have attempted to probe systematically individual symptoms. The few, highly imaginative studies that aim to "visualise" cerebral activation differences linked to the subjective experience of auditory hallucinations tend to rely on the subjects' ability to report such experiences "on line". Such research subjects must be selected for an unusual degree of insight into their own "reality testing" dysfunction. Consequently, it is possible that either the subjective experience reported and "visualised" on functional imaging in such studies is phenomenologically different from hallucinations in the usual sense or that what the method is measuring is activation associated with a high level of self-monitoring.

5.2.3 Need for Specific Neurocognitive Probes

As regards neuropsychological measurement, there is a paucity of validated neurocognitive probes specifically designed for the study of schizophrenic symptoms. The majority of the standard neuropsychological batteries and tests used in schizophrenia research were originally calibrated on brain-damaged clinical populations. The sensitivity of the present neuropsychological tools to detect "differential deficits" in brain functioning related to individual symptoms (as opposed to diffuse impairment) may be too low (Frith 1996; Gur et al. 1997).

5.2.4 Possible Fallacies of Interpretation

Finally, both neurocognitive and dynamic neuroimaging studies tend to reveal a complex picture of distributed activity (Schröder et al. 1996; Andreasen et al. 1997) that has no unique interpretation. The variation in brain activation that is due to processes specific to schizophrenia is difficult to disentangle from confounding variation originating in many other sources, both intra- and extracerebral. At the level of interpretation, predictions based on current cognitive models of schizophrenia often lack the specificity that would match the phenomenological description of symptoms. In the absence of a strong predictive hypothesis and of robust symptom measurement, varying ad hoc interpretations may be fitted to the data.

5.2.5 Possibility and Promise of Correlational Research

Despite such limitations, there is a forming consensus that the identification of neurobehavioural phenotypes correlated with imaging data is possible. For example, one of the few neuroimaging studies comparing rCBF profiles across diagnostic categories (Dolan et al. 1993) led to the conclusion that the dysfunction in the dorsolateral prefrontal cortex, associated with poverty of speech, is related to symptoms rather than to the disease. Such findings are of particular relevance to genetic studies where tentative causal associations are more likely to be found with intermediate "endophenotypes" rather than with the diagnostic category.

Epidemiology of Schizophrenic Disorders

1 Studies of Incidence – Benefits and Problems

The two main measures of rates used in epidemiological studies are incidence and prevalence. The latter is determined both by the incidence of a disorder and by its course, which itself is a product of natural history and available treatments. Hence the interpretation of differences in prevalence rates is far from simple. Consequently, in this chapter we shall concentrate on what has been learned from incidence rates.

The principle value of comparisons of incidence rates is the possible identification of aetiological factors. The aetiology of schizophrenia remains obscure despite decades of research focused on the problem, so that studies of the incidence of the disorder continue to be a prime strategy. We have deliberately referred to schizophrenia as a *disorder* because its status as a disease has yet to be firmly established. There are boundary problems on at least two frontiers: on the one hand with the affective psychoses and on the other with schizophrenia spectrum disorders. Some psychiatrists point to the considerable overlap in symptoms and inheritance of schizophrenia and the affective psychoses and support the unitary psychosis concept, abolishing the Kraepelinian split between dementia praecox and manic-depressive psychoses. Among those who accept schizophrenia as a discrete entity, there are differing views about how narrow or broad the definition should be. There is also increasing support for the heterogeneity of the clinical concept, echoing Bleuler's formulation of a group of disorders under the title of the schizophrenias. The lack of agreement on the definition of schizophrenia has undermined much of the epidemiological research in the past. It has only been the advent of accepted international diagnostic systems, particularly the Diagnostic and Statistical Manual (DSM) and the International Classification of Diseases (ICD), that has enabled the field to progress. In fact, these systems have established a dialogue between epidemiology and classification. Internationally agreed definitions allow the comparison of incidence rates across countries, which in turn reflects back on the definitions, indicating modifications and adjustments.

2 International Studies of Schizophrenia

The first international study of psychoses managed by the World Health Organisation (WHO) was the International Pilot Study of Schizophrenia (IPSS). This pioneering research broke new ground in equipping a group of psychiatrists from nine different countries with the ability to use the same semi-structured clinical interview, the Present State Examination (PSE) (Wing et al. 1974). Data from the PSE were processed by a computerised program, CATEGO, incorporating an algorithm which assigned each patient to a diagnostic class. The application of this reference classification showed that there was close agreement between psychiatrists from seven of the centres in their diagnosis of schizophrenia, with a heavy reliance on Schneider's (1957) first-rank symptoms. The two outliers were Moscow and Washington (World Health Organisation 1973; Leff 1977). Subsequently, diagnostic practices in the United States swung dramatically from a broad concept of schizophrenia to a very narrow one, which is embodied in DSM-III.

The demonstration by the IPSS of reasonable international agreement on the diagnosis of schizophrenia and the value of a computerised reference classification enabled the WHO to proceed with the next epidemiological study, the Determinants of Outcome of Severe Mental Disorders (DOSMD). Whereas the IPSS was designed to compare series of consecutive admissions or contacts with the services in the participating centres, DOSMD had the much more ambitious aim of collecting all psychotic patients in the catchment areas of the centres making contact with psychiatric services during the study period. Thus the samples were intended to be truly epidemiological, allowing a comparison of first contact rates for schizophrenia across centres. One of the main points of interest was to compare rates between developing and developed countries in view of major social and cultural differences between them which might be implicated in aetiology (Sartorius et al. 1986). Consequently, two of the participating centres were in developing countries, Ibadan in Nigeria and Chandigarh in India. Chandigarh was divided into a city, which is relatively developed, and the surrounding countryside, in which a traditional agricultural lifestyle still thrives. The problems of establishing a comprehensive case-finding network in a developing centre are formidable and need to include traditional healers. In the event, it was considered that too much leakage of cases occurred in Ibadan for the data to be included. The results from the other centres are displayed in Table 1.

It is evident that the rates for narrowly defined, Schneiderian schizophrenia (S+ in the CATEGO classification) do not differ across centres (Jablensky et al. 1992). This remarkable finding has attracted much interest, since no other disease has an invariant incidence across the world. This finding suggests that the aetiological factors for Schneiderian schizophrenia

Table 1. First contact rates of schizophrenia per 100,000 population according to different diagnostic definitions (adapted from Jablensky et al. 1992)

Country	Broad schizophrenia (n)*	S+ (n)**	Non-S+ (n)***
Aarhus	15	7	8
Chandigarh rural	42	11	31
Chandigarh urban	35	9	26
Dublin	22	9	13
Honolulu	16	9	7
Moscow	28	12	16
Nagasaki	20	10	10
Nottingham	22	14	8
χ^2	39.8	7.7	61.8

S+, patients with at least one of Schneiders' first-rank symptoms; non S+, patients without Schneiders' symptoms but with other non-affective delusions and/or hallucinations.
*$p < 0.00001$; **not significant; ***$p < 0.000001$; $df = 7$.

are likely to be independent of the social and cultural environment. By contrast, the rates for broadly defined schizophrenia, which include S+ and non-S+ classes, differ significantly. It is curious that in the publications from this study there has been no analysis reported for the non-S+ rates separately from the S+ rates. This analysis is shown in Table 1, from which it can be seen that the greatest variability across centres occurs with this category. There is a fourfold difference between the lowest rate in Aarhus, Denmark and the highest rate in the rural area of Chandigarh. It is likely that variation in the operation of environmental factors between centres accounts for this striking difference in rates. Hence this study illustrates the way in which an epidemiological study can contribute to the diagnostics of schizophrenia. The findings suggest that the broad rubric of schizophrenia encompasses two entities with different aetiologies, Schneiderian schizophrenia and another group including paranoid schizophrenia without first-rank symptoms and catatonia.

3 Environmental Factors as Aetiological Agents and Gender Effects

The only intrinsic aetiological factor that has been identified as important in schizophrenia is inheritance (see Chap. 3, this volume). A number of environmental factors have been suggested as possibly aetiological, but the evidence for each of them remains inconclusive or controversial. Most of the evidence derives from epidemiological studies, which will be reviewed here. Hypotheses concerning physical factors have focused on oestrogens, viral infections in utero, anoxic brain damage at birth and maternal starvation. A protective effect of oestrogens has been postulated as the explanation of the gender difference in the age of onset of schizophrenia. It has generally emerged from epidemiological studies of the incidence of schizophrenia that affected men make contact with the psychiatric services at an earlier age than women, on average about 5 years earlier, although some carefully conducted studies have failed to find this difference (e.g. Iacono and Beiser 1992; Salokangas 1993; Jablensky and Cole 1997). Hambrecht et al. (1992) list the methodological problems of obtaining a true as opposed to a treated incidence rate and suggest that some of the contradictory findings are due to differing proportions of affected people in the community receiving treatment by the psychiatric services. They identify a gender bias in the diagnosis of early cases of schizophrenia as another confounder. For example, Löffler et al. (1994), using the Danish national psychiatric case register, found that, in comparison with PSE-CATEGO diagnoses, females were less often diagnosed as schizophrenic than males.

Häfner et al. (1991a) conducted a large-scale epidemiological study in a catchment area in Germany of 1.5 million people. They collected a sample of 392 people over 2 years who were between the ages of 12 and 59 and who were admitted for the first time with a diagnosis of schizophrenia. Applying a broad definition based on ICD categories, the cumulative incidence rates are displayed in Fig. 1.

The graphs for men and women show clearly the earlier onset in men. However, there is a second peak of onsets in women between the ages of 45 and 59, resulting in an equal lifetime incidence for both genders. Hambrecht et al. (1992) point out that, because women catch up with men only after the age of 45, studies that are confined to subjects younger than this will inevitably find a higher incidence in men. Iacono and Beiser (1992) found no new cases of first-onset schizophrenia after the age of 45, which they attribute to the exclusion of delusional psychosis from their study. Generally, European researchers tend to include late-onset psychoses with predominantly para-

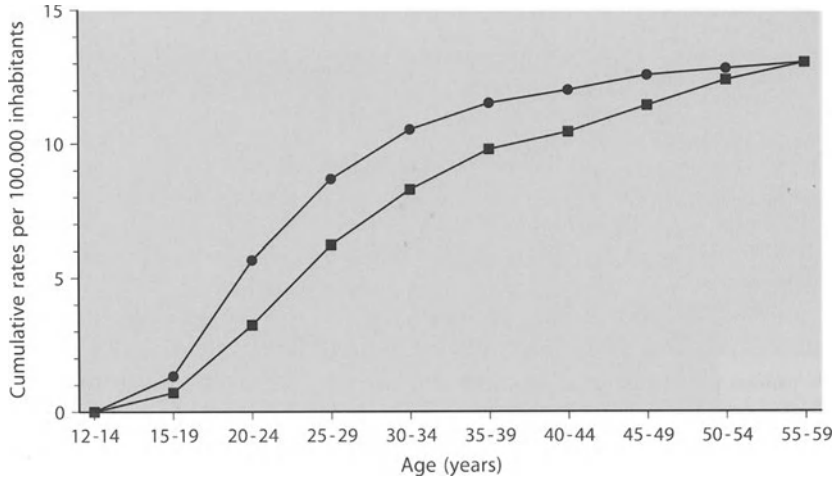

Fig. 1. Cumulative incidence rates for schizophrenia (broad definition; ICD 295, 297, 298.3 and 298.4). *Solid line*, males (patients in 2 years, 187; total population, 707,905; total rate, 13.21%); *dashed line*, females (patients in 2 years, 205; total population, 780,300; total rate, 13.14%). The source of data was a representative first-admission sample (1987/1989). The catchment area was Mannheim, Heidelberg, the Rhine-Neckar district and the Eastern Palatinate (Häfner et al. 1991b)

noid delusions in their series, which increases the incidence rate in women.

Hambrecht et al. (1992) have postulated that the delayed early onset in women is due to a neuromodulatory effect of oestrogens on the sensitivity of dopamine-2 receptors in the brain. This would also account for the late rise in incidence for women after the menopause. Häfner et al. (1991b) tested this hypothesis in animal experiments and found, as predicted, that long-term exposure to 17-β-oestradiol-2 reduced dopamine induced behaviour. Post-mortem striatal binding experiments with [^{3}H]sulpiride showed reduction of D2 receptor sensitivity in the brain as a result of the exposure to oestradiol. These findings are of great interest, but clearly need to be replicated.

A recent study by Jablensky and Cole (1997) merits presentation in some detail because it involves analysis of one of the largest data sets available. This comprises 1431 individuals with a first onset of schizophrenia collected for the WHO ten-country study of the incidence of severe mental disorders (Jablensky et al. 1992). A sequence of log linear models was fitted to the data to determine the contribution of gender, marital status, family history of mental illness, premorbid personality and setting (developed versus developing countries) on the age of onset. The results showed that marriage had a much larger effect on age at onset than gender. On average, marriage delayed the onset by 5 years for women and more than 8 years for men. In one of the log linear models, the effect of gender was replaced by the effects of the interaction between gender and marital status, and gender and centre. This apparently protective effect of marriage on the onset of schizophrenia is liable to a variety of interpretations, but it does throw into question biological explanations for the link between gender and age of onset.

4 Season of Birth Effect and Viruses as Aetiological Agents

A possible pathogenic environmental factor that has attracted interest as a result of epidemiological studies is the influenza virus. The hypothesis that this might be involved in the aetiology of schizophrenia was engendered by the uneven distribution throughout the year of the births of people who later developed schizophrenia. There has been an interest in the months of birth of schizophrenic patients since the 1930s, partly because these were readily available from the records of psychiatric hospitals. One of the earliest statistical analyses of a number of data sets was conducted by Barry and Barry (1961). They emphasised the importance of multiple independent studies with geographically separated samples because of the possible effect of local factors on the prevalence of mental illness, the policy on hospital admissions and the monthly distribution of births in the general population. Since their pioneering study, a substantial body of research has been built up which satisfies their recommendations. Studies have been conducted in many different countries, including some in the southern as well as the northern hemisphere, with the same excess appearing in the winter months. The most recent review has been that by Bradbury and Miller (1985), which demonstrates that this phenomenon is one of the most widely replicated findings in the epidemiological research on schizophrenia. However, the explanation for it remains elusive. Lewis

(1989) suggested that it might be an artefact resulting from the fact that more patients born in the early part of the year are likely to be included in a sample because the risk for schizophrenia increases with age. However, Rodrigo et al. (1992) carried out a study of season of birth controlling for the age–incidence effect and still found an excess for the months of January and December. The link between season of birth and influenza epidemics is at best associational, showing that women who were pregnant at the time of a major epidemic are more likely to produce offspring who later develop schizophrenia than those who were not exposed.

Few studies present unequivocal evidence that the women in question actually suffered an influenzal infection. One of the most solid is the analysis by Crow and Done (1992) of a prospective sample of children born to mothers in the United Kingdom in March 1958. Fortuitously, these children would have been in the second trimester of pregnancy during the 1957 influenza epidemic. Crow and Done failed to find an excess of schizophrenia in the offspring of those mothers who reported having had influenza at the time. McGrath and Castle (1995) point out the unreliability of mothers' recall of whether they had had influenza some months previously and recommend that future studies should document aetiological evidence of an antibody response to the influenza virus. In the absence of this vital evidence, Mednick et al. (1988) caution that the association could be mediated by over-the-counter drugs taken by the mothers to relieve symptoms of influenza or the high fever developed.

Two factors have been identified which modify the season of birth effect: gender and place of birth. McGrath and Castle (1995) draw attention to the fact that, in five out of the six studies in which the effect of gender was examined, the positive association found was mainly or exclusively in females. This finding has been repeated in a study from Japan (Kunugi et al. 1995) which was not included in the review by McGrath and Castle. These results suggest that female foetuses are more vulnerable than males to whatever pathogen is operating during pregnancy. The other factor concerns urban as opposed to rural births. Machón et al. (1983) were among the first investigators to link the season of birth effect to place of birth. They studied a sample of children at high risk for schizophrenia because they were born to mothers with severe chronic schizophrenia. The proportions of the high-risk children who developed schizophrenia were 23.3% for winter urban births, 8.4% for non-winter urban births, 0% for winter rural births and 6.3% for non-winter rural births. The association between winter births and urban place of birth was significant. This finding has been replicated by Takei et al. (1995) for England and Wales and O'Callaghan et al. (1995) for Ireland. One interpretation is that infectious diseases are transmitted more easily in the dense populations of towns than in the countryside.

In order to investigate this possibility directly, Verdoux et al. (1997) used data from public departments of psychiatry in metropolitan France. They related the month of birth of 4139 schizophrenic patients to the density of population in the administrative region in which they were born. Patients born in the five most densely populated areas were 1.21 times more likely to be born during the winter months than those born in other areas. This effect was not found to differ between males and females. The authors acknowledge that the specific environmental risk factor or factors underlying the winter birth excess in urban areas have not yet been identified, but consider that sociological factors are implausible because they would not preferentially affect subjects born in the winter. The association between the urban excess of schizophrenic patients making a first contact with the psychiatric services and sociological factors was one of the first observations to interest psychiatric epidemiologists. It has been neglected for many years, since the explanation was generally believed to have been established, but there has been a recent revival of interest in this topic.

5 Distribution of Schizophrenia in Cities

The classic work on the ecology of schizophrenia was conducted by Faris and Dunham (1939) in the city of Chicago. They found that the distribution of mental hospital admissions for schizophrenia was not random, but was concentrated in the "zone in transition", an inner city ring immediately adjacent to the centre in which there was a high level of social deprivation. Two contrasting explanations have been advanced for this finding, which has been extensively replicated in developed countries. The social breeder hypothesis states that poor social conditions lead to a higher incidence of severe mental illness, while the social drift hypothesis, first proposed by Myerson (1940), attributes the accumulation of severely mentally ill in inner cities to a descent down the social scale. After decades of controversy about the evidence for and against each of these hypotheses, the argument appeared to be clinched by two studies with unequivocal findings. Dunham (1965) conducted a study in the city of Detroit in which he documented the length of residence of patients making a first contact with the psychiatric services. He focused on two areas, one with a high rate of schizophrenia, the other with a low rate.

He found that the excess rate was entirely contributed to by patients who had moved into the area within the past 5 years. These mobile people were mostly born in places other than large cities and were of a lower social class than the residentially stable patients. In fact, the mobile patients were responsible for the excess in the lowest social class found by Dunham in his sample. Dunham's study of geographical drift was complemented by a study of social drift by Golberg and Morrison (1963). They compared the social class of young men admitted to a mental hospital for the first time with the social class of their fathers at a comparable age. They found the usual excess in social class V for the young men, whereas the social class distribution of their fathers did not differ from that of the general population. They concluded that the young men had started to drift down the social scale before they developed overt signs of schizophrenia, usually in early adolescence.

These two studies were generally accepted to have resolved the controversy, and little work was done in this area for many years. However, it is rash to assume in psychiatry that one or two studies can settle the dust on an ideological argument, and contradictory evidence has been appearing lately. Lewis et al. (1992) used data from a cohort of over 49,000 male Swedish conscripts which was linked to the Swedish National Register of Psychiatric Care. Men who were brought up in cities had an incidence of schizophrenia which was 1.65 times that of men who were reared in the countryside. After adjusting for possible confounding factors, including family finances, a family history of mental illness and parental divorce, the odds ratio was reduced slightly to 1.57, which was still highly significant. An urban excess of this magnitude is common in the literature, but in this sample could not be explained by geographical drift, since all the urban patients had been brought up in cities since their childhood. Castle et al. (1993) used a case-control design to investigate the same issue. They utilised the Camberwell Case Register to identify schizophrenic patients making their first contact with psychiatric services and selected the next non-psychotic patient on the register matched for age and sex as a control. Cases were more likely than controls to have been born in an inner city area and to have fathers whose occupations were manual rather than non-manual. These observations contradict the hypotheses of social and geographical drift and suggest that socio-economic deprivation during early life predisposes to the later development of schizophrenia. These findings reopen an area of research and demand further work, but if correct, would implicate some social or physical factor or factors in the urban environment in the aetiology of schizophrenia. Proponents of the viral hypothesis view them as supportive evidence for their theory.

6 Food Intake During Pregnancy

Another environmental factor that has been invoked is maternal nutrition during pregnancy. The opportunity to explore this arose out of a tragic occurrence during the Second World War when a Nazi blockade of Holland was set up. Between 1944 and 1945, famine conditions existed in the west of Holland. Susser and Lin (1992) studied the birth cohorts from these years and compared cohorts exposed to severe food deprivation with those not so exposed. The authors found that birth cohorts exposed to severe food deprivation during the first trimester of pregnancy showed a greater than twofold increase in admissions for schizophrenia, although this was found to apply only to women and not to men. The apparently specific vulnerability of the female foetus to poor maternal nutrition echoes the finding that females rather than males show the season of birth effect. The possible pathogenic effect of poor maternal nutrition requires confirmation, but it is difficult to imagine another situation in which famine was so clearly delimited in time.

7 Is the Incidence of Schizophrenia Falling?

So far we have considered variations in the incidence of schizophrenia which point to possible aetiological factors. However, there have been recent claims that the incidence of schizophrenia generally is falling. If this were correct, it would have enormous implications for the provision of psychiatric services as well as stimulating a search for the possible reasons for the decline in incidence, although no explanation has been proposed by those who have documented the decline other than a suggestion that schizophrenia is becoming a milder disease and hence those affected are less likely to contact psychiatric services. Because of problems of changing methods of ascertaining cases and of assigning diagnoses over time, the most reliable technology for investigating temporal variations in incidence is the case register. Der et al. (1990) reviewed six studies documenting a decreasing first admission or first contact rate for schizophrenia, three from Scotland and one each from Denmark, Australia and New Zealand. They mounted their own investigation using data on admissions obtained from the Mental Health Enquiry for England and Wales. They identified a problem in distinguishing first admissions from readmissions, a common source of error with this type of data (Ni Nullain et al. 1987). Der et al. grouped together schizophrenia, schizoaffective psychosis and

paranoia and found a considerable decrease in first admissions between 1970 and 1986. They concluded that possible artefacts did not entirely account for this decline. However, the Mental Health Enquiry data were derived from psychiatric departments throughout the country and the diagnoses were recorded by hundreds of different people, not all of whom were psychiatrists.

Changing fashions in diagnosis could constitute the major explanation for this finding. Kendell et al. (1993) analysed first-admission rates for schizophrenia and other psychoses in Edinburgh between 1971 and 1989. The inception rate for schizophrenia fell significantly over this period, but they found evidence that the diagnostic criteria had narrowed during this time and also drew attention to the fact that a substantial and changing proportion of recorded first admissions had had previous admissions. For these reasons, they considered that it was not possible to conclude that the incidence of schizophrenia had fallen. Case register diagnoses are the responsibility of a small number of people and hence tend to be much more consistent than hospital admission diagnoses. Since the review by Der et al. (1990), analyses of data from three case registers have been published. Data from the case registers in Nottingham (Harrison et al. 1991) and Camberwell (Castle et al. 1991) in the United Kingdom showed no decline in the incidence of schizophrenia over time, whereas a decline was indicated by data from the nation-wide case register in Denmark (Munk-Jorgensen and Mortensen 1992). An intriguing possibility raised by Castle et al. (1991) is that a decline in the incidence of schizophrenia affecting the majority white population may be obscured by a high incidence in Afro-Caribbeans who migrated to the United Kingdom in the 1950s.

8
High Rate of Schizophrenia in Afro-Caribbeans

A number of studies showed a high incidence of schizophrenia in the Afro-Caribbean population in the United Kingdom (Cochrane 1977; Rwegellera 1977, Dean et al. 1981). These early studies used hospital admission diagnoses or unstructured interviews, so the results were suspect. In recent years, a series of studies has been published which have employed standardised interviewing and diagnostic techniques and have been rigorously conducted. The first of these was sited in the WHO centre in Nottingham (Harrison et al. 1988) and found incidence rates in the Afro-Caribbean population that were remarkably higher than those for native whites. Using ICD-9 or DSM-III criteria, the rates for the age-groups 16–29 and 30–44 were 12 to 13 times higher than among whites. The calculation of the denominator for the two ethnic groups was based on data derived from a survey of heads of households, which may have led to some inaccuracies. In addition, the numerator for Afro-Caribbeans in the age-group 30–44 was only seven. Consequently, doubt has been cast on these extraordinarily high rates. Two subsequent studies used data from the 1991 census to calculate the denominators, which are likely to have been more accurate as this was the first census in which respondents were asked to ascribe their ethnicity. King et al. (1994) found that the incidence of schizophrenia for the Black population in a district in north London was four times that of the whites. They included Africans and Afro-Caribbeans in their Black sample, which numbered 24 in all. They also calculated the incidence for the Asian population, which was even higher than that of the Black group, but was based on only eight patients. Bhugra et al. (1997) also determined incidence rates for a variety of ethnic groups in London, in two districts in the south and east. They found that the rate for Afro-Caribbeans was twice that of the whites, being based on 38 patients. The rate for Asians was based on 24 cases and was slightly but not significantly higher than that for whites. It is noteworthy that most of the Afro-Caribbean patients in the two recent studies were born in the United Kingdom.

These findings are supported by one study outside the United Kingdom, in the Netherlands. Selten and Sijben (1994) used data from the Dutch national register to determine first-admission rates for schizophrenia for four immigrant groups, those from Surinam, the Dutch Antilles, Turkey and Morocco. The age-stratified rates for people from Surinam and the Antilles were from twice to five times the rates for the native-born. Young males from Morocco also had very high rates, but those for the other ethnic groups did not exceed the rates for the native-born. This study is not as rigorous as the two recent British studies, as the researchers relied on hospital diagnoses rather than standardised interviews. Nevertheless, this body of work taken as a whole indicates an exceptionally high incidence of schizophrenia in Afro-Caribbeans who have migrated to Europe or who are born of migrant parents. While other migrant groups have elevated rates, they do not appear to have the same level of susceptibility as Afro-Caribbeans. The fact that these high rates persist in the second generation rules out the stress of the migratory experience as an explanation. Another possibility is a high rate of schizophrenia in the West Indian islands, but two epidemiological studies, in Jamaica (Hickling et al. 1996) and Trinidad (Bhugra et al. 1996) have shown that the rates there are not elevated. Selective migration remains a possible explanation, but is less plausible for the second generation than for the first, and moreover the incidence of mania is also several times higher in the

Afro-Caribbean population in the United Kingdom than among the whites (Leff et al. 1976; Harrison et al. 1988). Hence it would have to be postulated that people of schizoid and of cyclothymic personality were more likely to migrate than the rest of the West Indian population.

The most likely explanation is that factors in the social or physical environment are responsible for the excess rate of schizophrenia, although it will be necessary to identify factors that operate differentially on Afro-Caribbeans as opposed to other ethnic minority groups that do not show such an excess. Substance abuse, particularly cannabis, has been suggested as a cause of the high incidence rate, but there is no evidence that more U.K. Afro-Caribbeans smoke cannabis than U.K. whites. These findings direct attention again to the possibly pathogenic environment of deprived inner cities, as these are where the recent migrants settle. This area is deserving of further research, as it holds out the hope of illuminating the aetiology of schizophrenia.

9 Is Schizoid Personality Related to Schizophrenia?

The hypothesis of selective migration raises the question of the relationship between schizoid personality and schizophrenia. Kraepelin (1913) first introduced the idea that the personality changes which can be detected well before the onset of frank schizophrenic symptoms are likely to be a manifestation of the same causes as the psychosis. In a historical review of the field, Kendler (1985) noted that there have been two conceptual trajectories, one concerned with schizoid traits in relatives of schizophrenic patients, the other with borderline personalities. The latter term has been applied to people who are not necessarily related to schizophrenic patients, but who are deemed to show the fundamental features of chronic schizophrenia without any of the characteristic signs or severe deterioration. Kendler pointed out that there has often been a failure to distinguish between these different concepts, leading to confused thinking and equivocal findings.

Kety et al. (1971), in the Danish adoption study, stated that they were operating on the hypothesis that schizophrenia need not be transmitted as such, but could appear as a broader spectrum of disorders. They coined the term "schizophrenia spectrum", which has been used in subsequent family studies. Spitzer et al. (1979) used data from the Danish study to develop personality inventories for schizotypal personality and borderline personality, which were to be incorporated in the Diagnostic and Statistical Manual. Kendler (1985), in reviewing the criteria employed by Kety and colleagues for "spectrum disorder", identifies some as defining schizoid traits to be expected in relatives of schizophrenic patients, such as social isolation, aloof/cold affect and suspiciousness, and others which characterise borderline personality, such as magical thinking, recurrent illusions and ideas of reference.

Kendler et al. (1995) have attempted to clarify this area by determining the ability of a broad range of schizotypal factors to discriminate between the relatives of patients with various psychiatric conditions and relatives of normal controls. The data they used for the analysis were derived from the Roscommon Family Study, which is being conducted in a relatively poor, rural county in the West of Ireland. Roscommon is one of the counties covered by the Three County Case Register, established in 1973. Patients with psychosis and those with major affective disorder were ascertained from the case register, and age- and sex-matched controls were identified from the electoral register. Interviews were conducted with all probands and their first-degree relatives over the age of 16. The interviewers, who were blind to the diagnosis or control status of the respondents, used the Structured Interview for Schizotypy (SIS), which comprises 14 symptoms and 11 signs.

Factor analysis of the data on 1272 relatives revealed seven distinct factors, indicating the complexity of the construct. The relatives of patients with schizophrenia were most clearly differentiated from the relatives of controls by four factors: odd speech, social dysfunction, avoidant symptoms and negative symptoms (poor rapport, aloofness/coldness, guardedness and odd behaviour). Borderline symptoms failed to discriminate usefully, confirming the distinction made by Kendler (1985) in his historical review. The SIS factors showed some ability to discriminate relatives of schizophrenic patients from relatives of patients with affective disorders, but the distinction was not as clear as from relatives of controls, weakening the specificity with which these factors reflect a familial vulnerability to schizophrenia. Kendler et al. (1995) point out that a major component of the SIS factors were signs as opposed to symptoms, which would inevitably be omitted from self-report questionnaires. This study represents a major advance in illuminating the complex nature of the concept of schizotypy and in identifying the key signs and symptoms to be ascertained in relatives of patients with schizophrenia.

10 Conclusions

This review has highlighted an increasing research interest in using epidemiological techniques to search

for the causes of schizophrenia. This is certainly due in part to the ground-breaking international studies of schizophrenia initiated by WHO. While epidemiology can do no more than indicate potential candidates for aetiological factors, the studies reviewed have thrown up a number of innovative hypotheses which will undoubtedly be explored experimentally in the near future. They have also opened up old controversies about the role of social deprivation, which deserve renewed interest alongside the burgeoning of biological investigations.

Genetics, Risk Factors, and Personality Factors

1 Introduction

It is no longer heresy to state that schizophrenia has a neurobiological basis (Henn 1995) and that the most convincing risk factor is genetic loading for the disorder (Eaton et al. 1995). A recent workshop on schizophrenia recommended that a major focus should be on the search for predisposing genes and that there should be parallel research in many other areas (Barondes et al. 1997). Theorizing about schizophrenia now seems to have abandoned fiction and to have rediscovered facts. The fact is that, of all the currently known risk factors for the disease, genes are the most important: winter birth, stressful life events, unmarried, and low economic status increase the relative risk for schizophrenia by 1.1, 2.7, 2, and 4 respectively, whereas inferred genetic factors lead to relative risks ranging from 10 to 50 (Häfner 1987; Eaton et al. 1995; Jablensky 1995). Today, no serious scientist denies the importance of genetic factors in schizophrenia, while the magnitude of the genetic contribution is still a matter of debate with estimates ranging from low (Torrey 1992) to completely genetic (McGuffin et al. 1994). Heritability was estimated to lie between 70% and 89% (Rao et al. 1981; Risch and Baron 1984; Farmer et al. 1987).

We shall briefly summarize the current state of knowledge about the effect and likely chromosomal locations of schizophrenia risk genes (for reviews, see Propping 1989; Gottesman 1991; Kendler and Diehl 1993; Moises 1995; McGuffin and Owen 1996; Vogel and Motulsky 1996; Moldin and Gottesman 1997; Plomin et al. 1997).

2 Formal Genetics

2.1 Involvement of Genes in the Etiology of Schizophrenia

Whether genes are involved in the etiology of schizophrenia can be answered by controlling for gene dosage as the independent variable and observing the risk for schizophrenia and related disorders as the dependent variable. Genetic similarity and hence the number of risk genes for schizophrenia (gene dosage) increases from biologically unrelated (adoption studies) to biologically related individuals of a schizophrenic proband (family studies) and reaches its maximum in monozygotic twins (twin studies).

2.1.1 Adoption Studies

Adoption studies (Heston 1966; Tienari 1991; Kendler et al. 1994; Kety et al. 1994) are especially valuable to examine separately genetic and environmental factors. Extensive adoption studies in Denmark observed a significantly greater prevalence of chronic schizophrenia and spectrum disorders in biological relatives of adoptees with chronic schizophrenia compared to controls. Interestingly, the Finnish study found that most of the psychotics lived in disturbed adoptive families, while similar family situations in the control group did not lead to psychoses (Tienari et al. 1994). The findings are consistent with genetic control of sensitivity to the environment (Wahlberg et al. 1997).

2.1.2 Family Studies

The risk for developing schizophrenia increases with the degree of genetic similarity to a schizophrenic relative (see Fig. 1), severity of illness (Schulz 1932; Kallmann 1938), and age of onset (Kay 1963). The sex difference in age of onset is smaller in cases with a high genetic load (Häfner and an der Heiden 1997). All these factors can be interpreted as the result of a gene-dosage effect. A larger number of schizophrenia risk genes result in earlier onset, reduced sex differences, a more severe course of the disease, and a higher risk for family members.

2.1.3 Twin Studies

The similarities in gene dosage between members of monozygotic (100% identical) and dizygotic twin pairs (50% on average) can be used to estimate the "relative powers of nature and nurture" (Galton 1875), assuming that there is no systematic difference in environmental factors between these two twin types. A review of the six most recent twin studies reveals a median concordance rate for monozygotic twins of 48%, approximately three times the corresponding rate for dizygotic twins (17%), suggesting that genes play a significant role in the pathogenesis of schizophrenia (Gottesman 1991). In summary, adoption, family, and twin studies demonstrate that genes play an important role in the pathogenesis of schizophrenia.

2.2 Environmental Risk Factors

A monozygotic concordance rate of 48% strongly implicates a role for nongenetic factors. Nearly one

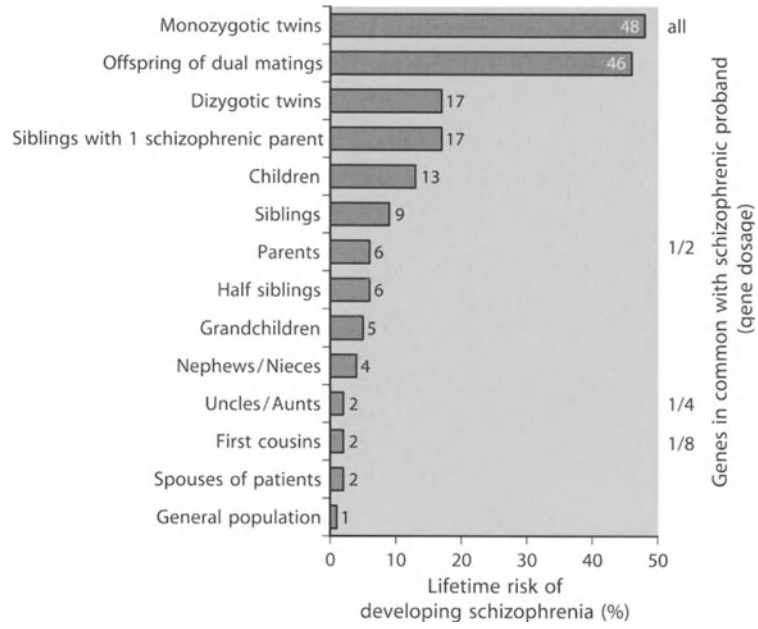

Fig. 1. Average risks for developing schizophrenia compiled from the family and twin studies conducted in European populations between 1920 and 1987. (Adapted from Gottesman 1991)

quarter of the total liability to schizophrenia has been found to be due to chance environmental factors, where as the importance of shared familial environmental factors seems to be marginal (McGue et al. 1983; Heath et al. 1989). It is possible that "nongenetic" factors consist entirely of stochastic events affecting gene expression or structure (McGuffin et al. 1994; Woolf 1997). The facts do not support any purely psychological or environmental theory of schizophrenia.

Environmental risk factors possibly contributing towards the liability to schizophrenia, or to its release, include stress in the form of life events (Norman and Malla 1993) or disruptive patterns of emotional expression within families (Bebbington and Kuipers 1994; Tienari et al. 1994; Wahlberg et al. 1997), winter birth (Machon et al. 1983; Pulver et al. 1990; Beckmann and Franzek 1992), maternal virus infections, pregnancy, and birth complications (Cardno and McGuffin 1996). The winter birth effect might be explained by an intrauterine viral etiology of schizophrenia during the second trimester of gestation, a critical period for brain development due to extensive neuronal migration. Stress has never been shown to cause schizophrenia but to trigger a new acute psychotic episode in individuals already suffering from the disease.

In the future, the identification of risk genes by molecular genetic methods (see below) will provide the means for searching for environmental risk factors in genetically sensitive individuals. Since it is easier to change the environment than to change genes, this knowledge might be the key to the prevention of schizophrenia.

2.3 Number of Genes Involved

Family data are in agreement with models involving two loci (oligogenic model) or numerous genes of small effect (polygenic model) (Risch 1990; Gottesman 1991), whereas the results of linkage analyses suggest, depending on the criteria employed, at least two (Moldin and Gottesman 1997), eight (see Fig. 2) or more vulnerability-increasing genes for schizophrenia.

2.4 Transmission of Schizophrenia Genes

The multifactorial-polygenic model (MFP) of schizophrenia developed by Gottesman and Shields (1967) has survived three decades of testing by segregation and linkage analyses and is therefore most likely to be correct (Moises 1995). Although monogenic or single major locus models (SML) of schizophrenia cannot be ruled out for some families or postulated subforms such as periodic catatonia (Leonhard 1979), they seem unlikely to be correct for the large majority of schizophrenia patients (Risch 1990). Additional factors, such as heterogeneity and anticipation, have been postulated, leading to more complex models.

Etiological or genetic heterogeneity of schizophrenia has often been hypothesized (e.g. Bleuler 1911; Tsuang et al. 1990) and has especially been emphasized by the

Fig. 2

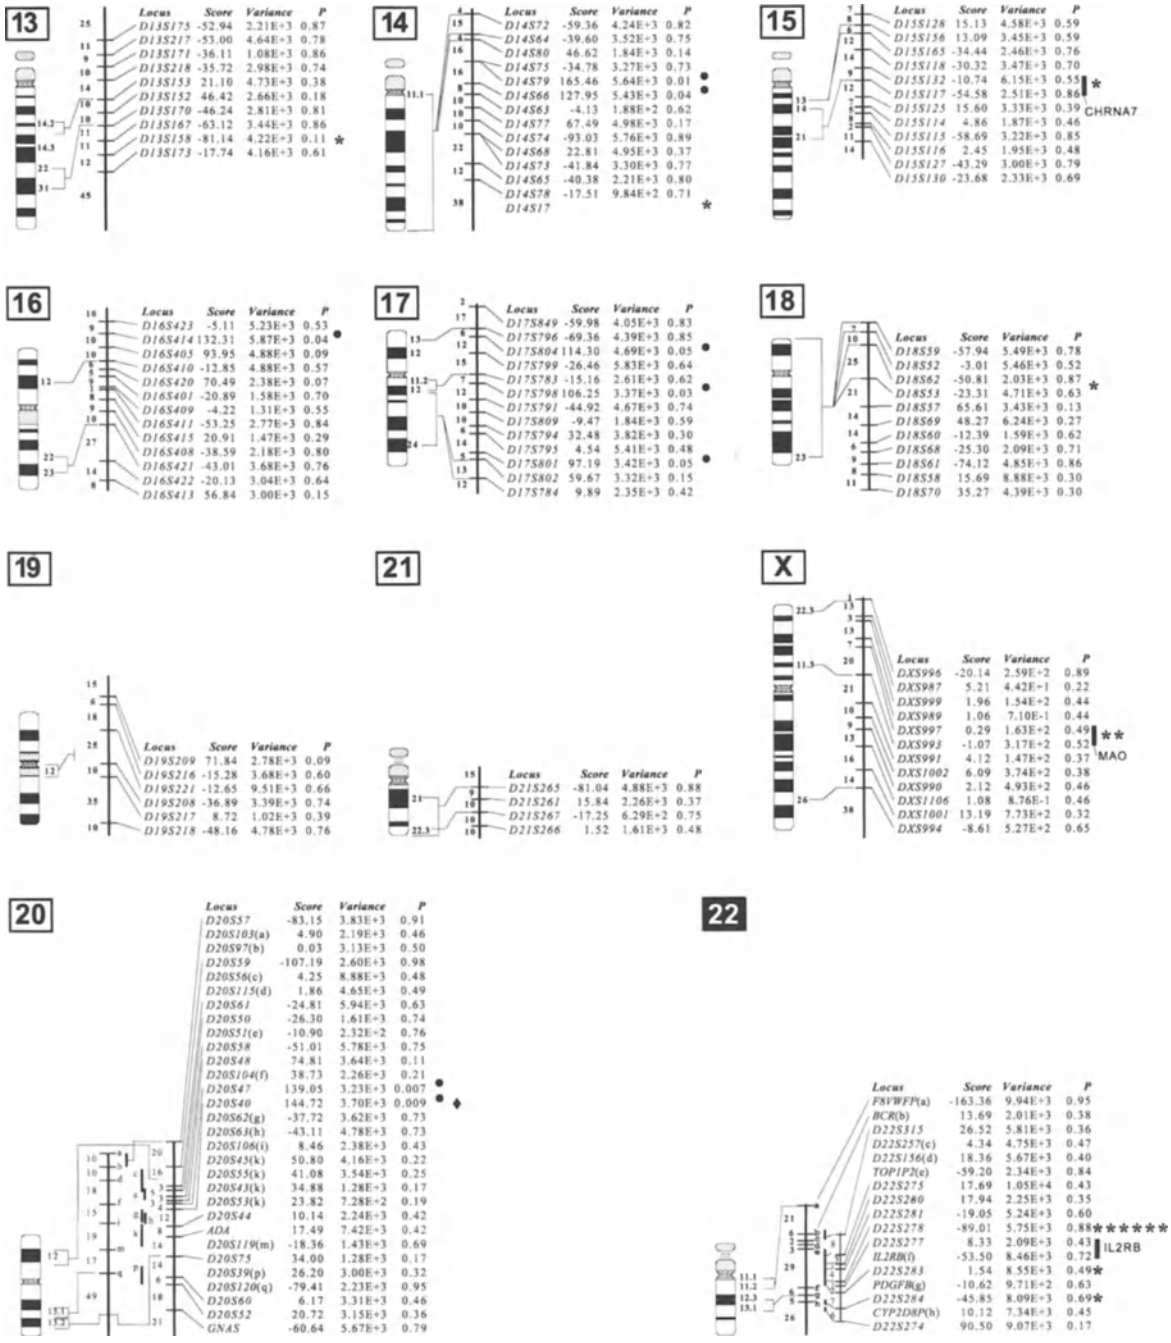

Fig. 2. Genome-wide probability map of schizophrenia susceptibility genes. Each *dot*, *diamond*, or *asterisk* represents evidence for linkage from independent samples. *Dots* (as well as score, variance, and *p* value) and *diamonds* display the results of stage I and II, respectively, of the two-stage genome scan by Moises et al. 1995a, *asterisks* the results from other studies (see Table 1) with lod scores ranging from 1.0 to 6.49 or *p* values from 0.05 to 0.000001 (chromosome 2). Eight chromosomes, highlighted in *black*, show clustering of positive linkage results (defined as $p < 0.05$ or lod score > 1.0) in the same region from at least two independent groups of investigators and therefore have a high probability of harboring susceptibility genes for schizophrenia. (Adapted from Moises et al. 1995a with the kind permission of *Nature Genetics*)

Wernicke-Kleist-Leonhard-Beckmann school (Leonhard 1979; Beckmann et al. 1996), while others found evidence in favor of continuity between affective disorders and schizophrenia (Crow 1986; Maier et al. 1993). The cloning of risk-increasing genes will provide powerful tools for testing these hypotheses.

Anticipation, defined as an increase in severity and a decrease in age of onset across generations, has been observed in all clinical studies (e.g. Thibaut et al. 1995; Bassett and Husted 1997; Johnson et al. 1997). In several monogenic neuropsychiatric disorders, anticipation is caused by unstable DNA, an expansion of triplet repeats such as CAG or CTG through consecutive generations leading to dysfunctional proteins (Petronis and Kennedy 1995). The molecular search for triplet expansions in schizophrenia has so far yielded negative results with two exceptions (Morris et al. 1995; O'Donovan et al. 1996).

2.5
Phenotype Corresponding to the Schizophrenia Genotype

In families and twins, Eugen Bleuler and Essen-Möller observed an extension of the schizophrenia genotype to schizophrenia-like personality disorders, the so-called schizoid disorders (Essen-Möller 1946). Adoption studies and blindfolded family studies later confirmed this concept in the form of schizophrenia spectrum disorders, including schizophrenia, schizoaffective psychosis, and paranoid, schizoid, and schizotypal personality disorders.

Several phenotypes serving as intermediators between genes and clinical disease, termed "endophenotypes" (Gottesman and Shields 1972) or "vulnerability markers" (Nuechterlein et al. 1990), have been postulated in schizophrenia, e.g. schizothymic constitution (Kretschmer 1925), Minnesota Multiphasic Personality Inventory (MMPI) psychometric index (Moldin et al. 1990), reduced reaction time for modality shift (Maier et al. 1994), structural brain abnormalities (Cannon and Marco 1994), reduced span of apprehension (Suslow and Arolt 1996), auditory event-related potentials (Frangou et al. 1997), backward masking performance (Green et al. 1997), P50 auditory-evoked potential gating deficit (Freedman et al. 1997), and deviant smooth-pursuit eye movements (SPEM) (Holzman 1992). For the latter two phenotypes, chromosomal linkages have been reported (Arolt et al. 1996; Freedman et al. 1997).

3
Molecular Genetics

3.1
Genes Predisposing to Schizophrenia

If risk genes play a significant role in the etiology of schizophrenia, as numerous formal genetic studies have demonstrated beyond doubt, one of the most important steps to follow is the identification of risk genes and their function. The development of recombinant DNA technology (S.N. Cohen et al. 1973) and genetic maps (Botstein et al. 1980) laid the foundations for identifying genes involved in schizophrenia. The positional cloning strategy (Collins 1992; Ghosh and Collins 1996) offers a straightforward approach for identifying risk genes. It has been successfully employed in nearly 100 diseases, among them such important disorders as Alzheimer's disease, breast cancer, colon cancer, Crohn's disease, diabetes, and Huntington's disease (see the NIH webpage http://www.nhgri.nih.gov/dir/gtb/clone/) and consists mainly of four steps:

1. *Chromosomal localization* of disease genes using families, genetic markers, and genetic maps
2. *Gene identification* by allelic association (linkage disequilibrium), mutation search, and phenotypic covariations
3. Investigations into the *pathogenesis of the disorder* using expression studies and transgenic and gene knockout animal models
4. *Therapeutic and preventional studies*

3.1.1 Chromosomal Localizations

In principle, chromosomal localizations of risk genes can be found by using as clues chromosomal aberrations producing a schizophrenia-like phenotype (Propping 1983; DeLisi et al. 1994b; Moises 1995) or by screening the entire human genome using linkage analysis and a dense map of genetic markers (Weissenbach et al. 1992). To date, the results of three complete genome scans have been reported (Coon et al. 1994; Moises et al. 1995a; Levinson et al. 1998). One of these employed a two-stage strategy (Moises et al. 1995a), a procedure that in principal has a built-in validation facility (Peltonen 1995). Figure 2 gives a genome-wide overview of positive linkage findings (for references, see Table 1).

Some of the reported locations are probably true, while others are false-positive findings. Several groups found evidence for linkage to schizophrenia on chromosomes 2, 4–6, 8, 9, 11, and 22, indicating that these chromosomal regions are likely harboring risk genes for the disease. The linkage findings on chromosome 2 and 6 fulfill the criteria for significant linkage ($p < 0.00002$) according to Lander and Kruglyak (1995). The situation on chromosome 6p24-p21 is complex (see Fig. 3), involving approximately 55 cM (for reviews, see Peltonen 1995; Straub et al. 1996).

3.1.2 Methodological Problems

Linkage Analysis

Linkage analysis, primarily developed for monogenic disorders, is employed to find chromosomal localiza-

tion of genes in schizophrenia and other such complex genetic disorders. However, unlike monogenic diseases, in the complex disorders a certain gene under investigation is neither necessary nor sufficient, resulting in variations of risk genes between individuals and incomplete cosegregation within families (Greenberg 1993; Sing et al. 1996). As a consequence, significant linkage results are much more difficult to obtain in complex disorders. For genes with a small effect, required sample sizes are well over 2000 families (Risch and Merikangas 1996), and the original sample size has to be multiplied by approximately the number of genes involved in the disorder in order to obtain sufficient power for replication (Suarez et al. 1994). Not surprisingly, confirmation of initial linkage results is difficult and a matter of debate in schizophrenia (Crow 1997; Moldin 1997). The debate in schizophrenia is not dissimilar to the situation in other complex disorders after reports of inconsistent linkage findings and prior to the identification of the relevant gene (e.g. in atopy see, Cookson et al. 1989; Morton 1992; Shirakawa et al. 1994; Fölster-Holst et al. 1998). To avoid a flood of false-positive claims, strict guidelines for interpreting linkage results in complex disorders have been proposed by Lander and Kruglyak (1995). While strict linkage criteria are necessary to decrease the probability of false-positive results (type II error), they will also increase the probability of false-negative results (type I error), an especially undesirable effect in complex disorders considering the difficulties in obtaining evidence for linkage, even if the risk genes are known, as in some HLA-associated disorders, breast cancer, atopy, and ApoE in Alzheimer's disease (Thorlacius et al. 1995; Fölster-Holst et al. 1998; Cai et al. 1997). The only way to reduce type II and I errors is to have further relevant evidence available, such as several studies reporting evidence for linkage in the same region (see Fig. 2) and the cloning of the gene. The latter has never been successful in complex disorders by using a pure positional cloning approach (Collins et al. 1997) except when one of two strategies has been applied: (1) haplotype studies in isolated human populations or (2) identification of a subphenotype in pedigrees in which the disease behaves in a near-mendelian fashion. In other words, cloning of the first schizophrenia gene is most likely to be successful by using isolated populations from Iceland, Northern Sweden, Finland, and Micronesia or near-mendelian endophenotypes such as P50 auditory-evoked potential gating deficit or deviant SPEM. In any case, we should not forget that linkage statistics cannot prove the existence of a risk-increasing gene; the inference only becomes more or less probable. The final proof has to come from the demonstration of concomitant variations between the gene and the phenotype. Problems and strategies in complex disorders are discussed by Weeks and Lathrop (1995), Ott (1996), Risch and Merikangas (1996), Sing et al. (1996), and Pawlowtzki et al. (1997).

Association Studies

Association studies in the general population of unrelated cases using a case-control design are a rather ambiguous approach (Kidd 1993) because of the high rate of false-positive findings of up to 99.5% (Crowe 1993). In other words, unreplicated positive findings from case-control studies and the associated media hype about gene "discoveries" are probably incorrect.

3.1.3 Candidate Genes

Using mostly association studies and a case-control design, a large number of candidate genes for schizo-

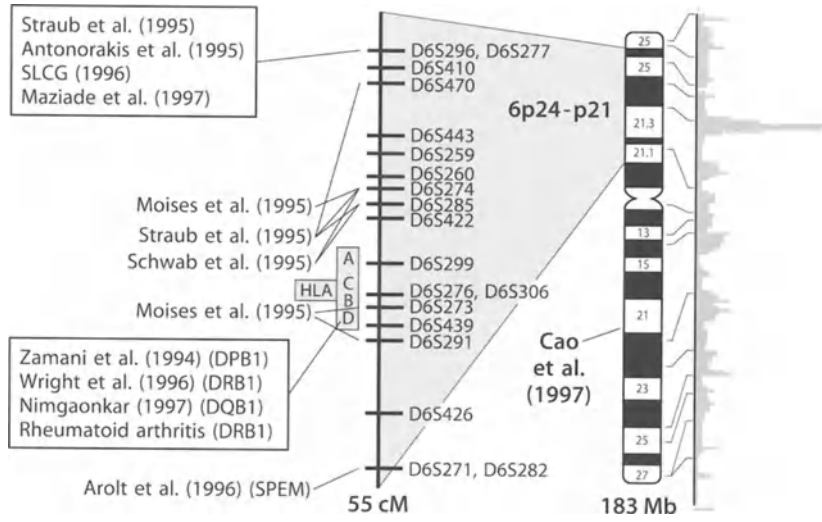

Fig. 3. Positive linkage and association studies on chromosome 6. The density of genes mapped to chromosome 6 is shown to the *right* (data from Schuler et al. 1996). *SPEM*, smooth-pursuit eye movement

phrenia have been investigated (for a review, see Moises 1995). More recently, positive results have been reported for genes of the androgen receptor (Crow et al. 1993), D_2–D_5 dopamine receptors (Arinami et al. 1997; Ebstein et al. 1997; Catalano et al. 1993; N.M. Williams et al. 1997), dopamine transporter (Persico and Macciardi 1997), dopamine-β-hydroxylase (Wei et al. 1997), serotonin 2A receptor (HTR2A) (Inayama et al. 1996; J. Williams et al. 1996), SCA1 (Wang et al. 1996), in the HLA-region B35, DRB1, DPB1, CD4, DQB1 (Blackwood et al. 1996; Wright et al. 1996; Zamani et al. 1994; Nimgaonkar et al. 1997), and the α_7-nicotinic receptor (Leonard et al 1996; Freedman et al. 1997).

More importantly, the α_7-nicotinic receptor has been found by linkage analysis and genome scanning using as endophenotype a measure of the known deficit of inhibitory mechanism in schizophrenics, the P50 auditory-evoked potential gating deficit. In schizophrenia families, significant linkage was obtained between an abnormal P50 ratio and a marker on chromosome 15q13-q14, D15S1360, the localization of the α_7-nicotinic receptor gene (Leonard et al. 1996; Freedman et al. 1997). Different subforms of epilepsy also show evidence of linkage to this gene (Elmslie et al. 1997; Neubauer et al. 1998). Hints for candidate genes can also come from an association between schizophrenia and other diseases with a known genetic component, such as rheumatoid arthritis (RA) and cancer.

Negative Associations with Rheumatoid Arthritis and Cancer

In schizophrenic patients, a decreased risk in cancer mortality and in RA has been documented (Dupont et al. 1986; Vinogradov et al. 1991). Despite the fact that schizophrenics are heavy smokers, the rate for lung cancer is only 38% of normal subjects. In turn, lung cancer and RA are positively associated (Mellemkjaer et al. 1996). For the latter, an association with loci of the HLA region on chromosome 6p is well known (Weyand and Goronzy 1995). Chromosome 6p has also been implicated in schizophrenia by linkage studies.

4 Past, Future, and Ethical Problems

In the nineteenth century, Charles Darwin's (1809–1882) cousin Francis Galton (1822–1911) developed a plan to "improve" the human race and societies by excluding individuals with "bad" genes from reproduction; he named his strategy "eugenics." In the twentieth century, the eugenics movement – also termed "race hygiene" – became influential in many countries, leading in the USA to preferential immigration from Northern Europe and racial segregation, to compulsory sterilization of nearly 500,000 individuals in 11 American states, Germany, and Sweden, and finally under the Nazi regime to the killing of five million Europeans of Jewish ancestry and nearly 70,000 patients, many of them schizophrenic patients (Propping 1989, 1992; Gottesman and Bertelsen 1996; Weber 1996; Gejman 1997; Moldin and Gottesman 1997; Watson 1997). Not only is mass, government-mandated eugenics inhuman but also unfeasible, because the genes for many common disorders such as schizophrenia are so widely distributed in populations that preventing the reproduction of risk genes seems only be possible by preventing the reproduction of the human species. Furthermore, even if we could reduce the rate of vulnerability genes for schizophrenia, it is

rather doubtful whether we should, since they may also be involved in disease resistance or some positive, even creative, human behaviors.

Summing up the current state of knowledge, the majority of people suffering from schizophrenia most probably have a polygenic disorder with a strong genetic component involving unknown environmental factors and probably more than eight risk genes of unknown function, some at least localized on chromosomes 2, 4–6, 8, 9, 11, and 22. In the near future, one or more of the genes will be cloned, thereby revealing through expression studies the network of genes involved in the pathophysiological pathways of schizophrenia. As in depression research (e.g. Edwards et al. 1992), genetically modified animals will provide models to study schizophrenia's pathogenesis, course, rational treatment, and prevention. The discovery process will be considerably accelerated by the Human Genome Project.

By 2005, the Human Genome Project, a three-step, three billion dollar program initiated by the U.S. government and arguably the single most important organized international research project in the history of medicine (Guyer and Collins 1993), is expected to reveal to mankind the chromosomal localization and structure of the estimated 100,000 human genes (Cohen 1993; Guyer and Collins 1995; Rowen et al. 1997, webpage: http://www.ornl.gov/TechResources/Human_Genome/home.html). The first two steps of the program have already been completed. Comparable only to the nineteenth century's discovery of the building blocks of chemistry in the form of the periodic table, the twentieth century's discovery of the building blocks of life will give us biology's "periodic table," leading to more predictability in the life sciences (Lander 1996). Likewise, the impact on biology, industry, medicine, and society will be profound.

New medical disciplines will emerge, such as molecular and predictive medicine based on genetic testing for disease susceptibilities. Medicine's emphasis will probably shift from treatment to prevention and counseling of individuals at risk (Dausset 1986; Gottesman and Collins 1994). Ethical, legal, and social issues (ELSI) are anticipated, and solutions are being discussed within the framework of the Human Genome Project (see webpage http://lbl.gov/education/ELSI/ELSI.html). A central ethical problem of predictive medicine is confidentiality. There is agreement among geneticists that results of risk tests should not be made available to employers or insurance agencies. However, according to surveys, most health professionals are not prepared to integrate genetics into clinical practice (Collins 1997).

The appreciation of genetic nonidentity as a simple fact of life will be another important consequence of the "genetic revolution." It is impossible to fight against existing genetic inequality by denying its existence. What is needed are medical and social strategies to counterbalance existing suffering whatever their proximate or distant origins may be. The famous Nobel laureate James D. Watson (1997) put it this way:

> Genetics as a discipline must strive to be the servant of the people, as opposed to governments, working to mitigate the genetic inequalities arising from the random mutations that generate our genetic diseases.

In human history, lesser crimes against humanity than the holocaust for the supposed "benefit" of society have never been forgotten. Therefore, "we are well advised to look back to the founder of scientific medicine, Hippocrates, whose oath is the basis of biomedical ethics" (Ganten 1997). Furthermore, in light of the past, psychiatrists and geneticists should be the first to fight against possible misuse of genetic information and to use gene technology to the benefit of patients and those who are disadvantaged.

A. Heinz, D.R. Weinberger

Schizophrenia: The Neurodevelopmental Hypothesis

1 Historical Background

1.1 Schizophrenia as a Premature Dementia

Kraepelin conceptualized schizophrenia as a premature dementia, presenting in the second or third decade of life and deteriorating over the course of the illness (Kraepelin 1899). Both Bleuler (1911) and Kraepelin (1899, 1919) noticed that childhood characteristics such as seclusion, withdrawal, or irritability preceded the manifestation of psychotic symptoms in some schizophrenic patients. However, the prevailing biological perspective suggested that schizophrenia results from a pathological degenerative process that occurs in early adult life shortly before the onset of manifest symptoms. It was generally assumed that, in most cases, the brain was relatively normal until the illness struck and that the pathological changes would increase as the illness progressed (Weinberger 1995).

1.2 Schizophrenia as a Neurodevelopmental Disorder

In recent years, a fundamental shift in the perception of the underlying neurobiological process has occurred. Most researchers now see schizophrenia as a neurodevelopmental disorder and suggest that many or most cases of schizophrenia are caused by a defect in early brain development (Weinberger 1987, 1995; Murray et al. 1988; Crow et al. 1989). It is hypothesized that the neurodevelopmental abnormality will not manifest in a diagnostically recognizable form until after a considerable postnatal delay period and that normal developmental processes or additional pathogenic factors trigger the manifestation of the illness (Weinberger 1995).

1.3 Why the Shift in Neurobiological Disease Concepts Occurred

The reasons for this conceptual shift come from different areas of schizophrenia research. In neuropathological and brain imaging studies of schizophrenics, adult-onset pathological cerebral changes and indicators of pathological progress have remained elusive, while replicable evidence of early cortical maldevelopment was found (Bachneff 1991; Weinberger 1995). Studies of childhood behavior in subsequent schizophrenics have indicated a considerable degree of psychomotor anomalies, which has been attributed to abnormal brain development (Walker et al. 1994). Furthermore, neurobiological models exist which may explain the relationship between brain maldevelopment and the clinical features of schizophrenia (Deutch 1992; Weinberger and Lipska 1995). This evidence links schizophrenia to neuropathological changes in early brain development.

2 Indicators of Developmental Neuropathology

In 1982, Feinberg suggested that schizophrenia may be due to a fault in synaptic elimination during adolescence. While this hypothesis did not account for the neurodevelopmental changes that have later been associated with schizophrenia, it was an impetus to examine the question of neurodevelopmental problems in schizophrenia. Indicators of abnormal intrauterine development range from rather weak and circumstantial findings such as a slight overrepresentation of minor physical abnormalities (MPA) to compelling evidence of in vivo and ex vivo cerebral morphometric abnormalities. While the sum of these findings can be interpreted as a coherent story of developmental abnormalities, inconsistencies and methodological problems exist at the level of individual findings (Weinberger 1996).

2.1 Minor Physical Abnormalities

2.1.1 Abnormalities as an Indication of Developmental Pathology

Abnormal intrauterine events are expected to affect the development of extracerebral tissue and hence MPA such as deformed ears or high palate have been found in patients with neurodevelopmental disorders. In schizophrenic patients, increased frequency of MPA was associated with greater dermatoglyphic asymmetry (total finger ridge count and left–right ridge count), which is supposed to reflect second-trimester asymmetry (Torrey et al. 1994a). In monozygotic twins discordant for schizophrenia, a subgroup of patients displayed increased frequencies of MPA, dermatoglyphic asymmetry, and perinatal complications or low birth weight. These findings were interpreted as indicators of prenatal events, inducing neurodevelopmental abnormalities (Bracha et al. 1992; Davis and Bracha 1996). Several studies reported an excess of MPA in schizophrenics. The occurrence of MPA in schizophrenic patients has therefore been interpreted

as an indication of intrauterine developmental pathology which may have affected neuronal organization in the second or third trimester of gestation (O'Connell et al. 1997).

2.1.2 Inconsistencies in Studies

In spite of the plausibility of second-trimester insults in the etiopathogenesis of schizophrenia, fundamental problems with the data exist. No consistent pattern of association between certain MPA and schizophrenia has been found. Studies that report increases in MPA tend to lump them together as if they all signify a similar neurodevelopmental pathology, when, in fact, their relative frequencies are not correlated with each other (Torrey et al. 1994b). Moreover, association studies usually lacked well-matched control samples, and none of the studies seems to have been carried out as a blind comparison. Finally, an association between certain MPA and schizophrenia was often noticed only after the sample of schizophrenic patients had been broken down post hoc into putative subgroups. Currently, the existing data do not support the notion that MPA are good indicators of cerebral maldevelopment in schizophrenia (Weinberger 1995).

2.2 Ventricular Enlargement and Reduction of Cerebral Volume

2.2.1 Ventricular Enlargement in Neuroimaging Studies

Enlarged cerebral ventricles in postmortem specimens from hebephrenic patients were described by Hecker as early as 1871. In vivo imaging studies show that ventricular enlargement is the most frequently confirmed neurobiological finding in schizophrenic patients (Van Horn and McManus 1992). The interindividual variation in ventricular size is large and effect size of the finding in schizophrenics is relatively small; therefore, negative reports have been published, especially in studies with a small sample size. However, in studies of monozygotic twins discordant for schizophrenia, even affected twins with relatively small ventricles had larger ventricles than their healthy co-twins (Reveley et al. 1982; Suddath et al. 1990). These results suggest that the underlying pathological process is a subtle but commonplace feature of the disorder. They do not, however, address the question of whether these changes are due to neurodevelopmental pathology.

2.2.2 Lack of Brain Tissue in Neuroimaging Studies

Enlarged brain ventricles indicate a nonproduction or reduction of brain tissue. In fact, morphometric assessment of brain structures with high-resolution magnetic resonance imaging (MRI) techniques have provided evidence for an overall reduction in gray matter volume by 5%–10% in schizophrenic patients compared to healthy control subjects (Andreasen et al. 1994a; Zipursky et al. 1994). The loss of cortical volume was most frequently reported for the mesial temporal cortex in the area of the rostral hippocampus and for the superior temporal gyrus (Bogerts et al. 1990; Suddath et al. 1990; Shenton et al. 1992). Reductions in the volumes of other brain areas such as the prefrontal and parietal cortices, the basal ganglia, and the thalamus have also been reported, but the findings were less consistent (Andreasen et al. 1994b; Schlaepfer et al. 1994).

2.2.3 Indicators of Lateralized Brain Pathology

Some controversy exists around the question of whether the pathological changes are pronounced in the left hemisphere, especially in the left temporal lobe (Crow et al. 1989). However, most studies describe bilateral differences between patients and controls (Crow et al. 1989; Shenton et al. 1992). A related issue involves the question of whether schizophrenia is associated with a pathology in the development of normal human cerebral asymmetries, e.g. in the width of the occipital lobes or the lengths of the sylvian fissures. Normal human brain asymmetries are formed in the second trimester of gestation (Chi et al. 1977), so that abnormalities in these asymmetries might indicate second-trimester insults (Roberts 1991). These observations are interesting in light of findings indicating that patients with schizophrenia may be less completely lateralized than normal individuals when handedness, dichotic listening asymmetries, and lateralized cognitive tasks are assessed (Gruzelier et al. 1988). However, negative studies are common (Bartley et al. 1993; Kulynych et al. 1996). A reason for these contradictory results might be that asymmetries are less obvious in individuals who are incompletely right-handed and that mixed dominance appears to be more frequent in schizophrenic patients (Myslobodsky and Weinberger 1987). Incomplete anatomical asymmetries may therefore be a nonspecific sign of developmental variance which is found independent of schizophrenia and is not associated with schizophrenia per se (Weinberger 1995).

2.2.4 Attempts to Confirm the Reductions in Cerebral Volume by Postmortem Studies

Postmortem studies of brains of schizophrenic patients found increased ventricular size and reductions in various cortical regions, especially the hippocampal formation, confirming the results of the in vivo imaging studies (Bogerts et al. 1985; Crow et al. 1989). In accordance with these observations, neuronal counts were reduced in certain cortical and periventricular regions (Falkai and Bogerts 1995). Altogether, a fairly widespread neuropathological process was implicated. Some studies, however, did not confirm these findings (Heckers et al. 1990; Benes et al. 1991a); the reasons for these inconsistencies are not known (Weinberger 1995).

2.3 Clinical Correlates of Brain Abnormalities in Neuroimaging Studies

2.3.1 Lack of Correlation Between Ventricular Enlargement and Reductions in Brain Tissue and the Duration of Illness

The observation of ventricular enlargement and reduction of cerebral tissue in schizophrenic patients does not address the question of when these abnormalities were acquired. A comparison of brain imaging and clinical data shows that ventricular enlargement does not correlate with the duration of illness, which would have been expected if the progression of the illness were accompanied by an ongoing pathological process causing brain atrophy and ventricular enlargement (Weinberger et al. 1979; Raz and Raz 1990). Studies in first-break patients show that ventricular enlargement and reduced hippocampal volume were present at the onset of the clinical illness (Bogerts et al. 1990; Lieberman et al. 1993). These findings indicate that ventricular enlargement and reduction in brain tissue predate illness onset, perhaps by many years.

2.3.2 Clinical Correlates of Ventricular Enlargement

When the pathopsychological correlates of ventricular enlargement in adult schizophrenic patients were studied, an association with poor premorbid social and educational adjustment during early childhood was found (Weinberger et al. 1980). It was this rather surprising finding which first alerted researchers that the neuropathological abnormalities may have occurred years before the onset of psychotic symptoms (Weinberger 1995). Further studies showed correlations between ventricular enlargement and obstetric complications, supporting the hypothesis that the underlying pathological process may originate from early in life (Owen et al. 1988).

2.4 Clinical Indicators of Early Neurodevelopmental Pathology

2.4.1 Premorbid Neuropsychological Tests and Social Functioning

If a prenatal neuropathological process occurred in subsequent schizophrenics, subtle indications of abnormal neural function would be expected to be present during childhood. Several studies examined premorbid neuropsychological tests and found that individuals who later became schizophrenic did worse than their healthy siblings, although negative results have also appeared (Torrey et al. 1994a,b). In the prospective British National Child Development Study, reduced premorbid social functioning and increased social anxiety during childhood was found in patients later admitted for treatment of schizophrenia (Done et al. 1994). In a second study of childhood neurofunctional development that examined the birth cohort of 1946, gross motor and speech milestones were significantly delayed and educational test scores were significantly lower in patients later treated for schizophrenia (Jones et al. 1994).

2.4.2 Indicators of Abnormal Neurological Functioning in Childhood

Walker and coworkers examined home movies filmed during the childhood of adult-onset schizophrenic patients and their siblings. In a blind comparison, the affected family member was invariably identified by subtle neuromotor abnormalities such as slight posturing of the hand or transient choreoathetoid movements. The deficits were quite subtle, occurred primarily on the left side of the body, and tended to disappear after 2 years of life (Walker and Lewine 1990; Walker et al. 1994). Follow-up studies showed that these abnormalities were pronounced only in a subgroup of children who later developed schizophrenia (Neumann et al. 1995).

2.4.3 Association of Childhood Neuromotor Abnormalities and Ventricular Enlargement

In adult patients, childhood neuromotor abnormalities and negative affect were associated with ventricular

enlargement (Walker et al. 1996). This finding supports the hypothesis that ventricular enlargement in schizophrenics results from early neurodevelopmental malfunction and not from a disease process active during the clinical onset of manifest psychotic symptoms (Weinberger 1995).

2.5 Indicators of Neurodevelopmental Pathology in Postmortem Findings

Postmortem studies generally reported a lack of gliosis in neocortex, hippocampus, and parahippocampal cortices. This finding is inconsistent with adult-onset neurodegenerative conditions, but has been found in neuropathologial events that occur early in development, i.e., before the third trimester of gestation (Knable and Weinberger 1995). The presence of cortical changes without gliosis has been interpreted as circumstantial evidence that the neuropathological changes observed in brain tissue of schizophrenics occur prenatally. As a general disruption of the earliest events in cortical maturation is associated with severe abnormalities not found in schizophrenia, it is unlikely that the observed neuropathological changes result from insults before the sixth fetal week (Rakic 1988). The neuropathological findings therefore implicate a time of insult around the second trimester of gestation.

2.6 Cytoarchitectural Abnormalities

Laminar patterns of cortical neurons, their orientation, and internal relationships are formed during the second trimester of gestation and are assumed not to change during life. Abnormalities of cytoarchitecture would therefore strongly implicate prenatal pathological neurodevelopment. Different studies of cytoarchitecture in schizophrenic brain tissue found structural abnormalities, which implicate pathological development.

2.6.1 Orientation of Hippocampal Pyramidal Cells

Abnormal orientation of hippocampal pyramidal cells was found by Kovelman and Scheibel (1984) in the left hemispheres of chronic schizophrenic patients. Similar alterations were found in the right hemisphere by Conrad et al. (1991). This finding was interpreted as indicating a defect in neuronal migration. However, several studies failed to replicate these findings (Weinberger 1995).

2.6.2 Laminar Organization in the Entorhinal Cortex

What is potentially a landmark study on laminar organization in the entorhinal cortex was published by Jakob and Beckmann in 1986. They studied the entorhinal cortex in the region of the amygdala and pes hippocampus, where the most consistent reductions in brain tissue have been found in postmortem and in vivo studies (Weinberger 1995). Using Nissl-stained sections, Jakob and Beckmann (1986) found attenuation of cellularity in layers I and II, incomplete clustering of neurons into normal glomerular structures in layer II, and the presence of such clusters in deeper layers, where they are normally not found. This observation may indicate a disruption of neuronal migration to cortex in the second trimester of gestation, in which neurons proceed outward from the periventricular zone to reach their cortical destination. In this process, younger neurons have to pass over older ones on their way to more superficial layers (Rakic 1988). Jakob and Beckmann postulated that their findings may indicate an arrest of migration, in which a younger generation of neurons was held up in deeper layers.

2.6.3 Attempts to Replicate Evidence for a Developmental Pathology in the Entorhinal Cortex

Using the same technique, Arnold et al. (1991) found similar abnormalities as described by Jakob and Beckmann (1986). Moreover, they observed anomalous entorhinal sulci in their specimens. Like Jakob and Beckmann (1986), they interpreted their findings as indications of an abnormality of entorhinal cortex development, hypothetically due to a migration failure. Several studies, however, failed to replicate these findings. Hyde and Saunders (1991) observed that more caudal areas of the entorhinal cortex in normal controls look increasingly like the findings reported by Jakob and Beckmann (1986) in schizophrenic brains, indicating that slight differences in the examined entorhinal areas can produce substantially different cytoarchitectural results. A study by Heinsen and Gössman (1996) supports the hypothesis that the variability in the human entorhinal cortex may confound the detection of neurodevelopmental abnormalities in the brains of schizophrenic patients. The authors argued that in the rostromedial entorhinal area, regionally circumscribed features of so-called pre-beta clusters were probably misinterpreted as neurodevelopmental disturbances by Jakob and Beckmann

(1986). Moreover, Heinsen and Gössman (1996) did not find an association between "anomalous" entorhinal sulci and schizophrenia, as suggested by Arnold et al. (1991). Two attempts to directly replicate the findings of Jakob and Beckmann (1986) failed and supported the notion that disordered rows of neurons in the superficial layers of schizophrenic patients are characteristic of the olfactory region of normal brains (Akil and Lewis 1997; Krimer et al. 1997). These studies do not support the hypothesis that a migration failure of cortical neurons in the entorhinal cortex is associated with schizophrenia, although it does not rule out the existence of other abnormalities of neuronal circuitry in this area.

2.6.4 Cytotarchitectural Abnormalities in the Frontal Cortex

Akbarian et al. (1993a) studied primarily GABAergic neurons that express the enzyme nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) in the superior frontal gyrus region of the dorsolateral prefrontal cortex. They found a reduction in the number of neurons in cortical layers I–III and increased numbers in deep layers, a finding which resembled the results of Jakob and Beckmann (1986) in the entorhinal cortex. Similar results were reported by Benes et al. (1991b), who studied small, presumably GABAergic cells in the prefrontal and cingulate cortex of schizophrenic patients. They found a reduction in small neurons in the superficial layers and larger numbers in deeper layers. These findings might indicate a failure of neuronal migration to superficial layers during the second trimester of gestation (Weinberger 1995).

2.6.5 Attempts to Replicate Other Evidence for a Cortical Developmental Pathology

An attempt to replicate the observations of Benes et al. (1991b) failed (Bunney et al. 1993). In a study of the lateral temporal neocortex and the mesial limbic cortex of schizophrenics, Akbarian et al. (1993b) observed similar cytoarchitectural abnormalities in NADPH-d neurons as in the prefrontal cortex (Akbarian et al. 1993b). However, while these abnormalities were present in the lateral temporal cortex and the hippocampus, the entorhinal cortex was normal (Akbarian et al. 1993b). It is possible that this failure to replicate the observations of Jakob and Beckmann (1986) is due to the fact that Akbarian et al. (1993b) studied primarily GABAergic neurons, while the layer II entorhinal neurons examined by Jakob and Beckmann (1986) are primarily glutamatergic. On the other hand, the presence of abnormalities in the cytoarchitectural distribution of NADPH-d neurons in other cortical areas (Akbarian et al. 1993a) and the failure of other groups to replicate cytoarchitectural abnormalities in the entorhinal cortex (Akil and Lewis 1997; Krimer et al. 1997) do not support the hypothesis of a developmental defect in the entorhinal cortices of schizophrenic patients.

2.6.6 Overall Outcome of Studies Assessing Neurodevelopmental Abnormalities in Schizophrenic Patients

Several studies of cortical cytoarchitecture in schizophrenics suggest subtle multifocal or diffuse anatomical deviations that are hard to explain on the basis of anything that might happen to a brain after birth (Weinberger 1996). Specifically, they point to a disruption of neuronal migration to superficial cortical layers in the second trimester of gestation. However, various inconsistencies exist and attempts to replicate important findings have repeatedly failed. Further studies are therefore needed before the uncertainties can be resolved (Weinberger 1995).

3 Etiologic Considerations

The etiology of the potential developmental defect is unknown. It is reasonable to assume that several genetic and environmental factors play a part. Recent studies implicated environmental influences such as obstetric complications, in utero virus infections, and malnutrition, at least in some patients (O'Connell et al. 1997).

3.1 Obstetric Abnormalities

Abnormal fetal development is often associated with abnormal delivery. The literature on this topic is difficult to interpret, as the same methods are rarely used and the same findings are rarely replicated. Sibship studies are important because uncertainty about the validity of maternal recall is less problematic (Weinberger 1995). Within these limitations, a majority of studies have found a trend toward more frequent complications during both pregnancy and delivery in births of individuals who subsequently suffered from schizophrenia (McNeil 1988). However, obstetric complications are a poor predictor of schizophrenia, increasing the risk of schizophrenia by at most 1% (Goodman 1988).

3.2
Prenatal Fetal Abnormalities as a Possible Cause of Obstetric Complications

Perinatal injuries are typically characterized by gliosis. It is therefore unlikely that perinatal obstetric complications are directly associated with the neuropathological findings of schizophrenic brain tissue described above (Knable and Weinberger 1995). Instead, it has been hypothesized that preexisting fetal abnormalities predispose to an increased frequency of obstetric complications (Weinberger 1995), an interpretation first proposed in 1897 by Freud (1968) in reference to cerebral palsy.

3.3
Prenatal Viral Exposure

Mednick et al. (1988) found an association between the manifestation of schizophrenia and the Helsinki influenza A2 epidemic of 1957. Patients who had been in their second trimester during the height of the epidemic had a significantly higher percentage of subsequent schizophrenic psychoses. This result stimulated a series of subsequent studies examining the risk of schizophrenia after potential intrauterine exposure to influenza in Europe and the United States. A slight majority of studies claimed to find such an association; however, it accounted for at most 4% of the variance (Weinberger 1995). A limitation of these studies is that they usually did not document actual maternal infection and reported associations only between the general risk of intrauteral exposure to influenza and manifestation of schizophrenia in adulthood. One study assessed children of mothers who had been diagnosed as having influenza during their second trimester of pregnancy. No increased risk of schizophrenia was found in the children of these mothers (Crow and Done 1992). However, the study was criticized for possibly having a low ascertainment rate of cases of schizophrenia (Weinberger 1995). In conclusion, the perinatal exposure literature is provocative but inconclusive. Even if validated by further studies, viral exposure will account for at most a small percentage of cases (Weinberger 1995).

3.4
Prenatal Malnutrition

Another environmental risk factor was addressed by the study carried out by Susser and Lin (1992), who examined a Dutch birth cohort exposed to starvation caused by the Nazi blockade of the Netherlands. They observed a twofold increase in the subsequent manifestation of schizophrenia in probands who had been exposed to severe famine during the first 2 months of gestation. As in the case of influenza exposition, severe malnutrition in utero is an unusual example of prenatal environmental stress and probably accounts for at most a very small number of cases. Nevertheless, the statistical association of these intrauterine insults with an increased risk for schizophrenia supports the hypothesis that certain disturbances of the intrauterine environment can help set the stage for the manifestation of schizophrenia in adulthood (Weinberger 1995).

3.5
Genetic Factors

It is widely accepted that genetic factors convey susceptibility to schizophrenia. Since approximately 30% of the genome is expressed in the brain, and many genes are turned on and off during discrete phases of brain development, it has been speculated that genetic factors may induce cerebral maldevelopment in schizophrenia. Different mechanisms such as a primary genetic defect or an increased vulnerability to intrauterine or perinatal environmental stresses have been suggested. As no current data link schizophrenia with a defect in any known gene related to brain development, these hypotheses require further research (Weinberger 1995; O'Connell et al. 1997).

4
Hypothetical Mechanisms of Delayed Manifestation of Psychotic Symptoms

4.1
Normal Brain Development Versus a Second Pathological Process

If schizophrenia is related to an abnormality of early brain development, potential mechanisms of delayed onset of the clinical illness have to be addressed. It has been hypothesized that the manifestation of psychotic symptoms is either due to an additional, independent pathological process or to an interaction between a static neurodevelopmental defect and normal development programs. Postulating an additional pathological process that is active around the age of illness onset requires the unlikely scenario of a second primary pathology (Weinberger 1995).

4.2 Neurological Analogies

It has been observed in certain neurological diseases that the likelihood of psychotic symptoms is related to the state of brain development, even if the neuropathological changes do not vary with age. Metachromatic leukodystrophy, for example, results in a "dysconnection" of cortical regions, and patients present with psychotic symptoms nearly exclusively between the ages of 13 and 30 years. When metachromatic leukodystrophy appears outside of this critical age, psychotic symptoms are almost never found. This example shows that a dysconnection of cortical regions can lead to the manifestation of psychotic symptoms if it interacts with a certain stage of brain development (Weinberger 1995).

4.3 Prefrontal Dysfunction

Brain imaging studies under certain conditions such as the Wisconsin Card Sorting Test showed a hypoactivity of the prefrontal cortex, which was reversed when amphetamine was applied, hypothetically reversing a prefrontal dopamine deficit (Daniel et al. 1991). Weinberger (1987) hypothesized that a dysfunction of the prefrontal cortex is associated with cognitive deficits and negative symptoms and induces a disinhibition of subcortical dopamine release, which may be associated with the manifestation of positive symptoms. Thus a prefrontal dopamine deficit may be due to neurodevelopmental pathology and result in a failure to regulate subcortical dopaminergic transmission.

4.4 Animal Models of Cortico-subcortical Dopaminergic Dysregulation

In certain animal models, a prefrontal dopaminergic lesion disinhibits subcortical dopamine release, especially under stress conditions. However, the effect is usually not persistent, and no long-term delay in the onset of dopaminergic dysregulation has been observed (Deutch 1992). A neonatal lesion of the mesial temporolimbic cortex in rats is, on the other hand, clinically silent until puberty. After puberty, the neonatally lesioned rats become hyperresponsive to dopaminergic drugs and to environmental stresses, behaviors that are ameliorated by antidopaminergic drugs (Weinberger and Lipska 1995). These findings indicate that a neonatally acquired lesion of the mesial temporal cortex can lead to a delayed onset of a stress-related dysfunction of dopaminergic transmission.

4.5 Stimulation of Dopaminergic Transmission by Stress

Studies in rhesus monkeys illustrate potential mechanisms by which environmental stress factors can trigger a dysfunction of dopaminergic transmission in subjects with a neonatal mesiotemporal lesion. Environmental stress can trigger dopamine release, especially in the prefrontal cortex (Abercrombie et al. 1989). Prefrontal monoaminergic stimulation reduces subcortical dopamine release in normal adult monkeys and in monkeys with an adult lesion of the mesial temporal cortex (Kolachana et al. 1995). Adult monkeys with a neonatal lesion of the mesial temporal cortex, on the other hand, show signs of a dysregulation of striatal dopaminergic transmission which seems to be due to a failure of prefrontal regulation of subcortical dopamine release (Saunders et al. 1998; Heinz et al. 1999). A failure of the prefrontal regulation of subcortical dopamine release might involve a dysfunction of inhibitory GABAergic interneurons in the prefrontal cortex (Bachneff 1991) and a subsequent disinhibition of glutamatergic projections to midbrain dopaminergic neurons (Taber et al. 1995). Olney and Farber (1996) hypothesized that a dysfunction of GABAergic interneurons may be due to *N*-methyl-D-aspartate (NMDA) receptor hypofunction present in the developing human brain at birth. However, GABAergic medication fails to improve schizophrenic symptoms, and animal models of neonatally induced NMDA receptor dysfunction displayed gliosis, which is absent in schizophrenia (Olney and Farber 1995; Knable and Weinberger 1995). Whatever the cause, an early developmental dysconnection between the temporolimbic and prefrontal cortex may lead to a stimulus-dependent disinhibition of subcortical dopaminergic transmission in adolescence, when cortico-subcortical connections are restructured (Anderson et al. 1995) and the stresses of independent adult life are present (Weinberger 1987).

5 Conclusions

The neurodevelopmental hypothesis of schizophrenia has developed over the past years as a heuristically useful approach to study schizophrenia. It was stimulated by the static nature of ventricular enlargement and cerebral brain reduction in in vivo studies, the correlations with early life adaptation, and the absence of gliosis in neuropathological studies. The neurodevelopmental hypothesis has stimulated new lines of research such as developmental neurobiology and clinical epidemiology and is responsible for animal

models of core neurobiological constellations of the syndrome which attest to the neurobiological plausibility of the hypothesis. Inconsistencies exist within the data implicating developmental neuropathology, which are either indirect or based on inconclusive studies. Further research will be necessary to support or falsify this cornerstone of the neurodevelopmental hypothesis of schizophrenia.

Schizophrenia: Disturbances of Hemispheric Lateralization

Translator: E. Taub

1 Introduction

Hemispheric asymmetry is likely to have developed over the course of evolution and is demonstrable in humans, primates, rats, and birds. A further projection of the right hemisphere anteriorly and of the left hemisphere posteriorly has been found in both Peking man, who lived some 500,000 years ago, and Neanderthal man, who lived some 50,000 years ago. The increasing specialization of each hemisphere presumably led to the development of a greater repertoire of functions than would have been possible with symmetrical hemispheres (Kertesz and Naeser 1994). The earliest demonstration of a lateralized function of the brain was by Broca (1863), who recognized the relationship between left hemispheric lesions and aphasia.

Many studies on the lateralization of brain function have been carried out in recent decades. It has become clear that language and handedness are the most highly lateralized functions. Hemispheric specialization has also been studied with respect to attention, visual and auditory perception, affectivity, and autonomic regulation (Hellige 1993). Even though a direct comparison of left- and right-hemisphere functioning appears problematic because of the complexity of the subject, many groups of researchers have concluded that the left hemisphere more effectively performs cognitive tasks requiring a comparison of stimuli, while the right hemisphere is better at comparing and integrating different features. A brief overview of the functions ascribed to the left and right hemispheres in the past century is given in Table 1.

It was already postulated in the nineteenth century that schizophrenic manifestations were related to left-sided, rather than right-sided, cerebral disturbances (see, e.g. Crichton-Browne 1879). Such hypotheses played a relatively small role in psychiatric thought until the mid-1970s, when neuropsychological studies (Flor-Henry 1976; Gruzelier and Venables 1974) and, later, neuroimaging and neuropathological studies revealed the presence of left-hemisphere abnormalities and a reduction of the normal physiological asymmetry of the brain. These structural and functional findings were incorporated into the etiopathogenetic concepts of schizophrenia by a number of authors (see, e.g. Crow et al. 1989; Jaynes 1976). This led to the performance of many further informative studies and to the generation of considerable debate.

The structural findings are discussed in Chap. 10 (Vol. 1, Part 1). In this chapter, we will provide an overview of the functional findings, particularly with respect to handedness, language, and spatial and emotional perception, and the results of functional neuroimaging studies in the schizophrenias. Because of space restrictions, only the most important studies can be discussed.

Table 1. Hypotheses concerning the different functions of the two hemispheres over the last 130 years (after Cutting 1990)

Period	Left hemisphere	Right hemisphere
1860–1910	Language, motor function	Undetermined, complex perception
1950	Language	Spatial
1960	Verbal and analytic	Nonverbal and synthetic
1970–present	Analytic Serial processing Detail-oriented Logical Rational	Holistic Parallel processing Gestalt-oriented Creative Emotional, affective

2 Handedness

Handedness has been used as a parameter to assess possible alterations of hemispheric asymmetry. The earlier studies yielded inconsistent findings, possibly because they made a dichotomous distinction between right- and left-handedness. It is much more likely, however, that handedness is a continuously distributed variable, ranging from strong right-handedness, through a spectrum of mixed states, to strong left-handedness. Mixed handedness was, therefore, considered as a third category in later studies, and this led to a higher degree of agreement across studies.

It has since been established that mixed handedness is more common among schizophrenics than among normal control individuals. Nelson et al. (1993), for example, found mixed handedness in 43% of patients and only 14.3% of controls, while Cannon et al. (1995) arrived at figures of 34.4% versus 11.6%. Schizophrenics with mixed handedness more commonly switch hands during the performance of a task (Gorynia and Uebelhack 1992).

Satz and Green (1999), using a different methodological approach, determined the direction of the displacement of handedness in schizophrenic patients. They found that 14 studies had shown a leftward displacement, seven no definite displacement, and two a rightward displacement. These findings suggest that the prevalence of strong right-handedness is diminished among schizophrenics and that there is a displacement of handedness toward the left side. In complex motor tasks, patients with mixed handedness

tend to lateralize to the right more than to the left. When this is taken into account, mixed handedness is found to be reduced by as much as 50% (Nelson et al. 1993). Fleminger et al. (1977), in a very large study in which 800 patients and 800 control subjects were examined, found that male schizophrenics are less often right-handed than female schizophrenics.

There is a relationship between left-handedness and clinical findings and disease manifestations. Tyler et al. (1995) found that left-handed schizophrenics ($n = 94$), in comparison to right-handed ones ($n = 592$), were more likely to have had perinatal difficulties and severe cognitive and behavioral abnormalities in childhood and more frequently suffered from persistent auditory hallucinations. Cannon et al. (1995) found that mixed handedness was associated with the chronification of psychosis, and the genetic load tended to be less than that seen in right-handed patients. This led the authors to attribute mixed handedness to a disturbance of neural development. Further studies revealed an association between mixed handedness and cognitive abnormalities, as well as an increased ventricle-to-brain ratio (see Satz and Green 1999). Manoach (1994) found that left-handedness in schizophrenics is associated with formal thought disorders (in men) and with disturbances of language function. Their interpretation was that atypical handedness is a marker of a left-hemispherec disturbance.

3 Further Aspects of Motor Function

The study of motor function with neuroimaging techniques is particularly informative, because the greater localizing ability of these techniques can be used to address the question of lateralization more precisely. Schröder et al. (1995), using functional magnetic resonance imaging (fMRI), found that normal subjects performing a finger–thumb opposition task had an activation of the contralateral supplementary motor area and of the sensorimotor area bilaterally (left more than right). Schizophrenics, in contrast, had a lesser degree of activation and an inverted lateralization effect. In another fMRI study on schizophrenic patients, Mattay et al. (1997) found an increased degree of ipsilateral activation in the primary sensorimotor and lateral premotor regions and, as in the earlier study, a reduction of the lateralization quotient. The authors explained these findings as representing a failure of interhemispheric inhibition, which normally takes place by way of glutamatergic transcallosal projections impinging on the γ-aminobutyric acid (GABA)-ergic system and makes functional lateralization possible.

4 Language

Language, like handedness, has been used as a parameter of functional lateralization, because it is generally considered to be a function of the left hemisphere. The role of the right hemisphere in language has attracted attention only in recent years. Flor-Henry (1976), one of the first authors to postulate a left-hemisphere disturbance in schizophrenic patients, did so because of the finding of language-related disturbances in neuropsychological performance. This hypothesis has been tested in many subsequent studies. Many investigators made use of the fact that, in most normal individuals, linguistic stimuli are processed more rapidly and/or accurately by the left hemisphere, regardless of whether they are presented visually or acoustically. The fact that linguistic stimuli are processed more efficiently when presented to the right ear (and thus predominantly to the left hemisphere) is known as the right-ear advantage.

Most of the relevant studies have shown a reduction of the right-ear advantage in schizophrenics, but this reduction is related to the presence of florid symptoms, particularly auditory hallucinations (Bruder et al. 1995). This finding is in accordance with the demonstration, by functional neuroimaging techniques, that language centers in the left temporal lobe are activated during auditory hallucinations (Dierks et al. 1999). On the other hand, the fact that the right-ear advantage is also reduced in patients in remission (Wexler et al. 1991), "high-risk" children (Hallet and Green 1983), and parents implies that this finding is a genetically controlled "trait."

Further evidence for a left-hemisphere disorder comes from the fact that schizophrenic patients often produce unusual semantic associations (Bleuler 1911) and that the relationship of linguistic expression to context is loosened, particularly in patients with thought disorders. Weisbrod et al. (1998) used tachistoscopic testing to show that this excessive activation of semantic associations in schizophrenics is, in fact, attributable to a deficient ability to focus semantic activation in the left hemisphere.

More recent studies have shown, however, that language is not exclusively a left-hemisphere function. The right hemisphere recognizes and generates prosody and plays a major role in the interpretation of the emotional aspects of language and in the understanding of metaphors and jokes. Right-hemisphere linguistic

functioning in schizophrenics has been investigated, to our knowledge, in only one study to date (Spitzer 1993). In this study, normal subjects and schizophrenic patients were presented with proverbs and, immediately afterward, with words related to the abstract and metaphorical semantic content of the proverbs. The recognition of these words was facilitated in normal subjects but not in schizophrenics, which implies the presence of a right-hemisphere disorder.

Language requires the integrated functioning of the two hemispheres, each of which is specialized for different functions. In this context, the older finding that schizophrenic patients perform poorly in assessing the agreement of binaurally presented verbal stimuli (Beaumont and Diamond 1973) remains of interest. Patients were also better able to understand stories when they were presented in a single ear rather than both (Green and Kotenko 1980). These findings suggest that a disturbance of the integration of the linguistic functions of the two hemispheres may also contribute to the linguistic abnormalities of schizophrenic patients.

5 Spatial Perception and Facial Recognition

Right-hemisphere function has frequently been assessed by neuropsychological testing of spatial perception and facial recognition, because the right hemisphere is known to perform better than the left in spatial perception, pattern recognition (Warrington and Rabin 1970), and the judgment of spatial orientation and distance (Benton and Tranel 1993). Borod et al. (1993), for example, found that schizophrenic patients with negative symptoms were as severely impaired in the recognition of regular abstract patterns (Visual Matrices Test) as patients with right-hemisphere brain injury. Two further studies employing interhemispheric comparisons, however, failed to demonstrate a loss of the right-hemisphere advantage in spatial tasks (Connolly et al. 1979; Gur 1978).

Facial recognition is also considered to be predominantly a function of the right hemisphere (Rizolatti et al. 1971). Conrad (1958) had already described the "physiognomization" of the environment in early schizophrenic psychosis. In two recent studies, the normal advantage of the right hemisphere over the left in the recognition of faces was, indeed, not found (Borod et al. 1993; White et al. 1998); this can be interpreted as suggesting a right-hemisphere functional disturbance. Two other studies, however, came to the opposite conclusion (Ellis et al. 1993; George and Neufeld 1987).

The recognition of facial emotional expression seems to be, more clearly than the simple recognition of faces, a function of the right hemisphere (Borod et al. 1986). Numerous studies have shown a corresponding deficit in schizophrenic patients, independent of their ability to recognize faces or general spatial patterns (Borod et al. 1993). This disturbance probably represents a "trait," as suggested, for example, by the findings of Wölwer et al. (1996) and of Addington and Addington (1998), who studied not only symptomatic patients, but also patients in remission.

The results of neuropsychological studies in which both linguistic and visuospatial abilities were tested can be summarized as follows (see also Chap. 8, this volume): linguistic function is usually more severely impaired than visuospatial ability in schizophrenic patients. This implies that the neuropsychological deficit resides predominantly in the left hemisphere (Flor-Henry 1976; Ragland et al. 1999). In view of the presence of sex-specific differences in laterality shown by the study by Ragland et al. (1999), sex will have to be taken into account in future studies.

6 Early Auditory Information Processing

Abnormalities of the electroencephalogram and of event-correlated potentials in schizophrenics indicating the presence of a disturbance of hemispheric lateralization have been discussed in the chapter on neurophysiological techniques (Chap. 9, Vol. 1). In this section, we will discuss more fully three studies employing magnetoencephalography (MEG) that yielded further, highly indicative findings. In all three of them, interhemispheric functional differences were detected by measuring neuromagnetic fields after stimulation with a binaurally delivered tone, with special attention to the M100 peak, which is generated after about 100 ms in the area of the primary auditory cortex. The M100 can be characterized as a dipole, and the interhemispheric comparison of dipoles can be used as an index of hemispheric lateralization. These studies thus dealt with early auditory information processing in schizophrenics.

Reite et al. (1997) first determined the localization of the M100 dipole in normal subjects using a seven-channel MEG system and found that the neuroanatomical source of the M100 in the right hemisphere was anterior to that in the left hemisphere and that this asymmetry was more pronounced in men than in women. No asymmetry was found in male schizophrenics, while female schizophrenics had a more pronounced asymmetry than female control subjects. Reite and colleagues attributed these findings to a sex-specific disturbance of hemispheric lateralization,

which may occur during intrauterine development under estrogenic influence. In another study employing a 31-channel system (Hajek et al. 1997a,b), the findings were less clear with regard to dipole localization, but comparable with regard to dipole orientation, which can be measured more reliably: A deviation of the dipole in comparison to same-sex controls was demonstrated in the left hemisphere in male schizophrenics and in the right hemisphere in female schizophrenics. The possible explanations for these phenomena are discussed elsewhere in greater detail (see Sauer et al. 1998).

In the third study (Tiihonen et al. 1998), evidence was found for a reversal of cerebral asymmetry, but in only 32% of patients; further calculations revealed that this finding was predominantly due to left-hemisphere alterations. Nonetheless, 16% of patients had a stronger asymmetry than the control subjects; the authors concluded that the development of cerebral asymmetry in schizophrenics is subject to faulty regulatory control. Reversed asymmetry was found to be associated with a higher general psychopathology score.

With regard to the interpretation of these studies, it must be emphasized that only the cortical response to stimuli is detected by the MEG. Taken together, the three studies indicate that there are differences of laterality between men and women, and between schizophrenics and control subjects. The etiopathogenetic significance of the change in the M100 source has, however, not yet been explained. It may be no more than an anatomical index; if so, then the findings presumably reflect a disturbance of hemispheric lateralization occurring in utero under the influence of sex hormones between the 20th and 30th weeks of gestation, as hypothesized by Reite. On the other hand, it remains possible that the dipole abnormalities come about as a result of the disease itself or its treatment. This question could be answered by a study of "high-risk" children or of patients showing the earliest manifestations of the disease.

7 Attention

Disturbances of attention have been of central importance for the understanding of schizophrenia since the time of Kraepelin and Bleuler and are a particularly complex set of phenomena. In this section, we will discuss high-resolution fMRI studies in which changes of cerebral blood flow were measured during the performance of a task. A remaining problem in the interpretation of the results obtained with such paradigms is that the changes measured are usually due not only to attention, but also to other cognitive functions at the same time.

The complexity of attention processes was demonstrated in an fMRI study performed on normal subjects by Peterson et al. (1999). While the subjects were performing the Stroop Test, a word–color interference test that also contains a component relating to impulse control, activations were found primarily in the anterior cingulum and the mesiofrontal cortex. These were correlated with activity in several other brain areas that have been implicated in the processes of sensory perception, language comprehension, vigilance, working memory, selection of responses, and the planning and performance of motor functions. Evidence was also found in favor of the existence of several distinct attention systems, which are probably coordinated and integrated by the cingulate gyrus (see Chap. 7, this volume). There was no evidence for a lateralization of attention in normal subjects.

In a further fMRI study employing a single-slice technique, Häger et al. (1998) applied the Continuous Performance Test (CPT), which had been used in "high-risk" studies to determine which of a group of currently healthy individuals would later develop schizophrenia. The CPT is a test of attention span, but the version used in the study also tests working memory. The largest activations were found in the mesiofrontal cortex, cingulate gyrus, and dorsolateral prefrontal cortex on the right side and in the thalamus bilaterally. The same group of researchers, in a later publication, compared the activation patterns of normal subjects and schizophrenics (Volz et al. 1999). Schizophrenics had a lesser degree of activation than normal controls in the right mesiofrontal cortex, the right cingulate gyrus, and the left thalamus. Further analysis revealed that the smaller increase in cerebral blood flow was largely independent of the subject's performance on the test.

Even if only a few preliminary studies are currently available, it is clear that multiple brain areas are activated during complex processes such as attention and that distinct attention systems exist. It seems that one of these systems is more strongly localized to the right hemisphere than the other and is subject to a disturbance of activation, predominantly in the right hemisphere, in schizophrenic patients.

8 Conclusion

The studies discussed above did not yield consistent results on the question of hemispheric lateralization in the schizophrenias. The findings with regard to brain morphology (see Chap. 10, Vol. 1, Part 1),

the electroencephalogram (Chap. 9, Vol. 1, Part 1), and brain function, especially as revealed by studies of handedness and language (this chapter), all suggest the presence of a left-hemisphere disturbance. Further evidence for a left-hemisphere disturbance and an ensuing loss of the normal physiologic asymmetry of the hemispheres comes from quantitative MEG studies of early auditory information processing. On the other hand, a right-hemisphere disturbance is suggested by findings regarding attention, spatial perception, and the recognition of facial and linguistic emotional expression; these findings are less consistent than the left-hemisphere findings. There have also been several methodologically sound studies of right-hemisphere function in which schizophrenic patients were not found to have any abnormality. There is thus more evidence overall for a left-hemisphere than for a right-hemisphere functional disturbance.

When a disturbance is found in a particular brain function attributed to one hemisphere, or when functional imaging studies reveal an abnormality in one hemisphere, the inference that the seat of the dysfunction actually lies in that hemisphere remains provisional, because the possible effects of normal and disturbed interhemispheric connectivity are not yet adequately understood. Moreover, it has become evident in recent years that many variables can influence the results of studies of hemispheric lateralization. For example, lateralization abnormalities detected by MEG are dependent on sex: left-hemisphere abnormalities were found in male schizophrenics, and possible right-hemisphere abnormalities in female schizophrenics. Hemispheric lateralization is also influenced by psychopathological features, as seen, e.g. in the effect of auditory hallucinations on the reduction of the right-ear advantage. The acuity of the illness, too, modulates the disturbance of hemispheric lateralization: mixed handedness, for example, is more common in acute psychosis than during remission.

These abnormalities of hemispheric lateralization have been explained in various ways. Crow (1997), for example, postulates that a gene localized in the homologous region of the X chromosome, and responsible for the ontogenic development of hemispheric lateralization, bears an etiopathogenetic relationship to schizophrenia. This hypothesis can only be considered speculative at present. It seems more plausible that abnormal lateralization results from the same disturbance of neural development that is currently thought to cause the later cerebral morphologic and functional abnormalities of the schizophrenias in general (Chap. 4, Vol. 3, Part 1). Several lines of evidence point to such a developmental disturbance, most likely occurring in the second trimester of pregnancy, which is the period in which cerebral lateralization develops. The more severe involvement of the left hemisphere than of the right hemisphere may be attributable to the fact that it matures more slowly during fetal development (Saugstad 1998) and is thus more vulnerable to genetically based disturbances or exogenous injury (Bracha 1991).

Pathogenetic models of schizophrenia have now become more complex and are no longer based solely on circumscribed functional abnormalities, such as hypofrontality or temporofrontal disconnection. The "cognitive dysmetria" model (Andreasen et al. 1998), for example, postulates a disturbance of interconnected frontal, thalamic, cerebellar, and (in its most recent version; Andreasen 1999) temporal systems. Yet even these current, more complex models fail to integrate the findings on hemispheric lateralization. This is a difficult task, and it will remain so because, as the studies discussed here show, abnormal lateralization can no longer be understood as a single alteration equally affecting all regions of the brain and all cerebral functions. Future studies of hemispheric lateralization must be carried out more specifically, with respect to individual cerebral structures and functions, and future models of schizophrenia are thus likely to be more complex than current models. Such investigations may lead the way to a better understanding of those clinical findings and disease manifestations whose occurrence and degree of severity are related to an abnormality of cerebral lateralization.

H. Beckmann

Neuropathology of the Endogenous Psychoses

Translator: E. Taub
Dedicated to Hermann Jakob for his 80th birthday.
I thank Mrs. Sabine Voss for her competent and thorough assistance with the preparation of the manuscript.

1 Introduction

Although research into the etiology of the schizophrenic diseases is still largely dominated by genetic, biochemical, (socio-)psychological, and analytical methods, an increasing number of neuropathological studies have also been published recently. The search for "specific" anatomic and histologic alterations in the psychoses had already begun by the late nineteenth century. The existence of focal areas of neuronal loss (*Lückenfelder*, i.e. "lacunar fields") noted by the earlier authors (Alzheimer 1897; Josephy 1923; Fünfgeld 1952) was later confirmed in adequately controlled studies by Dunlap (1928), Spielmeyer (1930), and Peters (1937), but was considered thereafter to be merely a reflection of age-related changes in the nervous system, intercurrent illnesses, and terminal conditions. Questions concerning the histopathology of schizophrenia were not raised again until the First International Congress of Neuropathology was held in Rome in 1952.

At this congress, Cécile and Oskar Vogt and their students presented some of the earlier findings again and introduced the so-called dwindling disease (*Schwunderkrankung*) and fatty degeneration as new criteria for the pathology of schizophrenia (Vogt and Vogt 1952). Peters (1956, 1967) was the most prominent critic of these reported findings, which related to the central nuclei, including the dorsomedial thalamic nuclei, the pallidum, and the anterior portion of the cingulate gyrus. He regarded these alterations as artifacts of preparation or as agonal cellular changes. It was primarily because of his influence that research in the specialized area of the pathological anatomy of the psychoses came to an almost complete halt in the institutions in which it had been carried out up to that time. Pathological anatomy was no longer mentioned, even as a possible point of departure for basic research in schizophrenia. Schizophrenia remained a subject of neuropathological research in a small number of centers, but none of the findings obtained were consistent and specific enough to be considered a basic process with clinical relevance (Jellinger 1985).

The critical evaluation of pathoanatomic findings requires a thorough understanding of the histologic techniques applied. All pressure on the brain must be avoided from the moment it is removed, including during positioning. Faulty positioning of the brain and the addition of water can lead to homogeneous neuronal alterations, including cloudy swelling (Cammermeyer 1967; Lindenberg and Haymaker 1982), that are often mistaken for pathological processes by inexperienced investigators (Hyden and Hartelius 1948). The practice of fixing the brain in formalin for several months, which has recently become standard, has the advantage of leaving brain volume nearly unchanged, but the long fixation time leads to an obscuring of structure and to artifacts, at least on Nissl staining (Benes 1988; Casanova and Kleinman 1990), and this material is therefore suitable only for volumetry. Artifactual changes in the parenchyma must be excluded by means of histologic study. The postmortem interval, correction factors for shrinkage, and variations in the cutting angle may also lead to considerable differences in quantitative studies.

The mutual inconsistency of many findings may have several causes in addition to those already mentioned. Differences in the origin of the histologic preparations are critically important. The two most important large collections of tissue that are used for such studies are the Vogt Collection in Düsseldorf and the Yakovlev Collection in Washington, DC. The methods of tissue preparation in these two collections differ considerably: in the former collection, the brains are embedded in paraffin, in the latter in celloidin. The celloidin embedding process is much less damaging to the tissue than the paraffin embedding process. Because the process of dehydration is very slow, shrinkage and other artifacts are nearly completely absent, and lipids are preserved relatively well. In contrast, in the paraffin process, the tissue shrinks more extensively, and lipids are almost completely dissolved during embedding (Blackwood 1976).

These complex methodological considerations may serve to explain why anatomic and histologic research in the area of the so-called endogenous psychoses is carried out by only a small number of scientists. The earliest findings of morphological abnormalities in the schizophrenic brain that are now held to be securely confirmed were made in radiological studies. Studies employing pneumoencephalography, echoencephalography, and, later, computed tomography yielded the finding of cerebral atrophy or degeneration of a previously unknown type, which was taken to be an important pathogenetic factor. This consisted of a usually asymmetrical, regionally more pronounced dilatation of the lateral ventricles and the third ventricle, and a similarly locally variable dilatation of the cerebral sulci.

2 Macroscopic Alterations

Macroscopic alterations of the brain in schizophrenic patients are rather mild and are not found in all cases. There is usually an overall reduction in volume of the entire brain in patients with affective disorders, as

compared to normal control subjects. This volume reduction is associated with a reduction in the overall length of the brain and with dilatation of the lateral ventricles (Crow et al. 1989). The weight of the brain may be either reduced (Pakkenberg 1987) or normal (Bogerts et al. 1990), perhaps because different macroscopic forms exist. Stereological methods also usually reveal volume reduction in schizophrenia (Pakkenberg 1987, 1989). When leukotomized and non-leukotomized brains were compared, there was a reduction of volume only in the white matter and the central nuclei, but the number of neurons in the neocortex was not reduced (Pakkenberg 1993). The cortical volume was reduced, however, and it was proposed that this was due to changes in the neuropil. On the other hand, the same method applied to the brains of schizophrenics revealed no significant changes of this nature in either the cortex or the white matter (Heckers et al. 1991).

A quantitative postmortem study of the brains of 35 schizophrenic patients revealed a significant reduction in the length of the left sylvian fissure, which in the normal brain is markedly longer than the right sylvian fissure. This finding and the observed dilatation of the inferior horn of the left lateral ventricle may be interpreted as expressions of a developmental anomaly (Crow et al. 1992; Falkai et al. 1992).

In 108 cases of chronic schizophrenia, including four cases of manic-depressive illness, macroscopic abnormalities were found mainly in the middle and inferior temporal gyri, far more frequently on the left side than on the right (Jakob and Beckmann 1989; Beckmann and Jakob 1991). The brains were found to be divisible into two groups on the basis of their pathological features:

1. Brains of *type 1* had normal mass and no macroscopic abnormality other than an abnormal gyral pattern of the left temporal lobe, in which the inferior and middle temporal gyri ran not sagittally, but diagonally, from caudal and inferior to rostral and superior, toward the superior temporal gyrus. These two gyri were usually interrupted by several vertically oriented grooves.
2. Brains of *type 2* were of mildly reduced mass (approx. 1100–1150 g) and were characterized by an abnormal configuration. They were usually smaller, with blunting of the frontal poles and a tendency toward micro- or brachyencephaly. The temporal gyri were generally full and the surface smooth, without the otherwise typical fine relief pattern. These rather nonspecific anomalies are also found in other disorders, such as oligophrenia or multiple congenital anomalies (Le Mire et al. 1975; Jakob and Beckmann 1989).

These findings were later confirmed in vivo by magnetic resonance imaging (MRI) with three-dimensional surface rendering of the brain in 15 schizophrenic patients and 15 control subjects. The qualitative analysis was primarily based on measurements of the sulci and revealed a more vertical orientation of the left temporal sulci, with an interrupted course, resulting from a diagonal orientation of the gyri. The control subjects, in contrast, had more horizontally oriented gyri and sulci, without interruptions. It was quantitatively confirmed that there were significantly more sulcal lines with interrupted courses, predominantly on the left side, and particularly in the left temporal lobe (Kikinis et al. 1994).

It is of interest in this context that the pattern of gyri and sulci in the lateral inferior portion of the human temporal lobe appears relatively late in fetal development, from the seventh to the eighth month of gestation (Le Mire et al. 1975). The gyri develop at different times. The superior temporal gyrus, along with the parahippocampal gyrus, appears relatively early, at about 23 weeks. The development of a finer pattern in the superior temporal gyrus occurs only in the last month of gestation (Dooling et al. 1983). After the macroscopic formation of these structures, further time is needed for the formation of afferent and associative pathways and for synaptogenesis.

These macroscopic abnormalities of cortical development are probably to be grouped within the overall complex of developmental disorders. Nonetheless, the macroscopic features of the two types of brains described above are highly variable and were found only in most, but not all, of the cases with chronic schizophrenia. The question of a possible correlation between these different macroscopic types and the clinical subgroups of the schizophrenias has not yet been adequately addressed.

A significant reduction in the volume of the amygdala, the hippocampus, the parahippocampal gyrus, and the internal pallidal segment on both sides was found by Bogerts and collaborators in serial sections from the Vogt Collection and was interpreted by them as focal atrophy of unknown etiology (Bogerts 1986; Bogerts et al. 1985). Doubt was cast on this hypothesis by later radiologic studies demonstrating that the hypothetical atrophic process is present even before the earliest clinical manifestations of disease.

Gliosis in the periventricular area around the third ventricle, in the hypothalamus, in several frontobasal areas, in periaqueductal areas of the midbrain, and in the rostral pons was demonstrated quite early in paraffin and frozen sections with the Holzer method. Granulations were also found on the ventricular ependyma. These abnormalities were most pro-

nounced in pathways and nuclei of the limbic system: the centromedial nuclei of the amygdala, the dorsomedial thalamic nuclei, the caudate nucleus, and the nucleus accumbens (Stevens 1982). The presence of gliosis could not be confirmed, however, by quantitative methods with the glial fibrillary acid protein (GFAP) immunoperoxidase technique (Roberts et al. 1986, 1987). Stevens and Casanova (1988) pointed out that gliosis is not a reliable finding and is not associated with specific areas, but, rather, differs from brain to brain. According to these authors, the GFAP-immunohistochemical methods are more suitable for tumors and experimental pathology and are applicable only under certain conditions (Hirano 1985) that were not fulfilled in Roberts's study.

Gliosis, such as has been described in several areas of the brain, need not be associated with major parenchymal injury. The severity of tissue injury and the density of gliosis are not always proportional to each other. According to Scholz (1957a,b), meningeal or ependymal inflammation (among other causes) may give rise to gliotic reactions without damaging nervous tissue to a comparable extent. Mild edema, especially protein-rich exudates, may result in the production of fibrous precipitates that resemble fibrous gliosis, without destruction of the parenchyma. This type of gliosis formation may occur either on the outer or on the inner surface of the brain, i.e. the ventricular wall, where subependymal glial fiber deposits may form. Surface phenomena and tension effects play an important role in this process.

Concepts of the pathogenesis of schizophrenia slowly changed as a result of the discovery of a number of local abnormalities in central areas of the limbic system. The findings obtained to date in schizophrenia and its subgroups will now be presented according to their anatomic locations.

3 Hippocampus

The hippocampus is the central structure of the limbic system. It consists of supramodal association cortex and projects to many other complex supramodal association areas, to visceromotor control systems, and to the nucleus accumbens (Swanson 1983). The perforant pathway links the hippocampus with the entorhinal area, with which it forms a functionally important regulatory circuit ("entorhino-hippocampal loop"; Swanson et al. 1978). This fiber bundle passes from the entorhinal fields, primarily layer II pre-α, directly to the neurons of CA1–CA3 and also, as an axodendritic connection, to the granule cells of the dentate gyrus (Segal and Landis 1974; Fifkova 1974). The Papez regulatory circuit connects the hippocampus by way of the fornix, the cingulum, and the mamillary body with the anterior thalamic nuclei and, by way of the septal nuclei, with the hypothalamus (Hassler 1964; Stephan 1975). The hippocampus thus occupies a central position in which it integrates information from all sensory modalities (O'Keefe and Nadel 1978; Turner et al. 1980) and influences somatomotor, visceral, voluntary, and cognitive mechanisms at the cortical level (Swanson et al. 1978; Braitenberg and Schüz 1983).

Scheibel and Kovelman (1981; Kovelman and Scheibel 1984), using Nissl and Golgi methods, found pronounced alterations of the orientation of the pyramidal cells and their dendrites. The degree of axial disorientation of the pyramidal cells was as high as 180° in places. Disorientation was most severe in the intermediate areas between the subiculum and CA1 and between CA1 and CA2, but was present only in some of the cases studied. It was stated that the histologic appearance of this abnormality implies that it must arise at a relatively early stage of fetal development (Scheibel and Kovelman 1981). These findings were confirmed in material from the Yakovlev Collection (Altshuler et al. 1987) and also quantitatively, as a possibly bilateral phenomenon, by Conrad et al. (1991), who made similar findings in the right hippocampus.

These findings remained controversial, however, because they could not be confirmed in later studies of tissue from the Yakovlev Collection (Christison et al. 1989). Arnold et al. (1995) stated that they had found no significant abnormalities of this kind in a thorough investigation of 14 cases of chronic schizophrenia. They found only reduced neuronal size in the pyramidal cell layer, reaching significance in the subiculum and CA1 as well as in layer II of the posterior portion of the entorhinal cortex.

It is possible that these abnormalities are not generally present, and it must also be borne in mind that the Golgi method was not used in this area. These findings in distinct sectors of the pyramidal cell layer lead us to consider a possible relation to the adjacent entorhinal area, to which it is anatomically and functionally linked and which occupies a central position in the limbic system (Stephan 1975). The types of injury found there (see Sect. 5) may be caused, among other factors, by the same disturbances of fetal development in the second gestational trimester that give rise to neuronal disorientation. It is hypothesized that these pathological alterations may also affect the synaptic pattern and may thereby result in functional disturbances of information processing (Scheibel and Kovelman 1981; Kovelman and Scheibel 1984).

It is very difficult to make a judgment of reduced cell number in individual sectors of the hippocampus,

Table 1. Postmortem abnormalities of hippocampal neurons in patients with chronic schizophrenia

Authors	Origin of material, methods	Abnormalities
Bogerts et al. (1985, 1986)	Vogt Collection (paraffin, Nissl)	Reduced cell number in CA1 through CA4, also in the pallidum in cases with catatonia
Falkai and Bogerts (1986)	Vogt Collection (paraffin, Nissl; structural and quantitative studies)	Reduced cell number in CA1 through CA4 in internal and external pallidal segments
Scheibel and Kovelman (1981), Kovelman and Scheibel (1984)	The authors' own cases (Nissl and Golgi technique; Davenport)	Disorientation ("twisting") of pyramidal cells from the subiculum to CA1, as well as CA3 and CA4, in the left hippocampus, quantitatively demonstrated
Altshuler et al. (1987)	Yakovlev Collection (celloidin, Nissl)	"Pyramidal cell disarray" in the left hippocampus, pronounced abnormality of migration
Conrad et al. (1991)	Los Angeles Veterans Administration Medical Center (frozen section method, Nissl)	Abnormalities of hippocampal pyramidal cell orientation, quantitatively demonstrated on both sides
Christison et al. (1989)	Yakovlev Collection (celloidin, Nissl)	No "pyramidal cell disarray" in CA1 of the left hippocampus
Heckers et al. (1991)	The authors' own cases (own frozen section method; stereological methods in serial hippocampal sections)	No abnormality of cell number in CA1 through CA4
Benes et al. (1991)	McLean-Hospital, Belmont, Massachusetts (vibratome sections after brief fixation, cresyl violet; Nissl)	Reduced number of pyramidal cells in CA1; reduced size of pyramidal cells in sectors of the pyramidal cell layer; no "pyramidal cell disarray," no reduction of volume

because the number of cells depends on the age of the patient, on intercurrent illnesses, and on the histologic method used. The reported qualitative differences in neuronal density among different hippocampal sectors are, therefore, controversial (Table 1). The hippocampus – particularly sector CA1, the so-called Sommer sector – is highly susceptible to hypoxic damage. Hypoxia in the setting of intercurrent illnesses often leads to neuronal injury, ranging from a reduction in cell number to total neuronal loss (hippocampal sclerosis); vascular factors may also play a role in this process (Scholz 1957a).

The data with respect to reductions in hippocampal volume in schizophrenia are not entirely consistent (Table 2). Jeste and Lohr (1989), working with material from the Yakovlev Collection, Altshuler et al. (1990), using their own case material, and similarly Arnold et al. (1995) were unable to find a general reduction in volume at any site, with the exception of CA4. Heckers et al. (1990a,b) also found no significant reduction in volume in either the parahippocampal gyrus or the hippocampus, but there was a suggestion of volume reduction below the level of statistical significance on the left side (6%), which was limited to the anterior portion of the hippocampus. In view of the preservation of parenchyma in the different sectors of the pyramidal cell layer of Ammon's horn, this mild reduction in white matter volume might be attributable to the perforant pathway (see Sect. 5). This abnormality is also consistent with the occurrence of developmental disturbances nearly simultaneously in the entorhinal area and the hippocampus.

Benes (1989) studied myelin-stained sections of the frontal cortex, the parahippocampal gyrus, the perforant pathway, the cingulate gyrus, and the hippocampus to detect changes in myelination during development. Increased formation of myelin in late adolescence as compared to earlier times was detected in hippocampal areas and in the subiculum and presubiculum, where fibers of the perforant pathway and distal portions of the cingulate fiber bundle are distributed. The author relates these findings to the findings in schizophrenics discussed above and advances the hypothesis that certain early manifestations of schizophrenia in adolescence may bear a causal relationship to this relatively late development of myelination. These disease manifestations are seated in the anatomic connections of the limbic system and may be the result of inadequate integration of corticolimbic functional circuits.

Table 2. Postmortem findings regarding alterations of hippocampal volume in chronic schizophrenia

Authors	Origin of material, statistical and volumetric methods	Alterations of volume
Bogerts (1984, 1985, 1986)	Vogt Collection (paraffin, Nissl)	Reduced volume of hippocampus, parahippocampal gyrus, amygdala, and internal pallidal segment
Falkai and Bogerts (1986)	Vogt Collection (paraffin, Nissl)	Reduced hippocampal volume (CA1–CA4)
Bogerts (1989)	Vogt Collection (paraffin, Nissl)	Reduced volume of the hippocampal formation
Bogerts et al. (1990)	The authors' own cases (long fixation in formalin; paraplast, Nissl, and Heidenhain-Woelcke technique)	Reduced hippocampal volume; approximately 10% smaller volume of the internal pallidal segment in women compared to men, here also reduced volume of the nucleus accumbens
Jeste and Lohr (1989)	Yakovlev Collection (celloidin, Nissl)	No volume reduction of the hippocampus overall; volume reduction only in CA4, with reduction of pyramidal cell density
Altshuler et al. (1990)	Neuropathological Section of the National Institute of Mental Health, Bethesda, Maryland	No alteration of hippocampal volumes; reduced volume of the parahippocampal gyrus
Heckers et al. (1990a)	The authors' own cases (thick sections, serial Nissl sections)	No reduction of hippocampal or amygdalar volume
Heckers et al. (1990b, 1991)	The authors' own cases (thick sections, stereological methods in serial Nissl sections)	Reduced volume of the left hippocampus only (not significant); white matter changes
Arnold et al. (1995)	The authors' own cases (paraffin, Nissl, 15 μm)	No volume reduction of the hippocampus or the parahippocampal gyrus; reduced neuronal size in subiculum, CA1, and layer II of the entorhinal cortex (caudal portion)

4 Parahippocampal Gyrus

Macroscopic findings to date in the parahippocampal gyrus, which is located at the base of the temporal lobe and is cytoarchitecturally nearly identical to the entorhinal cortex, are highly variable; they are listed in Table 2. The topography of cytoarchitectural changes in the rostral portion of the entorhinal area within the parahippocampal gyrus, in the ventral portion of the claustrocortex (insular cortex), and in the rostral portion of the cingulate gyrus is depicted in Fig. 1 (hatched areas).

5 Entorhinal Area

The entorhinal area is an important, differentiated "association center" within the allocortex (Braak 1980). It is intimately connected to the hippocampus by way of the perforant pathway and thus forms, together with it, a multineuronal regulatory circuit at the center of the limbic system (see Sect. 3). Signals arriving in the entorhinal cortex proceed to the hippocampus, pass through several synapses, and return, in part, to the entorhinal cortex. This regulatory circuit seems to be of major importance for the storage of orientation and for memory (Braitenberg and Schüz 1983).

Studies in primates have shown that primary cortical fields and all secondary cortical fields with visual, auditory, and somatosensory functions have reciprocal connections with the entorhinal cortex, either directly or by way of the perirhinal area (Jones and Powell 1970; van Hoesen 1982; Pandya and Yeterian 1985). The multisensory areas in caudal portions of the orbitofrontal region, and the rostral and ventral fields of the claustrocortex, project mainly onto the rostral fields of the entorhinal area. The olfactory cortex is the only unimodal field that projects onto rostral entorhinal areas (Insausti et al. 1987). Furthermore, as extensive studies in the cat have shown, there are well-developed systems of both

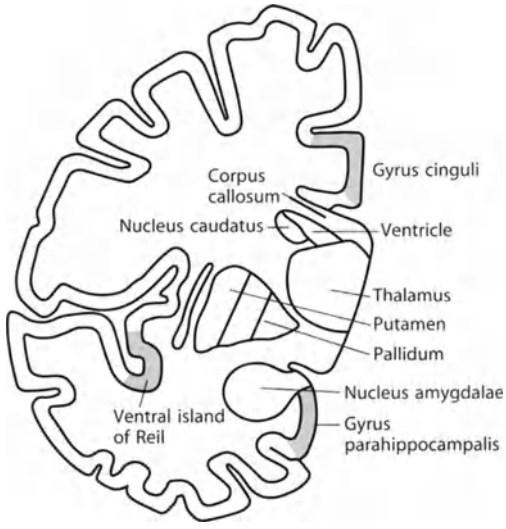

Fig. 1. Coronal section of the left hemisphere passing through frontal and temporal lobes at the level of the rostral portion of the amygdala; *hatching* indicates areas of cytoarchitectural alteration. (Modified from Jakob and Beckmann 1986)

longitudinal and transverse connections that enable the activity of systems within the entorhinal cortex to be integrated with the complex of afferent information. Sensory afferent information is delivered to the hippocampus by way of the upper layers of the perirhinal area and the entorhinal cortex. Efferent projections arise from the lower layers of the perirhinal and entorhinal areas. The entorhinal cortex thus integrates information from all sensory modalities from both the interior and the exterior of the organism (O'Keefe and Nadel 1978; Turner et al. 1980; Witter et al. 1986).

The allocortex is roughly divided, on a topographical basis, into medial, lateral, and perirhinal portions. The last-named area, which is also called the transentorhinal subregion (Braak 1980), lies between the lateral part of the entorhinal cortex and the isocortex of the temporal lobe (Stephan 1975). It displays the full array of cortical layers in a coronal section passing through the central portion of the amygdala, in the entorhinal central medial and lateral area (and the interpolar medial area); it is most highly differentiated in the central lateral area. The upper portion of the cortex, the principal external lamina, is divided according to Rose (1927) into the zonal lamina (I) and the Pre-α (II), Pre-β, and Pre-γ (III) layers, and the adjacent acellular layer, the lamina dissecans (layer IV). The lower portion of the cortex, the principal internal lamina, is subdivided into the Pri-α, Pri-$\alpha\beta$, and Pri-$\alpha\gamma$ sublayers (Pri layers), which consist mainly of pyramidal cells. In the central fields, layer II Pre-α consists mainly of islands of similar-appearing, medium-sized to large multipolar "modified" pyramidal cells with long axons extending into the white matter. This type of neuron is characteristic of this area and is not found elsewhere (Braak 1980).

Detailed observations concerning the development of this area were made in autoradiographic studies of rhesus monkey embryos at different developmental stages (Nowakowski and Rakic 1981; Rakic and Nowakowski 1981). These findings may be regarded as a model of the developmental process in humans (Nowakowski 1987; Sidman and Rakic 1973). The matrix for archi- and peri-archicortical areas corresponding to the hippocampus and the entorhinal cortex lies in the medial wall of the hemispheric vesicle, the initial embryonic precursor of the cerebral hemisphere. The neuroblasts destined to form the cerebral cortex are already determined at this stage (Rakic 1988a,b). While the neuroblasts of the ventricular zone form the lower layers of what will later become the entorhinal cortex, the subventricular zone gives rise to its upper layers. This is also the site where, after the last cell division, active movement of the neuroblasts (i.e. cell migration) begins. Neurons at this stage have a leading process, a fusiform, bipolar shape with an ovoid nucleus, and a long trailing process and are called "young neurons." The leading process is essential for movement of the migrating neuron (Rakic 1978; Caviness et al. 1981).

"Cohorts" of closely spaced young neurons migrate along the course of previously laid down glial fibers outward to the cortical plate, passing by groups of neurons that had reached their destinations earlier, and proceed to the outermost surface of the cortical plate, thus forming "vertical or ontogenetic columns" (Rakic 1988a). The young neurons do not assume their mature pyramidal or polygonal shapes until shortly before they reach their cortical destinations. Later, as further columns migrate to the surface, they become resubmerged in the deeper layers. Thus the outer cortical layers are formed last. This so-called inside-to-outside spatiotemporal gradient is operative for all neocortical and most allocortical areas of the human brain (Sidman and Rakic 1973; Nowakowski 1987). Even at early developmental stages, distant regions begin to make afferent connections, which radiate into the lower zone of the cortical plate (Rakic 1988a).

The development of the entorhinal area in humans is similar to the development in the rhesus monkey just described in many important respects, although it is not yet known in equivalent detail. Compared to other cortical areas, the entorhinal area develops in a relatively brief period of migration. The earliest evidence of a germinal epithelium, or matrix, in the developing fetus is found in the third month at the base of a caudal area of the lateral ventricle. The first signs of migration are demonstrable in embryos aged

approximately 10 weeks (Kostóvic et al. 1990). At the end of the third gestational month, entorhinal and presubicular areas can already be distinguished in the cortical plate (Macchi 1951; Kahle 1969). Positions in the cortex are occupied in the sixth month, and the matrix is entirely depleted in the seventh (Stephan 1975). Further details of the early development of the entorhinal cortex in humans remain controversial.

Among 108 cases of schizophrenia of various types studied histologically, including four cases of manic-depressive illness, 78 cases showed major cytoarchitectural abnormalities in the rostral portion of the entorhinal cortex. These abnormalities extended, in the anteroposterior direction, to the frontobasal area rostrally, but caudally only to the level of a section through the inferior horn of the lateral ventricle and the anterior portion of the hippocampus, where the cytoarchitecture became increasingly normal. The most pronounced abnormalities were found in the anterior sections. An increased number of glia was not observed anywhere (Jakob and Beckmann 1985, 1986, 1994).

As for technique, standard neuropathological methods were used (see Sect. 1), and the inferior portion of the left hemisphere, sectioned at the level of the amygdalar nucleus, was embedded in celloidin; 20-μm-thick celloidin sections were stained with Nissl and Heidenhain-Woelcke stains for histologic investigation, and 16 cases with other clinical diagnoses were selected for use as controls. Graded series of cases and controls were used to obtain an overall view of the extent of the histologic abnormalities.

The most pronounced findings were cytoarchitectural abnormalities in layers Pre-α and Pre-β; abnormalities of Pre-α in the central regions often consisted of only a few characteristic island-like formations. These layers were irregularly constructed. Because the structural abnormalities were variable, a uniform pathological picture could not be obtained. While only the Pre-α and Pre-β layers were affected in "mild" cases, the entire cortex was affected in "severe" cases. In the latter cases, layers III and IV (the Pri-layers) were depleted of approximately 20% and 40% of their neurons, respectively, in comparison with controls (Jakob and Beckmann 1986).

The most commonly encountered abnormalities of layers II Pre-α and III Pre-β appeared to be less of a quantitative than of a structural nature (Jakob and Beckmann 1994). The authors described two basic types of abnormality:

1. *Type 1:* absence of layer Pre-α, with only a few atypical neurons.
2. *Type 2:* here the insular formations of Pre-α were also absent.

Together with the upper portion of layer Pre-β, layer Pre-α had the appearance of a "double row." This consisted of a narrow upper layer, composed of a row of small neurons lying adjacent to one another, and a lower row of tightly spaced collections of groups of atypical neurons that normally do not appear at this site, clearly distinct from the pyramidal cells of layer Pre-β. The authors regarded these as malformed heterotopies. The entire layer thus takes on a markedly "spotted" appearance.

Two distinct, well-defined types of neuronal formation were found among the malformed heterotopies of layer Pre-β just discussed. One of these consisted of atypical pyramidal neurons, of considerably reduced volume, usually lying so close together that no separation between them was visible under the light microscope (Fig. 2). The other type of abnormal neuronal formation consisted of groups of loosely scattered fusiform or bipolar neurons in layer Pre-β, which were markedly smaller and were often arranged in columns (Fig. 3).

The histologically evident reduction of neuronal volume in layer III in schizophrenic patients can be documented with the aid of a computed analytical method. The two types of neuronal groups were encountered in alternating fashion in sections at different levels. The authors assumed that these atypical neurons, which are reminiscent of "young neurons" (Rakic 1975, 1988a) in their shape and arrangement, had become stuck, as it were, in the last phase of migration and stayed in place as "ectopic neurons" unable to reach their pre-assigned destinations in layer Pre-α. It thus appears that there may be a local disturbance of neuronal development and/or migration restricted to the rostral portion of the entorhinal area in a late phase of development (Jakob and Beckmann 1986, 1994; Beckmann and Jakob 1994).

In four cases of manic-depressive illness, there were cytoarchitectural abnormalities here and in the rostral ventral portion of the insular cortex that were similar to those described in the schizophrenic psychoses, agreeing in all histologic details. The common features of these two types of psychosis have been pointed out many times (Beckmann and Jakob 1991).

We still possess inadequate knowledge, however, of the possible differences between the overall constellations of neuropathological abnormalities in these two types of disease. At present, only scattered observations indicate that such differences may exist. Correlations of the pathological features of these two types of psychosis with their clinical manifestations will presumably be possible in the future through further, detailed histologic studies of potential differences in the severity and extent of alterations in the entorhinal cortex of the two hemispheres.

The existence of structural architectural abnormalities in the rostral entorhinal cortex of patients with either type of major psychosis was confirmed by two

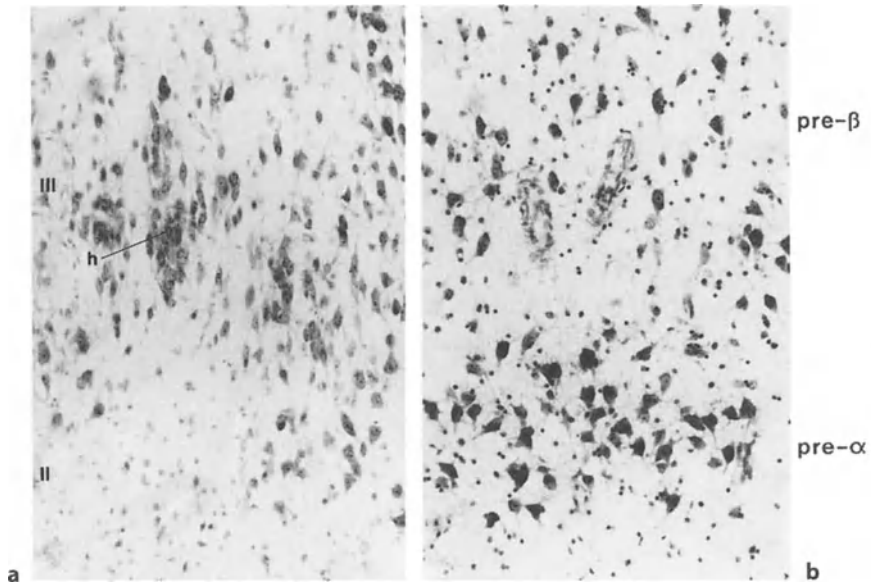

Fig. 2. a Focal malformation in the entorhinal area in a patient with chronic schizophrenia. Rostral cortical fields in a serial histologic study, fourth stage of the series, layers II/III Pre-α and Pre-β; layer II Pre-α shows irregularly scattered neurons without characteristic formation of cell islands; heterotopic groups (*h*) of presumably immature neurons in columnar configuration, in layer III Pre-β; and, below these areas, a neuron-free zone. **b** Control sections at the same level: layers Pre-α and Pre-β with normal cytoarchitectural structures. Nissl (20 μ), × 125. (After Jakob and Beckmann 1994)

further groups of investigators who studied cases taken from the Yakovlev Collection (Arnold et al. 1991). Quantitative studies yielded striking findings: in eight cases of schizophrenia, five cases of cyclothymia, and eight control subjects, the number of neurons in layer II Pre-α varied from zero, in severely affected cases, to normal. In such cases, the cytoarchitecture of the other layers was also markedly abnormal. Neurons of layer Pre-α were displaced into layer Pre-β. No significant differences were found between the two types of major psychosis (Casanova et al. 1991).

Krimer et al. (1997) studied the entorhinal area of schizophrenic patients and controls using inadequate methods. The fixation time was excessively long (up to 1 year), and the postmortem interval (average, 36 h) was unsuitable for sophisticated cytoarchitectural studies. Nonetheless, even in these authors' unclear illustrations, cytoarchitectural differences between control subjects and schizophrenics are evident. Senitz and Kalus (in press) were recently able to confirm the findings of Jakob and Beckmann (1986, 1994) in a series of 20 cases.

Cortical malformations of this type may have either of two possible causes:

1. The neurons are unable to begin migrating.
2. The migrating neurons remain in an ectopic position along the way to the cortex (Rakic 1988a,b).

The atypical neurons that do not belong in layer Pre-β seem to have encountered the second type of difficulty. Many of them are of obviously reduced volume when compared to other neurons in the same layer and to those of control subjects. These small neurons, which are often marked by a bipolar shape (see Fig. 3) or lie in layer Pre-β more as heterotopic clusters or as columns containing densely arrayed, undifferentiated neurons (see Fig. 2), seem to have become stuck along their way to the upper layer, Pre-α (Jakob and Beckmann 1994; Beckmann and Jakob 1994). A specific histologic demonstration of these neurons is not yet possible at present; they can be characterized only with the aid of an optimal staining technique.

These findings seem to imply that the malformation arises at a relatively late time in development. It is possible that there is a defect in the ontogenetic columns (second category; Rakic 1988b). The lower Pri-layers are heavily depopulated of cells in only a few cases. In view of the spectrum of alterations seen, and the time at which migration begins in the corresponding region of the human brain, a fetal injury at some time between the late third month and the fifth month of gestation can be presumed. A time of injury between the late fourth month and the fifth month is likely in most cases, because the upper cortical layers are often exclusively affected (Beckmann and Jakob 1994).

6
Temporal and Frontal Cortex

Evidence for a more generalized developmental disorder was obtained from the study of the temporal and frontal lobes of schizophrenics and control subjects. A particular type of neuron was studied that contains the

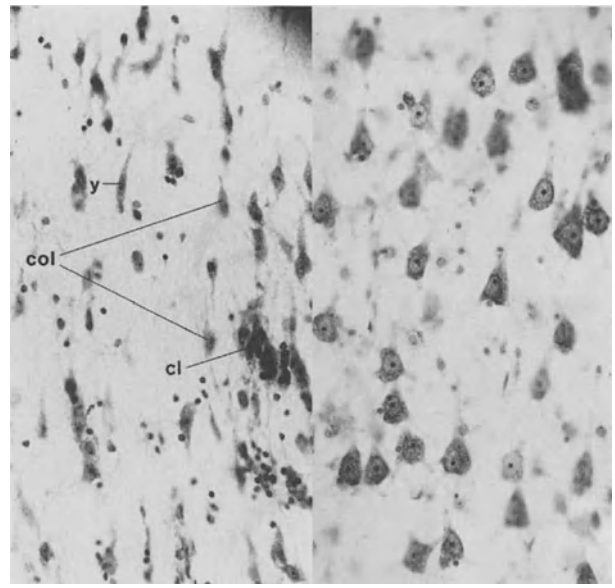

Fig. 3. a Sixth stage of the same serial histologic study as in Fig. 2 (left entorhinal area in a patient with chronic schizophrenia). Layer III Pre-β of the rostral portion of the left entorhinal area. Groups of small, undifferentiated neurons, either as clusters (*cl*) or as columnar arrays of fusiform cells (*col*); a few neurons clearly possess the characteristic features of "young" neurons (*y*). **b** Control: layer III of the left entorhinal region at the same level; considerable variation in the size and density of Pre-β pyramidal cells. Nissl (20 μ), × 200. (After Jakob and Beckmann 1994)

enzyme nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) and is normally found in the subcortical white matter. The number of nonpyramidal neurons of this type was significantly reduced in schizophrenic patients in the lower cortical layers and in the directly underlying white matter, both in the temporal isocortex and in the dorsolateral prefrontal cortex, but they were present at increased density in the deep white matter. This local difference was regarded by the authors as due to a disturbance in the development of the "subplate zone." It was postulated that these neurons fail to reach their destination while migrating toward the cortical plate and, instead, become stuck in the deep white matter as a consequence of a disturbance or inhibition of some type.

The "subplate zone" plays a vital role in the establishment of afferent pathways from other areas during the final phase of neuronal migration. A developmental disturbance in this area may thus affect widely dispersed frontal association fields. Defective functioning of the frontal lobe, particularly of association systems, is known to occur as a negative manifestation of schizophrenia (Akbarian et al. 1993a,b). Immunocytochemical studies employing neuron-specific antibodies also appear to indicate a disorder of migration in the frontal cortex of schizophrenics. The Cajal-Retzius cells (CRC) normally found in the molecular layer were distributed differently in schizophrenics and normal control subjects. The number of CRC in layer I did not differ in the two groups, but schizophrenics had significantly more of them in the lowest third of the layer than control subjects, in whom more CRC were found in the middle and uppermost thirds. The authors interpreted this finding as an expression of a disturbance of neuronal migration (Kalus et al. 1997a).

7 Orbitofrontal Area

Senitz and colleagues (Senitz et al. 1979; Senitz and Winkelmann 1981, 1991) used the Golgi technique as a routine method for the study of Brodmann areas 19 and 11 and were the first to find neuropathological abnormalities in the orbitofrontal region of schizophrenic patients. Because their method demonstrated the overall structure of the neurons, they were able to describe particularly striking and unusual neuronal forms:

- So-called "triangle cells" in layer VI were found to be more numerous and irregularly organized than in control cases.
- Many pyramidal cells were demonstrated in layer V that had forked major dendrites that could be followed all the way to layer II (Fig. 4). Dendritic duplication of this type can occur only during cortical development.
- Pyramidal cells were found in layer III that had relatively thick dendrites and atypically long, unusually shaped and thick spines. The number of spines was quantitatively measured and found to be significantly elevated on a large proportion of pyramidal cells. They often lay in tufts on the surface of the major dendrite or had several forked spine heads.

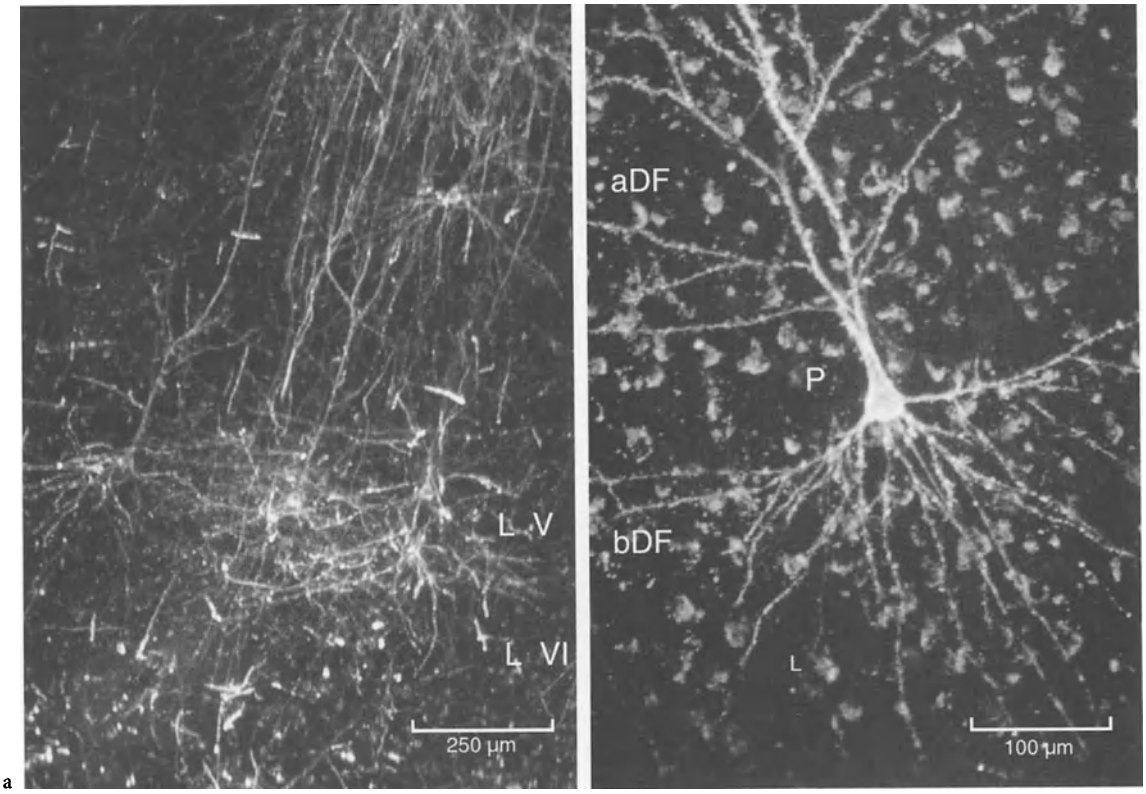

Fig. 4a,b. Orbitofrontal cortex (Brodmann area 11) in a schizophrenic patient. **a** Low-magnification view: histologic demonstration of a group of layer V pyramidal cells with multiply forked major dendrites. *LV*, *LVI*, cortical layers V and VI. **b** Detail: pyramidal cell with a singly forked major dendrite. *aDF*, apical dendritic field; *bDF*, basal dendritic field; *P*, perikaryon (cell body); *L*, lipofuscin in neuronal perikaryon. Confocal microscopy. Postmortem fluorescence technique with DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate). (Modified from Senitz and Winkelmann 1981; see also Supprian et al. 1993)

The findings in these neurons presumably reflect ordinary, nonpathological histologic features that are to be regarded as plastic alterations in the area of the dendritic trunk (Geinisman et al. 1989). They may be interpreted as an expression of altered functioning. Because this area is tightly linked to the rostral cortex (Insausti et al. 1987), it is possible that the abnormalities noted are due to a developmental disturbance occurring in the migratory phase as a result of the malformation in the entorhinal area. It is clear that the orbitofrontal cortex is subject both to independent, mild disturbances of development running in parallel to the entorhinal disturbance and to secondary compensation effects leading to plastic alterations in the pyramidal neurons of layer III. The topography of the areas projecting to the entorhinal area is depicted in Fig. 5. Orbitofrontal cortex and the rostral portion of the claustrocortex (insula) project onto rostral portions of the entorhinal cortex, while the cingulate gyrus and the fields of the superior temporal gyrus project onto caudal portions. The different fields of the perirhinal and parahippocampal cortical areas send their projections uniformly throughout the entire entorhinal area.

8 Claustrocortex

The cytoarchitectural abnormalities of the rostral ventral portion of the insular cortex are rather mild. They are restricted to a particular region and occur in tandem with the cytoarchitectural abnormalities of the rostral portion of entorhinal area (Jakob and Beckmann 1986; see Fig. 1). In this cortical region, the number of neurons in layers II and III is fairly uniformly reduced by approximately 30%. Their volume is also reduced. The neurons are not radially oriented, but rather diagonally oriented or twisted. These findings and the complete absence of gliosis are evidence against atrophy or hypoxic parenchymal injury (Jakob and Beckmann 1989). The fields of this region of the insula are characterized by a particular

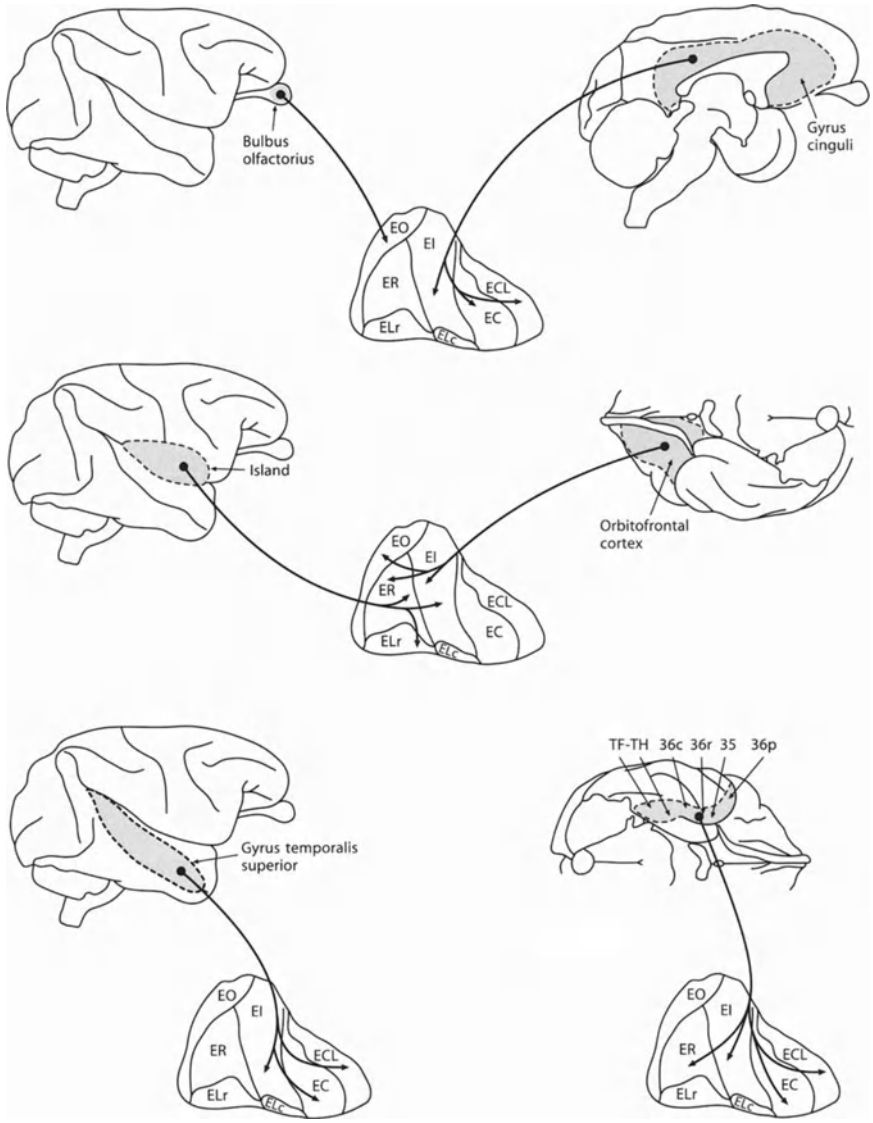

Fig. 5. Summary diagram of the (mostly cortical) afferent projections of the primate entorhinal area. *EO*, olfactory field; *ER*, rostral field; *Elr*, rostral-lateral field; *EI*, intermediate field; *EC*, caudal field; *Elc*, caudal-lateral field; *ECL*, caudal limiting field. (After Insausti et al. 1987)

cellular architecture (agranular region; Stephan 1975) and project onto rostral portions of the entorhinal cortex (see Fig. 5). It is not clear whether the alterations in this area are secondary ones occurring in the presence of a malformation.

9 Cingulate Gyrus

Neuronal clusters, which occur primarily in layer II of cingulate cortex but are also found in the prefrontal region, are thought to constitute the most important specific functional component of the cingulate gyrus. These groups of tightly associated cells are smaller and farther apart from each other in patients with endogenous psychoses than in normal control subjects. Furthermore, studies of the cingulate gyrus of patients with endogenous psychoses using immunohistochemical methods with neuron-specific antibodies have revealed that it contains a significantly increased number (25% increase) of long association fibers with a vertical course, particularly in the vicinity of blood vessels. This finding probably reflects an increase in associative neurons from frontal cortical areas (Benes

et al. 1992; Benes 1993). There were also cytoarchitectural changes of a more general nature in both cingulate and frontal cortex. There was a marked reduction in interneurons in layer II of both regions, more pronounced in the cingulate gyrus. Furthermore, the number of neurons in layer V of the cingulate gyrus, in layer VI of the frontal cortex, and in layer III of the motor cortex was significantly reduced in the absence of evidence of degenerative changes (Benes et al. 1986, 1991).

On the other hand, there was an increased number of pyramidal cells in layer V of the frontal cortex, which was thought to be related to an increase in associative afferent input. It is assumed that the increased number of vertical axons in the cingulate gyrus may arise from layer V and from the pyramidal cells of the prefrontal area (Benes et al. 1992; Benes 1993). The various types and subtypes of γ-aminobutyric acid (GABA)-ergic cortical interneurons in the rostral portion of the cingulate gyrus were analyzed by an immunohistochemical technique with antibodies against parvalbumin (PV). Most of the PV-positive interneurons were found in layers III and Vb of Brodmann area 24c (Kalus and Senitz 1996). Postmortem studies on the brains of schizophrenic patients at first revealed the same distribution of interneurons in the cerebral cortex as in normal controls. Nonetheless, even though the number of Nissl-stained neurons was unchanged, there was a significant increase in the number of neurons in layers Va and Vb. This finding, which must represent an increased number of interneurons at the expense of other neurons, was interpreted as a reflection of a developmental disturbance. The increased number of neurons might result in an increased inhibition of projection neurons, which could, in turn, influence the neuronal output of the rostral portion of the cingulate gyrus and, through it, the limbic functional circuit (Kalus et al. 1997b).

The fact that these cytoarchitectural changes occur precisely in the rostral portion of the cingulate gyrus, as has since been confirmed in multiple replicating studies, leads us to consider the connections of this area to the entorhinal cortex (see Fig. 5). Although the different groups of investigators arrived at partly conflicting conclusions, there is a consensus that neuronal disturbances occur in the lower layers of the cortex. This would be an unusual finding for a primary developmental disorder. It thus seems reasonable to assume that there is a secondary neuronal disorder resulting from the malformation in the entorhinal cortex.

The cytoarchitectural abnormalities of the entorhinal area and the anterior portion of the cingulate gyrus are among the best-validated findings in schizophrenia research (Talamini et al. 1995). Both of these structures, like the hippocampus, are essential components of the limbic system. There are connections between the cingulate gyrus and the frontal isocortex that enable an exchange of information at all levels (Lopez da Silva et al. 1990). Thus the anterior portion of the cingulate gyrus is a second connection between the frontal cortex and the hippocampal formation. The most important exit pathway of this system is via the nucleus accumbens, which is located in the ventral striatum (Sorensen and Witter 1983). The nucleus accumbens projects, in turn, by way of the internal pallidal segment and the mediodorsal thalamic nucleus back to the prefrontal cortex (Groenewegen and Russchen 1984; Groenewegen et al. 1990; Haber et al. 1985). Thus frontal cortical association areas are incorporated into the limbic regulatory circuit.

10 Other Cortical Areas

In a study of the brains of patients with schizophrenia and schizoaffective disorder, the cell density in Brodmann areas 9 and 46 of the frontal cortex and in area 17 of the occipital cortex (i.e. the primary visual cortex) was analyzed with respect to cytoarchitecture. In schizophrenic patients, the neuron density was significantly increased in the individual layers of area 9 (17%) and area 46 (layers II and III) of frontal cortex and in the visual cortex (10%). In area 9, the neuron density was increased in layers III–VI because of increased numbers of both pyramidal and nonpyramidal neurons. The neuron density was not parallel to either of the two parameters postmortem interval (PMI) or time in formaldehyde (TF). Cortical thickness, however, was reduced in schizophrenics to a mild but not statistically significant extent, combined with a relatively marked reduction of layer V in frontal area 9. In the frontal lobe, volume reduction was found only in the neurons, and not in the glia (Selemon et al. 1993; Rajkowska et al. 1994; Selemon et al. 1995).

The authors first postulated neuronal atrophy as a possible anatomic substrate for faulty information processing in schizophrenia. This was made less likely, however, by the finding that the lessened cortical thickness was not attributable to a uniform reduction of all of the layers. Considerable differences between individual layers were found; layer V was the most strongly affected in the brains of schizophrenic patients. This finding may be of functional significance precisely at this location in the frontal lobe, because these layers contain the neurons of origin for the corticocortical and corticostriatal projections; moreover, layer V contains a high concentration of D_1- and D_2-type dopamine receptors (Goldman-Rakic et al. 1990).

The greatest amount of variation in neuronal density among layers was found in the brains of patients with schizoaffective disorders. Densities were found to range from extreme values to an entirely normal distribution. Nonetheless, only one subgroup of patients with schizoaffective disorders also had an elevation of neuron density reminiscent of that seen in schizophrenia. These alterations in the layers may be attributable to a reduction in neuropil (Selemon et al. 1995; Watson and Meador-Woodruff 1995). In this case, these alterations, too, could be regarded as only secondary in the overall scheme of disturbances of cortical development that has been constructed to date; the developmental disturbances of the entorhinal cortex and of the cingulate gyrus would retain their primary importance (Talamini et al. 1995). It is reasonable to conclude that the malformation of the rostral portion of the entorhinal area, which has extensive connections to frontal areas and to all sensory areas, including the visual cortex (van Hoesen 1982; Insausti et al. 1987; Pandya and Yeterian 1985), is the cause of the reduction in neuropil.

With respect to its function, the prefrontal association cortex is a highly differentiated structure. This cortical area carries out the task of planning motor activity, after first assessing the consequences of possible future actions to the individual. Studies employing positron emission tomography (PET) and single photon emission computed tomography (SPECT) have shown that the prefrontal cortex functions abnormally in schizophrenic patients, particularly those with predominantly "negative" disease manifestations. Furthermore, lesions of frontal cortical areas, including limbic association areas, usually lead to deficits of attention and initiative, both of which are "negative" manifestations of schizophrenia (Talamini et al. 1995).

11 Subcortical Nuclei

In addition to the hippocampus, the basal ganglia and the thalamus have also been subjects of interest in schizophrenia research. The findings obtained to date remain controversial. Volumetric studies of the basal ganglia using material from the Vogt Collection revealed a reduction in volume of the internal pallidum and the amygdalar nucleus (Bogerts 1984, 1985; Bogerts et al. 1985); in cases of catatonic schizophrenia, the number of neurons was reduced in both the internal and the external pallidal segments (Bogerts et al. 1985). The nucleus accumbens was also reduced in volume in male schizophrenics (Bogerts et al. 1990). Unfortunately, these volumetric findings could not be confirmed in further studies employing stereological methods on serial Nissl sections of entire hemispheres. The volume of the amygdalar nucleus was not significantly reduced, while the volume of the striatum on the left side and that of the pallidum on the right side were significantly increased (Heckers et al. 1991).

Extensive postmortem studies of entire cerebral hemispheres were recently carried out on nine brains of schizophrenic patients and nine of normal control subjects, all of whom were less than 60 years old. Individual and regionally specific shrinkage factors and the ratio of the size of the basal ganglia to that of the entire hemisphere were taken into account in each case by the application of sophisticated statistical volumetric methods. A relative increase in volume – also designated volume density – was found for the striatum of both sides and for the right nucleus accumbens. In the same study, the neurons and glial cells in the striatum of both sides were counted by optical dissection under a stereomicroscope. A significantly increased number of neurons was found in the caudate nucleus–nucleus accumbens complex of the right side, but not in the right putamen. There was no alteration in the number of glial cells. An influence of the developmental disorder of limbic cortical areas on the course of the normally occurring process of apoptosis is under discussion as a possible pathogenetic mechanism (Lauer and Beckmann 1997; Beckmann and Lauer 1997). "Cell loss" in the intermediate and posterior thalamic nuclei was reported in early studies (Hempel and Treff 1959; Dom et al. 1981).

An improvement in stereological technique was brought about by the introduction of the so-called Cavalieri dissector combination, which employs two microscopes to differentiate neurons and glial cells from one another precisely, in three dimensions. This method allows both the numerical density and the total number of neurons to be determined, while avoiding double counting. No significant alterations were found in the numbers of neurons and glial cells in the inner pallidal segment or in the basolateral nucleus of the amygdala (Gundersen and Jensen 1987). The number of neurons was reduced by 40% in the mediodorsal thalamic nucleus and by 50% in the nucleus accumbens (Pakkenberg 1990). The mean volumes of the left thalamic nucleus and the nucleus accumbens were studied with similar methods and found to be reduced (Pakkenberg and Gundersen 1988; Pakkenberg 1990).

In functional anatomic terms, the subcortical nuclei are connected in many different ways with the limbic areas and functional circuits. Frontal, temporal, and parietal cortical association areas and the cingulate gyrus project principally onto the caudate nucleus (Selemon and Goldman-Rakic 1985). Limbic cortical

areas and the hippocampus provide afferent input to the nucleus accumbens (Pennartz et al. 1994). Particular attention has been paid to the position of the mediodorsal thalamic nuclei because of their intimate connections to the prefrontal cortex within the limbic system (Divac et al. 1978; Markowitsch 1982; Goldman-Rakic et al. 1984; Goldman-Rakic and Porrino 1985). They derive afferent input from frontal NADPH neurons (Giguere and Goldman-Rakic 1988).

The anterior thalamic nuclei derive afferent input from the hippocampal formation and project back to it by way of the cingulum (Papez regulatory circuit). They belong to a large group of cells that, among other functions, provide afferent input to the limbic system. Information is relayed from the brainstem to the limbic Papez regulatory circuit by way of the mamillary bodies, which have the function not only of regulating the forward flow of information, but also of relaying it back to the brainstem by way of the mamillotegmental tract (Swanson 1983). There are also connections to the nucleus accumbens within the Papez regulatory circuit. Descending fibers of the precommissural fornix arising in the subiculum divide into individual efferent connections to the lateral septum, medial portions of the nucleus accumbens, the frontal cortex, and the gyrus rectus (Rosene and van Hoesen 1977).

Thus both the anterior and the dorsomedial thalamic nuclei, the striatum, and the nucleus accumbens are either wholly incorporated into the limbic system or have multiple connections, not only with "ascending" fibers from the hypothalamus and parts of the brainstem, but also with "descending" fibers from the limbic area.

12 Brainstem

The anatomic structures under discussion here include areas of the midbrain, the pons, and the reticular formation, which extends downward into the medulla oblongata, and also the periventricular nuclei in the walls of the third ventricle.

A study of serial myelin-stained sections of the brains of schizophrenics and control subjects obtained from the Vogt Collection revealed a significant reduction in volume of the periventricular gray matter (Lesch and Bogerts 1984). The authors assumed that this reflected a loss of diencephalic gray matter and related these anatomic changes to the diencephalic dysfunction that can be observed in chronic schizophrenics. It remains questionable, however, whether such far-reaching conclusions can be drawn from myelin-stained sections alone.

More recently, the brainstem reticular formation was studied by immunocytochemical methods in a small group of schizophrenics and control subjects. The pedunculopontine nucleus (PPN), the lateral dorsal tegmental nucleus (LDT), and the locus ceruleus were studied as completely as possible at several sectional levels with the aid of three-dimensional reconstruction. Using NADPH diaphorase, the authors found that the PPN of schizophrenics contained an increased number of cholinergic neurons and was reduced in volume by approximately 30%. These changes in the gray matter were attributed to the effect of a central neuronal developmental disturbance (Karson et al. 1991).

As for the function of these nuclei, it is known that disturbances of non-rapid eye movements (NREM) and a reduction of the REM latency can occur in the sleep of schizophrenics (Feinberg et al. 1969; Itil et al. 1972; Zarcone et al. 1975; Tandon and Greden 1989). There are also specific anomalies of movement and posture (King 1974). These and other functions are modulated by the important cholinergic cell groups, the PPN and the LDT (Mesulam et al. 1984; Satoh and Fibiger 1985; Isaacson and Tanaka 1986; Woolf and Butcher 1986; Jones and Beaudet 1987). There are projections from the dorsolateral prefrontal cortex to the reticular formation and to the pontine nuclei in the primate brain, and it is therefore supposed that a functional disturbance of the reticular formation may provide the basis for the "hypofrontality" seen in schizophrenia (Arnsten and Goldman-Rakic 1984).

13 Conclusion

The neuropathological findings obtained since 1979 relating to cortical and subcortical developmental disturbances in the so-called endogenous psychoses, and particularly schizophrenia, have partly been confirmed in recent years, but have also led to the raising of new questions. As far as can be said today, the focal cortical alterations that have been confirmed to exist in a small number of specific areas share certain common features. Numerous variations in the involved areas, however, make each individual case unique. This, in turn, is reflected in the variety of clinical pictures encountered among the so-called endogenous psychoses. The findings available to date thus give rise to a mosaic.

The anterior portion of the entorhinal area, intimately connected with the hippocampus in the "entorhino-hippocampal loop," and the cingulate gyrus, which is connected to the hippocampus by the

Papez regulatory circuit, are the structures mainly affected by developmental disturbances of cytoarchitecture and are thus important areas of limbic functional disturbance (Talamini et al. 1995). Histologic abnormalities are seen more frequently in anterior than in posterior regions of the temporal lobe and cingulate gyrus, and it is therefore of interest that these rostral areas are much more closely connected to the prefrontal cortex than the caudal areas of these structures. Furthermore, the cytoarchitectural abnormalities are mainly or exclusively localized in the upper cortical layers, which, in general, are connected to other areas by way of afferent or efferent fibers. If histologic data of relevance to functional disorders and their consequences are to be obtained, this should be done by the study of the entire neuron, including its processes, spines, and synapses.

The question of why the course of endogenous psychoses may be phasic, stuttering, or chronic cannot yet be answered satisfactorily. It seems, however, that disturbances in the structures mentioned serve as "foci," which, in a process similar to "kindling," may progressively sensitize or "trigger" certain intracerebral regulatory circuits until these finally discharge and thereby release specific psychotic or affective manifestations (Racine et al. 1989). This hypothesis is supported by a number of findings discussed by Post et al. (1975, 1988), among others, and has a certain degree of plausibility.

Nothing conclusive can be said about the origin of the prenatal developmental disturbances that occur in the second trimester of gestation. Faulty genetic programming and toxic influences on the developing brain are under intense discussion as possible etiologies and are the object of further research that is currently being planned (Beckmann and Franzek 1992).

The Functional Involvement of the Anterior Cingulate Cortex in Schizophrenic Psychosis

1 Introduction: Schizophrenia

Schizophrenia is a serious, lifelong psychotic illness afflicting up to 1% of the world's population. Because the illness begins in late adolescence and continues unabated throughout life, affected years are many and medical need exceeds the mere disease incidence. It is an illness whose pathophysiology and etiology remain unknown. While its study is a challenge, it is an exercise with few critical signposts. What makes the serious biologic study of schizophrenia possible at all is the accelerated rate of discovery within basic neuroscience, providing details of mammalian brain anatomy, neurochemistry, and function to inform schizophrenia hypotheses. Studies of the schizophrenic brain have not yet uncovered the disease mechanisms. Clues from pathology have been veiled. The biology we know to look for and can measure is normal. Thus schizophrenia research is even more dependent on new neuroscience information to advance its disease concepts than many other brain diseases. In addition, the illness is a human one, without an animal model or useful surrogate preparation. Thus clinical studies in schizophrenia are called upon to contribute the critical observations and strategies for effective disease study, while basic neuroscience must supply the concepts and explanatory mechanisms underlying the hypotheses. With a promising formulation in hand, given the long history of previous attempts to study pathophysiology in this area, clinical research systems are primed for hypothesis testing with a view to identifying a vital mechanism.

Already, characteristic signs and symptoms of the illness have been identified by many astute clinicians (Sartorius et al. 1974). The data from a 1974 WHO study of schizophrenia asked the question of whether schizophrenia looks the same around the world and answered it in the affirmative (Sartorius et al. 1974). The descriptive list of common symptoms generated during this WHO study illustrates the groups of symptoms common to schizophrenia in order of their prevalence (Table 1). The most frequent symptom, lack of insight, is in many ways the most crippling aspect of the illness, prohibiting affected individuals from distinguishing their disordered mental symptoms from reality-based thinking.

Since the early descriptive studies, several large clinical data bases have been queried to discover whether schizophrenic subgroups exist, sorted by clinical characteristics (for a review, see Carpenter and Buchanan 1994; Andreasen 1995; Barnes and Liddle 1990; Liddle 1987). These studies have uniformly reported that certain symptoms of schizophrenia appear to run together. Positive symptoms (hallucinations, delusions, thought disorder) cluster together, as do negative symptoms (poverty of thought, asociality, alogia); both cognitive symptoms and depression form a symptom background for the variable positive and negative symptom expressions of the illness. Whether these analyses indicate that schizophrenia is a disease with multiple mechanisms and multiple etiologies (like, for example, anemia) or is a single illness with multiple manifestations (like, for example, diabetes) remains an unanswered question around which there has been much discussion and controversy (Carpenter et al. 1993; Carpenter and Buchanan 1989).

Table 1. Frequency of psychotic symptoms in schizophrenia (international pilot study)

Symptom	Frequency (%)
Lack of insight	97
Auditory hallucinations	74
Verbal hallucinations	70
Ideas of reference	70
Suspiciousness	65
Flatness of affect	65
Voices speaking	65
Paranoid state	64
Thought alienation	52
Thoughts spoken aloud	50

Adapted from Sartorius et al. (1974).

2 Localization of Schizophrenia

Brain scientists all presume that the mechanism of schizophrenia resides within the brain. The fundamental subsequent question is where. Various answers have been advanced, including the medial temporal cortex (Benes 1993; Heckers et al. 1998; Tamminga 1997; Weinberger et al. 1992), the middle frontal cortex (Andreasen et al. 1996; Gur et al. 1987; Carpenter and Buchanan 1989; Liddle and Morris 1991), or the anterior cingulate cortex (reviewed here). Methodologic challenges exist in applying techniques such as human brain imaging to this clinical question in schizophrenia (including the questions of subgrouping and of chronic medication effects); therefore, we began with an initial regional survey of schizophrenia using functional brain imaging in our own laboratory. Thereafter, we followed up these initial findings in subsequent clinical imaging and postmortem tissue experiments.

An initial "screening" study addressed a localization question in schizophrenia; it compared 12 drug-free schizophrenic volunteers with 12 healthy ones using

positron emission tomography (PET) and fluorodeoxyglucose (FDG). This was a crude, but initial screening study where a single question was addressed: where does regional neuronal activity differ between matched patient and healthy volunteers? The 12 schizophrenic volunteers were relatively young and not institutionalized; all were drug withdrawn and demonstrated positive psychotic symptoms. The schizophrenic volunteers were matched to 12 healthy volunteers with no immediate family history of schizophrenia. Each was scanned with PET/FDG in an at-rest condition (Tamminga et al. 1992). From these data, the answer to the study question emerged: schizophrenic volunteers differ from healthy volunteers in their limbic cortex metabolism. Specifically, the schizophrenic volunteers differed in having reduced neuronal activity in the anterior cingulate cortex and in the parahippocampal gyrus/hippocampus (Table 2). No other central nervous system (CNS) areas demonstrated significant differences between these two groups. Because these two brain regions are functionally connected in the mammalian CNS, the results were even more plausible. All patient volunteers in this study had clear positive symptoms. In a later functional imaging study with a new patient group, a significant correlation emerged among the patient volunteers between positive psychotic symptoms – Brief Psychiatric Rating Scale (BPRS) psychosis scores – and neuronal activity in the limbic cortex anterior cingulate and hippocampus (rCMRglu) (Fig. 1; Tamminga 1997). These data taken together suggest that the limbic system is involved in the generation or the mediation of positive psychotic symptoms in schizophrenia.

The crude localization study described above included patient volunteers who did ($n = 4$) and did not ($n = 7$) have persistent negative symptoms. These two patient groups were compared to see where neuronal activity differed in negative-symptom schizophrenia. The volunteers with negative symptoms in the first study demonstrated a profound decrease in cortical neuronal activity in the middle frontal and the inferior parietal cortices and in the thalamus. The schizophrenics with only positive symptoms had normal levels of neuronal

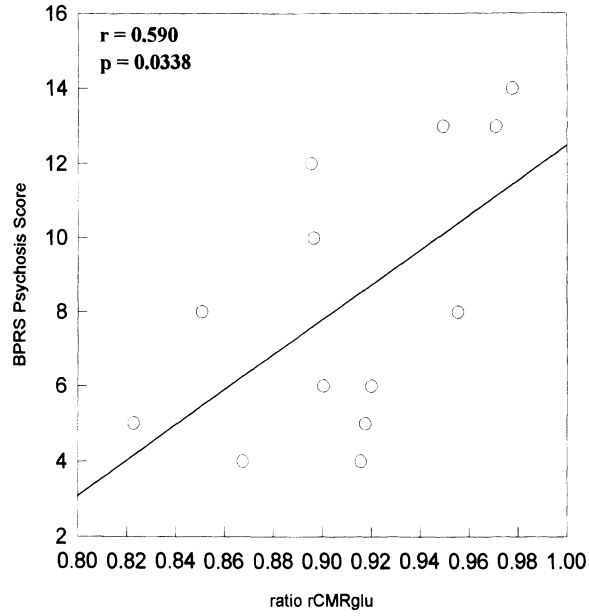

Fig. 1. Correlation between regional metabolism in the limbic cortex (hippocampal and cingulate) and the level of psychosis in 13 schizophrenic volunteers free from antipsychotic drugs. The correlation when drug free is $r = 0.59$, whereas no correlation was obtained in any brain region when the volunteers were treated with drugs and rescanned. *rCMRglu*, neuronal activity in the limbic cortex, anterior cingulate and hippocampus

activity in these "negative-symptom" brain regions. Both groups (with and without negative symptoms) showed functional limbic cortical dysfunction, however. A subsequent study from this laboratory using a prospective evaluation of regional cerebral blood flow (rCBF) (Lahti et al. 1998) in primary negative-symptom schizophrenic volunteers has confirmed this localization of persistent negative symptoms to the middle frontal and inferior parietal cortices bilaterally. Whether schizophrenia is a single pathology expressed in multiple CNS regions, associated with characteristic clinical syndromes, or multiple primary diseases in these regions is a question which is still unanswered by these data.

To pursue the line of research directed by these localization data, additional experiments were indicated. The simplistic working hypothesis at this time associated cingulate and hippocampal dysfunction with the positive symptoms of schizophrenia and frontal parietal dysfunction with negative symptoms. A study of the activity of the limbic cortex during psychosis exacerbation, during psychosis inhibition, and during cognitive task performance could further test this hypothesis. If psychosis is mediated by or generated within the limbic cortex, the anterior cingulate cortex dysfunction could be associated not only with increased psychosis, but also with behavioral dysfunction and alterations in cognition. Experimentally increasing psychosis (with ketamine), decreasing psychosis (with haloperidol), or provocation with a cognitive task would contribute to localizing schizophrenia pathophysiology across different functional states.

3 Psychosis

Ketamine is a commonly used pediatric anesthetic. Pharmacologically, the anesthetic is a mild, noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist which acts as an agonist at the phencyclidine (PCP) receptor within the NMDA ionophore. It is a chemical congener of PCP with lower affinity and potency (White et al. 1982). Ketamine retains the pharmacologic and behavioral properties of PCP, albeit with mild potency. Hence, based on known PCP pharmacology, mild psychotomimetic activity was predicted in patients and healthy volunteers with ketamine administration (Luby et al. 1959; Krystal et al. 1994). To evaluate this, the behavioral activity of a subanesthetic dose range of ketamine (0.1–0.5 mg/kg IV) was tested in these volunteer groups. A mild (<50% of baseline) and short-lived (25–45 min) symptomatic psychosis exacerbation occurred with the ketamine in the patient volunteers (Lahti et al. 1995). This response was distinctive in several respects. First, ketamine's action was not blocked by the traditional antipsychotic haloperidol, and not even blunted. Second, and perhaps more importantly, ketamine affected the patient's own symptoms, be they hallucinations, delusions, or thought disorder; it did not merely produce its own characteristic psychotomimetic effects, but mildly exacerbated the existent symptoms. This observation suggests that glutamatergic inhibition at the NMDA-sensitive glutamate receptor can provoke schizophrenic symptoms themselves, not just a general psychosis. These observations implicate glutamatergic transmission at some neuronal level in the mechanisms of schizophrenia, possibly close to the pathology of the illness. These clinical observations with ketamine fit into an extensive body of research which has already implicated glutamate in schizophrenia (Tamminga 1998).

The behavioral response to ketamine in schizophrenic volunteers suggested the importance of localizing this drug action and its behavioral correlates in the CNS, to identify brain regions involved with this drug response and with psychosis. Again, rCBF studies were carried out with both healthy and schizophrenic volunteers at regular time intervals over 60 min after ketamine administration. Ketamine, in a dose-sensitive fashion, produced a significant increase in rCBF in the anterior cingulate and contiguous medial frontal cortex as well as in a smaller right inferior frontal region. The largest rCBF decrease appeared in the cerebellum and essentially involved the entire cerebellar cortex (Fig. 2, Table 3). These rCBF changes induced by ketamine were not significantly different between the two subject groups tested (schizophrenia vs. healthy), even though the schizophrenic group had numerically higher activation levels. There were three brain regions where the behavioral response (total BPRS score) correlated with the drug-induced rCBF changes: (1) the anterior cingulate cortex, (2) the right inferior frontal cortex, and (3) an area in the brain stem, near the substantia nigra (Fig. 3). These correlational data suggest that these three brain regions may be involved in mediating this ketamine-induced behavioral response.

It is noteworthy that the brain region whose rCBF is prominently stimulated by ketamine, the anterior cingulate cortex, is the very region identified in our first PET/FDG psychosis "screening" study as being dysfunctional in schizophrenia. Glucose utilization (as a marker of neuronal activity) is lower in schizophrenic individuals at rest relative to normal subjects in the initial screening study, whereas with ketamine, psychosis is positively associated with anterior cingulate metabolism and rCBF activation. This apparent contradiction may be related to cortical behavior during the resting, unstimulated cognitive state of the initial scan.

4 Psychosis Reduction

The next study evaluated the localization of action of the traditional antipsychotic drug haloperidol to discover which brain regions are involved in antipsychotic action. Haloperidol was once the most commonly used antipsychotic drug (Klein and Davis 1969) and has its major action at the D_2 family of dopamine receptors in striatum, especially at the clinically effective dose levels used in schizophrenia. Moreover, haloperidol is a potent drug with no active metabolite, making pharmacokinetic and pharmacodynamic studies more informative. The question addressed by this experiment is which brain areas show altered neuronal activity when a psychotic person is treated with a standard and effective antipsychotic drug, suggesting which brain areas are involved in mediating that effect.

The action of haloperidol to displace dopaminergic ligands with an antagonist action at the striatal D_2 family dopamine receptor is well known (Wong et al. 1986). Animal model experiments suggest that potent pharmacologic actions at dopamine receptors in striatum have distant functional and neurochemical effects which are mediated through the well-known frontal cortical–subcortical segregated neuronal circuits (Alexander et al. 1986); these antipsychotic-induced functional and neurochemical changes are apparent throughout all regions of basal ganglia, thalamus, and cortex (Shirakawa and Tamminga 1994; Abercrombie and DeBoer 1997). The prediction in this study was that haloperidol would have both direct actions in striatum and indirect (projected) functional actions throughout basal ganglia, thalamus, and limbic and neocortical regions. This prediction is consistent with the distribution of the parallel, segregated cortical–subcortical prefrontal circuits already well described in primate brain (Alexander et al. 1986; Nauta 1989).

Volunteers with schizophrenia agreed to a clinical study where they received 0.3 mg haloperidol/kg per day for 4 weeks and then underwent a PET scan with

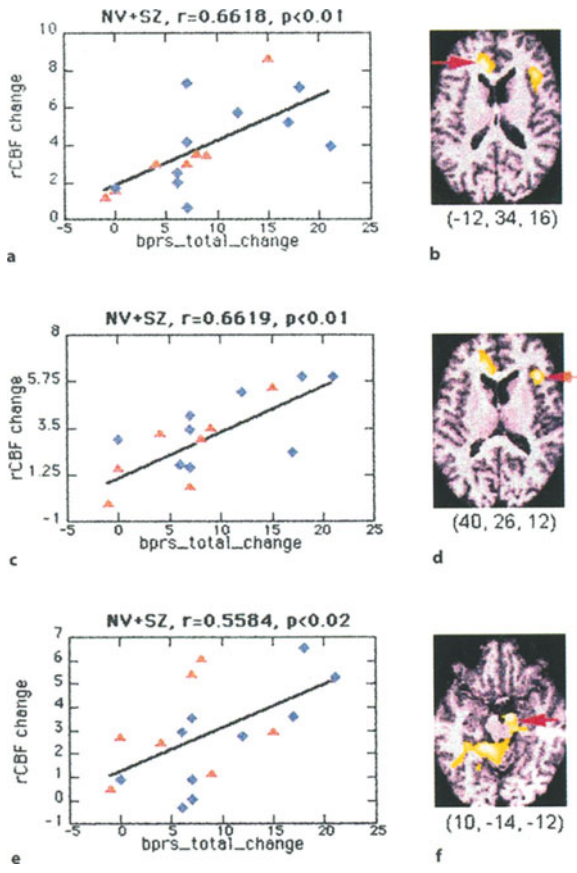

Fig. 3a–f. The three brain regions where the extent of the ketamine-induced regional cerebral blood flow (*rCBF*) change correlated with the extent of the psychotic symptoms induced. **a,b** Anterior cingulate cortex. **c,d** Right inferior frontal cortex. **e,f** A small region in the midbrain which could be the substantia nigra. The schizophrenic (*triangles, SZ*) and normal volunteers (*diamonds, NV*) are intermixed in these plots, suggesting that the process may be similar in both groups. The numbers in parentheses beneath the right-hand figures (**b,d,f**) indicate the Talairach atlas coordinates (*x, y, z*)

FDG. Next, the volunteers received a matched placebo regimen for the same time period and had a second PET/FDG scan. In an intra-subject analysis, the regional differences in activation between the two scans by the same individual were analyzed. Haloperidol, even with chronic administration, increases glucose metabolism (rCMRglu) in the caudate and putamen (Holcomb et al. 1996). This finding had been previously reported (Gur et al. 1987; Buchsbaum et al. 1982) and is readily explained on the basis of haloperidol's action in striatum to block dopamine, an inhibitory transmitter, hence producing activation by disinhibition. What was more surprising, and also a new finding with this study, was the haloperidol-induced activation in thalamus, greater in the anterior than posterior portion. One surprise in this response derives from knowing that the density of dopamine receptors is very low in human thalamus, suggesting an indirect action in that region. In cortical areas, only two delimited cortical regions demonstrated significant change with haloperidol: the frontal cortex and the anterior cingulate region. Moreover, this change was a decrease in rCMRglu, not an increase as seen in the basal ganglia and thalamus, again suggesting the possibility of an indirect action (Fig. 4). This distinctive pattern of overall brain activation changes could not easily be explained by a single common drug action of haloperidol in multiple brain regions. The most parsimonious explanation appeared to involve a single effect of haloperidol exerted in striatum with this effect transmitted to additional brain regions through the segregated cortical–subcortical neuronal pathways. The metabolic changes predicted by blocking striatal dopamine receptors using this hypothesis closely matched the data actually collected in this experiment. Thus these haloperidol-induced actions in the CNS can most cleanly be explained by a single, direct, and potent drug action in the striatum, with the functional effects in other regions being transmitted in a secondary and tertiary fashion through the basal ganglia to thalamus and on to the neocortex and limbic cortex. Thalamic activation and cortical deactivation with dopamine blockade in striatum has been previously described in animals (Abercrombie and DeBoer 1997).

Again, it is striking in this experiment that the anterior cingulate cortex is one of the few cortical regions functionally affected by chronic haloperidol treatment. These results strengthened the ongoing working hypothesis that this rCBRglu change in the anterior cingulate is associated with the drug-induced reduction in psychotic and cognitive symptoms. Additional haloperidol pharmacodynamic imaging studies in our laboratory have more fully demonstrated the action of haloperidol in stimulating rCBF in the caudate and thalamus and reducing rCBF in frontal and cingulate cortices data consistent with the initial rCMRglu findings (Fig. 5; Lahti et al. 1998). An association between the haloperidol-induced psychosis change and the rCBF alterations, also drug induced, in the anterior cingulate cortex is hypothesized and being further tested.

5 Cognitive Task Activation

Task-associated activation patterns provide information about cerebral strategies employed to carry out a defined mental task. Comparing task-related regional activation patterns between two subject groups is legitimate if performance characteristics of the task are

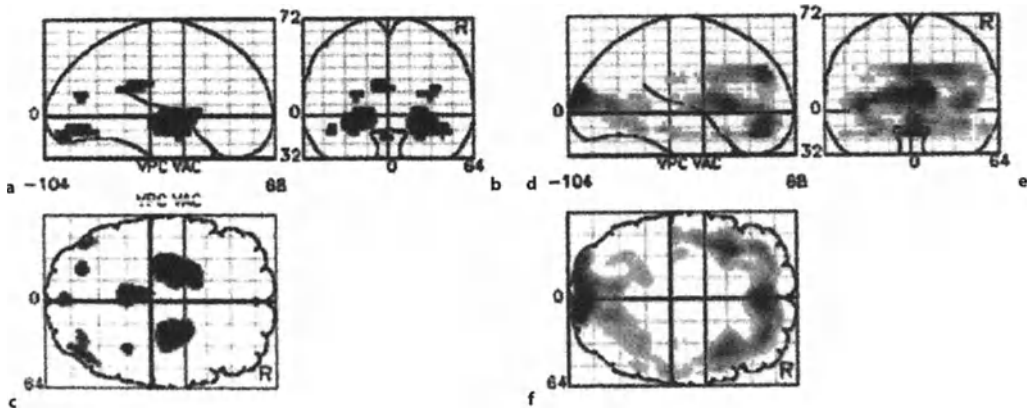

Fig. 4a–f. SPM analyses of haloperidol action in the human brain ($n = 12$). **a–c** Haloperiodol minus placebo. Activation of regional metabolism in the caudate/putamen (bilaterally) and in the thalamus (midline). **d–f** Placebo minus haloperidol. Fig. 5a,b. Pharmacodynamic characterization of haloperidol-induced regional cerebral blood flow (*rCBF*) change over time in **a** the caudate (−18, 4, 16) and **b** the thalamus (16, −18, 12) (numbers in parentheses indicate the Talairach atlas coordinates). The same patient group was analyzed in the initial set of scans (0–4 h) and in the late scan set (8–11 h), with the scan sets separated by 1 week for feasibility reasons

similar across individuals. This is difficult when studying schizophrenia because general task performance of volunteers with the illness is often diminished. In this experiment, however, schizophrenic and healthy volunteers were selected and trained to perform an auditory recognition task with performance fixed at 80% task accuracy by means of varying slightly the auditory stimuli. rCBF with PET and ^{15}O-water was carried out using this task condition under rest, sensorimotor control, and active task conditions. Usual analysis with SPM 96 (statistical parametric mapping) and hierarchical subtraction was performed to arrive at distinct activations in the control and in the task state by group (Holcomb et al. 1998). During the sensorimotor control task, individuals demonstrated activations in their primary auditory cortex and in the left postcentral gyrus (motor cortex). In the auditory task condition, with the control activation areas subtracted away, activations in the healthy volunteers were apparent in the right middle and inferior frontal cortex and in the anterior cingulate cortex, areas consistent with the

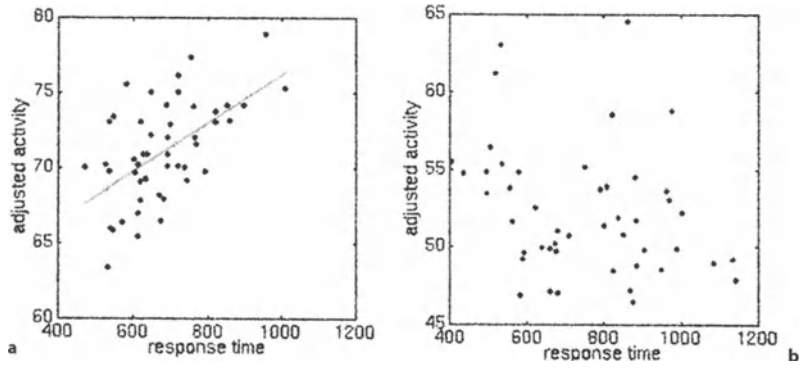

Fig. 6a,b. Correlation between a measure of task difficulty (reaction time) on the auditory discrimination task and regional cerebral blood flow (rCBF) in the anterior cingulate cortex. **a** Healthy volunteers. A positive correlation is apparent, suggesting that the harder the task becomes, the greater the rCBF activation in the anterior cingulate is. **b** The schizophrenic group. No correlation was obtained among these individuals, despite the fact that they were performing the same task at the same level

demands of the recognition task. When activation patterns of the schizophrenic volunteers were compared to patterns described in the healthy group, only one area showed an overall altered activation with task performance in schizophrenia: the anterior cingulate cortex (activation was reduced in schizophrenia) (Holcomb et al. 1999). Moreover, whereas there was a significant positive relationship between rCBF and reaction time (a measure of difficulty) in the anterior cingulate cortex in the healthy volunteer group, no such relationship was present or even suggested in the patient group (Fig. 6). This was the case even though the schizophrenic volunteers were successfully performing the task.

An additional correlational abnormality in schizophrenia was noted in the right frontal cortex, an area where, in an additional analysis, there were no activation differences between groups. Here, the healthy subject group showed a significant positive relationship between rCBF and reaction time (a measure of task difficulty), consistent with the rCBF behavior of the anterior cingulate cortex. However, the schizophrenic subject group showed a significant negative correlation in the frontal cortex between rCBF and task difficulty, a correlation opposite to that found in the normal subjects. This suggests that the two volunteer groups, who were both performing the task equivalently, each employed their own distinctive mental strategy for carrying out the work. The schizophrenic group, although able to perform the task well, was not able to engage their anterior cingulate or right middle frontal cortex normally or to vary the behavior performance of these areas with the difficulty of the task.

Of note again is the abnormal performance of the anterior cingulate cortex in this cognition task condition, associated with schizophrenia. In early studies, we noted that the abnormal rCBF response to task difficulty in the anterior cingulate cortex tends to normalize with antipsychotic treatment (Holcomb et al. 1999).

6 Conclusion

These functional imaging studies lead to the conclusion that the anterior cingulate cortex may be involved in schizophrenia, especially in the mediation of positive symptoms. The region is functionally involved in psychosis modulation and works abnormally during cognitively demanding tasks in schizophrenia. Not only the anterior cingulate, but also related cortical areas, such as the hippocampus, the middle frontal cortex, and the insular cortex also function abnormally in volunteers with schizophrenia.

Our current working hypothesis, based on these imaging data as well as results from animal studies with phencyclidine and MK801 (Gao and Tamminga 1995; Gao et al. 1998), and on human postmortem tissue analysis (Gao et al. 1999), suggests the possibility that the hippocampus may be a site of primary dysfunction in schizophrenia (or in any psychosis), with reduced hippocampal efferent signals aversely affecting each of its projection targets, possibly most prominently the anterior cingulate cortex. The anterior cingulate dysfunction can be associated with both positive and cognitive symptoms of the illness. This hypothesis involves areas of schizophrenic brain where prominent tissue pathology has already been reported (for a review, see Tamminga 1997) and abnormal functional imaging signals have been noted (Heckers et al. 1998). This working hypothesis provides a parsimonious and testable hypothesis for the positive symptoms of psychosis, i.e. a failure of hippocampal efferent activity,

whether induced by schizophrenia, a hallucinogen, or another psychotic illness such as bipolar disease. Such an explanation, no matter what the specific tissue pathology, would have the ability to explain several psychotic symptoms, particularly those mediated by a hippocampal target area, e.g. attention, as mediated by the anterior cingulate cortex, or short-term memory, as mediated by the middle frontal cortex.

The idea that overall limbic cortical function is impaired in schizophrenia, with the initiating defect located within hippocampus, is supported by our current data in schizophrenic postmortem tissue studies. Here we have found a normal binding of ^{3}H-glutamate to the NMDA-sensitive glutamate receptors; however, the expression of the NR_1 subunit of that receptor is reduced, and the NR_{2B} subunit expression is increased. This abnormality could imply reduced functional activity of the hippocampal NMDA receptor and possibly a reduced efferent glutamatergic signal, assuming that the reduced NR_1 expression results in more NMDA receptors with no critical NR_1 subunit. The testing of this straightforward hypothesis requires paired (i.e. from the same individual brain) hippocampal, anterior cingulate, and anterior thalamus tissue samples comparing healthy and schizophrenic tissue. These tissue samples should be examined both histologically and neurochemically for evidence consistent with or contradictory to this formulation. Because these regional defects can show variability by location, a complete examination (anterior to posterior) of the structures would be important.

The successful marriage of animal preparation experiments, clinical probe studies, in vivo human brain imaging, and postmortem tissue techniques in pursuing hypothesis-testing studies in schizophrenia may be important in arriving at clear answers to questions of etiology and mechanism. Such approaches hold promise for broadly informative research results in this area.

CHAPTER

8

T.W. Weickert, T.E. Goldberg

Neuropsychology of Schizophrenia

1 Introduction

Schizophrenia is a debilitating neuropsychiatric disorder which can result in variable behavioral symptomatology, including hallucinations, delusions, and flat affect. Additionally, schizophrenia has been characterized by impaired performance on a variety of neuropsychological measures which assess the cognitive domains of attention, higher-level executive function, memory, and motor control. While symptoms such as hallucinations and delusions may be independent of the classic cognitive domains such as memory and working memory, this is not to say that these symptoms do not have cognitive underpinnings, but rather that the cognitive underpinnings have not been well elucidated (see, e.g. our work below on thought disorder in which we attempt to put thought disorder in context; see also Frith 1996). Deficits in these cognitive domains broadly implicate the regions of the prefrontal cortex and the medial temporal lobes in the neuropsychopathology of schizophrenia. Moreover, the clinical psychopathology and cognitive domains may be relatively independent.

2 Symptoms, Motivation, and Cognition

It has been argued that the cognitive deficits observed in schizophrenia may occur as a result of the distracting influence of psychotic symptoms, such as hallucinations, distortions, avolition, and apathy. This argument would suggest that the cognitive deficits observed in schizophrenia are secondary to these symptoms and that remediation of the primary symptoms would, therefore, alleviate the cognitive abnormalities. In fact, antipsychotic medication has been demonstrated to ameliorate the cognitive deficits associated with schizophrenia to only a limited degree despite producing marked improvement in psychiatric symptoms (for reviews, see Medalia et al. 1988; Spohn and Strauss 1989). In fact, the two domains may be dissociable. For instance, Goldberg et al. (1993b) showed that, while psychiatric symptoms in schizophrenic patients improved dramatically with administration of conventional and atypical neuroleptic medication, attention, memory, and higher-level problem-solving abilities did not improve. Numerous studies have also addressed the issue of impairment in cognitive performance due to an overall lack of cooperation and motivation (Stuss et al. 1983; Schneider and Asarnow 1987; Levin et al. 1989). In general, these studies have shown that, while either instructions and/or reinforcers may improve schizophrenic patients' performance on tests of problem solving and set shifting described in further detail below, their performance still failed to normalize (Bellack et al. 1990; Goldberg et al. 1987; Summerfelt et al. 1991; Tompkins et al. 1991; Green et al. 1992).

Additionally, there has been a paucity of findings of strong correlations between neuropsychological deficits and psychotic symptoms. Faustman et al. (1988) found no relationship between cognitive performance and psychiatric symptoms in unmedicated patients. Likewise, Goldberg et al. (1993a) were unable to uncover a relationship between cognition and psychiatric symptoms in schizophrenic patients. In this study, symptom factors accounted for 15%–30% of the variance in cognitive performance of unipolar and bipolar depressed patients, whereas symptoms accounted for less than 5% of the variance in cognitive abilities in schizophrenic patients. Although Kibel et al. (1993) showed a moderate relationship between negative symptoms and cognitive deficits, negative symptoms accounted for less than half of the variance observed in the cognitive performance of schizophrenic patients. Neuropsychological testing may be a more reliable and precise method to characterize the disorder than symptoms, which are variable and subject to change with treatment.

In summary, the majority of cognitive deficits observed in schizophrenia tend to remain stable in spite of treatment with neuroleptic medication. Additionally, improvements in symptoms which follow neuroleptic treatment often fail to return patients to normal levels of cognitive performance. Thus the cognitive deficits of schizophrenia are independent of psychotic symptoms and appear to be central and enduring features of the disease.

2.1 Validity

A pertinent question arises as to whether such neurocognitive deficits are the product of the disease process or merely side effects of the neuroleptic medications administered to the schizophrenic patients. On the basis of "first break" studies, "medication-free" studies, and evidence from the preneuroleptic era, the pattern of results on neuropsychological batteries of tests administered to schizophrenic patients suggests that the neuropsychological deficits observed in schizophrenia are a product of the disease rather than an effect of treatment (for a detailed discussion, see Goldberg and Gold 1995). For example, Saykin et al. (1994) demonstrated no differences in performance on a neuropsychological battery

of tests between a group of neuroleptic naïve, first-episode schizophrenic patients and a group of previously treated, unmedicated schizophrenic patients. In this study, verbal learning and memory measures, attention, speeded visual–motor processing, and visual search tasks were impaired in both neuroleptic naïve and previously treated groups, and these groups also differed from a group of normal controls. In "medication-free" or dosage-reduction studies, in which patients have been withdrawn from neuroleptics and placed on placebo, usually in a double-blind design, investigators have demonstrated no effect of neuroleptic medication relative to the placebo condition on tests of higher cognitive functioning (Seidman et al. 1993; Cleghorn et al. 1990). However, in the Continuous Performance Test (CPT), which requires both vigilance and response readiness, improvements in performance following neuroleptic treatment in comparison to placebo have been frequently observed (see, e.g. Goldberg and Weinberger 1996; Oltmanns et al. 1978). Finally, Rapaport et al. (1945/1946) reported deficits of judgement, concentration, planning, anticipation, memory, and concept formation all prior to the era in which neuroleptic medications were introduced.

2.2 Frequency

In general, and perhaps unexpectedly, the distribution of specific neuropsychological test scores in the schizophrenic population appears to represent a negative "shift" in performance for the schizophrenic population as a whole relative to normal. While studies in which binary cutoffs were used to examine the cognitive deficits displayed in schizophrenia generally demonstrate that less than 40% of patients can be considered to be "abnormal" (Braff et al. 1991; Goldberg et al. 1988) and that patients generally fall within one to two standard deviations below the mean of the normal population on the majority of neuropsychological variables investigated (Sullivan et al. 1994), studies of monozygotic twins discordant for schizophrenia yield a different picture. In these studies, the affected twin routinely performed at a level that was lower in comparison to their unaffected co-twin irrespective of absolute level (Goldberg et al. 1993c, 1994). The twin findings therefore strongly suggest that nearly every patient would display cognitive impairment relative to the performance of their ideal control (in this case, a co-twin that would be matched for age, sex, genetic compliment, socioeconomic status, and education level, yet discordant for the presence of disease).

2.3 Predictive Validity

Delineation of the neuropsychological deficits associated with schizophrenia may also provide a better understanding of the impairment exhibited by schizophrenic patients with respect to their ability to perform routine activities of daily living. Deficits in the cognitive domains of attention, memory, and executive function would suggest severe functional impairment. Impairment in various cognitive domains displayed by psychiatric patients and patients with circumscribed brain lesions result in impairment of self-care, independent living, academic achievement, and vocational function (Heaton et al. 1978; Heaton and Pendleton 1981; Newnan et al. 1978). In a review of the literature pertaining to predictive and correlative relationships between various neuropsychological measures and functional outcome in schizophrenic patients, Green (1996) found relationships between verbal memory measures and all forms of functional outcome, vigilance and social problem solving and skill acquisition, the Wisconsin Card Sorting Test (WCST) and community functioning, and between negative symptoms and social problem solving. Similarly, Addington and Addington (1993) obtained significant correlations between neuropsychological measures (verbal reasoning and concept formation) and outcome. In a study that investigated neuropsychological differences between long-term hospitalized schizophrenic patients and schizophrenic patients successfully residing in the community for more than 3 years, Perlick et al. (1992) demonstrated that neuropsychological measures of motor coordination, perseveration, memory, and attention successfully discriminated between the two groups. Goldberg et al. (1993c) obtained significant correlations between Global Assessment Scale (GAS) scores (a scale used to measure the level of social and vocational functioning) and paired associates learning, memory for stories, verbal fluency, and the three-disk version of the Tower of Hanoi (a problem-solving task). In a study of monozygotic twins that were both discordant and concordant for schizophrenia, Goldberg and colleagues (1995) determined that cognitive measures were significant predictors of intrapair differences in GAS scores. Memory quotient (MQ) from the Wechsler Memory Scale–Revised (WMS-R), the number of categories obtained on the WCST, the easy (A) version of the trail-making task (a test of speed and scanning), and intelligence quotient (IQ) as measured by the Wechsler Adult Intelligence Scale–Revised (WAIS-R) accounted for over 90% of the variance. Taken together, these findings would suggest that neuropsychological measures are reliable predictors of functional abilities.

Furthermore, associations between positive symptoms and outcome measures have been weak. Jonsson and Nyman (1991) failed to obtain a relationship between psychotic symptoms and outcome variables. While Addington et al. (1991) and Breier et al. (1991) report associations between cognitive deficits and negative symptoms in schizophrenia, they also observed low correlations between neuropsychological measures and positive symptoms. These findings suggest that the factors underlying the neuropsychological impairment observed in schizophrenia accounts, in part, for the inability of these patients to execute routine functions of daily living and that these deficits are characteristic of the disease in the sense that they are better predictors of functional outcome than psychotic symptoms.

2.4 Course

No chapter on the neuropsychology of schizophrenia would be complete without a discussion addressing the nature and extent of the cognitive deficits throughout the course of the illness. Toward this end, it has been shown that the neuropsychological deficits observed in schizophrenia are maintained throughout the course of the illness without marked deterioration or improvement. Hyde et al. (1994) administered a battery of neuropsychological tests, routinely used to assess degenerative neurologic disorders, to schizophrenic patients grouped into five cohorts based on age (i.e. patients in their twenties, thirties, forties, fifties, and sixties). The results suggested that no progressive increase in cognitive impairment in schizophrenic patients was present across the five cohorts. Similarly, Heaton et al. (1994) found no difference between three schizophrenic groups (a young group with early onset, an elderly group with early onset, and a late-onset group) on the basis of age-adjusted neuropsychological tests that have been demonstrated to be sensitive to changes that occur with aging, schizophrenia, and dementia. In this sense, the course of schizophrenia has been portrayed as a static encephalopathy rather than as a progressive dementing illness. This view is not without controversy, and other investigators have found declines in cognitive function (Davidson et al. 1995; Waddington et al. 1997). However, declines were very small and not consistent with a progressive dementia. The remainder of this chapter will provide detailed neuropsychological interpretations of the impaired cognitive domains which characterize schizophrenia.

3 Deficit Profile

3.1 Attention

There is a large body of literature pertaining to attentional impairments in schizophrenia. In this chapter, we will only consider some of the more relevant issues. Attentional processes are thought to be composed of numerous subcomponents and may be under the direction of a distributed network within the brain. According to Posner (1995), there are three major attentional processes: orienting to sensory stimuli, detecting target events, and maintaining an alert state. Although Posner et al. (1988) demonstrated a deficit in schizophrenia patients for the processing of targets in the right visual field when attention was diverted, subsequent studies failed to obtain similar results (Strauss et al. 1991; Gold et al. 1992b).

Maruff et al. (1996) showed that, similar in extent to controls, medicated schizophrenic patients display the beginning of orienting responses. However, unlike controls, these patients were unable to make use of information (provided by the experimenter) which would inhibit directing attention to inappropriate peripheral cues. Thus, when informed of the correct location of the target prior to initiation of the task, normal controls were capable of inhibiting the urge to orient to an inappropriately located peripheral cue and use the occurrence of the inappropriate cue to orient to the correct contralateral target location. Schizophrenic patients, however, were incapable of ignoring the inappropriate peripheral cue and correctly orienting to the contralateral target location. These studies suggest that schizophrenic patients may have difficulty applying a strategy which conflicts with a previously learned response.

Schizophrenic patients typically display an increase in the number of omission errors or failures to respond to the presence of a target during the CPT. In one version of the CPT, a signal is given prior to the presence of the target, which is intended to prepare the subject for the possible occurrence of a target. Schizophrenic patients are not capable of effectively employing this "ready" signal, which would suggest that schizophrenic patients experience difficulty in maintaining a readiness to respond. Mirsky et al. (1992) have demonstrated that schizophrenic patients exhibit deficits in sustained attention on the CPT. Additionally, using the CPT, Servan-Schreiber et al. (1996) have shown that increasing the delay between cue and target stimuli results in a decrease in the number of correct responses and an increase in the number of commission errors (the tendency to report the presence of the

cue-target pair when none was present) in unmedicated schizophrenic patients relative to medicated schizophrenic patients and controls. Additionally, Servan-Schreiber et al. (1996) demonstrated that schizophrenic patients were unable to make use of a cue which would alert them to suppress an overlearned response. These findings contribute further evidence to the belief that schizophrenic patients are unable to maintain a readiness to respond. Additionally, since the performance of schizophrenic patients declined with an increase in the interval between cue and target, the finding by Servan-Schreiber et al. (1996) suggests that the CPT may not be a test of "attention" per se, but rather a test of working memory. The additional time between cue and target would appear to provide time during which the relationship between cue and target may decay.

3.2 Memory

Learning and memory, in the sense of the acquisition and retention of new information, is a domain that has been reliably demonstrated to be adversely affected in schizophrenia. Memory has been operationally divided into numerous subtypes (for reviews, see Squire 1992; Schacter and Tulving 1994; see also Vol. 1, Chap. 13). One mnemonic distinction that has particular relevance for schizophrenia is the differential performance observed between immediate and delayed recall.

Schizophrenic patients routinely display deficits with respect to immediate recall. The California Verbal Learning Test (CVLT) is a test of memory in which a list of 16 words is repeatedly presented over five trials with immediate recall occurring after each trial as well as delayed recall after a brief interval and again after a long interval of 20 min. Schizophrenic patients routinely score one to two standard deviations below the mean of the normal population on virtually all measures of the CVLT. The schizophrenic population as a whole also yields a similar performance on many of the mnemonic variables measured in the WMS-R, a battery of tests that assesses various types of immediate and delayed memory, e.g. paragraph recall, visual and verbal paired associate learning, and simple two-dimensional figure recall. Although schizophrenic patients display a relative deficit on immediate recall measures, they routinely exhibit normal savings over long-term delays (Goldberg et al. 1993c; Paulsen et al. 1995).

Memories, in general, are believed to be a product of three processes: encoding, storage, and retrieval. Encoding pertains to placing information to be remembered into a preexisting structure, storage refers to the process that maintains the information in the structure over time, and retrieval refers to the process of selecting information and putting it to use. The memory changes associated with schizophrenia have been demonstrated to be due to inefficient encoding and retrieval strategies. In a list-learning study in which schizophrenic patients and normal controls were required to memorize three lists of 20 words that were either unrelated, categorically related but not grouped by category, or categorically related and grouped by category, schizophrenic patients were impaired under all conditions relative to normal controls (Gold et al. 1992a). Though displaying improved performance during recall of words that were grouped by category relative to the other conditions (suggesting that they experience impaired encoding processes), the schizophrenic patients still demonstrated markedly impaired performance relative to controls. Moreover, in this study, recognition and recall were correlated, indicating that storage of the lists was problematic and the results were not solely due to inefficient encoding or retrieval. Additionally, in a large study in which the CVLT was administered to 175 schizophrenic patients and 229 normal controls, Paulsen et al. (1995) demonstrated that the schizophrenic patients displayed a retrieval deficit, as measured by disproportionate recall to recognition impairment (although recognition was still abnormal).

The neuropsychological findings of generalized impairment in mnemonic function in schizophrenia would suggest that schizophrenic patients experience at least some disruption of the connectivity between the hippocampal formation and other cortical regions involved in memory. Abnormalities in the schizophrenic performance on the CVLT and the logical memory segment of the WMS-R suggest a deficit in the rapid acquisition of new information, which has been demonstrated to be a function of the hippocampal formation (for a review, see Squire 1992). The demonstration of a correlation between the impaired performance of schizophrenic patients on the logical memory portion of the WMS-R and volumetric reductions of the left hippocampal region, as measured by magnetic resonance imaging (Goldberg et al. 1994), provides further evidence in support of the proposal that alterations of the hippocampal formation may be at least partly responsible for the memory deficit observed in schizophrenia.

3.2.1 Working Memory

Working memory is another form of memory that may be impaired in schizophrenic patients. Working memory has been defined as the ability to retain and manipulate information over short periods of time in the absence of external cues (for a review, see Baddeley and Hitch 1994). Working memory is believed to be

composed of three components: a central executive system (CES), an articulatory loop, and a visuospatial scratch pad. Executive function refers to complex thought processing and is defined as the ability to solve problems, plan, abstract, form concepts, and make adjustments or "shift sets" when older response sets are no longer adaptive. The CES is also thought to allocate resources among concurrent processes. The articulatory loop actively maintains verbal information, while the visuospatial scratch pad actively maintains visually presented information. Schizophrenic patients exhibit deficits in each of the systems that comprise working memory.

The CES is thought to provide a controlling mechanism during tasks that require multiple operations upon primary or immediate memory. Deficits during dual-task procedures are thought to represent CES impairment. Using a modified Brown-Peterson dual task in which participants are required to remember information, such as a list of words, while performing a distracter task, such as counting backwards, Fleming et al. (1995) obtained a decline in the performance of schizophrenic patients when the distracter task called for counting forward. This result would support the notion of a CES working memory impairment in schizophrenia, since the patients were unable to perform at a normal level even while performing a relatively simple distracter task. Additionally, when performing the dual task, schizophrenic patients displayed impaired performances on those distracter tasks which were more related to the memory task and thereby increased the load on working memory as opposed to tasks which were less related to the memory task (Fleming et al. 1995). However, while performing the simplest form of distracter task, finger tapping, which made little or no demands on verbal memory, schizophrenic patients performance on the recall task was no different than controls. Increasing the load on the working memory system of schizophrenic patients therefore results in impaired performance relative to normal controls.

Gold et al. (1997) demonstrated a strong positive correlation between impaired performance on a putative measure of working memory, the Letter–Number Span test, and impaired performance on the WCST in the schizophrenic population. The Letter–Number Span test is a test of immediate recall in which series of alternating letters and numbers are presented for memorization with an increasing series of digits presented after each successful recall. Impaired performance on tasks involving executive function has long been considered a hallmark of schizophrenia. The WCST requires the patient to match a sample card containing simple geometric shapes to an array of four cards on the basis of one of three attributes – color, form, or number. The patient is not told on which dimension to match the card in advance, but rather only whether or not their choice was correct or incorrect. In this sense, patients are required to formulate the rules of the test, which alternate in a predetermined manner. The WCST is thus believed to be a test of problem solving and set shifting. Fey (1951) used the WCST to differentiate between schizophrenic patients and normal controls. The WCST has been used extensively and is thought to be a classic test of executive function (Milner 1963). Relatively few numbers of categories obtained and relatively high percentages of perseverative errors on the WCST is the characteristic performance observed in schizophrenic patients (Goldberg et al. 1988).

The integrity of the prefrontal cortex has long been associated with performance on the WCST (Milner 1963). Both lesion studies and studies of activation in normal controls undergoing functional neuroimaging have suggested that the prefrontal cortex is necessary for performance on the WCST (Milner 1963; Goldberg et al. 1994). Seidman et al. (1994) demonstrated strong, significant, inverse correlations between impaired performance on the WCST and volumetric reductions of the dorsolateral prefrontal cortex as measured by magnetic resonance imaging in schizophrenic patients. Using difference scores between monozygotic twins that were discordant for schizophrenia, Goldberg et al. (1994) demonstrated a strong correlation between prefrontal regional cerebral blood flow (rCBF) and perseveration on the WCST. With respect to the number of categories obtained and the number of perseverative errors committed on the WCST, Sullivan et al. (1994) demonstrated that the performance of schizophrenic patients fell between one and two standard deviation units below normal controls. These findings in schizophrenic patients suggest that working memory may be a critical component of WCST performance and that the function of the prefrontal cortex is compromised in schizophrenia.

In addition to displaying deficits of the CES of the working memory system, procedures which measure articulatory loop and visuospatial scratch pad performance also elicit deficits in the schizophrenic population. Using an occulomotor delayed-response task thought to be a test of visuospatial working memory in which the participant must make a delayed motoric response to the correct spatial location of a target stimulus, Park and Holzman (1992) demonstrated significant impairment in schizophrenic patients relative to controls. Additionally, Fleming et al. (1997) demonstrated impaired performance of schizophrenic patients in visuospatial tasks that required working memory: WMS-R visual memory span and a spatial delayed-response task. In the same study, the schizophrenic patients did not display deficits on a visuo-

spatial task which does not involve a delay, the judgement of line orientation, which selectively measures perceptual abilities and does not draw upon the resources of working memory. This pattern of results would implicate prefrontal cortical regions as opposed to occipital and temporal regions as being responsible, at least in part, for the observed working memory deficit in schizophrenia.

Perhaps the construct which best captures schizophrenic patients' inability to maintain and manipulate information in working memory is that of capacity limitations on the amount of information that working memory is capable of processing. For example, in the letter-number span study of Gold et al. (1997), schizophrenic patients performance declined relative to controls with increased span length. Additionally, Cohen and Servan-Schreiber (1992) observed a decrease in comprehension by schizophrenic patients when the distance between phrases increased. This increase of distance may represent an increase in the "load" or amount of information being handled by working memory and would suggest an impairment in the ability to manipulate such increases in schizophrenia.

3.2.2 Thought Disorder and Semantic Memory

Schizophrenic patients frequently exhibit formal thought disorder, as manifested in disorganized speech characterized by poverty of content of speech, derailment or tangentiality, illogicality, use of word approximations or neologisms, and loss of goal (Andreasen 1986). In schizophrenia, thought disorder appears to arise from an inability to produce coherent language rather than an inability to understand and comprehend language.

One hypothesis that addresses the neuropsychological basis for thought disorder in schizophrenia suggests that the speech production errors observed in schizophrenia are the result of a malfunction in the semantic organization of schizophrenic patients. Evidence in support of this hypothesis comes from work done on priming and fluency in schizophrenia. With respect to fluency, Gourovitch et al. (1996) demonstrated that schizophrenic patients displayed a superior performance for the generation of words (in 1-min epochs) from phonologic categories, (i.e. the letters *f*, *a*, and *s*), relative to semantic categories, (i.e. "animals," "fruits," and vegetables"), and the magnitude of the difference between these two measures of fluency was strongly correlated with the presence of thought disorder (Goldberg and Weinberger 2000). Additionally, Aloia et al. (1996) demonstrated that the "semantic space" in schizophrenia patients was disorganized relative to normal controls on the basis of a multidimensional scaling analysis of a verbal fluency task, suggesting an abnormal weighting of connection strengths between concepts or attributes in semantic memory.

Further evidence supporting the existence of semantic abnormalities in schizophrenia can be found in priming studies in which a word may "prime" or facilitate a future response on the basis of relatedness. For example, when the word "cat" follows the word "dog," it is responded to more rapidly than if it follows the word "stone," presumably due to increased connection strengths between the "nodes" representing the more frequently associated words. Work on semantic priming in schizophrenia is complex and has yielded mixed results, perhaps due to differences in paradigm or cohort (Barch et al. 1996; Chapin et al. 1989; Goldberg and Weinberger 2000; Ober et al. 1995; Spitzer 1997).

Although Chapin et al. (1989) and Ober et al. (1995) displayed similar semantic priming effects between schizophrenic patients and controls during a lexical decision task which required patients to make a decision as to whether or not a word was a member of a particular category, these studies also obtained slower reaction times for schizophrenic patients. Additionally, Chen et al. (1994) obtained slowed reaction times in schizophrenic patients versus controls during a task requiring determination of the degree to which words were exemplars of specific categories. These results would suggest that category boundaries are vague and overinclusive in schizophrenia, perhaps due to overactivation of marginally related concepts.

In an attempt to determine the cognitive mechanism of the slowed and inaccurate processing by schizophrenic patients during semantic priming, in particular, with the hope of being able to determine a cognitive mechanism for thought disorder in schizophrenia in general, we (Aloia et al. 1998) developed a priming task in which the prime and the target were either strongly, moderately, or weakly related words from a single semantic category. In this study, thought-disordered patients displayed "negative" priming, i.e. their responses were slower to strongly and moderately related words, which directly contrasts with the performance of normal controls producing faster responses to the strongly and moderately related words. This differential performance between thought-disordered schizophrenic patients and normal controls would suggest that, when a patient attempts to produce a word automatically on the basis of spreading activation, closely related words are not activated. Speculatively, in speech, an inappropriate but somewhat related word might be produced instead. The result would be interpreted by the clinician as a "loose," tangential, or irrelevant response on the part of the patient.

3.3 Motor Control

Schizophrenic patients also display deficits of motor control. Slowed reaction times on both simple and complex tests have been demonstrated in schizophrenia (Vrtunski et al. 1986). Additionally, impaired performance in schizophrenic patients has been demonstrated on tests of fine motor control such as the grooved peg board peg placement test and finger tapping (Saykin et al. 1994).

One problematic finding relates to the demonstration of the effect of neuroleptic medications on motor control and responses. The extrapyramidal side effects of neuroleptic medications can produce a retardation of reaction time. Thus the question arises of whether the slowing of motoric responses by the administration of neuroleptic medication in schizophrenia is accompanied by a generalized slowing of neuronal processing that results in the cognitive changes described above. As mentioned previously, on the basis of "first break" or neuroleptic naive studies (Saykin et al. 1994), drug-free studies, and comparisons with patients with movement disorder (Goldberg et al. 1990), the cognitive impairments demonstrated in schizophrenic patients tend to deteriorate in the absence of neuroleptic treatment and would therefore appear to occur independently of the presence of neuroleptic medications (for a review, see Goldberg and Weinberger 1996).

Indeed, instead of a neuroleptic effect, most of the cognitive changes described above appear to be enduring effects of the disease and dissociable from psychomotor slowing in general. Thus, when Hanes et al. (1996) compared schizophrenic patients to patients with known psychomotor slowing due to basal ganglia pathology (i.e. Huntington's disease), marked differences on several higher cognitive tasks were observed. Moreover, studies of procedural learning in schizophrenia have demonstrated that schizophrenic patients are capable of improving their motor skill learning at a rate which is analogous to that observed in normal control participants (Goldberg et al. 1993c). These results would suggest that the cognitive impairments observed in schizophrenia are not a product of a generalized motoric slowing.

4 Conclusions

Schizophrenia can be characterized by impaired performances in the areas of attention, episodic memory, working memory, executive function, semantic organization, and motor control. Impairment of these cognitive domains has serious consequences for the functional capacities of the schizophrenic patient, including social and vocational skills. Additionally, the characteristic neuropsychological profile of schizophrenic patients suggests cortical dysfunction in the regions of the frontal lobe, particularly in the motor, premotor, and prefrontal cortex, as well as the medial temporal lobe.

CHAPTER 9

W. Rössler

Schizophrenia: Psychosocial Factors

Translator: E. Taub

1 Historical Overview

The effect of psychosocial factors on the occurrence of schizophrenia and its course has been a subject of scientific investigation for just over 100 years. According to Kraepelin's view (1896), schizophrenia was caused by a (biological) disease process inevitably ending in "dementia" (*Verblödung*). Nonetheless, by the mid-twentieth century, it had become clear that the observed disease manifestations and behavioral abnormalities often did not, in fact, evolve in a uniformly negative way, even though this had been the conclusion of studies of long-term hospitalized patients around the turn of the century. Rather, it was found that they were subject to considerable influence from the custodial living conditions under which the patients were cared for (Wing and Freudenberg 1961; Wing and Brown 1970). The recognition that the patient's social environment can have a major effect on the course of severe mental illnesses, particularly schizophrenia, was an important motivating factor for the worldwide reforms in the care of the mentally ill that took place in the second half of the twentieth century.

The influence of psycho- and sociodynamic factors on schizophrenic manifestations and behavioral abnormalities was already a central element of Eugen Bleuler's concept of schizophrenia, which incorporated both the psychopathology of dementia praecox, as described by Kraepelin, and the psychodynamic dimension of Freudian theory (E. Bleuler 1911). The relationship of schizophrenic patients to their living environment was described in further detail by Manfred Bleuler (1972), according to whom negative influences in childhood were of particular importance for the development of schizophrenia. Manfred Bleuler later recognized, however, that childhood influences were relatively nonspecific; in the aftermath of his own observations, they were found to have comparable etiological importance for psychiatric illnesses other than schizophrenia (Benedetti 1995).

As early as the nineteenth century, psychiatrists had already suspected that harmful influences from the social environment might promote the appearance of mental illnesses or have a deleterious effect on their course. In that era, the isolation of the mentally ill in the "healthful" milieu of institutions far removed from their original living environment was held to be an appropriate means of shielding them from the disease-producing influences of their surroundings (Rössler 1992). In contrast, the twentieth-century reform movement sought to (re-)integrate patients in their normal living environment as rapidly as possible, because it was thought that their natural social network would make a major supporting contribution to the healing process.

The long-term deinstitutionalization of the mentally ill, predominantly schizophrenic patients who in some cases had been hospitalized for decades, succeeded only because the reform movement occurred in parallel with the introduction of neuroleptic medications for the treatment of schizophrenia. It soon became clear that long-term pharmacotherapy was also of major importance for the prevention of relapses, even though approximately one third of patients relapse despite medication, and approximately one fifth have a spontaneous remission without medication (Leff 1987). The fundamental contribution of the neuroleptics to the treatment of schizophrenia is uncontested.

Research on schizophrenia has therefore turned more toward defining its biological underpinnings since the 1970s, initially with the major objective of understanding the mechanisms of action of antipsychotic medications. This shift toward biological psychiatry was further accelerated by the development of new imaging techniques, new laboratory methods, and the field of genetic research.

The influence of genetic factors on the development of schizophrenia is universally accepted; it is immediately evident in the (approximately) 48% concordance rate for schizophrenia among monozygotic twins, for example. Similarly, the risk of developing schizophrenia is approximately 46% for the children of two schizophrenic parents (Gottesman 1991). It is precisely these unambiguous findings, however – in which a large portion, but by no means all, of the variance is accounted for by genetic factors – that indicate that other factors must also play a role. Furthermore, despite major research efforts, the specific genes involved in the development of schizophrenia have not yet been identified (DeLisi 1999). It therefore seems worthwhile to devote some attention to possible influential factors of other types, including psychosocial factors.

2 Conception of Illness in Relation to the Environment

The history of research on schizophrenia reveals that biology and social environment are not a dichotomous pair, but rather interact with each other to exert an influence on the disease. This is particularly true with respect to the course of the illness, less so, however, with respect to its onset.

Most theories of the etiology and course of schizophrenia are based on the so-called vulnerability–stress

model (Zubin and Spring 1977), according to which a biological vulnerability of undetermined origin and variable degree, accompanied by short- or long-term social stressors or other environmental factors, leads to the initial onset of the illness or to a relapse (Nuechterlein 1987).

The interaction-development model, which evolved from the vulnerability-stress model, postulates an active mutual influence between affected individuals and their environment. While the original vulnerability-stress model saw affected individuals as passive recipients of various psychosocial influences, the interaction-development model views them as active participants in the formation of their own environment (Strauss et al. 1985).

A systematic account of psychosocial factors should include a distinction between the immediate and the broader social environment. The immediate social environment comprises the social network of the affected individual, including family, friends, workplace, etc. Critical life events and family climate should also be included among the immediate social environment. Furthermore, not only the present situation, but also the developmental perspective should be considered; for example, one area of research interest deals with the relationship between the early childhood milieu and the later development of mental disturbances. The broader social environment includes sociocultural influences (also in an intercultural perspective) and, most importantly, socioeconomic factors.

3 Sociocultural Factors

3.1 Cultural Influences

The influence of culture on schizophrenia has long attracted considerable interest. A number of studies have shown (Pfeiffer 1994) that the disease takes on characteristic culture-specific forms. Comparative studies across cultures also suggest that the incidence and prevalence of schizophrenia are lower in developing countries than in industrial countries (Murphy and Raman 1971; Waxler 1979; Torrey 1980).

The lack of standardized comparative studies led the World Health Organization (WHO) to conduct multicenter comparative studies with uniform study instruments and follow-up examinations, starting in the 1960s (Sartorius et al. 1972; WHO 1974, 1975). The results of these studies imply that the incidence of the core manifestations of schizophrenia is approximately the same all over the world, but that the course of schizophrenic illnesses is highly variable and, in particular, differs between the developing and the industrial countries. Schizophrenics in developing countries have similar initial disease manifestations to those of patients in industrial countries, but they have a less chronic course of the illness, fewer relapses, and better social adaptation (WHO 1979; Sartorius et al. 1987; Jablensky et al. 1992). Further significant psychosocial factors were identified in addition to the developing versus industrial country factor, namely, family situation and social network (Sartorius et al. 1996).

It has been suggested that these differences in disease course between the developing and the industrial countries are attributable to the more easily mastered patterns of social interaction in less complex societies, in contrast to the complex, conflict-laden, and less easily grasped demands placed on the individual in modern industrial societies. Alternatively, it may be useful to discuss whether society, in the developing countries, places a less intense demand for autonomy and competitive behavior on vulnerable individuals and enables them to live in smaller, more stable, and longer-lasting social networks.

Migration studies also suggest an effect of the environment on the risk of developing schizophrenic illnesses. British studies, for example, have amply documented that immigrants from Trinidad and Jamaica, particularly in the second generation, have an elevated incidence of schizophrenic illnesses compared to the general population (e.g. Davies et al. 1995). Nonetheless, even if it seems plausible that unfavorable environmental conditions elevate the risk of developing disease, a number of confounding factors must also be taken into account.

Selection effects in migration are relevant in this connection. For example, Ødegaard (1932) showed, in a classic study, that Norwegian emigrants had an elevated incidence of schizophrenia, but Häfner (1980) showed that Turks in Germany were less likely to develop schizophrenia than the native population. This is presumably explained by the fact that strict health criteria were applied in the selection of guest workers coming to Germany.

Meanwhile, a number of more recent epidemiologic studies have shown no elevated risk of becoming ill among the populations of origin in Trinidad and Jamaica (Hickling and Rodgers-Johnson 1995; Bhugra et al. 1997). Now that other possible factors have also been studied (Hutchinson et al. 1997), it seems likely that the environment is a major risk factor for the development of schizophrenia, at least in this population group.

This is no longer an isolated finding. A Dutch study revealed that immigrants to the Netherlands from the

former colonies of Surinam and the Netherlands Antilles have a fourfold elevated risk of developing schizophrenia, as compared to the general Dutch population (Selten et al. 1997). Selection processes among the populations of origin are unlikely to have played a major role in this phenomenon, because large portions of the populations of origin took part in the migration to the Netherlands.

3.2 Socioeconomic Influences

The pioneering epidemiologic studies by Faris and Dunham (1939) of the ecological distribution of schizophrenia in Chicago in 1935 revived the discussion of the influence of social factors on the occurrence and course of schizophrenia. They found that the Chicago slums had the highest rates of individuals undergoing initial hospitalization for schizophrenia. The same pattern was found thereafter in many different cities and countries: in Bristol by Hare (1956), in Liverpool by Castle and Gittus (1957), in Nottingham by Giggs (1986), and in Mannheim (Germany) by Häfner and Reimann (1970). The Mannheim findings were later found to be essentially stable after a follow-up interval of 15 years (Weyerer and Häfner 1989).

The question of a relationship between the urban living environment and the risk of mental illness exercises a certain fascination even today. In a recent study, Torrey et al. (1997) analyzed U.S. census data from the year 1880 and found that the risk of developing psychosis was elevated by a factor of 1.6 in urban areas. Marcelis et al. (1998) used the Dutch national registry of psychiatric cases to study the relationship between place of birth and the risk of becoming ill and reported a moderately strong, but statistically significant association between urban birthplace and elevated incidence of disease. Mortensen et al. (1999), too, in their analysis of the Danish national registry, found a 2.4-fold elevation in the incidence of schizophrenia among individuals born in the national capital. At the same time, they found a ninefold elevation in incidence among subjects with a positive family history.

Evidence for a heterogeneous ecological distribution of schizophrenia is found not only within cities, but also in relation to urban–rural differences (Dohrenwend and Dohrenwend 1974). The largest North American epidemiologic study of the last few decades, however, revealed no urban–rural differences in the prevalence of schizophrenia when factors such as age, sex, and race were taken into account (Shapiro et al. 1984).

The heterogeneous ecological distribution of schizophrenia is in accordance with the demonstrated differences in the frequency of schizophrenia among different social classes. Numerous studies have documented an overrepresentation of schizophrenics in lower social classes (Clark 1948; Stein 1957; Hollingshead and Redlich 1958; Myers and Bean 1968; Eaton et al. 1988). In the review articles by Dohrenwend and Dohrenwend (1969) and Eaton (1974), it was reported that five of seven and 15 of 17 studies, respectively, had yielded this result. The explanation was sought mainly in the greater social isolation of the affected individuals and in the lack of social support in lower social classes.

Although, at the time of the reform movement in psychiatry in the 1960s and 1970s, it was thought that research findings of the type just discussed had conclusively demonstrated the social origin of schizophrenia, this interpretation is no longer accepted as valid today. These findings are now generally explained by the hypotheses of social decline and social selection. Social decline refers to the social consequences that follow the onset of illness, and social selection refers to the lack of social rise even before the onset of illness (Häfner 1992).

The social decline of schizophrenics has been amply documented. Marneros et al. (1991), for example, in a long-term study, found that 71% of schizophrenics studied had suffered a downward change of occupation, usually associated with a shift into a lower social class, and often also with a move into a neighborhood with social problems of many different kinds. The prevailing anonymity of such neighborhoods may sometimes be a positive feature for schizophrenics with disturbances of communication. Not least, a greater offering of social services is usually available in inner-city neighborhoods, which may be more attractive to affected individuals for this reason as well.

It is more difficult to find empirical support for the hypothesis of social selection, which is presumed to be primarily the effect of premorbid personality changes. Malmberg et al. (1998) studied a cohort of Swedish army recruits from the years 1969 and 1970 who developed schizophrenia over the following 15 years and found significant premorbid deficiencies of social adaptation.

The so-called break in the performance curve before the overt appearance of the disease is also well known. Ødegaard (1971), in an analysis of the Norwegian case registry, found that occupations requiring lower qualifications were significantly overrepresented among initially hospitalized schizophrenics. Goldberg and Morrison (1963), in a controlled study, showed that initially hospitalized schizophrenics were employed in occupations requiring lower qualifications than their own fathers' occupations.

Nonetheless, these findings, too, have alternative explanations. The largest German study of patients in

the earliest stages of schizophrenia revealed that initial hospitalization occurs on average approximately 4.5 years after the appearance of the first manifestations of any kind and approximately 2 years after the appearance of the first psychotic manifestations (Häfner et al. 1998). This suggests that the social abnormalities found in the period before the disease becomes overt ("social selection") are actually early signs of social decline.

4
Influences of the Immediate Social Environment

4.1
Early Childhood Environment

The presumed influence of the early childhood environment on the risk of developing schizophrenia played a major role in the psychosocial theories of the 1960s and 1970s.

According to Bateson and colleagues (Bateson 1972; Bateson et al. 1956), the cognitive and affective disturbances in schizophrenia are caused by an abnormal parent-child relationship. One aspect of this idea, the so-called double-bind hypothesis, became widely known: contradictory messages from parents to their children were said to lead inevitably to schizophrenic reactions. On the other hand, in the views of Wynne and Singer (1966) or Lidz (1975), particular types of conflicts between the parents were held to cause schizophrenia in their children.

The major weakness of these explanatory approaches – aside from the inappropriateness of constructing theories without adequate empirical support – lies in their failure to consider whether the observed phenomena represent causes or effects of illness. This deficiency might be remedied by long-term prospective studies. Such studies have been performed on individuals with an elevated risk of developing schizophrenia, so that an adequate number of schizophrenics would eventually be included in the study population; the risk-conferring feature usually chosen for this purpose has been genetic load.

Among five such long-term studies of subjects at elevated risk of developing schizophrenia, two showed that unfavorable family circumstances were an additional risk factor (Cornblatt and Obuchowski 1997). In the Copenhagen risk study, perinatal complications and unstable family circumstances in early childhood were found to be important risk factors (Cannon and Mednick 1993; Cannon et al. 1994). In the Finnish adoption study, schizophrenia appeared almost exclusively in individuals with a genetic risk, but, within this group, mainly in those who had grown up in difficult family circumstances (Tienari et al. 1989, 1994).

4.2
Family Atmosphere

Almost in parallel to the development of psychosocial theories discussed previously regarding unfavorable family influences in early childhood as risk factors for the development of schizophrenia, a branch of empirical research came into being that was concerned primarily with the influence of family circumstances on the course of the disease. The point of departure for this area of research, which came to be known under the heading of "expressed emotion," was the observation that schizophrenics discharged from inpatient treatment into the care of their families had a high rate of relapse (Brown 1959). The ensuing study conducted by Brown et al. (1962) showed that 76% of patients living in a family atmosphere characterized by criticism and hostility experienced a relapse, as compared to only 26% of those who experienced relatively little criticism and hostility.

In the years thereafter, many empirical studies were performed on the question of a relapse-promoting family atmosphere, most of which confirmed the findings of the original study (Leff and Vaughn 1985; Lam 1991; Bebbington and Kuipers 1994). Bebbington (1995), in a meta-analysis, found that a favorable family atmosphere had a more significant relapse-preventing effect than pharmacotherapy.

Even though these research findings regarding the influence of family atmosphere on the course of schizophrenia are relatively robust, it should not be forgotten that family atmosphere is also an expression of the course of the illness. Criticism and hostility tend to be expressed in families confronted with an unfavorable course. Like many of the findings discussed in the preceding section, these findings, too, are difficult to interpret because they provide no way of differentiating unambiguously between cause and effect.

4.3
Critical Life Events

A number of studies have investigated the extent to which difficult life situations may be involved in the development of schizophrenia. Steinberg and Durell (1968), for example, found a significant elevation of the incidence of schizophrenia in the months following induction into the army. The most important study in this category was that carried out by Brown and Birley (1968), which revealed that a significantly higher number of critical life events occurred in the

3 weeks preceding the onset of the illness. In the following years, a number of studies on this question were carried out in widely varying cultural environments and failed to provide an unambiguous answer (Bebbington 1995).

The fact that no clear statement can be made on this issue at present is largely due to the complexity of the object under study. Among the numerous methodological difficulties involved, we may mention just a few: first of all, there is no generally accepted definition of a critical life event. Critical life events are significant only in the individual context. Furthermore, as is known from studies in social psychology, possible psychosocial stress factors tend to be overemphasized in retrospective explanatory approaches, e.g. the attempt to explain what might have triggered the onset of schizophrenia. Moreover, the perception of such events and factors may already be distorted by the illness itself (Rössler and Lackus 1986). Finally, it must be considered that a possible clustering of critical life events shortly before the onset of disease might itself be produced by the disease in the offing.

5 Discussion

The scientific discourse of the 1950s and 1960s was mainly characterized by attempts to provide psycho- and sociodynamic explanations for the onset and course of schizophrenia. It was recognized that schizophrenia was most likely due to abnormal biological functions of some kind, but, on the whole, the possible variables of biological factors at work were, instead, devalued by the common designation of all such factors as "constitutional." The term "psychosocial" today is at risk of suffering the same fate. In current scientific discourse, psychosocial factors are often relegated to the status of a single variable of merely peripheral interest, without further specification. Neuroscience has, indeed, made enormous progress toward an understanding of the biological causes of schizophrenia, but it should not be forgotten that research in the social sciences has also yielded a considerable body of knowledge (even if, in part, contradictory) with respect to the psychosocial factors that influence it.

As mentioned above, the complexity of the social environment has often led researchers to resort to the use of socio-structural indicators. Such indicators as the percentage of unmarried or unemployed individuals, those raising children alone, or those receiving disability compensation, or the classification of the population by age, sex, and so forth, are routinely measured and used as bases for extrapolation (Rössler and Salize 1996). Figures of these types are quantitatively reliable, yet they qualify for modified interpretation only. Future research in the social sciences on schizophrenia will face the challenge of again finding more direct means of evaluating the social environment. In this context, Eaton and Harrison (1998) have suggested that a project might be undertaken to classify the human environment systematically, much as the Human Genome Project aims to catalogue all human genes.

Lastly, it should be mentioned that the psychosocial environment plays a paramount role in the practical care of schizophrenic patients. Most of the rehabilitative treatment approaches in use today are intended to influence the psychosocial environment in some way, be it by the elevation of the vulnerability threshold in a demanding environment or by providing for an appropriate living and working environment in which the individual is subject to less stress (Rössler, in press).

In a value system according the highest priority to the personal freedom and autonomy of affected individuals, these individuals themselves have an important voice in determining how their living environment is to be organized. A constructive dialogue with the affected individuals requires a still further deepening of our knowledge of the psychosocial factors influencing schizophrenia.

General Principles of the Treatment of Schizophrenic Disorders

Translator: E. Taub

1 Introduction

The treatment of patients with schizophrenic disorders is based on clear, empirically derived principles. Guidelines for treatment may be found in a number of published works (see below; Gaebel, in press). In countries with a structured health care sector, schizophrenic patients are treated in a system comprising multiple components. The psychiatrist is not necessarily the caregiver of first resort for such patients, but is, as a practically universal rule, consulted as a specialist – at least upon the initial presentation of the illness – and directs further treatment measures, in whatever component of the mental health care system they may take place. In the context of multidisciplinary treatment, the psychiatrist bears the ultimate responsibility for the development and implementation of an overall treatment plan.

2 Therapeutically Relevant Aspects of Disease Course

Schizophrenic disorders are generally characterized by a lifelong course, with the exception of rare cases of monoepisodic disease. E. Bleuler (1911) drew attention to the heterogeneity of the manifestations and course of schizophrenia by referring to the disease as "the group of schizophrenias" – in contrast to Kraepelin (1896), for whom "dementia praecox" was characterized by a uniform, unfavorable course.

Types of schizophrenia are diagnostically differentiated and encoded in the ICD-10 system according to the acuity of onset (acute, insidious, primary chronic), the pattern of acute episodes (phasic-remitting, episodic with stable or increasing residua), and the long-term outcome (e.g. remission, persisting positive and/or negative manifestations, psychosocial disability). Both the pattern of acute episodes and the long-term trend of disease course, which becomes evident after multiple episodes have occurred, display considerable intercultural as well as inter- and intraindividual variability. This fact is regarded as evidence for the psychosocial plasticity of the disease course and against its being purely biologically determined. A number of longitudinal studies have shown that the long-term course of schizophrenia is rather favorable (e.g. M. Bleuler et al. 1976; Tsuang et al. 1979; Harding et al. 1987).

2.1 Phases

With the exception of primarily continuous forms of schizophrenia, the course of the disease can generally be subdivided into the following phases, each of which requires specific therapy (APA 1997):

- The *acute decompensation phase* (lasting weeks or months) begins with nonspecific prodromal manifestations and/or specifically psychotic manifestations, sometimes with endangerment of the patient or others, which resolve more or less completely under treatment.
- The *postacute stabilization phase* (approx. 3–6 months) is characterized by further regression of positive manifestations and psychopathological stabilization, but negative manifestations and cognitive and sociocommunicative deficits often persist, and there is an increased likelihood of relapse.
- The stable (partial) *remission phase* (months or years) is characterized by the following (depending on the type of the disease course): disappearance or stable residua of positive manifestations, negative manifestations, and stable or increasingly impaired social competence, corresponding to the premorbid level.

2.2 Stages

The sequence of individual phases constitutes the overall disease course, which is itself divided into therapeutically relevant stages:

In the first 5–10 years of illness, there is an increased frequency of relapses, suicide attempts, and suicides (M. Bleuler et al. 1976; McGlashan 1991). This stage is characterized by frequent inpatient hospitalizations, in which the course is set for rehabilitative efforts, in accordance with the patient's overall prognosis, life situation, and coping ability.

After these turbulent years, a plateau phase is often reached in which relapses are less common and a certain degree of social stabilization takes place (M. Bleuler et al. 1976; McGlashan 1991).

2.3 Treatment and Course

The phenomenology of schizophrenic disorders is divided into positive, negative, and social manifesta-

tions (Strauss et al. 1974). Rehabilitative efforts are directed against so-called impairments, disabilities, and handicaps. This differentiated view of the disease necessitates a multidimensional concept for the assessment of treatment outcome. Thus, alongside the clinical dimension, rehabilitative and humanitarian dimensions and a dimension of public safety may be distinguished (McGlashan 1994). Individual aspects of disease course, such as disease manifestations, role function, relapse rate, and quality of life, are only moderately related. The treatment of schizophrenic disorders must be phase- and stage-specific and must take account of the varying objectives of treatment over the course of disease in the individual patient.

Several studies indicate that acute episodes respond less well to treatment the later it is instituted (Wyatt 1991; Loebel et al. 1992). It follows that treatment should be begun as early as possible, even though this does not seem to have a major influence on overall prognosis.

In cases of schizophrenia with a relapsing course, a decline in the therapeutic responsiveness of acute episodes to neuroleptics has been observed (Lieberman 1993). It has been speculated that repeated episodes of disease may exert a "toxic" or "kindling"-like effect and thus pave the way for further episodes that are less responsive to therapy.

2.4
Predictors of Course and Therapeutic Response

Many different aspects of schizophrenic patients have been investigated as possible predictors of the course of disease and of therapeutic responsiveness (Gaebel and Awad 1994). A well-developed premorbid personality, the presence of provoking factors, acute onset of illness, accompanying affective manifestations, absence of impoverishment of affect, and a psychologically favorable life situation have long been considered generally favorable prognostic signs (Langfeldt 1937). More recently, further characteristics of patients, of the disease, and of the environment (sometimes quantified in prognostic scales) and, increasingly, biological factors have also been extensively studied (Awad 1994; Möller 1994; Lieberman 1994). To summarize the results of these studies, it may be stated that no single feature or combination of features yet enables a reliable prediction upon which differential indications for therapy can be based in individual cases.

3
Diagnosis and Treatment

3.1
Diagnostic Concepts

Operational systems such as ICD-10 and DSM-IV can be used for the diagnosis of schizophrenic disorders. These systems require the presence or absence of certain manifestations, a deterioration of social functioning, and a specified minimum duration of illness as prerequisites for the diagnosis of schizophrenia. An organic etiology must be ruled out for the diagnosis to be made (in spite of the accumulating findings of biological abnormalities in schizophrenia). Additional diagnostic procedures must also be used. Drug screening and clinical laboratory testing, including complete blood count and urinalysis, are recommended in all cases. Pregnancy tests, electrocardiography (ECG), electroencephalography (EEG), computed tomography or magnetic resonance imaging, and neuropsychological or general psychological examination are recommended only if special questions are to be answered (Frances et al. 1996). The descriptive diagnostic criteria do not yield differential indications for therapy.

A biopsychosocial systems approach to diagnosis and treatment is appropriate for the development of a multidimensional model (Engel 1980). Such an approach affords a hypothetical framework in which potential biological and psychosocial causative factors and corresponding therapeutic measures may be critically considered.

The vulnerability-stress model (Nuechterlein 1987) goes a step further and posits hypothetical relationships between an elevated vulnerability to disease and factors that promote or inhibit the appearance of disease manifestations. It represents a heuristic framework in which vulnerability, stressors, and protective factors may be targets for therapeutic intervention.

3.2
Therapeutic Concepts

3.2.1 General Objectives of Treatment

The objective of treatment is to free patients from the manifestations of disease and the accompanying disabilities to the extent that they can lead their lives as they themselves see fit, with minimal dependence on clinical institutions (Helmchen 1978). Early, acute treatment of exacerbations and consistently maintained prophylaxis against relapses are the essential prerequisites for stable remission and may help

prevent the disease from becoming chronic. The major types of intervention are intended to reduce disease manifestations, vulnerability factors, and stressors and to strengthen coping strategies. Interventions intended to stabilize primarily or secondarily affected psychosocial functions round out the treatment program.

3.2.2 (Re-)Assessment and Monitoring

The time-consuming diagnostic process that is undertaken upon the initial manifestation of disease generally need not be repeated later, as long as no uncertainty exists about the diagnosis. Nonetheless, the various dimensions of disease course must be assessed at regular intervals so that the treatment can be correspondingly adjusted. The use of standardized instruments of assessment is sometimes beneficial. If patients do not respond to antischizophrenic medication, their compliance should be tested, e.g. by determining plasma levels, and their motivation for possible noncompliance should be clarified, above all by consideration of side effects.

The fine-grained (daily) monitoring of patient status performed in the acute phase can be reduced to weekly or monthly visits to the physician in the postacute phase; later, in the stable phase, some patients may see the physician as rarely as once every 3–6 months. The most important factor is the availability of a caregiver to the patient and the family, in case an acute need should arise.

3.2.3 Specific Therapeutic Interventions

The treatment of schizophrenic disorders has a multidimensional orientation. This means that biological/somatic, psychological/psychotherapeutic, and sociotherapeutic/rehabilitative aspects must all be considered whenever treatment and supportive care are offered. Different aspects may receive different emphases in the individual case, depending on the particular phase and stage of the disease.

The prevention or elimination of positive manifestations is the major objective of neuroleptic treatment, but negative manifestations, too, respond partially to such treatment (Carpenter et al. 1985; Goldberg 1985). No primary effects of neuroleptic treatment are expected on the social axis. Although a possible negative effect of classical neuroleptic treatment on the social dimension cannot be ruled out (May and Goldberg 1978), the patients' quality of life may be improved secondarily through the amelioration of disease manifestations and the prevention of relapses (Barnes et al. 1983; Awad 1992). The introduction of newer, atypical antipsychotic agents with more favorable side effect profiles has allowed still further improvement of these patients' quality of life and increased acceptance of pharmacotherapy.

The effectiveness of neuroleptic agents in the acute and long-term treatment of schizophrenic psychoses has been documented beyond doubt (Davis et al. 1980). Remission of manifestations and prevention of relapse can be achieved in approximately 70% of patients undergoing treatment in accordance with accepted recommendations. The monthly spontaneous relapse rate is 10% under placebo treatment and falls to approximately 3% under neuroleptic treatment (Davis 1985). Even though the spontaneous relapse rate tends to decrease over time, there is a lasting, significant difference between neuroleptic treatment and placebo (Hogarty and Ulrich 1977). Recommendations and guidelines exist for both acute and long-term neuroleptic treatment (Kissling 1991; Kane and Marder 1993; Gaebel and Marder 1996; Frances et al. 1996; APA 1997; DGPPN 1998; Lehman et al. 1998a). In long-term treatment, maintenance pharmacotherapy at the lowest possible neuroleptic dose, i.e. sufficient to suppress schizophrenic manifestations with minimal side effects in the individual case, is the preferred strategy, rather than intermittent neuroleptic treatment with early intervention (Schooler 1991; Pietzcker et al. 1993).

The options for treatment and the prognosis under long-term treatment are limited by a number of factors. As many as 50% of outpatients undergoing long-term pharmacotherapy fail to achieve drug levels in the therapeutic range because of inadequate compliance (Johnson 1984). Tardive dyskinesia in 10%–15% of patients (Gaebel 1993), inadequate response to treatment in 20%–30%, and an equally high rate of response to placebo (Hogarty et al. 1974) must all be taken into account in the risk–benefit analysis of long-term treatment. Currently available criteria for the indications for long-term treatment in the individual case are not reliable.

Antidepressant or phase-prophylactic agents such as lithium, carbamazepine, and valproate may be used in combination with neuroleptic agents, when indicated.

Pharmacotherapy is used in the framework of psychoeducational treatment, in which the causes and consequences of the disease, potential stressors (in the sense of the vulnerability-stress model), and possibilities for treatment are explained to patients and their families in a manner that will promote their cooperation. Indications for psychodynamically oriented individual psychotherapy are rare in the present-day treatment of schizophrenia (Fenton and Cole 1995).

The published results of this form of treatment are unconvincing, and it further harbors the risk of provoking disease manifestations. It should therefore be considered only in individual cases, in patients in

stable remission, with a solid therapeutic alliance, good drug compliance, and the capacity and motivation for introspective work. The goals of psychodynamic treatment are to improve control of self-destructive behavior and to promote emotional maturity (APA 1997).

Psychotherapy of schizophrenic patients must take account of the biological etiology of the disease and thereby focus on helping patients cope with the disease and its consequences (acceptance of chronic illness, self-management, problem-solving) (Coursey 1989). Essential elements of psychotherapy include psychoeducation, crisis intervention, support, practical counseling, and approaches to the normalization of inappropriate reactions related to illness; all of these must be carried out with due consideration of the patient's (neuro)psychological and sociocommunicative deficits. At present, these elements are usually incorporated into group therapy techniques, which may also include interactive elements, depending on individual condition (Fenton and Cole 1995).

It has been recognized, at least since the studies by Hogarty et al. (1974), that the combination of long-term neuroleptic treatment with psychosociotherapeutic techniques can further reduce the rate of relapse and favorably influence several aspects of long-term outcome (e.g. cognition, social adaptation).

Since then, a number of psychosocial treatment and rehabilitation techniques have been evaluated in individual, group, and family therapy interventions (Bellack and Mueser 1993; Fenton and Cole 1995), including the following:

- Family intervention
- Training of social skills
- Cognitive rehabilitation
- Coping skills training

General principles for psychosocial intervention include the following (McGlashan 1994):

- Evaluation
- Continuous reevaluation
- Timing
- Intensity
- Integration with psychopharmacotherapy

It is particularly important for the psychiatrist to consider the phase of disease and the individual patient's cognitive receptiveness and tolerance for stress when determining the timing and intensity of the psychosocial treatment and rehabilitation measures that are to be undertaken.

3.2.4 Principles of Psychiatric and Psychotherapeutic Treatment

The psychiatric and psychotherapeutic treatment ("therapeutic management") of the schizophrenic patient requires a comprehensive understanding of the patient and his or her needs, goals, intrapsychic conflicts, defense mechanisms, coping styles, and strengths (APA 1997). The psychiatrist must understand the biological, interpersonal, social, and cultural factors that influence both the course of disease and the patient's adaptive abilities. Specific components of psychiatric and psychotherapeutic treatment include the following (APA 1997):

- Establishment and maintenance of the therapeutic relationship
- Monitoring of the patient's psychiatric condition
- Education with regard to the disease and its treatment
- Establishment of indications for pharmacological and other specific treatment in the framework of an overall treatment plan
- Support of the patient in following the treatment plan
- Awakening of understanding of the psychosocial consequences of the disease and how they may be dealt with
- Early detection and treatment of new episodes of disease, including consideration of provocative or maintaining factors
- Measures to reduce family stress and to improve family interaction
- Facilitation of access to the care system, including coordination of resources in the mental and general health care sectors

3.2.5 Treatment Settings

The above-mentioned therapeutic techniques may be applied in a number of therapeutic settings. The German mental health care system possesses multiple components, each of which may be the appropriate setting for the treatment of a specific subset of schizophrenic patients, depending on disease phase, stage of progression, and prognosis. The available treatment settings include the following:

- Inpatient care (psychiatric wards, psychiatric hospitals, training hospitals)
- Partial hospitalization (day wards, night wards)
- Outpatient care (local general practitioners, psychiatrists, and neurologists; outpatient departments)
- Complementary settings (permanent residential homes, halfway houses, protected living arrangements, rehabilitation facilities)

These different treatment settings must be offered in a functionally integrated fashion, so that the patient can always receive treatment in the optimal setting, in accordance with changing individual needs (see below).

4
Principles of Phase-Specific Treatment

In this section, general principles of treatment will be discussed in relation to the individual phases of the course of schizophrenia.

4.1
Acute Phase

The primary objectives of treatment in the acute phase are as follows:

- Elimination of positive manifestations and prophylaxis against their recurrence
- Prevention of harm to the patient and others
- Preparation for the postacute stabilization phase

Treatment in the acute phase is intended not only to achieve remission of the acute psychopathological manifestations, but also to restore or improve the patient's ability to function in a social role on the highest possible level.

A complete diagnostic assessment is performed on initial presentation. If relapse occurs, the diagnosis should be reevaluated. The acute course under treatment should be monitored frequently. When the acute phase has passed, possible persistent cognitive and social deficits and ensuing needs for rehabilitation should be evaluated, and the appropriate measures taken.

Pharmacotherapy with neuroleptic agents is the first line of treatment in the acute phase, sometimes in combination with other drugs (e.g. benzodiazepines, antidepressants, antimanic agents). Electroconvulsive therapy may be indicated in patients with catatonia, accompanying severe depressive manifestations, or resistance to treatment (including with clozapine). The treatment continues until the end of the acute phase and the beginning of the postacute stabilization phase. Psychosocial techniques involving the patient's family, particularly psychoeducational techniques, are used as the situation becomes less acute.

The objectives of acute-phase treatment listed above can be achieved only after a therapeutic alliance has been established with the patient and his or her family. Short-term and medium-term treatment plans must be developed, and consideration must be taken of the modes of therapy and institutional settings that will be most suitable for future treatment.

Inpatient treatment plays an especially important role at the time of the initial presentation. Danger to the patient or others is an absolute indication for hospitalization. If the patient is not competent to give consent to hospitalization, the physician must act in accordance with the local law of involuntary commitment. In the case of later relapse, an attempt can be made to treat the patient in an outpatient setting. The choice between inpatient and outpatient treatment must be made in consideration of the patient's ability to cooperate with outpatient treatment and of the relatives' ability to accept the burden that it will place on them.

4.2
Postacute Stabilization Phase

The principal objectives of therapy in this phase are as follows:

- Achievement of stable remission
- Elimination of delusions and promotion of insight into the illness
- Elimination of disease-related deficits
- Education about concepts of the disease and its treatment
- Assurance of compliance with treatment
- Early recognition of threatened relapses
- Development of individual coping strategies
- Harmonization of family conflicts
- Preparation of rehabilitative measures (in the narrower sense)

In this phase, closely spaced discussions (approximately once per week, on an outpatient basis) with the treating specialist are necessary, particularly after a change of setting (see below), so that a new therapeutic alliance can be established and any changes in the patient's condition can be addressed rapidly with corresponding changes in therapy.

In the phase of postacute stabilization, pharmacotherapy is continued, the dosage is cautiously adjusted to the optimal level for the new outpatient setting, and psychoeducational interventions are carried out, as well as other nonpharmacological interventions, if needed (see above). Depot neuroleptic agents should be substituted if compliance is uncertain.

The therapeutic alliance must be maintained so that the patient can be supported throughout the process of social reintegration. Excessive "rehabilitation pressure" should be avoided, and any potential persistent risk of suicide must be recognized and openly discussed.

In this phase, inpatient stays (insofar as they were initially necessary) become progressively shorter, and treatment is often delivered in extramural settings, such as day clinics. During the transition from inpatient care to a partly or wholly outpatient setting, it must be realized that the patient remains more

irritable than normal and less able to cope with stress, and these problems may be exacerbated by changes of caregivers. Changes of setting must therefore be carefully planned and accompanied by appropriate treatment.

4.3 Remission Phase

The principal objectives of therapy in the remission phase are as follows:

- Suppression of manifestations
- Prophylaxis against relapse
- Social (re)integration

Contacts with caregivers can usually take place at less frequent intervals in this phase. Compliance with, and possible side effects of, pharmacotherapy should be assessed regularly, particularly tardive dyskinesia.

In addition to suppression of psychotic manifestations and pharmacotherapeutic prevention of relapse, supportive and rehabilitative measures are provided in this phase. The neuroleptic dose should be cautiously reduced, in steps, to the lowest possible maintenance dose. Small decreases should be made at intervals of 3–6 months in view of the latency between dosage changes and clinical changes in the remission phase. Attention must be paid to the possible appearance of prodromal manifestations to ensure that the dose does not drop below the critical threshold. If serious side effects should arise (e.g. weight gain, sexual dysfunction, tardive dyskinesia), a switch to another medication should be considered (such as an atypical neuroleptic agent or, if compliance is inadequate, a depot neuroleptic agent).

A special role is played by the repeated emergence of individual prodromal manifestations (even if these have not been shown to be definite predictors of relapse; see Gaebel et al. 1993) and of relapse behavior. As the patient stabilizes, there is greater motivation to initiate psychosocial and rehabilitative processes in case of need, and the patient's contact with his or her family is maintained.

The treatment of schizophrenic disorders in the remission phase is now usually carried out in the extramural setting, except in the case of acute reexacerbation. It has been shown that even chronic schizophrenics who have been hospitalized in psychiatric clinics for decades may be successfully "deinstitutionalized" into protected extramural living arrangements. Long-term care is thus now generally delivered on an outpatient basis, so that patients can be given the maximum degree of independence.

5 Principles of Phase-Independent Treatment

5.1 System of Care

The different forms of treatment discussed above can be applied sensibly only in a coordinated system of care. The cooperation of the patient's relatives is also indispensable.

Depending on the treatment setting, representatives of many different disciplines may participate in the care of the patient, including psychiatrists, psychologists, nurses, social workers, physical/occupational therapists, and others. The various methods of treatment and rehabilitation are applied in the context of a multidisciplinary team. The psychiatrist not only belongs to the team as one of the caregivers, but also bears the primary responsibility for establishing the treatment plan and seeing it through to its application. To do this, the psychiatrist must work alongside, advise, and supervise the other members of the patient care team.

Therapeutic continuity is an important general principle of treatment. It requires therapeutic information to be comprehensively exchanged, treatment measures to be coordinated among the members of the patient care team, and the patient to have a relationship of trust with "his" (or "her") therapist. The principle is imperfectly applied in practice because of discontinuities inherent in the system of care. On the other hand, the familiarity of the patient with a single caregiver or group of caregivers over the long term may, on occasion, be an obstacle to therapeutic innovation. If so, a change of setting or of caregiver may be indicated.

Deinstitutionalization and placement in the mainstream community are the guiding concepts of health policy with regard to the care of the mentally ill. There is controversy over the applicability of these principles to all patients (Häfner and an der Heiden 1991). Outpatient is generally preferable to inpatient treatment, whenever possible. On the other hand, for a subgroup of decompensated, homeless patients, the inpatient clinic may provide an "asylum" in the best sense and thereby constitute the more humane option, even today (McGlashan 1994).

A consequence of the trend toward shorter inpatient stays and prolonged outpatient treatment is that even acute treatment is now increasingly given on an outpatient basis, partly by mobile teams. Regardless of the setting in which acute treatment is delivered, the indicated diagnostic and therapeutic measures must still be carried out. Account must also be taken of the

family's need for an occasional period of respite, which may be provided by caring for the patient temporarily in a suitable setting.

The goal of treatment is a patient with insight into the diagnosis who has a say in determining what treatment will be provided and can consent to it of his or her own free will. In contrast to the paternalistic treatment model, this liberal model requires that the physician–patient relationship should be based on cooperation, information, and education. The "consumer perspective" deserves greater attention (Van Putten and May 1978); in other words, the patient's views and expectations (e.g. concerning the monitoring of side effects of medications) need to be taken into account. The liberal model of treatment is of limited applicability, however, when the patient's insight into the illness is transiently or permanently impaired to such an extent that the treating physician, having exhausted the available legal options, must act, for a time, on the patient's behalf.

The concept of case management is based on the observation that chronically mentally ill patients are liable to make inadequate use of the available therapeutic resources and that some work is required to coordinate these resources effectively. The case manager, usually a paraprofessional, has the task of guiding the patient through the mental health care system so that his or her needs are optimally met (Bachrach 1992). For schizophrenic disorders in particular, however, case management has not been found effective in preventing rehospitalization (Rössler et al. 1992).

5.2 Adaptive Versus Selective Indications

Two important goals are to make the validated methods of treatment more widely available and to tailor the treatment offered more closely to the needs of the patient. The latter goal has been called "subject–treatment matching" (Bellack and Mueser 1993).

5.3 Standardization of Interventions

It would be desirable for treatment to be given more often in accordance with empirically justified therapeutic guidelines. This can only occur if standardized guidelines are established and taught during residency training and continuing medical education. The various terms used in this connection should be explained: "directives" are binding rules for medical practice, "guidelines" are oriented toward providing a reference for diagnostic and therapeutic standards, and "recommendations" and "opinions" are merely of informational content, suggesting possible courses of action to the practitioner. Practice guidelines enable the practitioner to perform diagnosis and treatment in accordance with the prevailing rules of the discipline, while retaining the essential therapeutic freedom to make modifications in individual cases, whenever this is necessary or desirable.

Guidelines for the treatment of schizophrenia, based on empirical studies and a consensus of expert opinion are available (Kissling 1991; Frances et al. 1996; APA 1997; DGPPN 1998; Lehman et al. 1998a). In view of the finding that less than 50% of the current treatment of schizophrenia accords with published guidelines (Lehman et al. 1998b), the implementation of practice guidelines appears to be urgently necessary if treatment is to be optimized.

5.4 Combination Therapy

Most of the interventions discussed have been evaluated in combination with pharmacotherapy. As a rule, the success of one form of treatment is dependent on that of the other: psychosocial interventions are effective only against the background of effective pharmacotherapy. On the other hand, psychosocial interventions may improve the patient's motivation to participate in, and comply with, pharmacotherapy.

5.5 Timing and Duration of Interventions

Individual therapeutic interventions should be undertaken according to the phase of the illness. Pharmacotherapy should be instituted as early as possible in the course of the illness, before the initial manifestation or a relapse. Psychosocial interventions are mainly of use in the postacute phase.

A common feature of all interventions is that they are only effective while they are being applied. A lifelong need for treatment must therefore be assumed. Treatment must be given either continuously, as with pharmacotherapy, or in periodic installments, as with nonpharmacologic interventions.

5.6 Prevention

Potential methods for the primary prevention of schizophrenic disorders are attracting increasing attention (e.g. *British Journal of Psychiatry* 1998, vol. 172 Suppl. 33), but have not yet been adequately studied.

The major emphasis of therapy thus remains on secondary and tertiary prevention.

5.7 Quality Assurance

Awareness of the guidelines and preconditions for treatment discussed above and their promulgation in residency training and continuing medical education are necessary if schizophrenic patients are to be given the best possible treatment according to current scientific knowledge. At the institutional level, corresponding instruments must be introduced for the assessment of treatment outcomes, so that internal quality assurance and quality improvement may be carried out, on the basis of comparative analysis across institutions (Janssen et al. 1998). There is no doubt that the treatment of schizophrenic disorders would be optimized, and outcomes correspondingly improved, if these steps were taken today.

Drug Treatment of Patients with Schizophrenia

This is a modified and updated version of the chapter published in Maj and Sartorius (1999).

1 Introduction

Ever since antipsychotic drug treatment was introduced into clinical psychiatry almost half a century ago, establishing a breakthrough in the management of schizophrenic disorders, this new therapeutic area has been characterized by a continuing attempt to optimize the results of treatment efforts for these patients. A plethora of medications, called neuroleptics in classical terminology, a term increasingly replaced by the indication-driven word antipsychotics, has been synthesized and tested to this end. Molecules of different chemical structures, ranging from tricyclic phenothiazines to thioxanthenes, butyrophenones, dibenzazepines, substituted benzamides and benzisoxazole derivatives are now used in the treatment of schizophrenia. The development of clozapine was clearly a quantum leap in these efforts. This drug, available in some European countries since the early 1970s and introduced in the United States in the late 1980s, was the first antipsychotic to effectively treat the symptoms of schizophrenia with only a minimal risk of inducing extrapyramidal motor side-effects (EPS) (Fitton and Heel 1990; Kurz et al. 1995a). In addition to changing the mindset concerning clinical efficacy and adverse drug effects, the success of clozapine has also considerably influenced preclinical development strategies for new antipsychotics. By and large, this was fuelled by the recognition that clozapine has excellent antipsychotic efficacy without blocking nigrostriatal dopamine (D_2) receptors to a similar extent as classical neuroleptics (Farde et al. 1992). Up to this point, powerful D_2-blockade was seen as a prerequisite for an antipsychotic effect. Eventually, as a consequence of clozapine's differing pharmacological profile, a number of new points began to be considered in the preclinical screening of putative antipsychotic drugs. These include dopamine blockade in extrastriatal, mesofrontal and mesolimbic dopaminergic pathways, which have been studied using a host of different procedures, ranging from single neuron action potential recordings (Skarfeldt 1995) to the expression of neuropeptides (Bissette and Nemeroff 1995) and immediate early genes (Deutch and Duman 1996). Phases I and II in clinical psychopharmacology have also experienced a methodological boost, including modern neuroimaging techniques such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), which have proved helpful to characterize the action of new drugs both qualitatively and quantitatively (Nordström et al. 1995; Nyberg et al. 1997; Pilowsky et al. 1997; Farde and Nyberg 1998; Travis et al. 1998). These strategies are complemented by experiments evaluating non-dopaminergic systems, such the serotonergic (Roth and Meltzer 1995) and glutamatergic (Bunney et al. 1995) pathways. Thus clinical psychopharmacology, just as after the introduction of chlorpromazine, has catalysed new research in the neurobiology of schizophrenia.

Clozapine has also helped to change the demands on the clinical management of schizophrenia. While there used to be a strong emphasis on positive symptom reduction in the early days of pharmacological treatment, new therapeutic targets have now been identified. In addition to treating delusions and hallucinations, negative, affective and cognitive symptoms and the dimensions of suicide prevention, quality of life and psychosocial reintegration are now very much in the foreground of our considerations. Safety research has also become a major new focus.

The following review is restricted to pharmacological interventions. Clearly, modern concepts of schizophrenia management include psychosocial and rehabilitative measures. Even though pharmacotherapy is still very much the backbone of our treatment efforts, it should always be embedded in integrative treatment procedures which include all levels of intervention.

In the following, we will make an artificial distinction between short-term and long-term management, well aware that these cannot always be clearly differentiated. When discussing short-term treatment, we will focus on symptom control and crisis intervention, while making maintenance of therapeutic effects and relapse prevention main topics in the section on long-term treatment, together with aspects of quality of life and psychosocial reintegration.

2 Short-Term Treatment (Acute Treatment)

2.1 Choice of Drug

Before the launch of clozapine, it was generally taken for granted, and supported by many comparative trials, that the available neuroleptics differed in terms of tolerability but not in terms of their efficacy. As a rule of thumb, high-potency drugs were associated with a greater risk for extrapyramidal motor side-effects, while low-potency medication was said to have more autonomic adverse events. The latter have also been said to be more sedative, even though this was never formally studied in clinical trials (Wirshing et al. 1995). These differences in safety profile meant that the choice of drug was mainly guided by side-effects.

Other criteria of choice include the potential for plasma level measurements, which will be discussed in a separate section, as well as the availability of depot preparations. In patients who have been pre-exposed to antipsychotics, it is advisable to fall back on medication that has shown a favourable risk–benefit profile during the treatment of previous episodes. It should also be mentioned in this context that the choice of drug is of particular importance when treating patients for the first time, as a dysphoric response to an antipsychotic drug is known to influence the attitude towards further pharmacological treatments (Van Putten 1974). Particularly stressful side-effects may lead to a long-lasting negative attitude towards medication, which is unfortunate given the fact that many patients will eventually require long-term treatment.

Clozapine was the first drug for which qualitative and quantitative differences to traditional antipsychotics could be convincingly demonstrated (Gerlach et al. 1974; Fischer-Cornelssen and Ferner 1976; Kane et al. 1988a). Not only is clozapine more efficacious in patients suffering from treatment-resistant schizophrenia, but it has also been shown to have advantages in terms of the treatment of negative symptoms (Claghorn et al. 1987; Kane et al. 1988a) and in various psychosocial domains, including quality of life (Meltzer et al. 1990).

The fact that clozapine has good antipsychotic efficacy and a minimal risk of inducing EPS has led to the term "atypical" neuroleptic being used. This classification was originally designed to differentiate clozapine from the older, traditional neuroleptics, which are sometimes referred to as "typical". Historically, this was based on the finding that clozapine, in contrast to all neuroleptics available at the time, did not show cataleptogenic or apomorphine antagonistic effects, which was originally termed an "anomaly" (Schmutz et al. 1967; Stille and Hippius 1971). Unfortunately, neither preclinical nor clinical psychopharmacology offers a succinct definition for "atypicality". As a categorical distinction between "typical" and "atypical" antipsychotic drugs is not possible, some psychopharmacologists have fallen back on a dimensional point of view in which various antipsychotics with more or less "atypical" properties can be found. These properties include a low incidence of EPS, a reduced tendency to increase prolactin levels and greater improvements in the negative symptoms of schizophrenia than traditional drugs. This is where clozapine and other new drugs, which will be described in more detail at a later stage, show advantages over traditional neuroleptics. As the term "atypical antipsychotic" does not describe a homogeneous group of medications, it is really of very limited usefulness. New antipsychotics that were mainly developed to mirror the efficacy of clozapine should more correctly be classified as "novel" antipsychotics or as antipsychotics of the second generation.

Since clozapine cannot be used as a first-choice drug, given world-wide legal restrictions that arise from the drug's high risk of inducing agranulocytosis (Alvir et al. 1993), there was a strong urge to develop similar antipsychotics without the propensity to induce blood dyscrasias. This led to the development and consequent licensing of olanzapine, quetiapine, risperidone, sertindole, ziprasidone and zotepine. Much can be said in favour of the use of these agents as first-line drugs. Merely the fact that they have a significantly lower EPS risk than traditional neuroleptics (Fleischhacker and Hummer 1997) would be argument enough. One of the disadvantages of these novel antipsychotics, however, is the lack of parenteral formulations, including depot preparations. Moreover, many of the new drugs appear to be less sedative than traditional neuroleptics, which poses some problems in the treatment of acutely ill, highly agitated and aggressive patients. As most of the published data on the novel drugs provide results from pre-registration phase II and III clinical trials performed in a highly selected group of schizophrenic patients, we would be well advised to await additional phase IV data and experience gathered under routine treatment conditions before giving definitive recommendations for the use of these drugs. Lastly, pharmaco-economic aspects need to be acknowledged, as the new drugs are substantially more expensive than their predecessors. However, these high drug costs have been shown to be counterbalanced by a reduction in overall treatment costs, through lower relapse rates and fewer subsequent rehospitalizations, as has been shown in various long-term studies (Aitchison and Kerwin 1997; Glazer and Johnstone 1997).

In conclusion, it appears to be justified to recommend novel antipsychotics as first-line treatment, especially in patients with initial manifestations of schizophrenic disorders. It is still unclear whether these new drugs will eventually replace the traditional antipsychotics, which currently still play an important role, especially in the treatment of multi-episode patients, who have shown a good response to these drugs and have tolerated them well in the past.

2.2 Dose, Plasma Level and Route of Administration

Ever since neuroleptics were introduced into clinical practice, dose recommendations have varied up to 100-fold. On the basis of a meta-analysis of studies using traditional drugs, Baldessarini et al. (1988) stated that 100–700 mg chlorpromazine equivalents per day rep-

resent an adequate dose range for most psychotic patients. This has been confirmed in various more recent dose-finding studies. These showed that doses in excess of 20 mg haloperidol (Rifkin et al. 1991; Van Putten et al. 1992) or fluphenazine (Levinson et al. 1990) or 6 mg risperidone (Marder and Meibach 1994) daily do not provide substantial additional therapeutic benefit. The lower end of the dose spectrum is less well defined. While McEvoy et al. (1991), for instance, reported that most of their patients responded well to a mean of 3.4 mg haloperidol daily, Van Putten et al. (1992) found improvement in only 6% of their patients treated with less than 5 mg haloperidol. This discrepancy can at least in part be explained by different patient selection criteria in the respective studies: in the first trial, almost half of the patients were either first-episode schizophrenics or patients suffering from schizoaffective disorders, while the second team studied mainly chronically ill schizophrenic patients, who most likely differ from the first group of patients in terms of treatment response.

Various authors have also reported that the incidence of side-effects increases with dose (Baldessarini et al. 1988; Levinson et al. 1990; Van Putten et al. 1992; Fleischhacker et al. 1994a). This is especially well documented for EPS and implies that a potential efficacy advantage of a higher dose may by nullified by reduced tolerability. Clearly, the dose should be adjusted to the needs of individual patients within a certain frame of reference. Doses will therefore also be dependent on target syndromes, meaning that higher doses will be used in more agitated patients, while lower doses are given to patients with predominantly negative symptoms, although these recommendations come from a clinical empirical background rather than from controlled trials.

For clozapine there is a distinct discrepancy between the United States and Europe. The doses used in clinical trials and in everyday practice in many centres in the United States are about double the mean dose administered in many European countries (200–300 mg daily) (Fleischhacker et al. 1994a). The reasons for this are not entirely clear. A possible explanation is that clozapine is used more restrictively in the United States and is therefore mainly given to patients who are more severely ill. These differences in dose are of great clinical relevance, as at least some of the side-effects of clozapine, such as seizures or confusion, are dependent on dose and plasma level (Fleischhacker et al. 1994a; Haring et al. 1994). It seems strange that more than 20 years after the registration of clozapine, a sound dose-finding study is still lacking.

Some antipsychotics can also be administered parenterally. In principle, this route of administration should be confined to emergency situations, where lack of insight or acute psychopathology lead to a high risk of patients harming themselves or others. Furthermore, parenteral application may be necessary in certain patients in whom well-documented pharmacokinetic problems make it difficult to reach adequate drug plasma levels on oral medication.

There are no well-documented plasma level–efficacy correlation studies for most of the traditional antipsychotics, with the exception of fluphenazine and haloperidol. A haloperidol plasma level of around 15 ng/ml has been described as optimal by various independent groups (Volavka et al. 1992; Janicak et al. 1997; Coryell et al. 1998). Research also suggests that no additional therapeutic benefit is to be expected at fluphenazine plasma levels beyond 1.5–2 ng/ml (Levinson et al. 1995).

Judging effective clozapine plasma levels is much more difficult and has to be seen in the light of the dosing discrepancies discussed above. Consequently, U.S. authors recommend considerably higher plasma levels (Miller et al. 1994; Potkin et al. 1994) than those that have been documented in successfully treated European patients (Haring et al. 1990; Kurz et al. 1995b). It must be noted, however, that American data stem from prospectively designed plasma level response studies, while European authors have reported clozapine plasma concentrations derived from naturalistic study designs. In the most recent American report, VanderZwaag et al. (1996) suggest that optimal plasma levels range between 200 and 250 ng/ml and report that quite a few patients have also responded well to levels below this range. These numbers come closer to those found by European groups.

VanderZwaag et al. (1996) also stress that the time of venopuncture and the distribution of clozapine doses over the day have a considerable impact on clozapine plasma levels. Giving the full daily dose in the evening before blood for plasma levels is drawn, for instance, results in higher levels than if patients are treated with divided daily doses.

Even though plasma level monitoring of antipsychotics cannot yet be recommended as a routine procedure, it may be of help in certain instances. These include non-response to an adequate antipsychotic dose, the suspicion of compliance problems and the use of pharmacological combination treatment which may lead to pharmacokinetic interactions, such as combinations between certain antipsychotics and specific serotonin re-uptake inhibitors. Clinically significant elevations of clozapine plasma levels have been found when this drug was combined with fluvoxamine (Hiemke et al. 1994). The possibility of monitoring plasma levels should also be entertained in very young or old patients and in patients that suffer from relevant concomitant medical diseases. Unusual side-effects, especially if they occur at low doses, may also justify checking antipsychotic plasma levels.

2.3 Duration

As there is generally a great deal of inter-individual variation in the response to the acute treatment of schizophrenia, the question of when to expect the first signs of this response or, alternatively, at what point in time the response may be judged to be insufficient and a treatment change should be initiated, is commonly asked. Recommendations range between 1 and 2 weeks up to 6 months. Some answers may be found in reports such as that by Levinson et al. (1992), which documents that patients who ultimately respond to antipsychotic treatment have shown an amelioration of various non-specific symptoms, such as sleep disturbance or anxiety and agitation, but also of positive symptoms within the first 2 treatment weeks. It may be cautiously concluded from such studies that ongoing treatment needs to be re-evaluated if patients show no response whatsoever within the first few treatment weeks.

There are some suggestions from clozapine trials that more patience is required in treatment-resistant patients (Melzer 1989). Treatment trials of up to 3 months have been recommended.

2.4 Insufficient Treatment Response

The concept of treatment-resistant schizophrenia is not a homogeneous one. Only rarely do patients not respond at all to psychopharmacological interventions. Most patients show at least a partial response in one or the other symptom of their disorder. It is not uncommon, for instance, for delusions or hallucinations to remit, while negative symptoms remain unchanged. Sometimes, the definition of treatment-resistant schizophrenia also includes patients who do respond to antipsychotic treatment but do not tolerate it due to significant side-effects (Bondolfi et al. 1998).

The definition of treatment-resistant or treatment-refractory schizophrenia usually follows two different lines of thought: one is based on the necessity of reproducible research, while the other is built upon the needs of everyday clinical practice.

Research calls for well-defined criteria that allow study of the issue in different research centres and ultimately make a comparison of different studies possible. In addition to obtaining an exact drug history, patients in such studies usually undergo at least one prospective antipsychotic treatment trial (Kane et al. 1988a). Only if the history of the patient and the well-documented results of this treatment attempt yield no adequate response is such a patient classified as treatment resistant.

In routine clinical care, the treating physician usually cannot fall back on all of this sophisticated information. Judgement must often rely on an incomplete history provided either by the patients themselves or their significant others and on far from perfect case notes. This information is then amalgamated with the clinical impression, which usually concerns overall social functioning and quality of life in addition to psychopathology.

It is not uncommon for the researcher's and the clinician's judgements to differ quantitatively. Many patients in whom the clinician is not satisfied with the treatment response will not fulfil strict research criteria, while on the other hand patients entering research studies may represent a select population and results provided by the studies of such patients are sometimes difficult to generalize for a more clinical population.

It used to be common practice to switch patients who had not adequately responded to a neuroleptic to another drug of a different chemical class. Similarly, this was recommended for patients who did not tolerate certain medications. Research on this issue has produced controversial findings (Kinon et al. 1993; Shalev et al. 1993). So far clozapine is the only drug for which this procedure is unequivocally supported (Fleischhacker 1999).

Taking all the published evidence into account, we recommend the following in the case of inadequate treatment response: if patients have not shown at least partial response to an adequate dose of a traditional antipsychotic after 2–3 weeks, compliance and plasma levels should be checked. This may lead to additional supportive psychosocial measures or to an adaptation of dose. If these modifications do not yield relevant results within the next 2–3 weeks, switching to clozapine (or to another one of the novel antipsychotics) is indicated. This new treatment trial should last at least 2–3 months. If response remains unsatisfactory, various options should be considered. These include concomitant administration of lithium (Growe et al. 1979; Collins et al. 1991; Wilson 1993) or carbamazepine (Schulz et al. 1990) or, alternatively, the use of benzodiazepines (Wolkowitz et al. 1990), specific serotonin re-uptake inhibitors (Goff et al. 1990; Decina et al. 1994; Silver et al. 1996) or serotonin antagonists (Duinkerke et al. 1993). Electroconvulsive therapy also still has its place in these last-resort treatment trials (Krueger and Sackeim 1995). All of these options result from clinical experience rather than from controlled double-blind prospective treatment trials.

Novel antipsychotics are increasingly being used as drugs of first choice. What should be done if patients do not respond to these agents is still an open question. Increasing the dose, sometimes beyond the

levels recommended by the manufacturers, switching to other novel antipsychotics or to traditional neuroleptics, but also combining novel and classical drugs (Shiloh et al. 1997), appear to be the most commonly chosen alternatives.

It should be made very clear that the treatment of patients suffering from treatment-resistant schizophrenia represents a highly complex clinical problem that needs to be taken care of by experienced and well-trained specialists.

2.5 Adverse Effects During Acute Treatment with Antipsychotics

Table 1 gives an overview of antipsychotic-induced adverse events. This table is a general list that deliberately omits prevalence or incidence rates as, given the huge methodological differences between the available studies, unjustified comparisons of relative risks may

Table 1. Adverse effects of antipsychotic drugs

Systems concerned		
Central nervous system	Extrapyramidal	Acute: dystonia, dyskinesia, akathisia, parkinsonism Tardive: dyskinesia, dystonia (akathisia)
	EEG alterations, seizures Sedation Confusion Neuroleptic malignant syndrome	
Cardiovascular	Orthostatic hypotension ECG alterations	 Tachycardia Tachyarrhythmia Depressed ST segments Flattened U waves Prolonged QT intervals
Haematological	Leucocytosis Eosinophilia Thrombocytopenia Leucopenia, agranulocytosis	
Gastrointestinal and hepatic	Gastrointestinal motility disturbances Liver enzyme increase Cholestatic jaundice	
Autonomic nervous system	Dry mouth	
	Constipation Loss of accommodation (blurred vision) Urinary retention Sialorrhoea	
Endocrine and sexual	Prolactin increase	Gynaecomastia Galactorrhoea Menstrual irregularities
	Weight gain Glucose and lipid metabolism disturbances	
	Sexual disturbances	Diminished libido Orgasmic dysfunctions Erectile dysfunctions, priapism Ejaculatory disturbances: reduced volume, delayed ejaculation
Cutaneous	Allergic reactions Photosensitivity Seborrhoeic dermatitis	
Ocular	Lenticular changes Pigmentary retinopathy	

lead to misinterpretation. There is also no reference to the clinical relevance of the respective side-effects, as this will need to be determined on an individual basis in most instances. For the classical drugs, the main focus has traditionally been on EPS (Casey 1996). As the novel antipsychotics induce EPS to a significantly lesser extent (Fleischhacker and Hummer 1997), non-EPS-associated side-effects have gained interest following their introduction into clinical practice.

Many side-effects can be successfully managed by dose reduction or switching from one drug to another (Csernansky and Newcomer 1995). So far, specific pharmacological interventions are only successful against EPS. Even though the efficacy of anticholinergics against acute dystonia or parkinsonism (Remington and Bezchlibnyk-Butler 1996) and that of beta blockers in treating akathisia (Fleischhacker et al. 1990) are impressive, the former drugs in particular should be used cautiously. Anticholinergics are potent psychotropic drugs (Fleischhacker et al. 1987) that may lead to memory deficits (Fayen et al. 1988), substance abuse (Smith 1980) and to a worsening of psychotic symptoms (Tandon et al. 1990). The general prophylactic use of anticholinergic drugs is therefore discouraged, a position also reinforced by a World Health Organization (WHO) recommendation (World Health Organization 1990). The exception to this rule are patients with a high risk for EPS, such as young male patients or patients with a history of significant EPS.

Concerning many of the non-EPS-associated adverse events, including, e.g. sedation, orthostatic hypotension, or laboratory abnormalities, to name but a few of the more common problems, individual tolerance levels have to be discussed with the patients. This follows the general rule that there is increasing emphasis on the subjective attitude of patients and their relatives to pharmacotherapy, as this has been found to be a crucial factor for compliance (Marder 1998). Consequently, drug-induced side-effects must be an ongoing topic even during the acute treatment phase.

The use of the novel antipsychotics as first-line drugs is an important prophylactic measure to reduce the EPS risk. In addition, a slow increase in dose and the use of lower doses prevent some of the acute side-effects. This approach is obviously limited in very acutely, severely ill patients.

3
Long-Term Treatment

In addition to maintaining the effects of acute treatment and relapse prevention, an improvement in quality of life and psychosocial integration are the goals of long-term treatment of patients suffering from schizophrenic disorders.

There is increasing evidence that the long-term outcome of schizophrenia is correlated to early pharmacological interventions and successful relapse prevention (Crow et al. 1986; Wyatt 1992; Loebel et al. 1995). It is one of the best-documented and most reproduced results in psychiatric outcome research that long-term treatment with antipsychotics is the major factor in preventing relapses and recurrences of the disorder (Kane and Lieberman 1987; Csernansky and Newcomer 1995; Gilbert et al. 1995). The relapse risk is reduced by about two-thirds if long-term antipsychotic medication is sustained (Kissling 1991). In order to optimize treatment response, pharmacological measures have to be complemented by psychosocial interventions. As discussed in the introductory section, the latter are not the topic of this review and will be summarized elsewhere.

Even given optimal treatment conditions, about 20% of all schizophrenic patients will experience a relapse despite antipsychotic prophylaxis (Steingard et al. 1994). On the other hand, another 20% will suffer a single episode of schizophrenia only, regardless of whether they are treated or not (Möller and van Zerssen 1995). Unfortunately, we do not have any way of predicting the outcome of schizophrenia in individual patients. All patients suffering from schizophrenia, including those with first episodes, are therefore advised to continue medication on a long-term basis (Kissling et al. 1991; American Psychiatric Association 1997; Gaebel and Falkai 1998; Lehmann et al. 1998). The rare patient with brief psychotic episodes without negative psychosocial consequences may be an exception to this rule, as would be a patient with an intolerance to all existing antipsychotics.

3.1
Choice of Drug

The choice of the antipsychotic will follow similar considerations to those outlined in the acute treatment section. It has to be kept in mind that switching from one antipsychotic to another may pose problems, as the efficacy and tolerability of the different antipsychotics show significant intra-individual variation. It is therefore preferable to already plan long-term treatment when initiating acute treatment, in order not to have to change drugs between treatment phases.

Unfortunately, pharmaco-economic considerations play an increasing role in the choice of antipsychotics in many countries. As the novel drugs are considerably more expensive than traditional neuroleptics, clinicians and patients are increasingly confronted with restrictive reimbursement policies. This is especially

disturbing when we consider that pharmaco-economic studies have convincingly shown that higher drug costs are outweighed by savings in other areas of treatment, such as reduced rehospitalization and relapse rates (Aitchison and Kerwin 1997; Rosenheck et al. 1997).

In addition to efficacy, tolerability and subjective acceptance of a drug by the patient are important factors in long-term treatment. The risk–benefit profile of an antipsychotic has to be a regular topic in treatment sessions with patients and their significant others.

3.2 Duration

Two types of studies give direct and indirect information on the length of treatment issue: firstly, prospective placebo-controlled long-term trials and, secondly, discontinuation studies. In the latter, antipsychotics are discontinued under controlled conditions in patients who have been prophylactically treated for varying amounts of time. While prospective studies usually extend over time periods from 1 to 2 years, discontinuation studies often provide information about considerably longer courses of treatment. Both study options unanimously document a high relapse risk without antipsychotic prophylaxis (Kane and Lieberman 1987; Csernansky and Newcomer 1995; Gilbert et al. 1995).

One- to 2-year maintenance treatment is usually recommended for patients suffering their first episode of schizophrenia. Multi-episode patients should be in remission for at least 5 years before the discontinuation of antipsychotic treatment is discussed (Kissling et al. 1991; American Psychiatric Association 1997; Lehmann et al. 1998; Gaebel and Falkai 1998).

The time frames recommended above must be seen in the light of the fact that there are no prospective relapse prevention studies which cover a time period of more than 2 years and that all discontinuation trials have shown high relapse rates, even if patients had been in remission for many years before stopping antipsychotics. These recommendations must therefore be considered a minimal standard. Especially in first-episode patients, they are also influenced by practical considerations, insofar as it is unrealistic to suggest life-long pharmacological relapse prevention, even though, when judging the available evidence, this would not appear unreasonable. It is also evident that such recommendations, although commonplace in various chronic somatic diseases, are still met by much irrational criticism when applied to the psychiatrically ill.

In the last decade, five independent research groups have evaluated the effects of so-called intermittent pharmacological treatment (Jolley et al. 1989; Carpenter et al. 1990; Herz et al. 1991; Pietzcker et al. 1993; Schooler et al. 1997). These studies were based on the assumption that it should be possible to educate patients and their significant others about early warning signs of an impending relapse. In such patients, antipsychotics could be stopped after successful acute treatment and reinitiated in the case of impending relapse, detected by the advent of early warning signs. This was hypothesized to lead to a reduced use of antipsychoties, thereby minimizing the risk of long-term side-effects such as tardive dyskinesia.

Patients randomized to this type of management showed significantly higher relapse rates than patients on continuous antipsychotic treatment. Even though patients on intermittent treatment received significantly fewer cumulative antipsychotic doses, there were no differences in the incidence of tardive dyskinesia between groups. In summarizing the available evidence, it can be concluded that intermittent treatment has not been shown to be a generally practical alternative to the current recommendation of continuous antipsychotic administration, especially when considering a separate study in which an increased tardive dyskinesia risk was found in patients with multiple interruptions of neuroleptic treatment (Van Harten et al. 1998).

The strategic goal of the long-term treatment of patients suffering from schizophrenic disorders remains to minimize the risk of a psychotic relapse in order to avoid all its negative biological and psychosocial consequences.

3.3 Dose, Plasma Level and Route of Administration

In general, the same antipsychotic doses that have been efficacious during the acute and the stabilization phases are also recommended at the beginning of relapse prevention. For most patients, these doses range between 5 and 15 mg daily oral haloperidol or a respective equivalent dose of another antipsychotic (Kissling et al. 1991). Dose–response relationships of the novel antipsychotics have not yet been sufficiently studied; the few published double-blind, long-term continuation trials (Daniel et al. 1998; Tran et al. 1998) indicate that the principle of maintaining patients on the dose that was used in acute treatment is also helpful with these drugs.

If a dose reduction is indicated, it should not be performed in steps larger than 20% of the previous dose. The intervals between these steps should be between 3 and 6 months, as it is well known that relapses following insufficient neuroleptic doses may appear with a significant time lag (Johnson 1979; Kane and Lieberman 1987).

It should obviously be attempted to treat patients with a minimal effective dose. However, in clinical

practice this is not always easy and, while this dose is sought, may lead to a risk of underdosing and subsequent relapse.

The administration of depot antipsychotics is an important treatment option during long-term management. These injectable drugs produce relatively constant plasma levels of the neuroleptics over a period of several weeks (J.M. Davis et al. 1994). The disadvantages of this type of treatment include the fact that some patients refuse intramuscular injections or develop irritations at the injection site. Another problem is that the dose of a depot antipsychotic cannot be reduced once administered. Advantages include the facilitation of management due to certainty concerning compliance and the fact that patients do not need to take medication every day. Various expert groups have therefore promoted the use of depot antipsychotics (Kissling et al. 1991; J.M. Davis et al. 1994; Kane et al. 1998).

If treatment with these drugs is anticipated, patients should first be treated with the oral form of the antipsychotic, in order to gather information about dose requirements and the risk–benefit profile of the drug. Ideally, patients should be switched from the oral to the depot route after successful stabilization has been achieved. This should be done in an overlapping fashion, as depot medications reach steady-state plasma levels only after a certain period of time (Altamura et al. 1989).

Dose-finding studies are available for haloperidol and fluphenazine. They are the basis of the following recommendations: 50–200 mg haloperidol decanoate every 4 weeks (J.M. Davis et al. 1993) or 12.5–50 mg fluphenazine decanoate in biweekly intervals (J.M. Davis et al. 1994) represent an optimal dose range for many patients.

3.4 Adverse Effects of Long-Term Treatment with Antipsychotics

Most acute antipsychotic-induced side-effects can become chronic. Clearly, clinicians will do their best to avoid this, although in some instances compromises may be necessary, especially when clear benefits of medication outweigh the relevance of certain side-effects. As discussed previously, determining this risk–benefit ratio must be an integral component of all treatment strategies.

Some side-effects may already be apparent during acute treatment, but become relevant only during long-term management. These include sedation, weight gain and sexual dysfunctions (Whitworth and Fleischhacker 1995). As these adverse events are thought to have a negative impact on compliance, they warrant special consideration.

Tardive dyskinesia is a specific long-term side-effect that is relatively common with traditional antipsychotics (American Psychiatric Association 1992). The annual cumulative incidence rate is around 5% (Kane et al. 1988b). Given the increased attention to tardive dyskinesia and the implementation of prophylactic measures, severe and irreversible manifestations have become considerably less frequent. It is important to acknowledge that tardive dyskinesia is not necessarily irreversible.

Observations over long time periods have shown that this motor side-effect remits spontaneously in about half of the afflicted patients despite continuous antipsychotic treatment (Gardos et al. 1994).

While no well-documented case of clozapine-induced tardive dyskinesia has been published so far, it is important to note that this does not hold true for the other novel compounds. Even if these drugs are associated with a certain risk for tardive dyskinesia, this is still significantly lower than that found with traditional antipsychotics (Tollefson et al. 1997a).

The management of chronic side-effects of antipsychotics, with the exception of tardive dyskinesia, follows the same principles as have been described in the acute treatment section. Treating manifest tardive dyskinesia is still unsatisfactory; prophylactic measures are therefore of the utmost importance. Patients have to be examined regularly with regard to incipient tardive dyskinesia. As soon as such symptoms are found, if continuous antipsychotic treatment is considered necessary, an attempt to reduce the dose should be the first step. If tardive dyskinesia progresses despite this, treatment must be changed to clozapine or another compound with a low tardive dyskinesia risk. Some patients with a shorter duration of tardive dyskinesia may also profit from an addition of tocopherol (vitamin E) (Adler et al. 1998), although a large recent study has failed to find a positive effect of vitamin E (Adler et al. 1988).

4 Novel Antipsychotics

The problem of artificially categorizing all novel antipsychotics as "atypical" has been alluded to earlier in this review. A critical review of these drugs clarifies that they are pharmacologically heterogeneous substances (Fleischhacker and Hummer 1997). This most likely results in diverging clinical profiles, although these are not yet fully understood.

New developments are briefly summarized below. As this is currently a very prosperous field of research, the

Table 2. Novel antipsychotics

Drug	Receptor profile[a]	Recommended dose (mg per day)[b]
Amisulpride	D	300–800 (50–1200)
Clozapine	5HT, D, α, M, H	200–450 (50–900)
Olanzapine	5HT, D, M, α, H	10 (5–20)
Quetiapine	H, 5HT, α, D	150–750
Risperidone	5HT, D, α, H	2–6 (1–16)
Sertindole	5HT, D, α	12–20 (4–24)
Ziprasidone	5HT, D	40–160
Zotepine	5HT, D, α, H, M	100–300 (50–450)

D, dopamine; α, α-adrenergic; M, muscarinic; H, histamine; 5HT, serotonin.
[a]Listed in order of descending affinity.
[b]Doses in general correspond to the recommendations of the manufacturer; doses listed in parentheses represent extremes sometimes justified in individual patients.

interested reader is referred to the most recent publications in scientific journals. Table 2 summarizes receptor affinities and dose recommendations for the novel antipsychotics. As some of the special features of amisulpride and clozapine are mentioned elsewhere in the chapter, they will not be discussed in the following.

4.1 Olanzapine

Olanzapine is similar to clozapine both in its chemical structure and in its pharmacological properties (Bymaster et al. 1996). It has a plasma half-life of about 30 h (Eli Lilly & Co., Indianapolis, USA); the manufacturer recommends doses of between 5 and 20 mg daily.

Before registration, olanzapine was compared to placebo and haloperidol in clinical trials (Beasley et al. 1996; Tollefson et al. 1997b). It was shown to be superior to placebo (Beasley et al. 1996) and at least equal to haloperidol (Beasley et al. 1996; Tollefson et al. 1997b) when treating patients with schizophrenic or schizoaffective disorder. It was more effective than haloperidol in treating depressive (Tollefson et al. 1998) and negative symptoms (Tollefson et al. 1997c) in schizophrenic patients. The problems in interpreting these findings will be discussed at the end of this chapter.

All therapeutic effects of olanzapine are maintained over longer periods of time, as 1-year extension studies comparing the drug with placebo and haloperidol have shown (Hamilton et al. 1998; Tran et al. 1998).

In all clinical trials and at all dose levels, olanzapine induced extrapyramidal symptoms that, with the exception of akathisia, were not higher than those found in patients randomized to placebo and amounted to about 20% (Tran et al. 1997). Olanzapine was shown to be associated with a significantly lower tardive dyskinesia risk than haloperidol (Tollefson et al. 1997a). As with most other antipsychotics with strong anti-serotonergic effects, the treatment with olanzapine leads to a significant weight gain in a considerable number of patients (Allison et al. 1999; Beasley et al. 1996; Tollefson et al. 1997b; Weiss et al. 1998). Despite its similarities to clozapine, there is currently no indication that blood count monitoring beyond the recommendations given for antipsychotic treatment in general is warranted.

4.2 Quetiapine

While quetiapine also structurally resembles clozapine, its preclinical pharmacology is different, especially with respect to a lack of anticholinergic effects (Saller and Salama 1993). It has a short half-life (about 3 h; Fulton and Goa 1995). Dose recommendations range between 150 and 750 mg daily.

In phase II and III studies, quetiapine was found to be superior to placebo and comparable to haloperidol (Borison et al. 1996; Arvanitis et al. 1997; Small et al. 1997) and chlorpromazine (Hirsch et al. 1996).

The risk of inducing acute EPS was not higher than that of placebo, while data concerning incidence rates of tardive dyskinesia have not yet been published. Transient elevations of liver enzymes, dizziness and orthostatic hypotension, especially in the first few days of treatment, have led to the recommendation of a slow dose increase during the initiation of treatment.

4.3 Risperidone

Risperidone is a new molecule. Its elimination half-life has been reported to be between 3.2 and 24 h (Byerly and DeVane 1996). Recent dose recommendations are 2–6 mg daily. Risperidone has also been compared with placebo (Marder and Meibach 1994) and haloperidol (Peuskens 1995). As with the other drugs, its

therapeutic effect was found to be better than placebo and similar to haloperidol. For negative symptoms, advantages similar to those of olanzapine have been found when comparing the drug to haloperidol (Möller 1995). Preliminary results have also shown positive effects when treating children and adolescents (Mandoki 1995; Sternlicht and Wells 1995).

Risperidone is also associated with a lower risk of inducing acute EPS than traditional neuroleptics (Lemmens et al. 1999). In contrast to the other drugs, the EPS risk of risperidone is dose dependent. Higher doses start to resemble traditional antipsychotics; above 12 mg daily, the EPS rate is similar to that of haloperidol (Marder and Meibach 1994; Peuskens 1995).

As for quetiapine, a slow dose increase is recommended to prevent orthostatic hypotension.

4.4 Sertindole

Sertindole has the longest half-life of all the novel drugs (close to 3 days) (Dunn and Fitton 1996). Doses between 4 and 24 mg daily are used to treat patients with schizophrenia. Pre-registration clinical trials comparing sertindole to placebo (Zimbroff et al. 1997) and haloperidol (Van Kammen et al. 1996; Zimbroff et al. 1997) have yielded similar results as for the previously mentioned novel antipsychotics. A long-term study found significantly lower rehospitalization rates with sertindole compared with haloperidol (Daniel et al. 1988). The same holds true for its EPS profile. An unusual side-effect reported for sertindole is a reduction of the ejaculatory volume. In addition, weight gain has been observed.

Sertindole leads to a prolongation of the QTC interval on electrocardiography (ECG) (Hale et al. 1996; Van Kammen et al. 1996; Zimbroff et al. 1997). This effect is not only more common, but also more pronounced than with any other of the novel antipsychotics and is still being discussed with respect to its clinical relevance. At the time of writing, the European regulatory agency was re-evaluating the safety profile of this drug.

4.5 Ziprasidone

Ziprasidone differs pharmacologically from the previously described drugs by its potent 5-HT_{1A} agonistic effect and by the inhibition of serotonin and noradrenaline re-uptake (Davis and Markham 1997; Tandon et al. 1997). Its half-life is reported to be between 3.2 and 10 h (Davis and Markham 1997); the dose range is 80–160 mg daily.

These doses were also evaluated in clinical trials in which ziprasidone was compared with placebo (Keck et al. 1998) and/or haloperidol (Goff et al. 1998; Keck et al. 1998). Again, positive and negative symptoms (at higher doses) were improved, as found with other novel antipsychotics. In a placebo-controlled 1-year trial in which stable patients were switched to either ziprasidone or placebo, the former had a significantly higher efficacy than placebo in reducing the risk of impending relapse (Arato et al. 1997).

The EPS risk is comparable to the other new medications. The most commonly found side-effect is sedation. Interestingly, and in contrast to all the drugs discussed above and below, ziprasidone has not been found to induce weight gain.

4.6 Zotepine

Zotepine is also structurally related to clozapine (Prakash and Lam 1998). Similar to ziprasidone, it inhibits the re-uptake of noradrenaline with a potency comparable to tricyclic antidepressants (Rowley et al. 1998). The recommended dose is 50–450 mg daily.

Again, results of clinical trials resemble those found with other novel antipsychotics (Fleischhacker et al. 1989; Dieterle et al. 1991; Klieser et al. 1991; Petit et al. 1996). It was also used successfully in a small study treating patients with predominantly negative symptoms (Barnas et al. 1992). When patients with stable symptoms were switched to either placebo or zotepine and followed for 6 months, the risk of relapse was found to be significantly higher in the placebo group (Cooper et al. 2000).

Zotepine has fewer side-effects on the extrapyramidal motor system than haloperidol. Dose-dependent adverse effects include sedation, transient elevations of lever enzymes and seizures.

4.7 Methodological Considerations of Treatment Trials with Antipsychotic Drugs

When analysing the clinical trials initiated by various pharmaceutical companies in order to licence new antipsychotics over the last decade, it needs to be considered that all of these studies were performed in a highly selected group of patients. These were usually in their late thirties, and two-thirds were of male gender. The average duration of illness was over 10 years in many cases, and frequent hospitalizations have preceded the clinical trial. Little is known about the pre-treatment of these patients, and wash-out phases were generally short. In almost all studies,

about 20% of the population suffered from schizoaffective disorder.

When looking at response rates of these 6- to 8-week clinical trials, it becomes evident that the scores of the rating scales used to measure psychopathology (the Brief Psychiatric Rating Scale, BPRS; the Positive and Negative Symptom Scale, PANSS) were reduced by 20%–40% at the most. This holds true for both the experimental and the comparator drugs (mostly haloperidol or chlorpromazine).

As stated at the outset, this brief summary of recent clinical trials exemplifies that the investigated sample was a highly selected one. Chronically ill, frequently hospitalized male schizophrenic patients who have probably responded only insufficiently to previous treatment attempts, and were usually far from reaching full remission during the course of the clinical trial, constituted the core group on which the risk–benefit evaluation of the test substance was based.

The attempt to generalize results obtained from studying this group of patients to the overall population of patients with schizophrenia appears problematic, to say the least. The spectrum of schizophrenia includes many patients who hardly ever make it into phase II and III clinical trials. These range from early-onset female patients with suicidal ideation all the way to hostile and agitated treatment-refractory patients. It is therefore not surprising if the results from clinical trials cannot always be translated into clinical practice.

Some clinicians are disappointed with the efficacy of the novel compounds in treating acutely psychotic patients, which may be related to the fact that many of the new drugs have fewer sedative effects than their traditional counterparts. This often calls for additional sedative medication in the early stages of treatment. A lack of sedation must not be confused with a lack of antipsychotic efficacy, which, even with the older drugs, always takes days to weeks to kick in.

Most of the novel antipsychotics have been reported to be more efficacious in treating negative symptoms than traditional neuroleptics. These findings have to be interpreted with caution, as this effect is only documented for patients suffering from positive and negative symptoms concomitantly for most antipsychotics, with the exception of amisulpride (Loo et al. 1997) and, to a lesser extent, zotepine (Barnas et al. 1992). It is accepted knowledge that negative symptoms in this group of patients respond to treatment considerably better than primary enduring negative symptoms, as seen in patients with deficit states of schizophrenia (Carpenter 1996). Post hoc path analyses have been performed for olanzapine (Tollefson et al. 1997c) and risperidone (Möller 1995) to analyse how much the improvement of negative symptoms has been influenced by intervening variables. It has been reported that at least part of the therapeutic efficacy is independent of an improvement in positive symptoms or a reduction of EPS (Möller 1995; Tollefson et al. 1997c). As path analysis is not a confirmatory, inferential statistical method, these results need to be replicated using other study designs. Amisulpride (Loo et al. 1997), ritanserin (Duinkerke et al. 1993) and zotepine (Barnas et al. 1992) have been studied in patients with predominantly negative symptoms and have been documented to lead to an amelioration of deficit states. Ritanserin was used as an add-on to an ongoing neuroleptic treatment; amisulpride and zotepine were shown to be beneficial as monotherapy in low doses.

The evaluation of the tolerability of novel antipsychotics contains some potential pitfalls as well. Side-effect assessment is performed in different ways in different studies: while some trials include specific side-effect rating scales, others rely on spontaneous reporting by patients and/or clinicians. These two methods will understandably yield different incidence rates. A reliable comparison of antipsychotics is only possible if drugs are compared within the same clinical trial.

EPS present a specific problem. All published controlled clinical trials with the novel antipsychotics have found an EPS risk that corresponds to that found in the placebo group. In this context, it needs to be noted that patients in the placebo group generally develop EPS at a rate of about 20%. This seemingly paradox finding can be explained in different ways: as clinical trials tend to have brief wash-out periods, EPS resulting from pre-treatment often carry over into the comparative part of the study. If these effects occur, they may be misinterpreted as induced by whatever drug these patients are being treated with in the clinical trial. Withdrawal dyskinesias, which occur frequently upon cessation of treatment if tardive dyskinesia had been masked by traditional antipsychotics (Gardos and Cole 1995; Schultz et al. 1995), may be an alternative explanation. Furthermore, problems in differential diagnosis, such as distinguishing between acute akathisia and agitation in acutely psychotic patients, can lead to a misdiagnosis of motor symptoms (Miller and Fleischhacker 2000). Kraepelin (1919) already reported that schizophrenia may be accompanied by motor symptoms. Phenomenologically, these are very similar to drug-induced dyskinesias. Several reports in recent years have also found movement disorders in drug-naive patients with schizophrenia (Caligiuri et al. 1993; Chatterjee et al. 1995). Lastly, a true placebo effect, as may be expected in neuroleptic-experienced patients, and the tendency of patients abusing anticholinergics to feign EPS in order to receive the desired prescription may be seen as possible reasons for the surprisingly high EPS incidence in the placebo groups of clinical trials.

It must be borne in mind that the fact that the EPS rate of a new drug corresponds to that found with

placebo should not lead us to the false assumption that the novel compound has no EPS risk at all.

In conclusion, it is emphasized that efficacy and tolerability data from phase III clinical trials should be converted into everyday clinical practice with all due caution and with regard to the potential sources of error discussed above, in order to prevent unrealistic expectations.

5
Special Aspects of the Pharmacotherapy of Schizophrenia

5.1
Negative and Depressive Symptoms, Suicidality

Various methodological issues impede the interpretation of clinical trials in patients suffering from negative and/or depressive symptoms in the course of schizophrenia. Differential diagnosis is one of them: negative symptoms, depression and akinesia share many common features. This makes diagnosis difficult, especially in a cross-sectional evaluation. Negative symptoms can be of secondary nature, e.g. as a result of EPS or as sequelae of positive symptoms or psychosocial deprivation (Carpenter 1996). Depressive syndromes in schizophrenia are commonly seen as an inherent feature of the illness; they can also occur as a psychological reaction to the diagnosis (Liddle et al. 1993; Siris 1995). Problems of clinical trials evaluating negative symptoms have been dealt with in the previous section.

Imipramine has a positive effect against depressive syndromes in schizophrenia patients (Siris 1995). Recently, serotonin re-uptake inhibitors have also been shown to exert beneficial effects in this indication as well as against negative symptoms (Goff et al. 1995). Before pharmacological treatment is initiated, it is important to reach a reliable diagnosis. The fact that negative and depressive syndromes are difficult to manage should not lead to therapeutic nihilism. This is especially important in light of the fact that patients suffering from schizophrenia have a high suicide risk (Roy 1990). Preliminary results on the suicide prophylactic effect of clozapine are very encouraging (Meltzer and Okayli 1995).

5.2
Cognitive Functions

Cognitive disturbances have been described ever since the first systematic research in schizophrenia. They include a general intellectual deficit that has a special emphasis in memory and executive functions (Mortimer 1997; Sharma and Mockler 1998). These dysfunctions hinder the rehabilitation of patients regardless of the other psychopathological symptoms (Goldberg and Gold 1995). They constitute a negative predictor for the course of the illness (Kolakowska et al. 1985; Perlick et al. 1992). Classical neuroleptics have little influence on cognitive dysfunctions, if at all; they may even lead to a deterioration of cognitive abilities (Mortimer 1997). This seems to be different with novel antipsychotics. Clozapine, for instance, has been shown to ameliorate various cognitive functions, especially attention and verbal fluidity (Schall et al. 1998). An improvement of working memory has been found after treatment with risperidone (Green et al. 1997) and olantapine also enhanced cognition in a longer term study (Purdon et al. 2000). These findings and other research indicate that novel antipsychotics might also have advantages over the traditional drugs in this important facet of the schizophrenia syndrome.

5.3
Compliance

As in any other illness in which the long-term intake of medication is necessary, compliance is of high clinical relevance in patients suffering from schizophrenic disorders. This is also documented by the fact that less than 50% of patients with schizophrenia in long-term treatment take their medication according to the physician's recommendations (Fenton et al. 1997). Non-compliance has implications that go beyond mere patient management. It may distort the results of psychopharmacological trials, especially of placebo-controlled studies in which the experimental drug has more side-effects than placebo. In this case, non-compliance can be expected to be more prominent in the active treatment group than in the placebo-treated patients. Consequently, these non-compliant patients will show a lower rate of treatment response, whereby the difference between placebo and active compound may be artificially diminished. This may lead to an underestimation of potential therapeutic advantages of the experimental drug. Similar problems can occur in a comparison of two active drugs that show different side-effect profiles.

Compliance is influenced by a host of different variables. These are usually grouped into patient-related, clinician-related, treatment-related and environment-related factors (Fleischhacker et al. 1994b). Patient-related factors include demographic characteristics such as age (Schwartz et al. 1962), sex (Danion et al. 1987; Swett and Noones 1989) and social status, but also illness-associated characteristics such as type of disorder and psychopathological symptoms (Schou 1997; Drake et al. 1989; Pan and Tantam 1989).

Various aspects of the clinician–patient relationship (Ley and Spelman 1965; Meise et al. 1992) and the information accessible to patients are also part of the influences on compliance (Bäuml et al. 1993).

The psychosocial environment of patients also determines attitudes towards treatment and health belief concepts which, in turn, affect compliance (Blackwell 1973; Hoge et al. 1990).

Adverse effects of drugs are the best studied treatment-related factor. These include EPS, in particular akathisia (Van Putten 1974), as well as weight gain and sexual dysfunctions (Silverstone et al. 1988; Pfeiffer et al. 1991; Buchanan 1992). In contrast, several authors have reported that side-effects do not have a negative effect on compliance (Middelboe 1995; Fleischhacker et al. 1994b; Hummer et al. 1999). These findings can easily be explained by an indirect improvement of the clinician–patient relationship through information about treatment in the case of the advent of drug-induced adverse events which appears to have a positive influence on compliance that outweighs the negative consequences of side-effects. Another important treatment-related factor is the complexity of treatment. Polypharmacy and multiple therapists with poorly defined roles impede the cooperation between the patient and the treatment team.

Interventions to enhance compliance can be targeted to all of these levels (Hummer and Fleischhacker 1999). Ideally, they should be implemented at the beginning of treatment. The success of compliance-enhancing measures is well documented (Eckman et al. 1990; Kemp et al. 1998). On the basis of a working doctor–patient relationship, concise and relevant information provided for patients and their significant others must be an integral part of these efforts. Information must also include illness concepts, as these are often unrealistic. In addition, the prevention and/or rapid management of adverse effects plays a crucial role.

Lastly, compliance by clinicians with rational, scientifically determined treatment guidelines and recommendations will optimize treatment efforts and reduce the uncertainty of patients and/or relatives confronted with different treatment concepts suggested by different doctors.

6 Conclusion

Pharmacotherapy is the basis of the management of patients suffering from schizophrenic disorders. There is no doubt that the novel antipsychotics enhance the spectrum of acute and long-term treatment options. It is to be expected that the better tolerability of these agents, especially in terms of a reduced EPS risk, will also facilitate rehabilitative measures. An improvement in cognitive functions should contribute to that. On the other hand, it must be emphasized that antipsychotics may induce non-extrapyramidal side-effects which can have a negative influence on compliance and psychosocial treatment. The prescriber will therefore still be charged with establishing a sound risk–benefit profile of medication, which is not yet available for the novel antipsychotics to a satisfactory extent. More post-marketing research data are necessary to establish such profiles.

New findings in the field of psychopharmacology, together with advances in psychosocial treatment strategies, have given rise to a new optimism in the treatment of this severe psychiatric disorder. The continuous process of scientific evaluation of new treatment options is a prerequisite for an optimal integration of these into the treatment of schizophrenia.

CHAPTER 12

H.D. Brenner, H. Hoffmann, H. Heise

Sociotherapy and Psychotherapy of Schizophrenic Disorders

Translator: E. Taub

1 Introduction

Although the treatment of schizophrenic patients without sociotherapeutic interventions would be unthinkable today, the importance of psychotherapy in the narrower sense for these patients remains as controversial today as in the past. These two forms of therapy have come closer to one another in recent years, and it therefore hardly seems reasonable now to discuss them separately; however, each of them emerged from, and must be understood as the product of, a particular historical development.

If we take sociotherapy to include all types of treatment dealing with the social environment of the patient, then sociotherapy is certainly as old as psychiatry itself. In this sense, the unchaining of the patients of the Salpêtrière in 1772 on the order of Pinel must count as an early and much-applauded example of sociotherapeutic intervention. In the English-speaking countries, too, various reform movements devoted to a general improvement in the living conditions of the mentally ill, and advocating specific socio- and psychotherapeutic interventions, arose as early as the beginning of the nineteenth century. Especially worth mentioning in this context are the concepts of "moral treatment," based on the "open door" principle and the special training of nursing staff, and "no-restraint therapy."

In Germany, the social element was, at first, a strong emphasis of romantic psychiatry but was soon replaced, at least on the level of the construction of theories, by other focuses of interest. In practice, however, continuing efforts were made to reform psychiatric institutions and integrate mental patients into society. Griesinger's conception of the *Stadtasyl* (city asylum) (Griesinger 1868/1869) was, indeed, an early forerunner of many of the current principles of community-based psychiatric care.

Further developments in the second half of the nineteenth century seem, at first glance, to be characterized largely by an emphasis on somatic medical ideas and by the development of medically oriented university psychiatry. Nevertheless, even in this period, which has been called the age of "brain psychiatry," it was precisely the lack of effective somatic therapies in the everyday practice of the then dominant form of institutional psychiatry that forced even "somatically oriented" psychiatrists to apply sociotherapeutic treatment strategies and to develop them further. Indeed, many of these psychiatrists were thoroughly progressive with respect to their sociopsychiatric approach.

This complex interaction of multiple currents and forces is illustrated particularly vividly by the early history of work therapy. In the age before psychiatric institutions began to arise, the mobilization of the mentally ill into the workforce was more the rule than the exception, because exemption from labor was seen as a privilege of the aristocracy, for both the healthy and the mentally ill alike. The idea that the mentally ill had a just claim to medical treatment, which came about when psychiatric institutions were created, was followed at first by their large-scale exclusion from the workforce and then, shortly afterward, by a countermovement. While the proponents of "physical" treatment, by direct analogy to somatic medicine, advocated putting the brain at rest to promote healing, as would be done with any other diseased organ, the proponents of "moral" treatment thought that work had a major, beneficial therapeutic effect.

By 1850, patients had been put to work under medical supervision across a broad front in German psychiatric institutions, albeit mainly in helping in the running of the clinics themselves at first. Both therapeutic and economic considerations favored such a development. An early indication of the potential for conflict inherent to this situation is provided by the directive issued under Pienitz in 1828 at the *Königlich sächsische Heil- und Verpflegungsanstalt Sonnenstein* (Royal Saxon Healing and Boarding Institution Sonnenstein), to the effect that the work performed must be in accordance with the goal of healing (Willis and Reimer 1988).

In the second half of the nineteenth century, many institutions created special work opportunities for their patients, mainly in agriculture at first and then later also in industry (e.g. in Göppingen and Hildesheim). From 1880 onward, Koeppe elevated the concept of regular work to the dominating organizational principle of the Alt-Scherbitz Institution and, at the turn of the century, private sanatoria and healing institutions took the first steps toward the individualization of work therapy for middle-class patients. An emphasis was placed on personal motivation, and being able to carry out one's own occupation again was declared as the goal. This was the context in which two nearly synonymous terms were coined, *Arbeitstherapie* ("work therapy") and *Beschäftigungstherapie* ("keeping-busy therapy"), which were later adopted by institutional psychiatry to describe its own proffered forms of treatment.

During and after the First World War, an extreme shortage of staff and financial means made itself felt. It was in this setting that Hermann Simon, in 1919, assumed the direction of the not yet completed Gütersloh Institution and put the patients to work in finishing its construction. Once this work was over, he organized the clinic, in analogy to educational and military patterns, into classes, in each of which the patients were required to perform a different type of work. There was also a differential schedule of

disciplinary measures for refusal to work (H. Simon 1929). This model, tailored primarily to the needs of chronic patients, earned Simon the reputation of being the founder of work therapy.

The lack of effective somatic interventions that was still evident in the remainder of the first half of the twentieth century was also, in part, responsible for the rapid assumption of a central role in psychiatry by psychoanalysis, still a very young discipline at the time, and the consequent introduction of psychoanalytically inspired concepts into sociotherapy. Thus Sullivan (1931) was concerned with the creation of a "therapeutic milieu" and coined phrases such as "patient participation" or "patient government." These ideas paved the way for still more influential developments. While the understanding of mental illness had previously been based on medical or psychological conceptions relating to the individual patient, the findings of empirical social research began to have an impact on psychiatry in the 1940s in the English-speaking countries. Finally, against the background of sociopsychological theories such as those of Erikson, Parsons, and Lewin, the organizational structures of psychiatric institutions themselves and their effects on the course of mental illnesses came to be a topic of research and a point of departure for new conceptions of therapeutic communities.

The roots of sociotherapy can thus be traced back quite far into the past. Psychotherapy proper, in contrast, first arose in the latter years of the nineteenth century with the development of psychoanalysis. While Freud himself had low expectations for the success of psychoanalysis in schizophrenics, many of his pupils nonetheless made such attempts, mainly because any real therapeutic alternative was lacking until many years later.

An initial phase saw the development of an astounding variety of theoretical constructs, such as confrontation with a tyrannical superego (Hinsie 1930), strengthening of ego boundaries (Federn 1952), or unconditional motherly love (Schwing 1954). Klein (1930), however, advocated the nearly unchanged application of classical analytical techniques, as was done thereafter for many years, particularly in South America. Sullivan (1931) and Fromm-Reichmann (1950), during and after the Second World War, created an approach that was relatively far removed from its psychoanalytic roots and, in its practical application, already incorporated elements reminiscent of modern supportive and cognitive-behavioral techniques. The psychoanalytically oriented treatment of schizophrenia reached its zenith between 1945 and about 1965, after which the emphasis shifted to family therapy and, later, to cognitive-behavioral approaches. Nonetheless, the psychoanalytic therapy of schizophrenics is still alive today.

The different therapeutic orientations that emerged from these processes of historical development will be discussed individually below. Special attention will be paid to the present status of empirical research in these areas, in view of the current development of "guidelines" and the demand for quality assurance by means of "evidence-based medicine." Because, as already mentioned, sociotherapy and psychotherapy of schizophrenic patients are closely interconnected, the subdivision of topics below will not follow these two conceptual categories, but will rather be oriented toward the particular uses of, and differences between, the various therapeutic approaches in clinical practice.

2 Supportive Psychotherapy

The greatest number of therapeutic efforts in schizophrenic patients aside from pharmacological treatment fall into the category of supportive psychotherapy, earlier known in German as *Stütztherapie* ("support therapy"). For many years, the degree of theoretical interest in such measures was exceedingly low, despite their widespread application. This situation led Heim (1980) to remark:

> All of us practice these techniques to a greater or lesser degree; but we hardly ever talk about them with our colleagues, we organize no meetings on the subject, we scarcely find it mentioned in textbooks – we remain silent, as we are somewhat ashamed to use such straightforward methods to help those of our patients who, in fact, require them (p. 262).

Supportive psychotherapy was evidently held to stand in contradiction to the fundamental goal of psychotherapy, i.e. that of setting processes of deep-seated change in motion. It is primarily because of the emergence of a more sophisticated awareness of the possibilities and limitations of psychotherapy that supportive psychotherapy is now accepted as an independent treatment approach. Nonetheless, there is still no generally recognized definition of supportive psychotherapy and no truly satisfactory theoretical foundation for it. The conceptions that have been proposed are extremely diverse. Some think that supportive psychotherapy is based on a medical model of illness, others that it is a logical application of psychoanalytic concepts in a certain group of patients. According to other views, in accordance with the concepts of humanistic psychology, supportive psychotherapy is a practical collective term for the therapeutic techniques used in patients in which theoretical conceptions no longer afford any help. The relationship

between the therapist and the patient is generally identified as the major factor contributing to its efficacy.

Relatively elaborate conceptions of supportive psychotherapy were developed recently by Werman (1984) and by Hartland (1991). Both of these conceptions focused on the specific problems that were thought to be most amenable to supportive therapy: inadequately developed mental functions, lack of justified expectation of regaining the premorbid functional level, protracted psychiatric history, and repeated need for institutionalization and assistance in coping with everyday life. According to the conceptions of Werman and Hartland, the diagnostic categories in which supportive psychotherapy is most relevant include chronic psychoses, anxiety disorders that have become chronic, somatization disorders, depressive syndromes, and severe personality disorders.

The lack of any therapeutic progress worthy of the name in many patients in these diagnostic groups, and the fact that they frequently live on the margins of society, place especially high demands on the therapist (despite the prevailing opinion to the contrary). In addition to experience, absolute mastery of "technical" matters, and knowledge of one's own personality, including weaknesses and specific countertransference reactions, what is required most of all is a high frustration threshold and a lack of dependence on narcissistic confirmation.

With regard to the specific techniques to be used in supportive psychotherapy, only a few general remarks can be made. Rogers (1957) worked out a set of essential therapeutic variables that he considered necessary for successful treatment. We shall state these requirements in somewhat modified fashion. The therapist's behavior must be marked by genuineness, predictability, and preservation of the necessary emotional distance. Furthermore, an especially large measure of patience and flexibility is needed. According to many who have written on the subject, a durable therapeutic relationship for supportive psychotherapy is established less through conversations with the patient than through common activities such as shared meals or excursions, and by the communication of life experiences not only from patient to therapist, but also from therapist to patient.

In terms of content, the most important objective is coping with the demands of everyday life. The following elements of therapy are the most important ones contributing to the achievement of this goal: empathic listening, emotional support, clarification of acute problem situations, encouragement and active guidance toward problem-solving, strengthening of preexisting defense strategies and adaptive behavior, prevention of relapse by psychoeducation, and clear boundary-setting in case of regressive behavior. The duration and frequency of therapy sessions may vary greatly according to need, from a few minutes to an hour, and from once every 3–6 months to once a day in crisis situations.

The efficacy of supportive psychotherapy in schizophrenia has scarcely been considered an independent subject for empirical research until the present, but it has nevertheless been repeatedly measured as a control condition in group-comparison studies on schizophrenic patients, such as the widely known Boston Psychotherapy Study, in which supportive psychotherapy was found to be highly effective in comparison to psychoanalytic therapy (Stanton et al. 1984; Gunderson et al. 1984). Nonetheless, supportive psychotherapy in schizophrenic patients is not without a certain danger. If other types of psychotherapeutic intervention are rejected a priori, the appearance or progression of disease chronification may be promoted. It is perhaps a recognition of this possibility that underlies the current trend toward a fusion of supportive therapy with certain elements of psychoeducative and cognitive therapy, through which supportive therapy may become transformed into a special type of diagnosis-specific psychotherapy. Such a development would surely heighten scientific interest in supportive psychotherapy to a level more in keeping with its immense practical importance.

3 Psychoanalytic Therapy

Freud developed psychoanalysis both as a depth-psychological theory and as a therapeutic method on the basis of knowledge he had gained from treating patients with hysteria and other neurotic illnesses. As mentioned above, he was sceptical about the possibility of treating schizophrenics by psychoanalysis. He believed psychoanalytical healing to require the presence of a so-called transference neurosis, and he considered schizophrenic patients to be incapable of this because of their disturbed self- and object differentiation and the regression of their libido into the ego (Freud 1963).

As already mentioned in the brief historical survey at the beginning of this chapter, other early psychoanalysts were indeed very much occupied with the treatment of schizophrenic patients, including Abraham, Federn, and Jung (see Benedetti 1987; Müller 1972). Federn (1952) was the first to describe the loss of ego boundaries. Klein (1930) developed her own theoretical conception, in which she described the paranoid schizoid position, with its severe persecution anxieties, as a transitional syndrome of normal ego development. According to this view, projection and identification serve as defenses against anxiety in this stage. Schizophrenic patients suffer from these early

childhood anxieties and react to them with the corresponding defense mechanisms.

The psychoanalytic treatment of schizophrenia gained considerable ground, primarily in the United States, in the mid-twentieth century; the heyday of this form of therapy is connected with such names as Sullivan, Fromm-Reichmann, and Searls. The therapists of this period built up a relationship with the schizophrenic patient through enormous patience and endurance and then used the relationship as a bridge across which patients could come to terms with the outside world. The libido theory receded in importance for Sullivan (1962), whose conception instead stressed the development of interpersonal relationships leading progressively, through infantile, early, and late childhood stages, and several stages of adolescence, to maturity. Fromm-Reichmann's (1959) view of the influence of the mother on her schizophrenic child was widely transmitted in an oversimplified form. In its guise as the concept of the "schizophrenogenic mother," it led to the raising of completely unjustified accusations against the families of schizophrenics.

In the German-speaking countries, psychoanalysis came into widespread use again only after the end of the Second World War, because the National Socialist dictatorship had vilified its best-known proponents and forced them into exile. In 1949, Schindler (1980) introduced so-called bifocal group therapy in Vienna – two analytic groups led by the same therapist, one for the patients and another for their families. Individual psychotherapy on an analytical basis was initially practiced mainly in Switzerland (Sechehaye 1986; Benedetti 1987). Benedetti, in particular, made many contributions to understanding schizophrenics, proceeding from his own therapeutic observations and his wide experience with supervision. Among his other contributions, he worked out specific features of psychotic transference and special disturbances of symbol construction and also described levels of helpful relationships and the significance of the therapist's unconscious fantasies. In *Alienazione e Personazione nella Psicoterapia della Malattia Mentale* (Benedetti 1980), he gave a comprehensive account of the psychopathology, psychodynamics, and psychotherapeutic treatment of schizophrenic patients.

The task of demonstrating the effectiveness of psychoanalytic therapy for schizophrenic disorders is certainly fraught with major methodological difficulties, not least because of its special setting and long duration, but this fact cannot free its proponents of the responsibility of providing empirical support for it. In the Boston Psychotherapy Study, already mentioned above (Stanton et al. 1984; Gunderson et al. 1984), which is the most comprehensive of the few group comparison studies performed to date, no significant difference was found between the results of supportive and psychoanalytic therapy. Despite these rather disappointing results, however, this study also yielded indications that some patients, particularly the highly educated but poorly socially adapted, do indeed stand to benefit from a psychodynamically oriented treatment. The so-called Menninger Study of long-term analysis in 42 patients (Wallerstein 1989) further revealed that elements of supportive therapy are often applied in addition to psychoanalytical methods in the treatment of severely disturbed patients. Accordingly, further attempts have been made recently to develop specific psychodynamic approaches for schizophrenic patients (see Munich 1987; Rosberg and Stunden 1990; Mentzos 1992; Lotterman 1996).

The use of neuroleptics has brought about a major change in psychoanalytic therapy in the last 40 years. The enormously difficult and demanding therapies of the pre-neuroleptic age have given way to newer psychotherapeutic treatments; these are certainly still demanding, but are somewhat more "normal." Even psychoanalysts today generally carry out psychoanalytic therapy in only one or two sessions per week, instead of the classical psychoanalysis that was previously usual. An essential feature of psychoanalytic therapy that has remained constant is the endeavor to gain an understanding of symptoms and reactions, on the basis of which changes can then be attempted. Alongside the analytical process in the narrower sense, however, it is of the highest importance when treating schizophrenic patients to build a durable therapeutic relationship and to use elements of supportive treatment to help achieve this objective.

4 Cognitive-Behavioral Therapy

The development of effective antipsychotic medications, the process of deinstitutionalization, and, above all, the formulation and wide acceptance of the vulnerability–stress–coping model have led to a major expansion of the role of cognitive-behavioral therapy in the treatment of schizophrenic illnesses. According to the vulnerability–stress–coping model, an effective therapy for schizophrenia must favorably influence at least one of the following three pathogenetically interacting factors: (1) biologically determined neuropsychological vulnerability, (2) psychosocial stressors, and/or (3) the affected individual's coping ability. As Smith and colleagues discuss in their chapter on rehabilitation in schizophrenic illnesses (Chap. 13, Vol. 3, Part 1), this heuristic framework is also useful for the evaluation of rehabilitative efforts.

A great number of studies over the last two decades have shown that cognitive-behavioral therapy

processes counteract neuropsychological vulnerability both indirectly, by means of an improved compliance with medications, and directly, by means of compensation strategies; that they reduce psychosocial stressors in the patient's environment; and that they can strengthen the patient's coping resources (Bellack and Mueser 1993; Kopelowicz and Liberman 1995; Penn and Mueser 1996). They are thus used not only at the end of the acute phase, but also in the stabilization phase that follows, and in the remission phase of schizophrenic illnesses.

The boundaries between cognitive-behavioral therapy on the one hand and rehabilitative therapy on the other are fluid, and the same techniques may be used in both (see Chap. 13, Vol. 3, Part 1). Differences are evident with respect to the problem areas on which these two forms of therapy are focused and the content of therapy in the individual case. As for the results of treatment, it should be observed that the different forms of therapy are always applied in combination with neuroleptic therapy in the relevant studies. According to the most comprehensive meta-analysis performed to date (Mojtabai et al. 1998), a combination of this type leads to a more favorable outcome than any of these forms of therapy used alone.

4.1 Social Skills Training

Schizophrenic patients suffer from numerous instrumental and interpersonal deficits because of neuropsychological dysfunction interfering with their schooling, because of the manifestations of the illness itself, and (above all in chronic cases) because of a lack of social stimulation. All of these factors increase the likelihood of tense and stressful interactions and further social isolation and can thus contribute to a worsening of the course of the illness. Good instrumental and interpersonal competence, on the other hand, helps the patient obtain access to, and make good use of, the available social resources. The training of social skills is intended to promote these forms of competence. Relevant social situations and instrumental skill areas that are important for coping with illness are broken down into their elements in suitably designed training programs and then practiced through instruction, model learning, role playing, homework, and positive social reinforcement (see Chap. 13, this volume). The efficacy of such training programs in schizophrenic illnesses has been intensively investigated in a series of controlled treatment comparison studies reaching back to the early 1980s (Bellack et al. 1984; Wallace and Liberman 1985; Hogarty et al. 1986, 1991; Dobson et al. 1995; Hayes et al. 1995).

These studies and several meta-analyses (e.g. Benton and Schröder 1990) have shown that schizophrenic patients are able, in the long term, to acquire the originally deficient instrumental and social skills and to carry these over, at least in part, to their everyday social environment. Focused approaches aimed at an improvement of skills in narrowly defined instrumental skill areas that are especially important for dealing with the disease (e.g. medication and symptom management) have more strongly generalizable results than approaches aimed at general social competence. Many patients feel more self-assured after participating in social skills training, have fewer social anxieties, and, moreover, require shorter periods of hospitalization. Overall social adaptation, however, is only mildly and transiently improved by the training of social skills. Such training programs must apparently be applied for at least 6 months to 1 year, with refresher sessions afterwards, to maximize their therapeutic potential with respect to clinical indicators such as disease manifestations, level of social functioning, or recurrence rate. Severely disturbed patients may require even more time for the acquisition of individual skills.

Despite the large number of pertinent studies now available, a number of important questions remain unanswered. It is not yet known precisely how psychotic manifestations and neuropsychological deficits interfere with the acquisition of social skills. Open questions with respect to the efficacy of social skills training include its optimal frequency and duration, its specific effective components, and the specific techniques and specific intensity of treatment that provide the greatest therapeutic benefit at each stage of the disease. Not least, procedures must be developed for improving the transfer of the learned skills into the patient's natural living environment and the fulfillment of social roles, which is, of course, the ultimate goal of social skills training. Its potential additive and interactive effects with newer atypical neuroleptics and with other psychological treatment approaches are a particular focus of current interest. Finally, more attention must be paid in future to the integration of social skills training with work rehabilitation measures and with care strategies such as case management.

4.2 Cognitive Deficits

Another current application of cognitive-behavioral therapy is in the treatment of cognitive deficits. A distinction can be drawn between procedure-oriented and content-oriented techniques. Procedure-oriented techniques are aimed at deficits of information processing, i.e. deficits of attention, perception, concept formation, memory, and so forth, and are known in the

current literature as cognitive remediation. In recent years, such disturbances of information processing have been held to be important factors in the emergence of overt schizophrenic illness, and thus cognitive remediation may, in fact, be a means of rapid and effective therapeutic intervention. Both elementary and complex deficits of information processing may disrupt the acquisition, generalization, transfer, maintenance, and application of social skills and raise the patient's vulnerability to stress. Smith and colleagues (Chap. 13, Vol. 3, Part 1) point out that the disturbances of information processing typical of schizophrenia have a greater predictive value than the psychological manifestations of the illness with regard to the successful learning of treatment content. They therefore advocate the application of cognitive remediation techniques in psychiatric rehabilitation as well.

Content-oriented techniques, in contrast, are intended to reduce or eliminate persistent positive manifestations such as delusions and hallucinations. The latter are often accompanied by anxiety and depressive manifestations and usually lead to far-reaching difficulties in the social and occupational spheres and to a significant impairment of the overall quality of life of patients and their families.

A number of neuropsychological tests have been applied and tested for use in cognitive remediation in recent years, including the Continuous Performance Test (CPT), the Span of Apprehension Test (SAT), and especially the Wisconsin Card Sorting Test (WCST). It has been shown that the use of these tests can improve poor performance in specific areas. The greatest improvements in performance are apparently obtained through a combination of reinforcement and instruction techniques or through special procedural training techniques (e.g. support in isolated aspects of a task in which the patient is prone to error) (Green 1993; Penn and Mueser 1996).

The Integrated Psychological Therapy (IPT) Program for Schizophrenic Patients is an extended approach in the sense that it combines the remediation of procedural cognitive deficits with the training of social skills (Hodel and Brenner 1994; Brenner et al. 1994). It is assumed that defects in information processing and in instrumental and interpersonal skills reinforce each other in a vicious circle, and a set of subprograms is therefore used to redirect the therapeutic emphasis from the cognitive to the social aspects of behavior, while the interdependence of the two is always borne in mind.

Most studies on the efficacy of cognitive remediation techniques are based on very small samples. Much more extensive, controlled group studies are needed to document efficacy unequivocally. It is not yet definitively known how long the therapeutic benefit of such techniques lasts or whether it is transferred to neuropsychological vulnerability in general or to the acquisition of social skills and social competence in particular. A problem in the design of training programs is that it remains unclear which specific disturbances of information processing impede or prevent the acquisition of social skills and thus ought to be the focus of the therapeutic effort. Current developments are aimed at clarifying the relationship between cognitive dysfunction and social learning, so that comprehensive rehabilitation programs may be targeted at those particular types of cognitive dysfunction ("rate-limiting factors") that most severely limit the success of other therapeutic interventions in schizophrenic patients.

Two approaches to the treatment of content-related cognitive dysfunction in schizophrenic patients, in the sense of positive (residual) disease manifestations, have received much attention in the past 5–10 years: cognitive techniques and self-management techniques. Cognitive techniques are based on the assumption that schizophrenic delusions are based on irrational distortions of functional thought processes. These irrational cognitive styles are, accordingly, called into question; alternative, rational explanations are offered; and the truth content of delusional ideas is checked against reality. Several case studies have shown that this type of cognitive technique can bring about a major reduction in schizophrenic patients' subjective certainty about, and preoccupation with, their delusions and thereby alleviate the accompanying anxieties and depressive feelings (Chadwick and Lowe 1994). Furthermore, a change in patients' ideas concerning the origin, identity, power, and authority of auditory hallucinations can reduce their frequency of occurrence and mitigate their effects on the patients' behavior and subjective well-being (Chadwick and Birchwood 1994; Bentall et al. 1994).

Self-management techniques proceed in a different direction. Their objective is not the direct therapeutic amelioration of positive (residual) manifestations of disease, but rather an improvement of the patient's ability to cope with them. Therapy programs of this type begin with a detailed analysis of disease manifestations, the conditions that provoke them, and their consequences. Suitable coping strategies, making use of the coping mechanisms that each patient already has, are then selected for the individual manifestations. Finally, these strategies are practiced in simulated situations, or in vivo when positive manifestations are present. In a group comparison study (Tarrier et al. 1993), a self-management technique of this type was found to result in a significant reduction of the number and severity of positive manifestations and the anxiety accompanying them; nonetheless, the effect of a self-management technique on negative manifestations, depressive manifestations, and indicators of

the level of social functioning was no better than the effect of training in problem-solving or that of being in a waiting-list control group.

These findings give rise to hope that cognitive-behavioral therapy techniques might, in future, play a major role in the treatment of patients with persistent, neuroleptic-resistant positive manifestations. The empirical support for this hope is not yet solid, as controlled group-comparison studies are still lacking, and the list of open questions is long. There is an urgent need to determine how long the desired therapeutic benefit lasts, for example, and what effect it might have on other clinical parameters, such as recurrence rates or social adaptation. The data available on these questions to date are inconsistent. The individual techniques can be used selectively to best advantage only if their specific mechanisms of effectiveness are identified and distinguished from one another and their effects when used in combination with other therapeutic measures are determined.

4.3 Family Therapy

No other class of psychological therapies has been studied as intensively as cognitive-behavioral family therapy in the last 15–20 years. The motivation for research in this area came, on the one hand, from study findings that a family climate characterized by overprotective, critical, or hostile expressions ("high expressed emotion") affects the course of schizophrenic illnesses and, on the other hand, from the recognition that the families of schizophrenic patients carry an enormous psychological burden. Thus treatment concepts were developed that were intended to produce a change in types of family interaction that affect the disease course unfavorably (reduction of the level of expressed emotion) and/or amplify the family's coping resources.

Despite differences in content and therapeutic procedure, these concepts share essential core features. They all involve a structured procedure oriented toward concrete problem-solving, beginning with an introductory provision of information about the illness (psychoeducation) and proceeding to a more or less broad range of behavior-therapeutic interventions aimed at improving the interpersonal communication skills of the patient's family members, as well as their problem-solving ability and their ability to cope with stress. A brief list of the major common features of the different approaches with respect to content and procedure is found in Chap. 13 (Vol. 3, Part 1).

A number of controlled studies have been performed since the early 1980s to assess these types of intervention (Falloon et al. 1985; Leff et al. 1985; Tarrier et al. 1989; Hogarty et al. 1991; Randolph et al. 1994; Xiong et al. 1994; Zhang et al. 1994). These studies reveal that cognitive-behavioral family therapy can result in a significant reduction of the recurrence rate in the first 2 years after therapy is begun. In studies including an assessment of the length of hospitalization, the level of social functioning, and family stress as additional criteria for success, cognitive-behavioral family therapy was found to reduce the number of hospitalizations, improve social adaptation, and reduce the stress on family members (Falloon et al. 1985; Barrowclough and Tarrier 1990; Hogarty et al. 1991). Comparisons between therapies carried out with individual families and those carried out with groups of families, or groups of patients' relatives, have shown, in part, that the group format confers a greater benefit (Leff et al. 1990; McFarlane et al. 1995; Schooler et al. 1997). Studies have also shown that cognitive-behavioral family therapy is cost-effective, at least in the intermediate term (Cardin et al. 1985; Tarrier et al. 1991; Held et al. 1992; Rund et al. 1994).

The specific mechanisms by which these therapeutic techniques exert their beneficial effect, their optimal frequency and duration, and the therapeutic processes of change that they set in motion are still largely unknown. It is therefore difficult to plan therapy in a goal-directed manner with specific attention to the initial conditions, socioeconomic situation, and specific needs and resources of the individual patient's family. This may be one of the reasons why many families cannot be persuaded to participate in therapy at all or terminate it after a short time. It is also unclear how long the effect of therapy lasts after the therapy itself has come to an end. All of the studies have shown that the recurrence rate rises as the follow-up interval increases, which can be interpreted to imply that cognitive-behavioral family therapy mainly postpones recurrence, rather than preventing it. If so, it should be used in the long term, like pharmacotherapy, and perhaps during the entire period of the patient's life in which he or she is at risk. The follow-up study by Tarrier et al. (1994), however, showed that patients treated in this way still had a significantly lower rate of relapse than patients in the control group as long as 8 years after the end of therapy.

5 Systemic Therapy

Like cognitive-behavioral family therapy, systemic therapy today has a secure place in the outpatient and inpatient treatment of schizophrenia. The earliest, ground-breaking studies on the systemic therapy of schizophrenic disorders were performed in the United

States in the 1950s by three teams of researchers and therapists. These were the groups led by Lidz and by Wynne and the Palo Alto group of Bateson and colleagues, whose writings (e.g. Bateson et al. 1956; Bateson 1987) remain the most important sources for the theory of systemic therapy today. The further development of the systemic approach to the therapy of schizophrenia was carried out by the Milan group of Selvini Palazzoli and colleagues (Selvini Palazzoli 1985; Selvini Palazzoli et al. 1980) and, more recently, by the Heidelberg group of Stierlin and colleagues (Stierlin 1975; F.B. Simon 1988, 1990; Retzer 1994). Specific patterns of interaction of families with a schizophrenic member, and of families with a schizoaffective or manic-depressive member, have been identified and made the target of specifically designed therapeutic interventions (F.B. Simon et al. 1989; Retzer 1994).

The goal of systemic therapy is to set problem-stabilizing patterns of family interaction in motion and to design constructions of reality that facilitate a change toward an assumption of personal responsibility and autonomy. A further goal is to lessen the degree of importance attached to psychiatric diagnoses. Thus system therapists tend to take a sceptical view of the vulnerability–stress–coping model of schizophrenia, as well as other models. The systemic approach seems to be similarly incompatible with cognitive-behavioral approaches, based as they are on the concept of expressed emotion and on the vulnerability–stress–coping model. System therapists acknowledge that cognitive-behavioral therapy lessens the rate of relapse, but they also suspect that it promotes chronification – a hypothesis that is difficult to test empirically.

There are practically no empirical studies available on the efficacy of systemic therapy. Only Retzer (1994), in an uncontrolled follow-up study involving patients with schizophrenia according to the DSM-III-R criteria, was able to show that an improvement had occurred in 65% of patients and the relapse rate had fallen by 60% at an average of 3.2 years after the end of family therapy. The question of whether systemic therapy is as effective as other methods of treating families with a schizophrenic member thus remains to be definitively answered. Because even system therapists must acknowledge that they can do little to help once chronification has occurred, the Heidelberg group has recently devoted itself intensively to the theme of chronification (Simon and Weber 1987; F.B. Simon 1993).

6 Milieu Therapy

Although Sullivan (1931) had already pointed out the importance of the patient's social environment for the recovery process in schizophrenia, Cumming and Cumming are considered to have founded modern milieu therapy with their book *Ego and Milieu* (1962). Their basic conception was that the patient should do everything that he or she is capable of; they considered action, rather than the passive receipt of treatment, to be the essential therapeutic principle. Especially in psychotic patients, they maintained, such activity leads to an improvement of identity and to "ego growth."

Gunderson (1980) distinguished two fundamentally different types of milieu therapy: (1) the therapeutic community in the sense of Jones (1953) and (2) behavioral milieu therapy (e.g. the "token economy" approach; Ayllon and Azrin 1968). He stated that three qualitative factors were determinative of the success of milieu therapy: (1) the sharing of responsibility and decision-making authority, (2) the clear definition of treatment programs, roles, and leadership, and (3) a high degree of caregiver–patient interaction. Tucker (1983) understood the milieu as an expression both of the treating institution's particular attitude toward treatment and of its organizational structure. One of the most important aspects of the therapeutic community is the attempt to give patients the chance to assume responsibility for their own treatment and that of other patients. The distinguishing feature of behavioral milieu therapy is the consistent application of principles of learning theory in the framework of the individual patient's situation and treatment plan.

Therapeutic milieus differ considerably from one another with respect to the degree of control, support, structure, engagement, and evaluation. There are thus many different types of "milieu," and all psychiatric institutions today claim to offer milieu therapy. The concept of milieu therapy has thereby become diffuse and lost much of its original meaning. The concept of the therapeutic community has also undergone much change. Jones himself, in his later years, considered the distinction between the therapeutic community and milieu therapy superfluous and proposed the overarching concept of learning as a social process (Jones 1983).

Van Putten and May (1976) expressed the pessimistic view that milieu therapy has only a small additional effect beyond that of pharmacotherapy in an adequate dose. Gunderson (1980) and Ellsworth (1983), however, in their reviews of the literature, concluded that milieu therapy does indeed lead to a significant improvement of disease manifestations and of the level of social functioning in patients with both acute and chronic schizophrenic illnesses. Paul and Lentz (1977), in their pioneering study, were able to show that milieu therapy and social learning for the chronically mentally ill produce better results than treatment in a custodial environment, independently of the pharmacologic treatment given. This finding had a strong and far-reaching influence on the further

development of psychotherapeutic and psychosocial treatment programs for schizophrenic patients.

An exceptionally consistent application of the milieu-therapeutic approach to the treatment of schizophrenia was carried out in the San Francisco Soteria House, founded by Mosher et al. (1975), in which a small group of acutely affected schizophrenics were treated by lay caregivers in a community setting practically without the use of neuroleptic medications. After 2 years of clinical follow-up, Mosher and Menn (1978) found that the Soteria patients had done no better with respect to disease manifestations and recurrence rate than a control group of patients managed in a traditional inpatient setting, but they did have a higher rate of employment and were living more independently than the patients in the control group.

Ciompi, in Bern, Switzerland, replicated this concept and developed it further. On the basis of his theory of affect logic (Ciompi 1982), he laid down the following eight therapeutic principles for Soteria Bern (Ciompi et al. 1991):

1. A therapeutic milieu that is small, as "normal" as possible, transparent, relaxing, and protected from excessive stimulation
2. Attentive and continual emotional support during the psychotic crisis, provided by a small number of selected individuals
3. Continuity of concept and of treating staff, lasting from the phase of acute treatment all the way to reintegration in the community
4. Provision of clear and consistent information to patients, relatives, and caregivers with respect to the illness, its prognosis, and its treatment
5. Continual close cooperation with family members and significant others
6. Development of common concrete objectives and priorities on the living and work axes, with the generation of realistic, cautiously optimistic expectations
7. Use of neuroleptics only in the presence of not otherwise treatable danger to the patient or others, in the absence of signs of improvement after 4–5 weeks, or when the risk of relapse cannot be otherwise reduced in the post-acute treatment phase
8. Systematic post-acute treatment and relapse prophylaxis for 2 years on the basis of a preceding analysis of individual prodromal symptoms, stressful situations, and possible coping strategies, carried out with the cooperation of patients, their relatives, and caregivers

These principles of treatment, with the exception of (7), can be profitably carried over to other outpatient, part-outpatient, and inpatient therapeutic milieus as well. With regard to medication, however, the practice has changed, even at Soteria Bern, to the administration of a low basal dose of medication for relapse prevention, with an increase in dose if prodromal symptoms appear. In a controlled, prospective study involving follow-up at 2 years, the results of Soteria treatment with respect to social functioning level and recurrence rates were found to be comparable to those of treatment in traditional inpatient settings. While Soteria treatment reduced the use of neuroleptics by half, the patients stayed in the treating institution twice as long, which increased the cost of treatment (Ciompi et al. 1993). It was later possible to reduce the length of stay. These results are in accordance with those of Mosher and Menn (1978). Soteria treatment was also felt by many patients to be less traumatizing and stigmatizing (because less isolating) than inpatient treatment in a psychiatric ward.

The milieu-therapeutic Soteria approach has a number of evident limitations. This form of treatment is necessarily voluntary and is thus eminently unsuitable for use among young, chronically schizophrenic patients who have no insight into their illness, behave aggressively, and abuse addictive substances. Such difficult patients require a clearly structured milieu, and hospital wards of the traditional type often hold more than their share of them. A further problem is that the success of milieu therapy depends, in part, on a high degree of involvement on the part of the caregiver, who is, in turn, motivated by ideals and values propounded by a charismatic leader. This can easily lead to a romantic idealization of the proffered form of therapy.

7 Long-Term Care and Case Management

In the last 20 years, the deinstitutionalization process and the establishment of community-integrated structures for the delivery of social psychiatric care have led to the relocation of the focus of long-term care for schizophrenic patients from the hospital into the community. In line with this development, a broad range of facilities has developed, including outpatient and inpatient crisis centers, day clinics, low-threshold outpatient services serving as contact points, outpatient follow-up clinics, and visiting services, all of which offer diverse types of socio- and psychotherapeutic assistance in a community-based setting.

Regionalized or sectorized care structures, and the concepts of the long-term care team (Test 1979; Torrey 1986; Johnson et al. 1997) and case management (Sledge et al. 1995), were developed in order to enable patient-centered coordination of these diverse offerings and to ensure continuity of care. The long-term

"care team" is a multidisciplinary team of professionals that assumes responsibility for a defined group of patients, ideally in both the outpatient and the inpatient settings.

The concept of case management is represented by several considerably different approaches, ranging from the purely organizational concept of "brokering" (i.e. mediation of treatment and rehabilitation offerings) to the so-called clinical case management model, which bears a strong resemblance to the long-term caregiver model (Mueser et al. 1998). Studies by Bond et al. (1988) and by Borland et al. (1989) showed that intensive case management shortens hospital stays and may thereby result in a saving of costs, but it does not improve the patients' functional level or quality of life. These findings were not supported by Rössler et al. (1993), who found that care by a sociopsychiatric service reduced neither the rate of hospitalization nor the length of hospital stay. Similarly, a controlled study by Marshall et al. (1995) revealed no advantage to case management in the care of chronic patients.

On the other hand, Quinlivan et al. (1995) found that case management can indeed reduce costs significantly, and precisely in the group of chronic patients. Rosenheck et al. (1995) came to the same conclusion in a controlled multicenter study of long-term care; the most important factor in cost reduction was a reduced need for inpatient treatment. The limited efficacy of intensive approaches to long-term care may be due to the fact that such approaches still usually do not include any specific rehabilitation techniques that improve the level of cognitive or psychosocial functioning, e.g. techniques of cognitive remediation or social skills training.

Thus, although most of the findings have been encouraging, the present state of research on long-term care and case management does not yet allow any reliable conclusion about their efficacy. The results of different studies may conflict at least in part because long-term care and case management function optimally only when patients have a suitably comprehensive mental health care system and diverse therapeutic offerings at their disposal. The conditions under which the studies mentioned above were carried out varied widely in this respect. Related considerations of mental health care policy are discussed in greater detail in Chap. 13 (Vol. 3, Part 1).

Family care, which was practiced in Germany as early as the nineteenth century but was forgotten thereafter, is now assuming an importance that is not to be underestimated in the long-term care of chronically schizophrenic patients. In this form of care, a family framework with the necessary social support is provided by a family other than the patient's own, when the patient no longer needs inpatient treatment but cannot live alone. Recent studies have shown that the results obtained with family care for patients of this type are generally favorable (e.g. Schmidt-Michel et al. 1992).

8 Concluding Remarks

In the last two decades, major progress has been made in the socio- and psychotherapy of schizophrenic disorders. This is most evident in the larger role now played by cognitive-behavioral therapy approaches and in the increased attention paid to milieu-therapeutic aspects. Psychoanalytic therapy and, to a lesser degree, systemic therapy for schizophrenic disorders are less influential today than they once were, but innovative developments are still taking place in these fields.

All modern approaches to the socio- and psychotherapy of schizophrenic patients have in common a greater emphasis on the active participation of patients and family members, so that the result of treatment will be socially relevant, as well as on the optimal embedding in a coordinated overall treatment plan. As the scientific understanding of these forms of therapy has improved, questions have been raised about their differential indications, specific mechanisms of action, and interactions with other psychological interventions and various pharmacological treatment strategies – questions which must now be investigated more systematically than before. It also remains to be seen whether these various approaches can produce results in routine care that are as good as those obtained under experimental testing conditions, and whether their application is cost-effective.

Finally, a further major deficiency of the current state of scientific knowledge is that the effectiveness of different socio- or psychotherapeutic interventions and structures of psychiatric care has almost always been studied separately for each intervention or structure. This artificial separation will have to be overcome. A second generation of efficacy studies is needed in which an integrated evaluation of socio- and psychotherapy and of care structures is performed.

Schizophrenic Disorders: Rehabilitation

1 Importance of Rehabilitation Treatments for Schizophrenia

Pharmacotherapy with antipsychotic, mood-stabilizing, and antidepressant drugs forms the basis of treatment for the major psychotic and mood disorders, which include functional disability as a diagnostic criterion. While the evidence for the efficacy of these agents for the acute and maintenance treatment of these disorders is quite robust, limitations in their impact have been noted for primary negative symptoms, cognitive deficits, psychosocial functioning, and quality of life (Liberman et al. 1995). Side effects of maintenance pharmacotherapy diminish the value of these treatments, with examples including the sedation, autonomic, and neurological side effects that can impair social and vocational functioning (Mintz et al. 1992).

In addition, the subjective distress caused by side effects can trigger noncompliance with the drug regimen, with high risk for relapse. While the introduction of atypical antipsychotic drugs appears to confer additional benefits in terms of improvement in neurocognitive deficits (Green et al. 1997) and reductions in negative symptoms and side effects (Marder and Meibach 1994), the degree to which these new drugs will favorably alter the long-term course of psychotic disorders remains to be seen.

During the past two decades, substantial evidence has accumulated for the effectiveness of psychosocial interventions to supplement drug therapy for disabling mental disorders (Dilk and Bond 1996; Penn and Mueser 1996; Smith et al. 1996; Scott and Dixon 1995; Marder et al. 1996; Liberman and Kopelowicz 1995). Psychosocial interventions such as behavioral family management, social skills training, assertive case management, and supported employment have been designed to (a) reduce the stress experienced by individuals who are vulnerable to relapse – especially stressors from the family emotional climate, (b) strengthen the individual's coping capacities to improve social functioning, and (c) provide social supports that compensate for the deficits in community functioning and buffer stressors that afflict the seriously mentally ill. The advent of a combined biobehavioral approach to treatment of individuals with disabling forms of mental disorders has led to the development of the field of psychiatric rehabilitation.

Psychiatric rehabilitation can be defined as comprising those biobehavioral interventions that are aimed at enabling an individual with a disabling mental disorder to (a) build skills that improve adaptive functioning, (b) achieve personally relevant goals that are consistent with as high a level of independence and quality of life as is feasible, and (c) live in a supportive environment that enables the person to enjoy a higher quality of life when symptoms or deficiencies in life skills persist despite the best efforts at rehabilitation. Interventions are considered rehabilitative if they remove obstacles or impediments to these goals (e.g. symptoms, bizarre behavior, deficits in social functioning).

The conceptual framework underlying psychiatric rehabilitation is the vulnerability–stress–protective factors model of serious mental disorder. Vulnerability is presumed to be biologically and genetically mediated and to persist even during periods of symptomatic remission. Thus the aim of psychiatric rehabilitation is to reduce stressors and provide protection against vulnerability through strengthening the individual and modifying the environment.

Several conclusions can be articulated from the research literature on psychiatric rehabilitation. Psychosocial treatments are treatment specific; in other words, to achieve favorable vocational outcomes, vocational rehabilitation has to be highly structured and well-organized (e.g. supported employment), and to achieve improvements in social competence, structured methods of social skills training must be employed (Kopelowicz and Liberman 1998). A second conclusion is the importance of long-term deployment of psychosocial interventions for improving community tenure of patients. This has been well demonstrated in the studies of assertive community treatment where rehospitalization rates remain low as long as the case management continues to provide interventions with outreach and mobility. Finally, schizophrenia is a stress-related disorder; thus interventions aimed at reducing stress (e.g. high expressed emotion within families) are likely to succeed in reducing relapse rates (Scott and Dixon 1995).

Psychosocial treatment should be combined with optimal types and doses of antipsychotic medications, so that symptoms and side effects do not interfere with compliance and instrumental role functioning. Negative symptoms and conceptual disorganization/thought disorder, in particular, have been associated with poor outcomes from psychosocial treatment (Mueser et al. 1991; Kopelowicz et al. 1997). The new antipsychotic drugs may offer special promise in terms of reducing the neurocognitive and learning disabilities that can compromise the psychosocial rehabilitation of individuals with schizophrenia (Green 1996; Green et al. 1997; Mueser et al. 1991).

Finally, treatment and rehabilitation should be linked to the phase of the patient's disorder; thus the type of psychosocial intervention appropriate for the acute and florid phase of illness (e.g. involving the

family in a therapeutic alliance as through psychoeducation) will not necessarily be the same intervention used in the stable or recovery phase of the disorder (e.g. supported employment, intensive social skills training for conversation and friendship skills).

Psychosocial treatment and rehabilitation can be categorized as primarily remedial or primarily compensatory in terms of the psychosocial and functional deficits of individuals with schizophrenia. In remedial strategies, attempts are made to improve the individual's functional deficits as by teaching skills and broadening the individual's behavioral repertoire, coping capacities, and resilience to stress. Social skills training is an example of this strategy. In compensatory approaches, treatment aims to create environmental supports for the individual that reduce the burden, stress, and requirements for functioning, while at the same time providing for the individual's needs and quality of life. Assertive case management or training in community living, as well as supported employment and supported living techniques, reflect successful compensatory strategies of intervention (Test 1992; Burns and Santos 1995; Hromco et al. 1997; Bond et al. 1997).

Compensatory and remedial strategies for psychosocial rehabilitation can be viewed as means of overcoming obstacles to normative social and role functioning that are found in the environment, the individual, and in the roles that individuals must perform to function within the community. These various obstacles, or variables, are depicted in Fig. 1. Remedial interventions aim to strengthen an individual's coping capacity by teaching skills, while compensatory interventions are primarily imbedded in environmental supports. The following two sections of this chapter will review these strategies in detail.

2 Rehabilitation Services

Specific rehabilitation services include social skills training, family psychoeducation, cognitive remediation, vocational rehabilitation, and self-help programs. The utility and effectiveness of these services have been recognized, and they are critical elements of rehabilitation programs around the world.

2.1 Social Skills Training

Social skills training is defined by behavioral techniques or learning activities that enable patients to acquire instrumental and affiliative skills in domains required to meet the interpersonal, self-care, and coping demands of community living. Skills training can be done with individuals, patient groups, or families and may continue for years as the person's

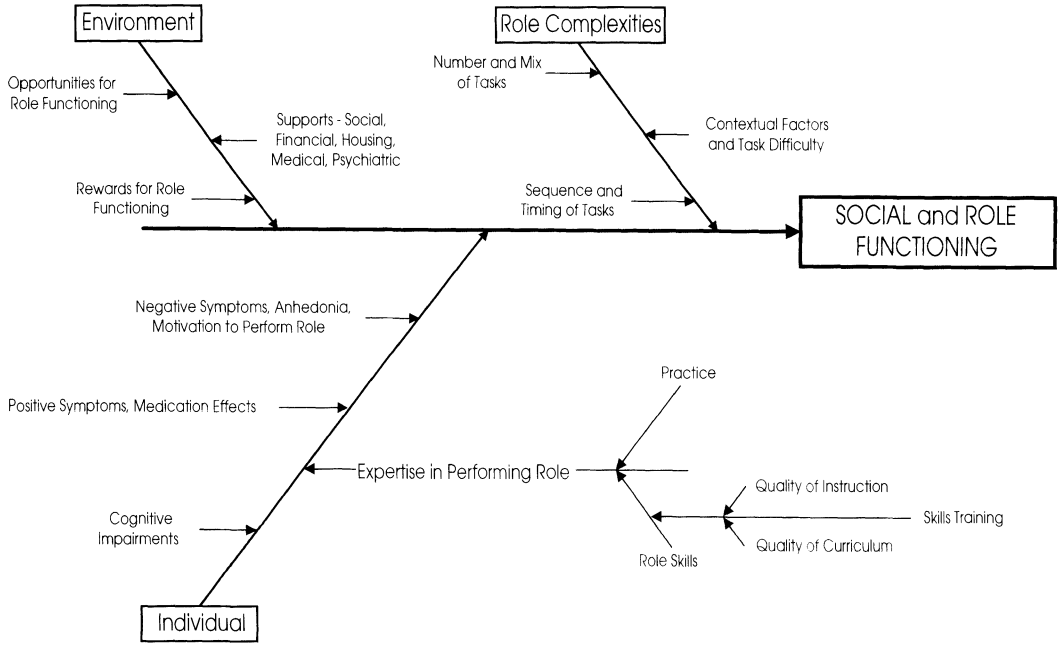

Fig. 1. Factors that influence social and role functioning

Table 1. Framework for social problem solving

	Problem-solving sequence	Cognitive-behavioral requirements
Step 1	Identifying the problem	Social and self-perception
Step 2	Generating list of potential solutions	Information-processing capacities
Step 3	Reviewing pros and cons of potential solutions	Information-processing capacities
Step 4	Choosing a solution	Decision-making abilities
Step 5	Implementing the plan	Behavioral skills
Step 6	Reviewing the outcome	Social and self-perception

abilities, goals, and values ascend a hierarchy of community adaptation.

Skills training approaches draw upon theoretical models of social problem-solving, which involve variations on a stepwise process of social perception, information processing, and behavioral response (Bellack et al. 1994). Patients with chronic psychotic disorders often have difficulty in accurately perceiving and interpreting affective and cognitive cues that are critical elements of communication. Training skills in social perception address these deficits and provide a foundation upon which more specific social and coping skills can be developed. As a next step, skills training uses cognitive techniques to teach strategies for identifying social problems, generating and evaluating alternative solutions, and choosing a plan of action. As a final step, skills training addresses discrete verbal, paralinguistic, and nonverbal skills which are used to effect a competent social response. Table 1 lists these social problem-solving strategies in sequential order.

Based on the social problem-solving model of social skills training, a set of psychoeducational modules has been developed at the University of California at Los Angeles (UCLA) Clinical Research Center for Schizophrenia and Psychiatric Rehabilitation (Liberman et al. 1993). Specific training modules target skills for self-management of antipsychotic medication, symptom management, grooming and personal hygiene, recreation for leisure, interpersonal problem-solving, job finding, community reintegration, safe and satisfying sex, family coping, and engaging in friendly conversations. These modules use instructional techniques including didactic lectures, videotape demonstrations, role-playing, and in vivo homework assignments to help patients master specific skill areas. Each module is a self-contained package that can be adopted alone or in combination with other modules in comprehensive rehabilitation programs.

Meta-analyses and reviews of the more than 50 controlled studies of social skills training have shown that individuals with schizophrenia can acquire and retain skills and that training is associated with significant favorable effects on social adjustment, symptoms, relapse, and rehospitalization rates (Benton and Schroeder 1990; Dilk and Bond 1996; Smith et al. 1996; Hogarty et al. 1997). Skills training is especially effective if it is intensive (more than two sessions per week) and of sufficient duration (at least 6 months). While schizophrenic patients with even high levels of hallucinations and delusions can acquire skills through systematic training, cognitive disorganization (e.g. severe distractibility and thought disorder) and the deficit syndrome (i.e. primary negative symptoms) are likely to interfere with the training process.

2.2 Family Psychoeducation

Many studies have replicated the finding that family stress, often reflected in high expressed emotion attitudes of criticism and emotional overinvolvement toward the mentally ill relative, is a powerful predictor of relapse in schizophrenia (De Jesus Mari and Streiner 1994). Several modes of family intervention have therefore been designed and empirically validated for the ability to equip relatives with coping skills and thereby change the emotional climate of the family and reduce the incidence of relapses and rehospitalizations. Patients who have contact with their family members will benefit from participating in a psychoeducational and skill-building program aimed at improving communication and problem-solving.

Approaches to family psychoeducation share several features. First, it is essential that the treatment team develop collegial relationships with family members and other support persons. In this context of collaboration, specific psychoeducational techniques are used with the aim of teaching what is known scientifically about the patient's mental disorder and directing the family and other caregivers to locally available treatment and rehabilitation services. Another feature involves the assumption of least pathology. The attitude is taken that family members are always doing the best they can and acting in the interests of the

patient and family, given their coping capacities and biobehavioral vulnerabilities. This approach sets the stage for the development of communication and problem-solving abilities. To produce durable clinical effects, family interventions must go beyond education to train family members in necessary coping skills, including basic communication and contingency management. Examples of communication skills that form the basis for effective problem-solving include active listening, giving positive feedback, and making positive requests.

Over two dozen well-controlled studies in the past decade have examined the effects of family psychoeducation on patients and their families (Scott and Dixon 1995; Solomon et al. 1996; Anderson et al. 1986; McFarlane et al. 1995). Results showed that the relapse and hospitalization rates for patients who participated in family psychoeducation were significantly less than for patients who completed various comparison treatments. Studies have also shown that family psychoeducation significantly lowers family burden and improves self-efficacy and esteem.

2.3 Cognitive Remediation

In recent years, there has been interest in cognitive remediation treatments for schizophrenia. The cognitive and neuropsychological deficits that are core features of the disorder play a role in determining the success of rehabilitation strategies, with studies showing that enduring thought disorder and short-term memory and verbal learning deficits are more predictive of skill acquisition than psychotic symptoms (Mueser et al. 1991; Kern et al. 1992; McKee et al. 1997). In addition, deficits in vigilance, memory, and executive functioning have also repeatedly been associated with social skills and overall social adjustment (Green 1996). While many clinicians have assumed that the cognitive deficits of schizophrenia represent an irreversible and enduring form of dementia and hence cannot be mitigated by rehabilitation, evidence is accumulating to justify strategies for remediation of these basic cognitive deficits.

Two types of cognitive remediation strategies have been developed. The first involves direct remediation of basic cognitive deficits. Demonstrations have shown that laboratory-based measures of cognitive dysfunctions such as vigilance and card sorting can improve significantly with behavioral training (Benedict et al. 1994; Stratta et al. 1994). Remediation strategies include repeated practice, instructional modification, positive reinforcement (e.g. money), and errorless learning that teaches discrimination and problem-solving in small steps where success is maximized and trial-and-error learning is minimized. Empirical evaluation of the efficacy of these direct approaches to cognitive training suggests that striking improvements are possible in the cognitive tasks, but the links between improvements in laboratory-based molecular levels and in molar social and clinical status have yet to be satisfactorily documented (Penn and Mueser 1996). Current research aims to promote clinical generalization of direct cognitive remediation through identifying and strengthening the cognitive, behavioral, and social processes that mediate learning of adaptive skills.

A different remediation strategy targets amelioration of psychotic symptoms through cognitive restructuring and behavioral learning principles. To date, strategies have been developed for treating delusions, hallucinations, and negative symptoms. Sometimes referred to as cognitive strategy enhancement, these approaches involve the identification of specific symptoms with subsequent training in the use of cognitive coping strategies including distraction, reframing, self-reinforcement, reality testing, and verbal challenging. Several reports have shown these strategies to be effective, at least during short-term follow-up in hospital and clinic settings (Tarrier et al. 1993).

2.4 Vocational Rehabilitation

Vocational rehabilitation techniques for schizophrenia have improved dramatically since the era of institution-bound, sheltered work programs. In the 1970s and 1980s, transitional employment programs were developed largely within psychosocial rehabilitation clubs and often without input from mental health professionals. Transitional employment comprised prevocational work activities or work enclaves in industrial settings that had the philosophy of "train then place" in a real job. A job in the competitive work sector was considered stressful, requiring gradual work hardening. Evaluations of the transitional employment model have produced mixed results, and there are concerns that this approach may be less effective due to the disparity between the controlled environments of prevocational activities and the competitive workplace (Wallace 1993).

The supported employment model of rehabilitation evolved in an effort to improve these vocational outcomes. This approach arises from the understanding that individuals with psychiatric disabilities require ongoing rehabilitation and support after they secure competitive employment. It de-emphasizes the importance of prevocational training, advocating instead a "place then train" approach. Clients are placed in employment settings based on their interests and

abilities and then offered the training and supports necessary to maintain their positions. In its fully applied form, individuals are offered services indefinitely, with job coaches visiting workplaces to help with learning and retention of technical, interpersonal, and problem-solving skills required to sustain employment.

Evaluations of supported employment have revealed successful job placements in competitive, community-based work in over 50% of participants (Bond et al. 1997; Drake and Becker 1996). Placement rates are substantially higher when the rehabilitation work is part of an integrated mental health treatment plan. Supported employment requires close collaboration and communication between the client, the vocational specialist or job coach, and the interdisciplinary treatment team. This is because many of the factors that negatively influence vocational rehabilitation are those commonly addressed by the clinical treatment team: severity of psychopathology (especially conceptual disorganization and negative symptoms), stress in the family (expressed emotion), neurocognitive deficits, and poor premorbid social and work adjustment.

3 Social and Community Support Programs

Over the past three decades, many countries have transferred the care of the seriously mentally ill from psychiatric hospitals to less restrictive community settings. This shift in locus of care required more aggressive outreach on the part of treatment providers, which is conceptualized in the community support/case management model. In this approach, interventions are delivered in a coordinated fashion by multidisciplinary teams of clinicians who assume long-term responsibility across the spectrum of mental health services, including inpatient units, outpatient programs, and psychosocial rehabilitation centers. Several key principles guide effective case management (Ellison et al. 1995). These include the commitment to treating clients with dignity and confidentiality and the requirement that services be adapted to the changing needs and preferences of each client on the basis of self-determined goals. Most importantly, the service delivery system must provide comprehensive, accessible services for as long as and whenever the client needs them, in settings that are the least restrictive and most normalized.

The many functions provided in case management/community support models of care delivery include the following:

- Outreach and engagement
- Support of basic needs
- Mental health care and treatment
- Crisis/emergency services
- Comprehensive psychosocial services
- Range of housing options
- Support and education for providers and families
- Development of natural supports
- Advocacy and protection
- Case management

Case management programs have been shown to increase community tenure of previously institutionalized patients (Solomon 1992).

Among the most effective adaptations of this approach is the Training in Community Living or Program of Assertive Community Treatment (PACT) developed in Madison, Wisconsin (Burns and Santos 1995; Test 1992). The PACT model uses broad-spectrum case management organized in round-the-clock continuous treatment teams. This program is effective in both rural and urban settings and has been replicated throughout the United States and Europe.

Although it is generally agreed that case management is a desired service for individuals with serious and persistent mental illness, there is little consensus as to which elements of the case management process are most clinically useful.

A case manager in a psychiatric rehabilitation setting has several specific tasks to perform. These include the following: assisting clients in building social networks; facilitating access to housing and employment opportunities; helping clients interact with various service organizations; teaching clients skills for illness management; monitoring clinical progress; and, when necessary, undertaking timely clinical interventions. By acting as the fixed point of responsibility within a continuum of care, case managers contribute to improved vocational functioning, less social isolation, and more independent living.

Another outgrowth of the deinstitutionalization era was the development of fellowship clubs of formerly hospitalized patients. Psychosocial clubhouses now exist in many large cities in Europe and the United States, including the Fountain House in New York City and Thresholds in Chicago. Clubhouses provide basic opportunities for acceptance, friendship, advocacy, housing, destigmatization, and social and recreational activities. Although the psychosocial clubhouse movement developed separately from the medically oriented community mental health approach, the past few years have witnessed an increase in the number of community mental health centers that have converted their traditional day treatment programs to the clubhouse model.

Central to the psychosocial self-help philosophy is the belief that individuals with mental disabilities have a fundamental right to work, socialization, and a home and that those basic needs, when satisfied, generate self-esteem and a positive identity necessary for community adjustment. Thus psychosocial clubhouses focus on developing employment opportunities, peer support, and housing programs tailored to the capabilities of their members. The success of these programs, including those operated by patients themselves (consumer-run agencies), is reflected by reimbursement of the services by government insurance programs, by their certification by accreditation agencies, and by the vitality of the International Association of Psychosocial Rehabilitation Services, an organization spawned by the clubhouse network. Increasingly, psychosocial self-help programs are evolving toward full service enterprises with assertive community management, pharmacotherapy, and community support.

Depressive Episodes

Translator: E. Taub

1 Introduction

Depressive disorders are among the most common mental illnesses. The prevailing concepts of their frequency, classification, course, and treatment have changed markedly in the last two decades. Epidemiological studies have shown that depressive disorders are more common, and have a less favorable course, than previously assumed. Concepts of diagnosis have also changed in the same period. The entity of endogenous depression, a part of the systematic, triadic nosology of Kraepelin (1913), was abandoned in favor of depressive episodes, as in ICD-10 (WHO 1992a), and major depression, as in DSM-IV (APA 1994), which became the new major diagnostic categories for depressive disorders. Meanwhile, many related diagnostic categories were developed to provide a more detailed description of the entire psychopathological spectrum of depressive disorders.

In this chapter, we describe the depressive episode and recurrent depressive disorder and present the current state of research into this disorder. This illness essentially corresponds to the major depression of DSM-IV (APA 1994) and is one of the main categories of the current diagnostic scheme for depression. We discuss not only its clinical manifestations, but also instruments that may be used for diagnostic assessment and differential diagnostic viewpoints. Finally, we consider research on the course of depressive disorders and empirical findings about prognostic factors.

2 Manifestations of Illness

2.1 Clinical Features

The term "depression" can be traced back to Cullen (1800). His use of the term reflected a pathophysiological view of this illness as being due to a loss of central vascular tone. This conception was in accordance with the tradition of British sensualism and with the "iatrophysical" characterization of this disease as secondary to a reduction of humoral tone in the brain (Schmidt-Degenhard 1983). The descriptive phenomenological content of the term was first worked out in our modern sense in the earlier decades of the nineteenth century, most notably by Heinroth (1818) (see Schmidt-Degenhard 1991). Nonetheless, interference from the competing concept of melancholia led to difficulties in distinguishing illnesses of relatively autonomous course, with or without psychotic content, from states similar to the familiar mood changes of everyday life. The term "endogenous depression," recently abandoned, also reflected this problem.

There was little movement in the descriptive phenomenology of depression from this early period until recent decades, when questions of symptomatology came under discussion with respect to classification. Nonetheless, many current textbooks and manuals of depression no longer contain a chapter devoted to the descriptive phenomenology of depressive illnesses (Beckham and Leber 1995). Instead, information about depressive manifestations is subsumed under the chapters on epidemiology or classification (Andreasen and Black 1993). There is a tacit assumption that the psychopathological phenomena may, in principle, be accepted as already defined and understood. Detailed descriptions of the manifestations of illness are today more likely to be found in the numerous books that have appeared for the benefit of affected individuals and their families (Luderer 1994; Wittchen et al. 1995; Wolfersdorf 1994).

Nonetheless, the traditional European conception of psychopathology differs from the American conception reflected in DSM, and it is precisely this discrepancy that necessitates a clear understanding of the basic elements of each. Until the 1970s, for example, German psychopathology customarily distinguished between subjectively experienced vital disturbances and objectifiable vegetative disturbances, depressive coenesthesiae in the sense of disturbances of body sensation and body image, and somatoform disorders, which were similar to conversion disorders. This framework of classification no longer exists. The collective term "somatic complaints" (DSM-IV) obliterates the distinctions between these categories, even though there is clearly no theoretical difficulty in separating at least the subjective vital disturbances from the objectifiable, physical vegetative disturbances.

Furthermore, the international English-language literature on anthropological-phenomenological psychopathology (see Chap. 21, Vol. 1, Part 1) is scarcely taken into account, even though this field has yielded important contributions to depression research since its most productive period in Europe, which lasted from the 1950s to the 1970s. These contributions include the descriptions of disturbances of temporal and spatial representation by Erwin Strauss, Viktor von Gebsattel, Ludwig Binswanger, and others (see also Mundt 1998), as well as the existential personality traits that result from these disturbances in depressive patients, including altered relationships to themselves, the world, and the future, as was later discussed by Beck et al. (1979).

In addition to anthropological phenomenology – a holistic ontological approach focusing on personality traits as ideal types – two further theoretical approaches

have taken root in contemporary depression research, which we may call the nosological medical approach and the functional pathopsychological approach. Kuhs and Tölle (1987), for example, classify manifestations of depression in a manner derived from "classical" psychopathology and Kraepelin's medical model, breaking them down into affective disturbances and disturbances of initiative, cognition, perception, and memory. Further types of manifestations include disturbances of body sensation, vital disturbances, daily fluctuations, sleep disturbances, and accessory manifestations that are universal in psychiatry but take on a special coloration when they arise in the setting of depression (e.g. compulsion, alienation, and the development of histrionic manifestations).

Wolfersdorf (1995) attempted to classify the manifestations of depression with reference to basic mental functions, distinguishing disorders of cognition and affect regulation, of initiative, and of vegetative-symptomatic functions. Hautzinger (1997) proposed a similar classification scheme, dividing the manifestations of depression into emotional, motivational, cognitive-imaginative, vegetative-physiological, and behavioral planes.

The reader is referred to chapters in earlier editions of this textbook for consideration of individual manifestations and for the phenomenological conception of melancholia (see Kuhs and Tölle 1987; Kraus 1980). There have been no fundamentally new findings in symptomatology since these chapters appeared, and only a few new findings in phenomenology, notably the anthropological conception of depression by Fuch (1994) as secondary to "uprooting" – an explanatory model that goes beyond the idea of experiences of loss as depression-releasing "life events" and that is of major importance for the psychiatric care of immigrant patients.

2.2 Empirical/Statistical Description

None of the manifestations listed above are found exclusively in patients with depression; they occur with variable frequency, and they may occur in individual patients in highly variable combinations. Thus, to facilitate clinical diagnosis, many attempts have been made to group the manifestations of depression into patterns. This was, at first, a primarily phenomenological process, but the last two decades have seen the increasing use of empirical and statistical techniques for help in finding patterns and establishing constructs. Such techniques play a role complementary to that of phenomenological research (Mundt 1991).

A simple, early approach to depression research consisted of determining the frequency of occurrence of certain manifestations in depressed patients (Winokur et al. 1969). It was found that some manifestations, such as disturbances of sleep, mood, and concentration, occur almost universally. Others, such as loss of appetite, daily fluctuations, and hopelessness, are found in a bare majority of patients, and yet others, such as delusions, suicide attempts, and auditory hallucinations, are much rarer. Hamilton (1989) arrives at similar conclusions, but also states that manifestations of anxiety are almost always present in depressed patients.

2.3 Core and Peripheral Manifestations

Empirical frequency analyses are the point of departure for the construction of further patterns by means of multivariate statistical processes. The overall concept of this research strategy is that the multivariate description of patterns of disease manifestations, rather than the consideration of individual manifestations, ought to lead to the identification of more characteristic subgroups. This approach has been discussed by Nelson and Charney (1981) and by Steck (1988).

Such multivariate analyses may be classified with respect to three main features: the type of patients studied (depressed or non-depressed patients), the statistical techniques used (factor analysis, cluster analysis, or discriminance analysis; Bortz 1985), and, finally, whether individuals or traits are grouped. Nelson and Charney (1981) reviewed a number of multivariate studies and concluded that most of them clearly reveal the presence of a melancholic core group of manifestations, including severe mood disturbance and psychomotor abnormalities such as inhibition, depressive delusions, self-reproach, loss of interest, and inability to be influenced by the environment. In contrast, Steck (1988) reviewed 54 original publications and concluded that a reliable differentiation of endogenous from neurotic clinical pictures was not possible. The study by Matussek (1983) was the only one in which separate endogenous and neurotic syndromes were identified. The findings of most studies, however, support the dichotomous concept of depression proposed by Kendell (1976) and by Blashfield and Morey (1979), in which two types of depression differ with regard to both the quality and the severity of manifestations. The first type is characterized by guilt feelings, sleep disturbances, weight loss, and depression of mood, while the second type is characterized by fluctuating manifestations and lesser severity.

Paykel (1971) performed a study in which four different clusters with varying manifestations of depression were found: a psychotic cluster with the

typical manifestations of endogenous depression, an anxious cluster, a hostile cluster, and a fourth cluster comprising younger patients with personality disorders. These results were replicated in a further study, which also revealed that the clusters respond differently to psychopharmacological treatment (Paykel and Henderson 1977). Andreasen et al. (1980), Andreasen and Grove (1982), and Steinmeyer (1980) all identified three clusters largely corresponding to those of Paykel (1971).

Another approach of classification research consists of multivariate analysis and grouping of the clinical features of these disorders. Philipp and Mayer (1987) empirically studied a number of competing operationalized classification schemes for depressive disorders and endogenous depression, first comparing them with one another on a descriptive level and then determining their common features with multivariate statistical techniques. The 19 classification systems they studied were based on 72 different manifestations of anxiety and depression. Factor analysis and hierarchical cluster analysis were performed in a study group of 1000 patients with mental disturbances not due to any known physical cause. Using these techniques, Philipp et al. (1991) were able to derive a core syndrome of depression, which consists largely, if not entirely, of the same manifestations as the DSM-defined major depression.

Since then, empirically and statistically oriented symptom and classification research has yielded a large amount of further data, from which a few convergent findings emerge. It has not been found possible to separate depressions clearly into endogenous and neurotic syndromes. It has been possible, however, to characterize a core syndrome of depression and to distinguish it from less stable peripheral syndromes. This core syndrome essentially corresponds to the concept of major depression. The existence of melancholic, somatic, and endogenous subtypes of the core syndrome is also a replicable finding.

This classification of depressive syndromes is likely to be provisional. The inconstancy of the findings of multivariate analyses of disease manifestations is reflected in the multiplicity of diagnostic concepts in the area of the depressive disorders. Nevertheless, most of the empirical results can be integrated into a differential continuity hypothesis, by which typical clinical syndromes are increasingly formed as depression becomes more severe (Kendell 1976).

2.4
Transcultural Findings

In recent years, there has been an increasing amount of research, and of controversy, on the question of whether this pattern of manifestations of depression is uniformly valid across cultures or is subject to the influence of cultural factors and, if so, to what extent (Jenkins et al. 1990; Kleinman and Good 1985; Mezzich et al. 1996; Pfeiffer 1994; see also Chap. 14, Vol. 2, Part 1). Most authors agree that there is a culture-independent core syndrome consisting of sad or anxious mood, loss of initiative and interests, diminution of sleep, and loss of appetite (Pfeiffer 1971; Sartorius et al. 1980). There are cultural differences, however, particularly in the degree of severity of feelings of guilt and shame and in the tendency toward somatization (Jenkins et al. 1990).

The dependence of depression inventories on culture has been documented repeatedly (Manson 1996). The Center for Epidemiologic Studies Depression Scale (CES-D; Radloff 1977) is one of the more thoroughly investigated inventories. Studies of construct validation in different cultures reveal differential factor structures of the CES-D and indicate that instruments of measurement for depression are strongly sample dependent, and thus that the experience of depression has a different "internal structure" in different cultures (Manson 1996). In particular, the distinction between affective and somatic patterns of depressive manifestations could not be discerned in societies that do not possess a mind–body dichotomy of this type. These findings also cast doubt on the notion that the core syndrome of depression is culturally independent (Pfeiffer 1990).

3
Classification

3.1
Diagnostic Criteria and Classification Systems

Depression is not only one of the more common psychiatric disorders, but also that for which the greatest number of competing definitions, classifications, and operationalizations have been developed (Philipp et al. 1991). Linden (1979) explains this phenomenon as a consequence of the heterogeneity of depressive mood disorders, as manifested in the variable intensity of simultaneously appearing manifestations, the multiplicity of situational framework conditions, and the variability of disease course. This heterogeneity of the depressive syndrome results in a continuous demand for new attempts at classification.

The two leading definitions of the depressive disorders today are those of DSM-IV (APA 1994) and of ICD-10 (WHO 1992a, 1993; Dilling et al. 1991, 1994). They are both products of much debate and consensus formation (see Chaps. 2 and 3, Vol. 1, Part 2). The multiplicity of manifestations of depression has led to

numerous suggestions of criteria for the definition of this syndrome. An early attempt at operational criteria, the St. Louis Criteria of Feighner et al. (1972), opened the way to the Research Diagnostic Criteria (RDC) of Spitzer et al. (1978), which are the basis of the classification criteria in use today. In contrast to the "classical" concept of endogenous depression, as represented by Weitbrecht (1972), for example, the two classification systems in widest use today, ICD-10 and DSM-IV, postulate the existence either of a broadly conceived main syndrome of depression or of depressive episodes. Individual subgroups of depression are, in turn, differentiated from the main syndrome by means of further classifying criteria such as the psychopathological manifestations and course of the disorder.

The consensus definitions are the product of a long history of controversy. Kraepelin (1913) classified depression under the broad category of "manic-depressive insanity" (*Irresein*), a unitary conception of the affective disorders. Bleuler (1916) and Schneider (1932) perpetuated this conception. In the years that followed, many classification systems were proposed for subtypes of depressive disorders (Paykel 1992). Neurotic depression was defined in distinction to psychotic depression. It was, however, the division of depression into reactive and endogenous types that long dominated the diagnostic conception of this disorder.

Further subdivisions were proposed, such as that of primary versus secondary depression, and that of unipolar and bipolar disorder (Angst 1966; Perris 1966). Among classifications at the syndrome level, the division into an agitated–anxious syndrome and an inhibited–depressed syndrome was important for pharmacological treatment (Kielholz 1971). The occult vegetative depressive syndrome (*vegetativ larviertes depressives Syndrom*) was held to be distinct from these syndromes. A further distinction at the syndrome level was the division of delusional psychotic depression (Parker et al. 1991; Schatzberg and Rothschild 1992) into forms with mood-congruent and mood-incongruent delusional manifestations (Bellini et al. 1992; Burch et al. 1994; Kendler 1991).

Other classification schemes used the course of the disorder as a classifying feature. One such distinction was that between early-onset and late-onset, or involutional, depression. Further possibilities of classification on the basis of types of disease course were proposed by Merikangas et al. (1994) and Angst (1990). The criterion for classification is the course of disease, more specifically, the extent and duration of depressive manifestations and the frequency of depressive phases. Consideration of duration yields a division into brief depressive episodes, and chronic courses. Consideration of the frequency of episodes yields a division into courses with a single depressive episode and recurrent courses. Consideration of intensity yields a division into minor and major depression. These classifying principles underlie DSM-IV (APA 1994). A further entity is that of "double depression," i.e. the comorbid occurrence of a dysthymic disorder with a "superimposed" major depression.

While ICD-9 (WHO 1978; Degwitz et al. 1980) was still oriented toward the classical concept of endogenous depression, ICD-10 has moved toward the position of DSM-IV with its concept of the depressive episode. Depressive disorder as described in ICD-10 is thus nearly identical to major depression as described in DSM-IV. The definition of the depressive episode is broader in DSM-IV than in ICD-10, however, because the former requires the presence of only one of the core manifestations of affective mood disturbance and loss of interest, while ICD-10 requires the simultaneous presence of both.

In DSM-IV, the individual types of disorder of the depressive episode can be characterized more specifically with so-called specifiers, which take into account aspects of the severity of the disorder, the presence of psychotic manifestations, and the course of illness (on a scale ranging from full remission to chronic persistence). Other factors that are taken into account include the appearance of melancholic, catatonic, and atypical features, the presence of seasonal dependence or of a "rapid cycling" course, and the onset of the depressive episode. In contrast, ICD-10 bases its subdivision of depressive syndromes mainly on their duration and the presence or absence of relapses, as well as on severity and the presence of somatic or psychotic manifestations. In principle, both systems strive to be as descriptive and atheoretical as possible and to avoid the incorporation of etiological, genetic, or therapeutic considerations in the classifying criteria.

According to the DSM-IV diagnostic criteria for major depression, the principal manifestations of this disorder are sad mood disturbance and loss of interest. One of these manifestations must be present. Furthermore, at least five of the following must be present: loss of weight, insomnia, psychomotor agitation, inhibition, fatigue or loss of energy, a feeling of worthlessness, and disturbance of concentration. Recurring thoughts of death count as a criterion only if present over a 2-week period. Exclusion criteria include mixed episodes with manic features, and toxic effects of substance ingestion. The syndrome must also be distinguished from a grief reaction. A positive diagnosis generally requires a clinically significant degree of suffering or an impairment of performance ability.

The principal manifestations of depression according to ICD-10 are mood disturbance and diminution of initiative. Other manifestations of diagnostic impor-

tance include diminished concentration and attention, diminished self-confidence and sense of worth, feelings of guilt and worthlessness, negative and pessimistic perspectives on the future, contemplated or actual self-destructive or suicidal behavior, disturbance of sleep, and diminished appetite (Dilling et al. 1991). The subtype "depressive episode with somatic syndrome" is present when at least four of the following manifestations are present: loss of interest or joylessness, lack of ability to react emotionally, early morning awakening, morning low, psychomotor inhibition or agitation, loss of appetite, weight loss, and loss of libido.

When the current DSM-IV and ICD-10 systems are considered from the perspective of the historical controversies about the classification of depressive disorders, it becomes clear that the distinction between unipolar and bipolar disorders has prevailed and that classification on the subsyndrome level has been taken up again, in somewhat modified form. Subclassification with respect to psychotic features is also reflected in the current classification systems. On the other hand, the distinction between primary and secondary depressive disorders has been abandoned, because it was incompatible with the concept of comorbidity (see Chap. 3, Vol. 1, Part 2). The division of depression into disorders of early and late onset has also been abandoned because it was found to be unreliable: the precise time of onset of the illness turned out to be extremely difficult to define. The main change that occurred in the transition from ICD-9 to ICD-10 was the abandonment of the distinction between endogenous and neurotic forms of depression: this distinction was considered to be too etiologically oriented, and it could not be adequately validated on an empirical basis.

3.2 Empirical Validation of Criteria and Systems

The question arises as to the extent to which these new diagnostic conceptions actually lead to their desired result, i.e. the ability to make more reliable and valid diagnoses of the depressive disorders (Spitzer and Fleiss 1974). The World Health Organization (WHO) sponsored a multicenter, multinational field study for the evaluation of the ICD diagnostic criteria. Sartorius et al. (1993) reported that the WHO field study yielded satisfactory reliability coefficients of 0.66 and 0.69 for the diagnoses of depressive episode and recurrent depressive disorder, respectively. Only a few subcategories seemed to have unacceptable reliability coefficients. In the portion of the WHO study carried out in the German-speaking countries (Freyberger et al. 1990; Dilling et al. 1990), similarly high values were obtained for the overall category of the affective disorders, but there was a low degree of agreement on the definition of a depressive episode, for which a κ-value of 0.19 was obtained.

Substantially better reliability coefficients were reported for the ICD-10 research criteria (Thiel et al. 1996). These studies, too, revealed that ICD-10 has moved very close to DSM-III-R: a κ-value of 0.97 was obtained for agreement between the two systems (Freyberger et al. 1990). Siebel et al. (1997), in their multicenter reliability study for depressive disorders, found a κ-coefficient of only 0.40, which corresponds to a low degree of agreement. This value was lower than the value for all disorders taken together, as well as the value for schizophrenic psychoses.

Hiller et al. (1993) obtained similar findings. The ICD-10 diagnoses for all diagnostic categories taken together were satisfactorily reliable, with a κ-value of 0.80, but the κ-value for depressive disorders was only 0.40. Similarly low values were obtained for subtyping classifications, in particular for the determination of the severity of the depressive disorder. The question remains open, at least as far as the reliability studies in the German-speaking countries are concerned, as to whether the new ICD-10 criteria are any more reliable than the older criteria, which were criticized by Spitzer and Fleiss (1974) because of their low κ-coefficient of 0.24 for endogenous depression. Despite the substantial overall improvement of reliability values, no study has yet yielded entirely satisfactory results.

The evaluation of the criteria for major depression in a DSM-IV field study yielded reliability values between 0.52 and 0.72; only the retest reliability was somewhat worse (0.43) (M.B. Keller et al. 1995). The low stability of the diagnosis of a depressive disorder was pointed out by Clayton et al. (1992). After an interval of 6 years, fewer than half of the patients received the same diagnosis, despite the application of a standardized interview. Even though they are operationally defined, depressive disorders cannot be assessed as reliably as most other psychiatric syndromes. This is particularly true of the assessment of severity.

3.3 Critique of the Operational Diagnosis of Depression and Perspectives on Classification

Although a few of the international field studies did yield high reliability values, several studies revealed a low interrater reliability for the diagnosis of depressive disorder. An adequate interrater reliability for the main categories of the disorder seems to be possible only when standardized interviews are administered by trained examiners (Wittchen and Unland 1991). While this procedure is now accepted as standard in scientific research, it is only rarely applied in the clinical field. In

addition to the problem of reliability, the question of validity arises. There are diverse opinions regarding the usefulness of diagnostic classification schemes for psychotherapeutic treatment. According to Schulte and Wittchen (1988) and D. Schulte (1994), diagnosis according to classification schemes is increasingly important in clinical practice, above all because it enables, and is indeed a prerequisite for, the development of more disorder-specific forms of treatment (Fiedler 1997).

A negative feature of the currently practiced classification of depressive disorders is, according to Saß (1987), the polydiagnostic combination of different classification systems that are only partly compatible with one another and, in addition, reappear continually in modified form at intervals of only a few years. Any advantage to be gained from the use of these systems is offset by the uncertainty over whether scientific findings obtained with the use of an older version of a system remain applicable when a newer version is used. A further point concerns the restriction of the concept of disease features to easily observable phenomena. According to Saß (1987), the development of diagnostic instruments has now reached a boundary beyond which a consideration of the psychopathological basis of these disorders is required.

An entirely different attempt to solve this problem consists of the development of diagnostic criteria on the basis of biological or psychosocial processes. The "learned helplessness" described by Abramson et al. (1978) may be cited here as an example: evidence was found for a pathogenetic relationship of the findings in this disorder (though nonspecific) to hypercortisolism and a disturbance of regulation of the hypothalamic–pituitary–adrenal endocrine axis. Another prototypic classification scheme of this type was proposed by Klerman et al. (1984), who found four types of interpersonal problems in connection with depression and formulated a specific form of treatment for each. The advantage of an etiologically oriented classification lies in the differential implications for treatment. It remains unclear whether descriptively oriented classification will continue to hold its ground, or whether more attention will be paid once again to psychopathological and etiological concepts. The multiaxial extension of the classification systems is an attempt to integrate such perspectives more intensively.

4 Instruments of Assessment

There are now many instruments of assessment that may be used to evaluate the nature and severity of depressive disorders and their manifestations in a standardized, reliable, and valid way. When any such technique is used, it must be borne in mind whether its purpose is an assessment on the level of disease manifestations, the determination of the presence of a particular syndrome, or the assignment of a diagnosis of a particular psychiatric disorder. The two most important techniques of this type are the expert interview and the self-assessment scale. Among the available diagnostic instruments for depression, some are intended to assess the manifestations of depression only, while others aim at a multidimensional psychopathological description of the patient's condition; some are intended to determine specifically whether the overall diagnosis of "depression" is applicable, while others also measure the individual manifestations (see Chap. 6, Vol. 1, Part 2). Several reviews are available that discuss diagnostic instruments for depression and the current state of psychometric assessment (Bech 1992, 1993; Erdberg 1990; Hautzinger 1994; Katz et al. 1995; Röhrle 1988; Sartorius and Ban 1986; Stieglitz 1997; Westhoff 1993; see also Chap. 6, Vol. 1, Part 2).

The instruments of assessment that have been developed in recent years constitute a foundation for empirical statistical research on the depressive disorders. The use of a standardized interview for the assignment of a diagnosis is now a standard procedure in depression research. Thus, to understand and evaluate the findings of research in this field, one must first be acquainted with the instruments used and know the theoretical assumptions that underlie them and the psychometric criteria for their validity.

4.1 Assessment of Depression by Interview

Several structured interviews are currently available for the diagnostic assessment and differential diagnosis of depression (see Chap. 6, Vol. 1, Part 2), including the *Strukturiertes Klinisches Interview für DSM-IV* (SKID-I, in German; Wittchen et al. 1997), the Composite International Diagnostic Interview (CIDI; Wittchen and Semler 1991), and the Schedule for Clinical Assessment in Neuropsychiatry (SCAN; Wing et al. 1990); the last is the most widely used. An appropriately trained interviewer may use these techniques to carry out a highly reliable psychiatric assessment and thereby significantly raise the rate of diagnostic agreement beyond that obtainable with standard clinical diagnosis. Thus Wittchen et al. (1991) report a κ-coefficient of 0.70 for the presence of major depression as assessed by the SKID-I. The problem of

reference remains, i.e. an interviewer can only be reliable in relation to his or her particular reference group (Möller and von Zerssen 1983). In addition, the problem of the assessment of the severity of a depressive disorder is still inadequately addressed by these interviews. The use of a standardized interview for the generation of homogeneous samples is now a standard research technique.

The abandonment of the concept of stratification in these diagnostic systems led to the creation of the now extensively developed field of comorbidity research (Feinstein 1970). It is not yet entirely clear whether comorbidity research actually opens substantially new conceptual perspectives or simply reflects methodological problems inherent in the diagnostic instruments used. High reliability rates have been reported only for the application of a particular diagnostic concept, but not for diagnostic agreement in relation to individual patients. The pathogenetic, etiological, and psychodynamic significance of the determined comorbidities thereby remains unexplained.

The most commonly applied procedure for the assessment of the depressive syndrome with a semi-structured interview is the Hamilton Depression Scale (HAM, or HAM-D in its German version; Hamilton 1960; Baumann 1976; CIPS 1986). The HAM was the point of departure for a number of abbreviated scales and adaptations such as the Bech-Rafaelson Melancholia Scale (BRMS; Bech and Rafaelsen 1986) and the Montgomery-Asberg Depression Scale (MADRS; Montgomery and Asberg 1979). In a study by Maier and Philipp (1993), the HAM-D, BRMS, and MADRS were compared with respect to their psychometric properties. The results suggest that the HAM-D should not be used as the single standard for depression research. The AMDP System (AMDP 1995; Woggon 1986) is also frequently used for evaluation on the level of manifestations and on the syndrome level. A newly developed German-language scale, the *Inventar Depressiver Symptome* (IDS), is oriented toward the concepts of DSM-III-R (Hautzinger and Bailer 1994). The IDS is particularly effective in the measurement of changes (van Gülick-Bailer and Hautzinger 1990).

The severity of depression is gauged by the magnitude of the raw numerical values obtained by these instruments. Such conclusions can be drawn only with certain limitations, because of the unclear factorial structure of these instruments, their differential weighting of individual types of depressive manifestations, and their differential validity for individual subgroups of depression. The severity of illness is more reliably assessed by means of these scales than by evaluation in the sense of ICD-10 (Freyberger and Dilling 1996), but these instruments cannot be used for the assignment of a psychiatric diagnosis.

4.2 Assessment of Depression by Questionnaire

According to Bouman (1993), there are more than 100 different questionnaires for depression, most of them in the English language. Depression scales may be divided into instruments that measure psychopathological manifestations multidimensionally and specific questionnaires for depression (see Chap. 6, Vol. 1, Part 2). A further group consists of questionnaires that attempt only to assess specific aspects of the depressive disorders (Hautzinger 1994; Röhrle 1988).

The best established and most commonly used questionnaires in the assessment of depression on the syndrome level are certainly the Beck Depression Inventory (BDI; Beck et al. 1961; Beck 1978; Hautzinger et al. 1993) and the Self-Rating Depression Scale (SDS; Zung 1965). In the German-speaking countries, the *Paranoid-Depressivitäts-Skala* (PD-S; von Zerssen 1976a) and the *Allgemeine Depressionsskala* (ADS; Hautzinger and Bailer 1993) have been used increasingly alongside these. In addition to questionnaires that attempt to assess depression unidimensionally as a symptom, there are a large number of scales that characterize specific aspects of depression on the levels of mood, behavior, and cognition (Hautzinger 1994; Röhrle 1988).

In summary, questionnaires are an important extension of expert assessment by means of structured and semi-structured interviews. Despite their low diagnostic potential and the difficulty of using them to distinguish depression from related constructs, such as anxiety, they have become indispensable for scientific research. If we consider how often depressive disorders remain unrecognized even today, we realize that these scales offer an economic means of screening. Progress is to be expected primarily in the development of new and more valid depression scales and of scales for specific patient groups, as well as in the assessment of specific individual aspects of depression.

4.3 Comparison of Different Techniques and Instruments

The question arises as to whether different depression questionnaires all measure the same thing, and whether assessment by means of interviews and questionnaires may lead to different conclusions. The results of interviews and questionnaires for the assessment of depression are, in general, moderately highly correlated. In a review of the subject, Bouman and Kok (1987) found an average correlation of 0.53 between the assessment modalities, although approximately 30% of the correlations lay between 0.20 and

0.40. Considerably higher values were reported by Bech (1992), who found an average correlation of 0.73 (0.61–0.86) between the HAM-D and the BDI and similar values for other depression inventories. A more recent meta-analysis by Richter et al. (1998) revealed lower values for this correlation – a mean of 0.56 and a range of 0.34 to 0.86.

The correlation of depression questionnaires with one another was somewhat higher, with a value of 0.69 (Bouman 1993). It was also pointed out, however, that depression questionnaires were just as highly correlated with anxiety questionnaires and neuroticism scales. This implies that depression scales actually measure depression to an average extent of about 30% (Paykel and Norton 1986). While interviews have the highest degree of external validity, questionnaires for the assessment of depression are typified by higher reliability. A degree of external validity and of reliability as high as this is obtainable with interview assessment techniques only after intensive training of the interviewer. Although questionnaire techniques have a high degree of apparent validity, the development of psychometric test procedures has still not yielded any single one that can be recommended unreservedly and has established itself as a standard.

4.4
Discussion of a Standard Test Battery for Depression

More than 100 diagnostic questionnaires for depression are now available (Bouman 1993; Katz et al. 1995; see also Chap. 6, Vol. 1, Part 2). Many diagnostic instruments for depression have not been adequately evaluated. The most commonly used techniques suffer from major defects. In recent years, therefore, there has been a discussion of which test procedures and instruments of assessment should be incorporated into a standard test battery for the diagnostic assessment of depression (Fydrich et al. 1996a; Katz et al. 1995). In view of the current state of research, this question can only be answered provisionally. The most important considerations for the development of a standard test battery are the quality of the instruments as psychometric tools, their clinical usefulness, and the confirmation of their value by experience. The underlying idea of using multiple measurements in depression is to capitalize on the advantages of each technique while lessening the effect of their individual disadvantages.

Katz et al. (1995) recommended a test battery that we, too, recommend here, albeit in somewhat modified form; we further suggest alternative instruments of measurement for each of those used in this battery. Either the SKID-I or the HAM-D can be used as an expert interview in the initial diagnostic phase. If the diagnosis is to be made according to ICD-10, the SCAN interview should be used. The IDS may be used as an alternative to the HAM-D. Among self-assessment instruments, the Symptom Checklist (SCL-90-R) and the BDI can be used at the beginning of treatment. For the measurement of changes, the BDI or, alternatively, the ADS, can be used at intervals of 2–4 weeks. The German-language *Depressivitäts-Skala* ("Depressivity Scale," D-S; von Zerssen 1976a) may also be used for this purpose; norm values of the D-S are available for a representative sample group. Assessment at the end of a period of treatment can be performed by renewed application of the SKID-I or the SCL-90-R. Furthermore, the visual analogue scale of Aitken (1969) can be used for daily assessment of depressivity, but, if this is done, circadian fluctuations must be taken into account by testing both in the morning and in the evening.

These recommendations seem not to be reflected in the customary manner of use of instruments for the assessment of depression, at least as it was until the mid-1980s. Thus Fähndrich et al. (1986) showed that the three instruments for depression most commonly used in German-language studies were the *Befindlichkeits-Skala* ("Well-Being Scale," Bf-S) of von Zerssen (1976b), the HAM-D, and the AMDP-System (AMDP 1995). The BDI and the visual analogue scales were applied in fewer than 5% of the studies. Diagnostic habits may well have changed in the last few years, although there are no more recent empirical studies to document this possibility. In larger research studies, the problem of the absence of a diagnostic standard is usually solved by the parallel application of several instruments on a single level of assessment, which, in turn, leads to new methodological problems.

5
Diagnostic Boundaries, Differential Diagnosis, and Comorbidity

It has been found that a high percentage of patients in whom a depressive disorder has been diagnosed also have other mental and physical illnesses. The percentage of depressed patients with comorbid illnesses is higher than that among patients with psychiatric disorders of other types (Moldin et al. 1993; Mezzich et al. 1990). Rohde et al. (1991) showed that 42% of unipolar depressives fulfill the criteria for one or more further DSM-III diagnoses. The most common of these were anxiety disorders (18%–20%) and substance dependencies (14%–20%). The frequency of physical illness in depressed patients is comparably high, though also relatively strongly influenced by the age of the group under study.

These comorbid disturbances are of great importance not only for diagnostic assessment, differential

diagnosis, and treatment planning, but also for the scientific understanding of mental and physical illnesses. Beyond classical psychopathological diagnosis, comorbidity research, which has by now established itself as a field of study in its own right (Feinstein 1970), has yielded findings of importance to differential diagnosis. These findings have been made in both epidemiological and clinical studies (Maser and Cloninger 1990; Robertson and Katona 1997).

Under the influence of descriptively conceived diagnostic systems such as ICD-10 and DSM-IV, the prevailing concept of diagnosis has evolved from a stratified concept to a concept of comorbidity. Several flowcharts and decision schemes for syndromal differential diagnosis have been developed (Saß et al. 1996; Linden 1979). Nonetheless, a complete clinical diagnostic assessment requires not only the identification of a syndrome, but also the development of an etiopathogenetic hypothesis (Seidenstücker and Baumann 1978) – and this is all the more so when several disorders are present simultaneously.

One of the most important problems regarding the drawing of diagnostic boundaries is the differentiation of affective disorders from each other, but their differentiation from other axis I disorders, such as schizoaffective and dementing disorders, may also be difficult. An increasing amount of attention is being devoted to the differential diagnosis of depressive disorders from personality disorders and organic illnesses. Alongside descriptive comorbidity research, more complex etiology-theoretic models have been developed in recent years to explain the coexistence of these disorders and their overlapping features (Klein et al. 1993; Mayou 1997). As yet, however, there is little empirical confirmation of these models, and little evidence to show in what sphere each of them is valid.

5.1 Differentiation Within the Affective Disorders

Reviews of this subject have been written by Maser et al. (1995), Maser and Cloninger (1990), and Clayton (Chap. 15, Vol. 3, Part 1). The dichotomy between unipolar and bipolar disorders, which was established in the wake of the studies by Leonhard et al. (1962), Winokur et al. (1969), Perris (1966), and Angst (1966), is now coming under criticism again, for several reasons. One problem is that it is not known which patients will later develop a bipolar disorder. The literature documents rates between 4% and 33% (Clayton 1981) and between 0% and 41% (Coryell and Winokur 1992), depending on the duration of observation. The risk of developing a bipolar disorder does not decrease even after numerous exclusively depressive phases have occurred (Angst 1978).

In contrast, Marneros et al. (1991) found that a syndrome change rarely occurred more than 5 years into the course of the illness. A further difficulty is that of retrospectively diagnosing manic and, especially, hypomanic phases, not least because these often do not cause the patients any suffering and may not be perceived at all as being pathological. The same may be said for hypomanic fluctuations after the termination of a depressive phase. Yet another differential diagnostic problem is posed by the existence of mixed states and mixed affects lying in between the depressive and manic syndromes (Kuhs and Tölle 1987; Cassidy et al. 1997).

One of the most difficult differential diagnoses is that of a depressive disorder from a dysthymic disorder. The question of whether we are dealing here with a bimodal distribution of two separable syndromes or, alternatively, with a continuum (Kendell and Gourlay 1970; Judd 1997) has not yet been definitively answered. While several studies on the subtyping of depression have revealed that a melancholic symptom pattern is characteristic of endogenous depression, syndromes of peripheral types are considerably less stable and less typical. Differential diagnosis is further complicated by the concept of depressive personality disorder (Hirschfeld 1994).

In addition to the psychopathological findings, the course of the disorder is a further, crucial differential diagnostic criterion. Here, too, consideration must be given to aspects of comorbidity. The concept of "double depression" refers to a course in which one or more episodes of major depression are superimposed on a dysthymic disorder (Keller and Shapiro 1982). In the latter study, dysthymia was diagnosed in 26% of patients who underwent outpatient and then inpatient treatment for major depression. In the Epidemiological Catchment Area Study, patients with dysthymia were found to have a comorbidity with major depression in almost 40% of cases. Longitudinal studies have revealed that 90% of individuals with a dysthymic disorder eventually develop major depression (Akiskal et al. 1981; Lewinsohn et al. 1991). The opposite sequence, i.e. the development of dysthymia after major depression, is rare.

A further topic of increasing importance is the differentiation of a depressive episode from subsyndromal or subdiagnostic depressive disorders, primarily as they are conceived of in DSM-IV (APA 1994; see Chap. 16, Vol. 3, Part 1). According to Angst and Merikangas (1997), these include recurrent brief depression, minor depression, and "subsyndromal depressive symptomatology." It was shown that subsyndromal forms of depression are common and cause significant impairment. They are a risk factor for the development of major depression as well as a phase in the disease course of patients with diagnosed major depression (Helmchen et al. 1996; Judd 1997). There is

now debate over whether these findings should be interpreted as reflecting the existence of a spectrum of depressive disorders (Winokur 1979). There is also a question as to whether depression with psychotic features must be granted a special position within this spectrum (Coryell 1997).

Symptoms of anxiety are very common in depressive disorders and are not uncommonly severe enough to merit designation as a disorder in their own right (Stavrakaki and Vargo 1986). The odds ratio is a measure of the degree to which anxiety disorder and depressive disorder occur together more often than would be predicted by chance. The Zurich study yielded the following odds ratios for disorders in association with major depression: for agoraphobia, 2.8; for panic disorders, 1.9; and for generalized anxiety disorder, 4.2 (Angst 1993). The values reported by Boyd et al. (1984) were considerably higher. Rohde et al. (1991) found an anxiety disorder in 20% of the depressed patients they studied, while Sanderson et al. (1990) arrived at the figure of 42%. From the point of view of temporal sequence, it seems to be more common for a patient with an anxiety disorder to develop superimposed major depression than for the reverse to occur (Angst et al. 1990). Nonetheless, the latter occurrence was reported by Sanderson et al. (1990). It should be recalled that instruments of assessment never measure depressivity or manifestations of anxiety alone; rather, such instruments are confounded with one another and have a high degree of statistical correlation.

Kuhs (1990) found that melancholic and neurotic-depressive patients experience anxiety differently. Qualitative analysis revealed that patients with endogenous depression suffered more from everyday anxieties, while situational anxieties and anxieties related to interpersonal problems predominated in neurotic depressives, with a broader spectrum of content.

A mixed disorder composed of both anxiety of depression was introduced as a new diagnostic category in ICD-10. This disorder may be diagnosed in the presence of manifestations belonging to both groups, even when the diagnostic criteria for a depressive episode or for an anxiety disorder are not fulfilled (Sartorius and Üstün 1995). The practical value of this additional diagnostic category, alongside other types of subsyndromal disorder, is a topic of current research (Wittchen and Essau 1993; Boulenger and Lavallée 1993; Liebowitz 1993).

5.2 Differentiation from Other Psychiatric Disorders

The differentiation of depressive disorder from the schizoaffective psychoses and schizophrenias is very important. The differential diagnosis of depressive disorder from the dementing diseases is also of great practical relevance. In addition, depressive disorders often appear together with alcohol and drug dependency and with Parkinson's disease (Maser et al. 1995).

Many patients (15%–57%) with schizophrenic disorders also suffer from depressive disorders (Maser et al. 1995). The risk of developing major depression is elevated by a factor of almost 30 in schizophrenic patients. Not uncommonly, post-remission depression develops after the end of the schizophrenic phase. According to the findings of Marneros et al. (1991), 6% of patients who initially present with major depression of melancholic type go on to develop a schizoaffective psychosis.

As for the differential diagnosis of depression and the dementing diseases (see also Chap. 8, Vol. 2, Part 1), epidemiological studies have shown that depression is the second most common mental illness in old age, after dementia. A problem of differential diagnosis regularly arises in clinical practice because of the similarity of the manifestations of depression and dementia. A major difference between them is that the cognitive impairment associated with depression, which has been given the designation "pseudodementia," is not associated with morphological changes and regresses after the depressive manifestations have subsided. Pseudodementia remains a controversial concept (Zimmer and Lauter 1984) despite a number of suggestions for the definition of diagnostic criteria (Rabins et al. 1984). Clinical diagnosis must take multiple criteria of prior history, psychiatric exploration, neuropsychological findings, and the results of functional imaging studies into account (Kurz 1997).

It has been found repeatedly that incipient dementia imparts an elevated risk for depression. There are conflicting findings on the question of whether, conversely, a preexisting depression predisposes to the development of a dementing illness. Devanand et al. (1996) were able to show such an effect, but Ernst and Angst (1995) found no elevation of the risk of dementia in elderly depressed patients. Further longitudinal studies taking account of specific etiological and risk factors are needed to determine whether depression and dementia are comorbid disorders in the strict sense, or whether a more complex relationship exists between them.

5.3 Depression and Personality Disorders

The differential diagnosis of the depressive disorders must also take personality disorders into account (Millon and Kotik-Harper 1995). Comorbidity studies have revealed the presence of a personality disorder in

30%–70% of patients with major depression (Farmer and Nelson-Gray 1990). Fydrich et al. (1996b) cited studies with comorbidity rates of 35%–88%. Figures obtained by the use of questionnaires were somewhat higher than those obtained by diagnostic interviews. At least half of all patients with major depression have an accompanying personality disorder. The most commonly diagnosed personality disorders are the insecure (anxious-avoidant), dependent, and compulsive personality disorders. A more detailed discussion of the relationship of depression to individual personality disorders is found in Millon and Kotik-Harper (1995).

The reintroduction of the concept of depressive personality disorder in the research supplement to DSM-IV led to new difficulties for differential diagnosis (Philipps et al. 1990; Sherman 1995). Although theoretical explanations have been given, the relationships between depressive disorder, dysthymia, and depressive personality disorder have not yet been adequately clarified (Hirschfeld 1994). Differential diagnosis is particularly difficult in chronic cases (Shea and Hirschfeld 1996). There are extremely divergent explanatory models for the relationship between personality and depression. The most important models, including the predisposition, complication, coeffect, spectrum, and overlapping-symptom models, and the empirical support for each, are discussed by Klein et al. (1993).

The comorbidity of subaffective personality disorders with depressive manifestations and disorders has been intensively studied in recent years (Herpertz et al. 1996). This spectrum also includes studies of "typus melancholicus," a personality configuration often found in patients with depressive disorder (Mundt et al. 1997). Pfohl et al. (1991) found that depressive patients with personality disorders differed from those without by their earlier age of disease onset, lesser degree of social support, greater psychosocial stress, and worse response to treatment. These findings led to the development of initial attempts at differential psychotherapeutic treatment strategies (Mundt 1996).

5.4 Differentiation from Organic Disorders

Physically ill individuals suffer from depressive disorders at an elevated frequency (Robertson and Katona 1997; Lang 1991). Conversely, depressive patients are more likely to have physical illnesses (Stevens et al. 1995). Lobo and Campos (1997), in their study of patients in the primary medical care system, reported on rates of major depression ranging from 4.8% to 13.5%. Rodin et al. (1991) found an overall rate of 22% and a still higher rate for patients with neurological disorders. When the frequency of depressive manifestations, rather than of depression, is measured, it is found to be even higher, with reported rates between 20% and 83% (Stevens et al. 1995). Similar results on the frequency of depressive disorders in hospitalized patients were reported by Arolt (1997). Arolt et al. (1995) found that 4.1% of surgical and internal medical patients had at least one depressive episode.

Despite their common occurrence, depressive disorders in the physically ill are often overlooked (Lobo and Campos 1997). Thus Ormel et al. (1991) found that general practitioners recognized the presence of depressive disorders and anxiety disorders in their physically ill patients in only 47% of cases. Coyne et al. (1995) reported similar findings.

Comorbidity research regarding depression and physical illness must be seen in the context of the traditional conceptions of primary and secondary depression (Feighner et al. 1972). In recent years, this conceptual area has been extended by the proposal of increasingly complex models of the relationship between these two types of disorders (Moffic and Paykel 1975; Lang 1991). The presence of a physical illness is held to be an important predictor of an unfavorable course of the depressive disorder and of its chronification (Angst 1988b; Zimmer 1991). In this context, F. Post (1962) formulated the hypothesis of age-dependent vulnerability, according to which younger individuals develop depression because of their genetic predisposition and personality factors, while elderly persons require an additional physical illness, or a disorder of the brain, before a depressive phase can be triggered, often on a subsyndromal level.

It can also be difficult to differentiate an organically caused depressive disorder from another form of comorbidity. Such relationships may be quite complex in individual cases. Several studies have demonstrated that depressive patients with and without accompanying physical illnesses have different patterns of disease manifestations and clinical features (Berrios and Samuel 1987; Clarke et al. 1983).

Somatized or occult depression poses a special diagnostic problem. Bridges and Goldberg (1985) offered a definition of somatized depression. Lobo et al. (1996) found this type of depressive disorder in 15% of patients with a depressive episode. Nonetheless, the conceptual problems of differential diagnosis in this area have not yet been satisfactorily solved.

Somatic illnesses are often associated with a depressive disorder, but subsyndromal depression occurs even more frequently, mostly in the elderly. Several studies have revealed that depression is correlated not with the presence of illness per se, but with the resulting limitation of everyday activities. Likewise, it is not old age itself that is a risk factor for the development of depression, but rather the age-associated

risk of having one's everyday activities limited by illness (Helmchen et al. 1996; Zeiss et al. 1996).

Such problems regarding the drawing of diagnostic boundaries are highly relevant not only to differential diagnosis in clinical practice, but also to the further refinement of scientific concepts of classification and etiology. Research findings concerning the frequency of disorders occurring together are an important contribution in this direction and also serve as a point of departure for the further development of models concerning the relationships among these disorders and for the empirical study of these models' applicability. An appreciation of the significance of comorbid disorders in depression is very important for the development of new therapeutic strategies.

6 Disease Course and Prognostic Factors

6.1 Historic and Terminological Aspects of Research on Disease Course

Kraepelin (1913) developed the model of manic-depressive illness as a disorder with a phasic and remitting course. Bleuler (1916) and Schneider (1932) adopted Kraepelin's conception that depressive disorder had a relatively favorable prognosis. According to Paykel (1994), research on the course of depression was dominated by this idea and, at first, by therapeutic optimism, from the 1950s until the 1970s. Non-remitting depressive manifestations were viewed during this period as characterologic deviations of personality. It was only in the late 1970s that the findings of longitudinal studies of disease course led to the realization that depressive disorders had a less favorable course than previously assumed (Angst 1987). The prospective clinical and epidemiologic studies of disease course carried out in recent years, some of them on a large scale, confirmed and refined this new appraisal. Research on disease course has concentrated in recent years on the performance of prospective studies, the definition of uniform standards for use in research, and the study of the problem of unfavorable courses, chronic depressive states, prodromal manifestations, and milder forms of depression.

The first large-scale studies of disease course were carried out in Scandinavia in the 1960s (Astrup et al. 1959; Lundquist 1945; Perris 1966; Stenstedt 1952), in Switzerland by Kinkelin (1954) and Angst (1966), and in the United States by Winokur et al. (1969). The main finding of these studies was that unipolar and bipolar affective illnesses have different course dynamics. This finding, along with the results of genetic studies of the affective disorders (Angst 1966; Perris 1966; Zerbin-Rüdin 1969), led to the abandonment of Kraepelin's unitary conception of manic-depressive illness. This found its expression in the St. Louis Criteria (Feighner et al. 1972) and the Research Diagnostic Criteria (RDC; Spitzer et al. 1978). The second important consequence of these studies was a revision of the previously optimistic view of the course of the affective disorders, which turned out to be marked by frequent relapses, chronification, and suicidal outcomes much more commonly than had been assumed.

Although a large number of studies have been performed on the course of the depressive disorders, it is difficult to judge their results collectively, because of the lack of uniformity in the definition of terms used to characterize disease course (Angst 1987). For this reason, efforts have been made in recent years to establish uniform, operationally defined terms for use in research on the course of depressive disorders. Prien et al. (1991) discuss several different operational criteria for the definition of terms relating to disease course and treatment outcome in major depression.

Frank et al. (1991) recommended specific operationalized definitions of the most important terms used to describe disease course. They drew distinctions between remission, recovery, relapse, and recurrence of illness. These terms correspond to the division of forms of treatment into acute, maintenance, and chronic treatment (Thase 1992). Remission was defined as a state of partial or complete improvement of the depressive manifestations. Recovery was taken to imply a complete remission over a longer period of time (2–6 months, depending on the particular criterion used). Frank et al. (1991) criticized the absence of a distinction between remission and recovery in most studies. Relapse was defined as the appearance of depressive manifestations during a period of remission. Recurrence of illness, finally, can occur only after a patient has recovered. Chronic depression is a depressive episode that persists over the entire relevant period of observation (generally at least 2 years).

It is impossible to draw such distinctions from the reported results of most of the earlier studies of disease course. Von Riso et al. (1997) proposed operational definitions of these terms used to describe disease course based on the use of clinical rating scales and well-defined temporal intervals. This study yielded evidence for the predictive validity of such criteria. The definitions presented by Frank et al. (1991) were an important contribution to the unification of terminology in research on the course of depressive disorders and made it possible to compare results obtained across studies.

6.2 Long-Term Outcome of Depression

Piccinelli and Wilkinson (1994) performed a meta-analysis of the then available studies on the course of depression on the basis of the definitions provided by Frank et al. (1991). They analyzed 51 studies published from 1979 to 1992 and classified them by the length of clinical observation in each: 6 months, 1 year, 2–5 years, and more than 10 years. In data obtained as a weighted average from the studies involving more than 10 years of observation, recovery was found to have occurred during the period of observation in 24% of patients, while a course with recurrences occurred in 76%. Chronic depression was found in an average of 12% of patients studied (*note:* the use of weighted averages may result in percentages that sum to more than 100%). There was a high correlation between the length of the period of observation and the number of disease recurrences. On the other hand, there was no statistically significant relationship between the length of the period of observation and the number of patients developing chronic depression. These calculated frequencies of the individual types of disease course in depressive disorder are largely in agreement with the results reported by Angst (1987), M.B. Keller (1994), and Judd (1997).

Data concerning the frequency of unipolar depressive disorders consisting of a single episode are inconsistent and heavily dependent on the sample populations and periods of observation used. Angst (1990) concluded from his review of the literature on epidemiologic studies that an average of 50% of all individuals with depression have only a single depressive episode. Coryell and Winokur (1992) found a monophasic course in 5%–60% of patients in the studies of long-term course reviewed by them; however, in an epidemiologic sample consisting of very young individuals (age 20), Angst (1990) found a rate of only 22% of monophasic courses over a period of 10 years. Wittchen and von Zerssen (1987) reported a rate of 28% of monophasic courses in depressive patients who had undergone inpatient treatment.

A further question concerns the frequency of courses with relapse, as well as the chronification of depressive disorders. According to Angst (1990), 20% of cases of depression in the general population have a relapsing course. This is in marked distinction to the 80% frequency of relapsing courses reported in patients who had undergone inpatient treatment for endogenous depression, after periods of observation of 13–17 years. A total of 20% of patients had two phases, and 60% had three or more (Angst and Frey 1977). The average number of episodes that a patient with depression suffers during his or her lifetime is four (Judd 1997). With regard to relapse dynamics, it was found that the period after discharge from inpatient psychiatric treatment is particularly fraught with risk. A total of 25% of these patients have a relapse in the first 3 months after discharge, 33% within 1 year, and 73% over the next 8 years (M.B. Keller et al. 1983). The National Institute of Mental Health (NIMH-NIH 1985) estimates, on the basis of the available studies, that 50% of patients suffer a relapse within 2 years. Similar results on the prediction of relapses in depression were obtained in the Heidelberg Study (Mundt et al. 1998a).

The descriptive parameters used in longitudinal studies of the depressive disorders to characterize the course of the disease include the age of onset, the number and duration of phases, the duration of the asymptomatic interval, and the duration of the cycle (i.e. the interval between the onset of two consecutive phases).

A depressive disorder may appear at any age, even in childhood (Speier et al. 1995). Although a median age of onset of 30–40 years was found in earlier studies (Lewinsohn et al. 1986; Angst 1987), more recent studies have moved the apparent peak of the age distribution of disease onset to between 20 and 30 years (Kessler et al. 1994). The distribution of ages of onset is skewed to the left, i.e. the risk of developing a depressive disorder declines steadily with age. Knäuper and Wittchen (1995) also found that younger age cohorts have a significantly elevated risk of developing depressive disorders, and a less pronounced difference of incidence between the sexes, than older age cohorts. The age of earliest manifestations of the disease does not differ between the sexes (Lewinsohn et al. 1986). The bimodal distribution of the age of onset of disease postulated by Angst (1987) was confirmed by the Baltimore Epidemiologic Catchment Area Follow-up Study (Eaton et al. 1997), which revealed a smaller peak between 50 and 60 years of age. The hypothesis that depressive disorders of later onset have a worse prognosis (Angst 1987) was not confirmed in more recent studies (Hinrichsen 1992). Nonetheless, the interpretation of findings is complicated here by the problem of incomparability of sample groups (Maj 1994).

Earlier authors estimated the average duration of depressive episodes as between 3 and 6 months (Pilcz 1901; Ziehen 1896); Kraepelin's figure (1913) was between 6 and 8 months. Recent studies, practically all of which reveal a median episode duration of approximately 5 months (Angst 1987; Solomon et al. 1997), are in accordance with these estimates. This means that modern pharmacotherapy has not led to a shorter duration of episodes, even though it has led to marked alleviation and suppression of depressive manifestations. Graphs of the number of patients in remission over time are typically logarithmic in shape,

i.e. remission becomes increasingly unlikely the longer depressive manifestations have been present (Coryell and Winokur 1992).

M.B. Keller et al. (1992) found that 54% of the patients they studied recovered within 6 months, 70% within 1 year, and 88% within 5 years. The available data are as yet insufficient to determine whether the duration of phases is intraindividually stable across episodes in patients suffering from multiple phases without chronification. While Angst (1987), Hautzinger (1997), and Coryell et al. (1994), among other authors, postulated such stability, the studies conducted by Maj et al. (1992) and Solomon et al. (1997) revealed no consistent relationship between the duration of phases of individual patients. An epidemiological study revealed a median duration of 3 months for the first episode and of only 2 months for subsequent episodes (Eaton et al. 1997).

Cycles are 4.5–5 years long on average (Angst 1986). It cannot be definitively stated whether cycles become shorter after several phases have occurred. It has been postulated that a logarithmic relationship obtains, whereby the second interval is much shorter than the first, but the shortening of subsequent intervals is much slower. Several studies, however, have failed to show any regular pattern of this kind (Cutler and Post 1982; Solomon et al. 1997).

It was primarily the findings of recent, large-scale epidemiologic studies that led to the revision of previous ideas about several descriptive features of the course of depression. These studies dealt with representative population samples and not, as in previous studies, with samples of patients who had presented for psychiatric treatment. The inclusion of milder and hitherto untreated cases of depression led to the correction and refinement of several previous conclusions. The mean duration of episodes is thus shorter, and monophasic courses are more common, than previously assumed. On the other hand, chronic depression is also more common than once thought.

A question that has received much attention recently is that of how frequently a chronic course of depression may be expected. Chronic depression appears in DSM-IV(APA 1994) under the category of "chronic major depression." A chronic course is said to obtain when the criteria for major depression are fulfilled over a period of 2 years. Older reviews stated that the frequency of chronic courses lies between 12% and 15% (E. Robins and Guze 1972; Weissman and Klerman 1977). Some of the more recent studies, however, have revealed higher rates, on the order of 25% (Angst 1990; M.B. Keller et al. 1986). The frequency of chronic courses in hospital-treated depression is 21% for patients with endogenous depression, according to the studies conducted by Wittchen and von Zerssen (1987), and 30% for patients with neurotic depression (Bronisch et al. 1985). Marneros et al. (1991) found that one third of the patients with affective psychoses in the Cologne Study underwent a lasting change to either a chronified subdepressive syndrome or a mild asthenic insufficiency syndrome. Although the treatment of depressive disorders has significantly improved, the percentage of chronic courses appears to have remained relatively stable over several decades (Paykel 1994).

The long-held assumption that chronic depression largely remains on the intermediately severe symptomatic level of a dysthymia must now be regarded as disproved. A total of 22% of patients with an episode of major depression without preceding dysthymia were found to have persistent manifestations at the level of severity of major depression over an interval of 2 years (M.B. Keller et al. 1983). The chronification of depressive manifestations does not represent a residual state in which no further improvement can be expected; on the contrary, several recent studies have shown that recovery is particularly likely to occur after a long symptomatic period (Keller and Shapiro 1982). The reported figures for complete remission in severe chronic cases vary between 27% and 43% (Gonzales et al. 1985; Keller and Lavori 1984). The cause of chronification seems to be multifactorial; empirical studies on this question are lacking. There are indications, however, that a comorbid mental disorder is associated with a higher risk of chronification (Zimmer 1991).

Alongside chronification, suicide is a common and feared outcome of depressive disorders. Individuals with depression are considered to be the leading risk group for suicidal behavior. It is estimated that 56% of depressed patients attempt suicide at least once (Goodwin and Jamison 1990). The Cologne Study found suicidal manifestations in 30% of the episodes of patients with melancholic manifestations; suicidal manifestations were less common in married and employed patients (Marneros et al. 1991). Over the entire course of illness, almost 60% of the patients had suicidal manifestations, 35% had suicidal thoughts and intentions, and 20% attempted suicide at least once. The probability of occurrence of suicidal manifestations was higher in women and in patients with a higher number and frequency of episodes (Marneros et al. 1991).

Even today, 10%–15% of severely depressed patients die by suicide (Angst 1980; Miles 1977; Winokur and Tsuang 1975). Guze and Robins (1970), in their review of the literature, found that 12%–19% of deceased patients who had suffered from an affective disorder had committed suicide. Patients with affective disorders thus have a risk of suicide 30 times higher than that of the general population (Guze and Robins 1970). The period of greatest risk for suicide is the first year after discharge from inpatient psychiatric treatment

(Fawcett et al. 1987, 1990). Avery and Winokur (1978) found that two thirds of suicides in previously hospitalized depressive patients occurred within 8 months of discharge.

Risk factors for suicide have been identified in several studies, including hopelessness (Beck 1986), feelings of worthlessness and guilt (Barraclough and Pallis 1975; Hole 1973), delusional manifestations, and sleep disturbances (Barraclough and Pallis 1975). A particularly high risk of suicide was found in depressed patients who simultaneously suffer from anxiety disorders (Rudd et al. 1993). A small number of studies are available regarding possible differences between depressive patients who do and do not attempt suicide (Bronisch and Hecht 1987; Sonneck et al. 1976; Wolfersdorf et al. 1996). These studies show differences in the severity of depressive manifestations and in the presence of relationship problems, threats of separation, and subjectively experienced stress in the workplace (Wolfersdorf et al. 1996). Angst (1987) still held that long-term treatment had no effect on the suicide rate of depressed patients, but more recent longitudinal studies have shown that long-term treatment with lithium can significantly reduce suicide-related mortality in patients with affective disorders (Coppen et al. 1991; Ahrens et al. 1995).

6.3 Incipient Depression

While research on the long-term course and ultimate outcome of depression has a long history, the study of incipient depression and prodromal states is still only in its initial stages. This area of research will become more important, because the early recognition of depressive disorders is a precondition for preventive interventions. The distinction between prodromal manifestations and indicators of vulnerability must be borne in mind (Mundt 1998). Prodromal manifestations occur immediately before the beginning of the depressive episode, while indicators of vulnerability, according to prevailing models (Nuechterlein 1987; Zubin and Steinhauer 1981), are present long before and persist in the interval between depressive episodes. It remains unclear at present whether prodromal manifestations are an intensification of these vulnerability traits or are related to them in some other way. Earlier authors worked out a characteristic sequence of precursor manifestations (Mayer-Gross et al. 1969); more recent empirical studies have added further to our understanding. In what follows, we will discuss findings concerning the prodromal manifestations of depressive disorders. More information on indicators of vulnerability can be found in Chaps. 18–21 (Vol. 3, Part 1).

The prodromal syndrome is understood to be that state in which individual manifestations of a mental illness are present, but the criteria for the presence of a depressive disorder are not fulfilled (Frank et al. 1991). In their review of the literature, Klosterkötter and Steinmeyer (1996) estimated that one third of individuals with depression have prodromal manifestations. The most common of these are pain syndromes, adynamia, central-vegetative disorders, generalized anxieties or phobias, body dysesthesias, easy fatigability, and disorders of sleep and appetite. The wide divergences among studies in the estimated frequency of prodromal manifestations among depressed patients are the result of the absence of a uniform, operationalized definition.

Divergent results have also been obtained for the duration of prodromal manifestations, probably also because of the use of variable criteria in determining their presence. The study by Carlson and Goodwin (1973) found that they lasted from less than 2 to more than 4 weeks; another study gave the mean duration of prodromal manifestations of depression as just over 2 years (Hopkins 1965; Young and Grabler 1985). The mean duration of prodromal manifestations appears to be significantly higher in mania and in schizophrenia than in depression (Carlson and Goodwin 1973; Molnar et al. 1988). The prodromal manifestations of schizophrenic, schizoaffective, and affective psychoses have many common features. These findings have been cited in support of the continuity hypothesis of psychotic illnesses (Angst and Scharfetter 1990; Crow 1986).

A number of studies indicate that prodromal manifestations have both a high interindividual variability and a high intraindividual consistency (Fava et al. 1985; Fava and Kellner 1991; Molnar et al. 1988; Paykel et al. 1976). It remains unclear whether such a relationship also obtains between prodromal and residual manifestations (Fava and Kellner 1991).

Almost 2000 subjects were studied in the long term in the Baltimore Epidemiologic Catchment Area Program Study (Eaton et al. 1997). Almost all of the 71 patients with newly incident major depression had had prodromal manifestations. The individual manifestations had been present for variable periods before the onset of illness; overall, they had been present for a median time of approximately 1 year, but the median period was significantly higher – up to 5 years – for loss of appetite, suicidal thoughts, and dysphoria. The longer duration in comparison to earlier studies is presumably the result of the operational definition of the onset of the prodromal syndrome as the time of occurrence of the first psychiatric manifestation, as assessed by the Diagnostic Interview Schedule (DIS; L.N. Robins et al. 1981). A close relationship between precursor manifestations and the onset of a depressive

episode was found for diminished sexual interest, feelings of worthlessness and guilt, a brooding tendency, and sleep disturbances (Dryman and Eaton 1991; Eaton et al. 1995).

Horwarth et al. (1992) showed, in an epidemiological study, that 50% of newly incident cases of major depression had had early depressive manifestations. Depressive manifestations were found in one quarter of all participants in this study over the course of their lives; most of them had had these precursor manifestations without ever developing major depression. The responsible factors have not yet been identified. The hypothesis has been advanced that the experience of such mild depressive phases is a kind of training in self-directed coping and may thus have a preventive effect (Hautzinger 1997).

The conflicting nature of these findings makes it clear that the concept of a prodromal syndrome is in need of clarification and uniform definition. In the affective disorders, in particular, a problem arises in the differentiation of prodromes from the disorder itself. Future prospective studies must clarify whether this categorization is truly helpful, or whether it would be more reasonable to assume a continuity model for the depressive disorders. A particular methodological problem arises from the fact that retrospective studies of patients or prospective studies of populations at risk may yield valid high-risk profiles for depression but, because of their lack of specificity, remain of little use for primary prevention in practice. The grouping of coarser bundles of factors as risk constellations thus seems to be more promising than the use of prodromes alone (see Mundt 1998). Research in this area proceeds in the hope that the early recognition of depression will lead to the more effective application of primary and secondary preventive treatment strategies.

6.4 Predictors of Disease Course

The large degree of heterogeneity in the course of the depressive disorders has led to an intensive search for favorable and unfavorable predictive factors – unfavorable meaning those that predispose to high rates of relapse, chronification of the disorder, and suicide. Many studies have dealt primarily with clinical and sociodemographic variables and, later, with psychosocial variables in relation to the onset and course of depressive disorders. The preceding clinical course has been considered to be the most important factor for the prognostication of the further course of the disorder (Angst 1988a).

Many studies have been performed with the purpose of making the course of illness easier to predict on the basis of multiple factors. Angst (1987) concluded his discussion of predictors of the course of depression by stating that the identification of risk factors, and the improvement of prognostication this would bring about, were still unfulfilled goals at that time, and that the question had not yet been adequately studied. In recent years, however, many relevant studies have been performed. Review articles on predictors of the course of depression not uncommonly contain tables listing more than 100 such factors, each one characterized by the strength of the supporting empirical evidence (Kaelber et al. 1995).

The numerous review articles on prognostic factors in depression are also confusing, because the analysis has not been carried out in a systematic fashion. There must be systematization, at the very least, with respect to the course of illness. A distinction must be made, for instance, between predictors, in the sense of risk factors, for the first appearance of depression and predictors of the time at which recovery or relapse will occur; the latter must, in turn, be distinguished from predictors of chronification. A second aspect of systematic analysis is the classification of prognostic factors according to the period of time over which they are operative. A distinction is usually drawn between short-term predictors, which apply over a time interval of 1–2 years, and long-term predictors. The type of treatment must also be taken into account: it must be made clear whether predictors are discussed in connection with the natural course of illness or with a particular type of treatment.

A further reason for caution in the interpretation of the findings of these studies is that we know from several other studies that depressive disorders often go unrecognized and, when they are recognized, are often not treated. Most of the research findings in this area were made with respect to samples of hospitalized depressed patients. Yet another difficulty arises from the fact that it is not made clear in most publications whether data are provided for all of the variables that were studied as potential predictors or only for those where positive findings were made. As the published findings are almost exclusively positive, publication bias must be suspected. Furthermore, explicit hypotheses for investigation are not stated in any of these studies. The purely exploratory research strategy that this suggests is not compatible with present standards for psychiatric research.

A number of sociodemographic, clinical, personality-psychological, and social factors have been studied as possible risk factors for the unfavorable course of depressive disorders. The importance of illness-specific factors is universally accepted. Angst (1988a,b) concluded that the previous course of depression is the best predictor of its further course. In addition to these illness-specific factors, the importance of psychosocial

factors such as life events, personality factors, and relationship variables was also demonstrated; but the results obtained by Paykel et al. (1996) provoked a new debate about the significance of psychosocial predictor variables for the course of depressive disorders. In their large-scale study, Paykel et al. (1996) showed that illness-specific prognostic factors have significant predictive value, but they did not find any further improvement of predictive value from the consideration of psychosocial traits. Similar findings had already been made long before by Angst and Weis (1967) by means of multivariate analysis of individual predictors. All of these findings are compatible with either of two hypotheses with regard to predictors of depressive disorder. It remains to be clarified, first, whether different predictive factors are operative for milder and more severe cases of depression; and, second, whether there are different predictive factors for the first, second, and later appearances of the illness (R.M. Post 1992).

Maj (1994) attempted to give structure to the findings regarding predictors of disease course in depression by methodological assessment of the design of the studies in which these findings had been made. An ideal predictor study, according to Maj (1994), is one which deals with a specific depressive disorder, ascertained in operationalized fashion by means of a structured interview. The study design should be prospective, and possible predictors should be assessed with standard instruments. Dropouts from the study should be reported, and no systematic selection effects should be present. Furthermore, the study must define clearly what is meant by remission, both with regard to the severity and number of depressive manifestations, and with regard to the duration of the required asymptomatic interval. Relevant information must be provided about treatments carried out during the period of investigation. Significant predictors must be shown to be free of possible confounding effects. For the analysis of predictors of recurrence, Maj (1994) further requires a clear definition of recurrence, a distinction between recurrence and relapse, and the exclusion of patients who developed bipolar illness in the course of the study.

Such a meta-analysis of the findings regarding the prediction of relapses can never be better than the original publications on which it is based and is, in addition, even more subject to the problem of publication bias. Significant predictors are often reported in published articles without mention of which putative predictors were found not to be significant. This inevitably leads to an overestimation of significant predictors. Future studies on the course of illness must, therefore, conform to present standards of research by testing explicitly stated hypotheses and by providing data on all of the variables studied.

In his review, Maj (1994) stated that the following are documented predictors of a longer time to recovery: the duration of the disease before the beginning of the study and before the beginning of treatment (M.B. Keller et al. 1986), the severity of depressive manifestations, and comorbid psychiatric disorders, particularly dysthymia (M.B. Keller et al. 1992; Wells et al. 1992). Sociodemographic predictors of the time to recovery include old age, female sex, and low family income. Neuroticism is the personality trait most clearly demonstrated to be a predictor. Recent studies have shown that an accompanying personality disorder is predictive of delayed recovery. Multiple studies have revealed an influence of life events on disease course. Partnership and family dysfunctionality is a further predictor. In the study by Maj et al. (1992), patients with three or more episodes had an elevated risk of relapse; in the Heidelberg study, patients with a single previous episode had a risk of relapse comparable to that of patients with multiple previous episodes (Mundt et al. 1998a).

The predictors for relapse of major depression overlap with those for recovery; the most important predictive feature of the disease itself seems to be the number of previous depressive episodes. A large body of evidence suggests that different predictors are operative for initial disease phases and for later recurrences. Thus, F. Keller et al. (1984) reported that there was a relationship between old age and recurrence only in patients in the initial phase of the illness. The findings concerning the influence of life events, social support, and interpersonal relationships are heterogeneous. Kronmüller and Mundt (1999), in a review article, pointed out that half of all studies supported the hypothesis of a predictive value of the concept of "expressed emotion" in depressed patients, while the other half did not. This finding contrasts with findings in bipolar patients, among whom the expressed emotion index has been demonstrated to be predictive for the course of the disorder by all of the studies performed on the question.

An almost totally neglected issue in predictor studies is the consideration of the treatment of depression as a moderating variable. Studies of disease course are almost always conceived exclusively in relation to features of the patients, and of their illnesses, as potential predictive factors. By analogy with the suggested model of Kiesler (1969) for research in psychotherapy, the question should rather be: What factors predict the further course of illness, in which patients, with what disease characteristics, and under what kinds of treatment? This is all the more important at present, now that we have a large number of treatment strategies for depression that have been demonstrated to be effective. The empirical findings in this area are largely of a global nature: continuous

treatment with antidepressants at adequate doses is associated with more rapid recovery and less frequent relapse. The duration before treatment with antidepressants accounts for almost half of the variance in the duration of episodes (Scott et al. 1992). There are hardly any available research findings to date on the influence of psychotherapeutic treatment on predictors of long-term course (Elkin 1994).

More recent findings, in addition to those dealt with by Maj (1994), include primarily those of the Cambridge Study (Paykel et al. 1996), the Heidelberg Study on the prediction of relapses in depression (Mundt et al. 1998a), and the NIMH multicenter study (Solomon et al. 1997). The Heidelberg Study identified numerous predictors for the 1- and 2-year course of depression. Half of the patients studied experienced a relapse within 2 years. Patients in the initial phase of the illness had a significantly more favorable course than those with one or more previous episodes. In addition, the severity of depression at the time of discharge was a further important predictor. Among personality features, neuroticism was shown to be an unfavorable predictor of disease course. A "typus melancholicus" personality structure (Tellenbach 1961) was associated with a better 2-year course. In contrast to the findings of Paykel et al. (1996), the course-predictive significance of life events was confirmed (Reck et al. 1999).

It was also possible to identify interpersonal traits of relationships with partners as predictors of relapse (Fiedler et al. 1998a,b). With the aid of multivariate weighting of individual predictors, it was shown that disease-specific and sociodemographic features indeed accounted for the largest fraction of the variance in the course of illness, but personality factors and features of interpersonal behavior accounted for a further portion (Backenstrass 1998; Mundt et al. 1998a). Marneros et al. (1991), in the Cologne Study, found that the previous course of illness and personality traits were the most important predictors of the further course of illness and the social adaptation of individuals with depression. These findings contrast with those of the studies by Paykel et al. (1996), Andrew et al. (1993), and Solomon et al. (1997), which, with very similar study designs, confirmed the influence of disease-specific features on the course of illness, but not that of psychosocial features.

There is thus a relatively broad consensus on the prognostic significance of disease-specific features. While it is agreed that psychosocial features also play a role, their importance for individual subgroups of patients with depressive disorders is subject to debate. Many differential findings of this nature have been obtained in recent years, but no unified picture has yet been constructed (Mundt et al. 1996). The further progress of research on the course of depression seems to depend both on the performance of hypothesis-based studies (an essential precondition) and on the investigation of differential effects on disease course. Further perspectives for research in this area may be derived from the analysis of the relationship of individual predictors to each other and their possible grouping into provocative factors, vulnerability factors, and symptom-determining factors, as suggested by Brown and Harris (1978), and from the question of whether latent biological susceptibility factors also play a role in the course of illness (R.M. Post 1992). The successful integration and application of these perspectives in future research studies will advance our understanding of the depressive disorders and their course.

P.J. Clayton

Clinical Picture and Course of Bipolar Affective Disorder

1 Definition

Bipolar I affective disorder is a disorder of mood characterized by periods of mania and depression. During the manic phase, the patient feels elated, euphoric, ecstatic, and/or irritable, along with associated symptoms of pressured speech, racing thoughts, distractibility, agitation or overactivity, decreased need for sleep, inflated self-esteem and grandiosity, and excessive involvement in pleasurable activities. In order to meet criteria for mania, the patient must have this mood and symptoms for at least 1 week. During the depressive phase, the patient feels depressed, sad, low, down in the dumps, fearful, anxious, or irritable, with the associated symptoms of diminished interest and pleasure, anorexia or weight loss or increased appetite and weight gain, insomnia or hypersomnia, psychomotor retardation or agitation, fatigue, feelings of worthlessness and guilt, hopelessness, inability to concentrate and recurrent thoughts of death, suicidal ideation, or suicide attempts. These symptoms must occur for a period of at least 2 weeks. Many patients actually experience mixed episodes (sometimes called dysphoric mania). The most conservative definition requires them to meet criteria for both mania and depression. With these criteria, about 5%–10% of episodes are mixed (Bauer et al. 1994). In addition, many patients have brief episodes during the manic phase of tearfulness and sadness and other depressive symptoms. If the patient has a manic episode for a shorter time, e.g. at least 4 days and with less impairment in functioning, the episode is called hypomania and the illness, if embedded in depressive phases, is called bipolar II. For the most part, this illness is distinct from bipolar I (Coryell 1996). The third disorder, cyclothymic disorder, characterizes a patient who has, for at least 2 years, episodes of hypomanic and depressive symptoms which do not meet criteria for either mania or major depression. Whether there should also be a diagnostic category for hyperthymia has not been evaluated. Some recurrent depressives are hyperthymic in recovery.

Although mania and depression as mental disorders were recognized by the Greeks and the bipolarity of the illness was characterized in the 1600s (Clayton 1994), the separation of bipolar illness from unipolar illness did not occur until the late 1960s (Perris 1966; Angst 1966; Winokur and Clayton 1967), and it did not become recognized in our nomenclature until the DSM-III (American Psychiatric Association 1980). Because of that, most studies are modern and still unfolding.

2 Epidemiology (see also Vol. 3, Part 1, Chap. 17)

The lifetime prevalence for bipolar I is 0.8% and bipolar II is 0.5% (Robins and Regier 1991). Kessler et al. (1997) estimated the lifetime prevalence of mania to be 0.9%. Hypomania or bipolar II were not ascertained, and there are no data on cyclothymia.

Bipolar I and bipolar II are nonoverlapping disorders. As compared to bipolar I disorder, data from five family studies of bipolar II disorder indicate that the most prevalent illness in relatives of bipolar II probands is bipolar II disorder, and rates of all major affective disorders (including major depression) are higher in bipolar II probands (Coryell 1996). Those bipolar II probands with bipolar I relatives may be misclassified. In addition, in a 10-year follow-up of bipolar II patients (Coryell et al. 1995), a maximum of 15% developed mania, again indicating the small percentage who belong in the bipolar I category. On the other hand, age of onset, numbers of episodes, propensity for seasonal affective disorder (SAD), and rapid cycling are similar in the two disorders. How these likenesses and differences relate to pharmacotherapy for the two disorders is unknown, and how bipolar II relates to other disorders, including somatoform disorders and borderline personality disorders, is not clear.

Bipolar I has a slight preponderance of women over men, although women, as expected, have more episodes of depression, and men of mania. Bipolar II, because it is mainly depressive, has a preponderance of women over men. There is little ethnic or urban/rural variation in the bipolar disorders.

3 Age of Onset and First Episode

The age of onset of the first episode is between 10 and 60, although new cases have been reported beyond the usual range (Geller and Luby 1997; Young and Klerman 1992). Approximately a third of patients have their first episode in their teenage years, and 1% have their first episode after 60 (Clayton 1981). More likely, after 60, a patient has had a depressive episode earlier and then manifests mania for the first time at an older age. The first episode in either bipolar I or II disorder is usually a depressive episode, particularly for women (Angst 1978). The average time from the first depression to the switch is 6 years (Akiskal et al. 1983), and known precipitants of such a switch are pregnancy and antidepressant medication (Altshuler et al. 1995). As many as 15% of patients with three previous episodes

of depression switch to mania years later. Other symptoms or syndromes known to be associated with an outcome of bipolarity are adolescent psychotic or severe depression, the occurrence of a postpartum psychosis, a history of attention deficit disorder in childhood, and perhaps the symptoms of hypersomnia and retardation.

4 Clinical Picture

Although the typical bipolar patient starts with an episode of depression, the defining feature of the illness is an episode of mania. Mania can begin suddenly with the development of symptoms over hours, or more likely over days, but it seldom takes weeks. Early in the course of illness (Ambelas 1987), there is a strong correlation between stressful life events and manic admissions, which lessen as the illness progresses. We have shown (Clayton 1998) a relationship between stress and disrupted sleep patterns, and Wehr et al. (1987) suggested that sleep reduction is the final common pathway to the precipitation of mania. In fact, in watching videotapes of depressed patients treated with sleep deprivation, it is apparent that some patients develop an elevated mood. What percentage do and whether they should be questioned for symptoms of hypomania has yet to be studied. Thus manic patients frequently have insomnia as a major symptom, which definitely worsens their episode, if indeed it is not precipitated by it. The triad of hyperactivity, flight of ideas, and push of speech is the key to the manic syndrome, although any one of these symptoms could be altered if the patient is taking antipsychotics or mood stabilizers. In addition to the mood of euphoria or irritability or both, patients show distractibility, circumstantiality, intrusiveness, attention to detail, and restlessness or extreme motor activity. They may be hypersexual, make excessive phone calls, and be extravagant by overspending or giving away items. Their speech is laced with sentences that clearly show elevated self-esteem and grandiosity. Fifty-three percent of bipolar I patients reported delusion and/or hallucination (Guze et al. 1975). These delusions are usually congruent with their high mood, but sometimes they are paranoid as an outgrowth of their overly active interpretation of their surroundings. The themes of their grandiosity and delusions are often religious, political, or business schemes or related to sex. Catatonic symptoms are also possible. A recent study (Bräunig et al. 1998) reported that 31% of manics had such symptoms and that they were markers for a more severe course and outcome. Patients may frequently lose interest in eating just because they are distracted by so many other thoughts and activities. They certainly sleep less and need less sleep. Because they do not have insight into the nature of their illness, they are frequently impatient with those around them, including family and spouses, who frequently bear the brunt of their irritability. Their impatience is often shown during the psychiatric interview. They have no regard for boundaries and therefore get themselves into trouble, e.g. by putting people down, by inappropriately touching, by arguing with someone in a bar, or trying to enter the White House to deliver a message to the president. Manic patients frequently drink more during an episode and are at risk of developing comorbid alcoholism or substance abuse. It is unclear whether they drink to treat their symptoms or because of their increased sociability. Most manic patients need to be hospitalized during the manic episode. One symptom that is often overlooked is that between 35% and 55% of manics, during their most acute phase, show disorientation or confusion. This was recognized by Kraepelin (1921), who termed it "delirious mania." It is a common symptom in postpartum mania.

A recent factor analysis of symptoms (Cassidy et al. 1998) reported that, in 237 bipolar patients (204 manic; 33 mixed, 14%), five factors emerged. The first and strongest was a depressive factor – depressed mood, anxiety, guilt, mood lability, suicide, and negative euphoria. The second was racing thoughts, pressured speech, increased motor activity, and increased contact. The third was grandiosity, psychosis (any delusion or hallucination), lack of insight, and paranoia (probably also delusional). Factor four was euphoric mood, increased sexuality, humor, and grandiosity, and the fifth was paranoia (more likely hypervigilance and suspiciousness), aggression, and irritability. The depressive factor remained even when the mixed manics were removed, again illustrating that most manic patients have depressive symptoms during an episode. One assumes that only the 14% who met the DSM-III-R criteria for both depression and mania were severely depressed. The duration and severity of these symptoms were not measured. We (Winokur et al. 1969) described depressive symptoms and found them not to be enduring in many patients, a finding consistent with the low rate of completed suicide during manic episodes. Strakowski et al. (1996a) reported that the severity of depressive symptoms was associated with "suicidality," which is confirmed by the factor analysis above.

Although the bulk of the literature supports the similarities rather than the differences between bipolar and unipolar depression, the most controversial issue is whether bipolar depressives have more psychomotor retardation than unipolar depressives. Early studies (Dunner et al. 1976) demonstrated differences in

depressive symptomatology between the two, particularly in psychomotor retardation. Casper et al. (1985) found minimal differences when symptoms were correlated for age. Mitchell et al. (1992) did not confirm these differences either. They only demonstrated that bipolar depressives had shorter episodes of depression and were more likely to be agitated and less likely to demonstrate slowed movements. There was a trend for retardation to be less common in the bipolar depressives. In the collaborative study of depression (P.J. Clayton, unpublished data), we compared the symptoms of 31 bipolar depressives with 327 unipolar depressives. All of the interview items from the Schedule for Affective Disorder and Schizophrenia (SADS) were compared. There were almost no differences between the unipolar and bipolar depressives, including hypersomnia, weight gain, or psychomotor retardation, although the bipolar depressives were more likely to be retarded rather than agitated – a finding not true for the unipolar depressives. The only significant symptom differences were that the unipolar depressives reported more severe insomnia and the bipolar depressives reported more use of alcohol in the current episode. This question needs to be further studied and the comparison needs to include bipolar I and bipolar II depressives as well as unipolar depressives.

5 Course and Outcome

Bipolar illness is a recurring illness. Virtually every patient who has an episode of mania has a recurrence, although the number of episodes in a lifetime varies from two to more than 30 (Grof et al. 1974). Between 15% and 20% of bipolar patients exhibit rapid cycling, meaning four or more episodes of mania, hypomania, or depression in a single year (Coryell et al. 1992).

The usual manic phase lasts approximately 3 months, and the depressive phase 4 months. A short depressive phase frequently precedes the mania, and depression often follows a mania. The episodes may be seasonal, with the depression occurring in the autumn and winter, and the mania in spring and summer, or they may have their own distinct patterns, e.g. mania in February, May, August, and November. At least 10% of patients have manias only and, as previously indicated, there are more men in this category. At the beginning of the illness, the interval between the episodes tends to decrease, e.g. it may be 4 years between the first and second episode, then 2 years until the next, and then 1 year until the next. Once the patient has gone through a number of episodes, however, the duration of the cycle, defined as the time from the beginning of one episode to the beginning of the next, becomes stable and bottoms out with a cycle of about 6–9 months. The best way to predict a patient's future course is by examining his or her course in the past 2 years (Grof et al. 1974).

Chronic mania is rare. Welner et al. (1977) were the first to highlight the debilitating nature of the illness by showing that chronicity, if defined as the presence of symptoms, social decline, or both, occurred in at least one third of bipolar patients. The symptoms are almost always depressive.

In addition to chronicity, other complications of the illness include heavy drinking, substance abuse, pathologic gambling, failure to marry, divorce, and some cognitive decline (Van Gorp et al. 1998).

Bipolar patients have higher suicide attempt rates than unipolar patients (Kessler et al. 1997) and similar completed suicide rates. Despite the availability of adequate treatments, there still are indications that between 10% and 15% of patients diagnosed as bipolar kill themselves during their lifetime. It may be that the trend for suicide in bipolar disease, as in unipolar illness, occurs early in the illness and less frequently as the disease continues (Tsuang and Woolson 1977; Tsuang 1978). There is also an increased mortality from other causes in bipolar illness, and some (Yates and Wallace 1987; Weeke et al. 1987; Sharma and Markar 1994) suggested that it is due to an excess in cardiovascular mortality.

6 Premorbid Personality

Studies on premorbid personality are confounded because they frequently report on interepisode assessment of personality or on those stabilized on lithium or bipolars who rate their "usual selves" after recovery. The other difficulty in most studies is that, although they compare them to similarly assessed unipolar patients, they do not have control groups. In two separate analyses (Angst and Clayton 1986; Clayton et al. 1994), we reported on the premorbid personality traits of Swiss men who later developed unipolar or bipolar disorders and compared them to controls. In both these instances, the bipolar men rated themselves as normal, i.e. their answers to the personality inventory were not different from those of men who did not develop psychiatric disorders. These findings are similar to those of Akiskal et al. (1995, 1998), who used 17 self-rated personality scales for patients and found that, in most instances, the postmorbid usual self of the bipolar I patient was sanguine. The bipolar II patient, in contrast, was cyclothymic and labile, and the depressed patient was always subanxious and subdepressive. This last finding is also similar to what

we reported as the premorbid personality of depressives in the Swiss studies. Sauer et al. (1997) reported that treated bipolar patients, when rating their "usual selves," compared to treated unipolar patients had higher scores on extroversion, even in remission. This is compatible with earlier work previously summarized (Clayton 1994) that also indicated that manics evaluated themselves in a positive way, even in remission.

7 Differential Diagnosis

Although differential diagnosis depends on the age of onset, two points need to be emphasized. Although obviously a biased group, in a recent survey sampling some of the members of National Depressive and Manic-Depressive Association (Lish et al. 1994), 59% of respondents indicated that they had their first symptoms in childhood or adolescence. Fifty percent (less so with early symptoms) consulted a professional within a year or so after the onset of symptoms. There was a substantial delay, however, in receiving the correct diagnosis. About one third were ill for more than 10 years before this was done. Ten percent had consulted seven or more professionals before receiving the correct diagnosis. So while this seems like a rather specific and obvious disorder, it is frequently misdiagnosed. The second important point is that there is considerable evidence now that psychotic mania, which occurs in 50% of the bipolar I patients, is still misdiagnosed, particularly in Afro-Americans (Strakowski et al. 1996b). Despite the fact that there were very few differences in affective symptoms, more Afro-Americans were misdiagnosed as schizophrenic. These two things need to be kept in mind when considering differential diagnosis.

7.1 Childhood, Adolescence, and Early Adulthood

In the occasional bipolar disorder that begins in childhood, the most common misdiagnosis is attention deficit/hyperactivity disorder (ADHD). It may precede mania, be comorbid with mania, or be mania instead of ADHD. These misdiagnoses occur during the manic presentation, which more frequently occurs in boys, as does ADHD. For a diagnosis of ADHD, at least one symptom must be present before age 7. In adolescence and early adulthood, it may still be possible to misdiagnose a patient as having ADHD, but other more important misdiagnoses are schizophrenia, especially when patients present with psychotic mania or psychotic depression, substance abuse of any kind, and conduct disorder.

7.2 Adulthood

The key differentiation in adulthood has to be between schizophrenia and bipolar affective disorder. The schizophrenic subcategory may be catatonic, paranoid, or disorganized. Schizophrenics certainly have grandiose delusions, so grandiosity per se does not help in the differential diagnosis. Moreover, manics have paranoid delusions, although usually the manic delusions are multiple and fleeting as opposed to the methodical, intricately developed scheme observed in schizophrenics. If the patient presents as a schizoaffective manic, he or she is more likely to be manic in the follow-up, whereas schizoaffective depressed patients are as frequently schizophrenic as bipolar. In this age-group, bipolar illness may be masked by a substance abuse disorder or misdiagnosed as a personality disorder such as borderline or antisocial disorder. There is also a smattering of patients with anxiety symptoms (including obsessive compulsive disorder usually embedded in a presenting depression) who have bipolar illness.

7.3 Elderly

Because most bipolar patients present at a younger age, the appearance of mania for the first time after 60, without a history of previous depression, must be considered secondary or induced mania (organic affective syndrome) until proven otherwise. Excellent reviews of the subject can be found in Winokur (1991) and Shulman (1997). The most common induced manias are those involved with some neurologic abnormality such as epilepsy or neoplasm, but clearly metabolic disturbances, infections, and various drugs such as steroids and levodopa can precipitate mania. This should be considered at any time when mania appears for the first time, but is an absolutely essential consideration in the elderly.

7.4 Summary

Although the differential diagnosis for each age-group is somewhat unique, the best underlying way to confirm a diagnosis of bipolar I disorder is by family history of mania or recurrent depression. The triad of push of speech, flight of ideas, and hyperactivity also

could differentiate mania from the other syndromes; however, if the patient is medicated, particularly with mood stabilizers or antipsychotic drugs, these symptoms are muted. Catatonia is more frequently a part of mania than schizophrenia. Two other variables are helpful: (1) age of onset – one third of consecutive bipolar patients are identified before age 20, whereas only 10% of schizophrenics are identified by that age (Clayton 1981); and (2) acuteness versus chronicity – there should be an "onset" for depression and mania and usually an "offset." ADHD, schizophrenia, and personality disorders are usually insidious in onset and continuous and/or unremitting in course.

8
Biologic Markers (see also Vol. 3, Part 1, Chap. 19)

The two most consistent findings in bipolar patients, mostly in the depressed state but also in the manic state, are also found in unipolar patients. These are hypercortisolemia (mostly as measured by dexamethasone suppression) and sleep abnormalities, including shortened rapid eye movement (REM) latency, reduced amount of slow-wave sleep, and increased frequency of eye movements during REM sleep. There are, however, no unequivocal findings reported for bipolar I patients. Recently, Bellivier et al. (1998) used the candidate gene strategy to look at the tryptophan hydroxylase (TPH) gene, which codes for the rate-limiting enzyme in serotonin biosynthesis. They suggested that there was increased presence of at least one copy of the TPH allele in patients with bipolar disorder. Unfortunately, they included both bipolar I and bipolar II patients. Perhaps, however, this method will be more successful than the previous assessment of various enzymes, neurotransmitters, hormones, or other biochemical markers in the illness. (For the current state of knowledge on genetics of affective disorders, see Vol. 3, Part 1, Chap. 18; for current treatment strategies for the bipolar illness, see Vol. 3, Part 1, Chaps. 23–25.)

9
Areas for Further Study

Although bipolar illness was separated from unipolar illness on the basis of differences in age of onset, course, family history, and response to treatment, this separation may not, in the end, prove valid. There are data that suggest, as Kraepelin (1921) did, that the two illnesses may be different forms of the same disorder, with bipolar illness being the more severe, earlier-onset form and the recurrent unipolar the later-onset form. The place of bipolar II in this continuum is between the two. In bipolar II disease, if 15% of patients become bipolar I and another percentage have family members who have bipolar I disease, still others may be similar to recurrent depressive disorder. It is clear that mania marks the illness distinctly, hypomania less so, and depression not at all. Embedded in the depression category are a solid group of patients who probably belong to the bipolar continuum. Lithium augmentation (Álvarez et al. 1997) for depressives who have characteristics similar to bipolar patients and lithium maintenance (Greil et al. 1996) for recurrent depressives add support to this hypothesis. How patients with SAD and psychotic depression fit into this continuum is unclear. In addition, as mentioned earlier, a large number of manic patients have depressive symptoms during their mania, and the most frequent affective disorder in the relatives of bipolar I and II patients (the latter more than the former) is depression. We must continue to search for those unipolar depressed patients who belong to the bipolar category. Thus we still need prospective studies of mania, hypomania, bipolar I depression, bipolar II depression, and major depression. The early-onset group, adolescents and young adults, would be ideal to study. In all five groups, we should study sleep (looking for decreased REM latencies and slow-wave sleep deficits), biologic markers (such as nonsuppression in the dexamethasone suppression test, DST), and treatment response. This would answer questions such as whether there are symptoms in bipolar I and II depression that are distinct from recurrent unipolar depression, what the intermorbid personalities of such patients are, and what the best treatments for these disorders are. We still also need to continue to explore the outcomes of patients with cyclothymia and hyperthymia, if there are enough of both or either.

The ideal treatment for the maintenance of this illness still needs to be found. Lithium is most certainly the drug of choice, but contradictory reports, owing perhaps to no or improper comparison groups, of the effect of lithium on the kidney need to be resolved. Perhaps a proper control in 1999 would be a group of similarly matched bipolar patients treated with different mood stabilizers rather than untreated bipolars, other psychiatric patients, or no comparison. Bipolar patients must be the controls, and they need to be followed for years. There are still unanswered questions about the efficacy of valproate in maintenance and the relationship between valproate and polycystic ovaries in young women who receive it for long-term treatment. Efficacy of optimal treatments during pregnancy and postpartum, the treatment of bipolar I and II depression, and the treatment of rapid cyclers all need systematic studies.

None of these issues deal with the comorbidity of this disorder with other disorders, particularly substance abuse. In a naturalistic study, the percentage of patients who abuse alcohol, smoke, or use cocaine or other drugs and the nature of the comorbid childhood conditions in these groups identified as teenagers or young adults need to be recorded. Certainly there, the retrospective diagnoses could be validated by sibs, parents, and teachers, something that cannot be done with older adults.

Finally, as well as looking for candidate genes for this disorder, its neurocircuitry needs to be mapped.

CHAPTER

16

R.J. Boland, M.B. Keller

Other Affective Disorders

1 Introduction

This chapter includes mood disorders that are not included in the category "major affective disorder." Some, such as dysthymia, have become an accepted part of the official nomenclature. Others, such as recurrent brief depression (RBD) and minor depression, remain controversial.

Many of these disorders are new to the nomenclature. In the past, disorders such as minor depression were not necessarily treated as distinct from other depressive disorders, but were instead considered on a continuum with the major mood disorders. DSM-III (American Psychiatric Association 1980), however, used criterion-based categorical diagnoses, separating major depression and bipolar disorder into distinct disorders. These criterion-based diagnoses required the presence of a minimum number of symptoms and a minimum duration of symptoms. This fundamental change in the method of diagnosing psychiatric disorders has been very useful in improving the reliability and validity of mood disorders. This new system has, however, left unrecognized several disorders which are no longer included under the umbrella of the major mood disorders.

These "other affective disorders" can differ from the major mood disorders in either cross-sectional criteria or longitudinal criteria. The disorders that differ in cross-sectional criteria usually have milder symptoms than major depression and are occasionally called "subsyndromal" disorders. These include minor depressive disorder and mixed anxiety–depressive disorder. Those that differ in a longitudinal sense generally have a shorter duration of symptoms than that required for major depression; they may also represent a subtype of major depression with a specialized course (as in seasonal depression). Some disorders, such as dysthymia and double depression, differ in both cross-sectional and longitudinal aspects.

Although organizing these disorders by their cross-sectional and longitudinal criteria helps to structure our discussion of these disorders, the lack of established criteria for many of these disorders leads to continued confusion and mixed terminology. For example, a variety of terms, such as "subsyndromal" and "subthreshold" may be used to describe disorders that do not meet the criteria of established diagnoses. More general categories, such as the use of "not otherwise specified" categories of the official nomenclature cast a wider net and can be used for both cross-sectional and longitudinal diagnoses that do not have an official status.

The fact that these disorders may be less severe than the major mood disorders does not mean that they are benign. Many of these disorders have a chronic course and may, as with double depression, imply a worse outcome than other forms of depression. As with other chronic disorders, such as diabetes or hypertension, considerable functional impairment, morbidity, and mortality is associated with chronic depressive disorders, even when they are relatively mild in severity (Keller and Hanks 1995).

2 Dysthymia

2.1 Definition

Dysthymia, or dysthymic disorder, is characterized by cross-sectional symptoms that are less severe than those of major depression. The longitudinal course, however, is usually chronic and unremitting.

2.2 Epidemiology and Etiology

Dysthymia is common in community samples, and 4% of the general population (Keller and Hanks 1995) are estimated to have this disorder. It may have a prevalence as high as 15% in primary care settings (Sansone and Sansone 1996).

The etiology of this disorder is not clear. Classically, this disorder was considered one of the "neurotic" disorders and was considered synonymous with depressive neurosis. This neurotic–psychotic distinction, though influential in theoretical and clinical approaches to dysthymia, suffered from questionable validity (Klerman 1984). As a result, the association with depression neurosis was abandoned, and the term "neurosis" was removed altogether from the official U.S. nomenclature.

Subsequent research has focused on the neurobiological aspects of this disorder. The emergence of dysthymia has been reported after subcortical lesions, particularly when accompanied by other focal neurological signs (such as dystonia or extrapyramidal symptoms) (Lauterbach et al. 1997). Other neurological disorders, such as multiple sclerosis, may be associated with the emergence of dysthymia (Moller et al. 1994). As with depression, dysthmic patients may have an abnormal cortisol response to cortisol stimulation tests (Leake et al. 1989). Treatment studies have also changed the way we look at dysthymia.

Classically, in keeping with the psychotic–neurotic distinction, dysthymia was thought less responsive to somatic treatment. Although there is inadequate research on this subject, available research suggests that this long-held assumption is not true. Compared with major depression, this disorder may respond preferentially to serotonin reuptake inhibitors, arguing for a serotonin-specific mechanism of the disorder. The result has been a gradual change in the view of dysthymia from being a type of personality disorder to a chronic form of mood disorder.

2.3 Diagnosis

In DSM-IV, dysthymia is included in the official nomenclature as a mood disorder and termed dysthymic disorder (American Psychiatric Association 1994). It is defined as a "depressed mood, for most of the day, for more days than not" which lasts for at least 2 years. Along with a depressed mood, the individual must have at least two out of six possible depressive symptoms (see Appendix A). In children, the mood may also be irritable instead of depressed and may last for only 1 year.

In DSM-IV, dysthymic disorder cannot directly follow an episode of major depression. This is required to distinguish dysthymia from an episode of major depression that is in partial remission. Dysthymia can be diagnosed after an episode of major depression if there has been a full remission from the major depressive episode.

A distinction is made between dysthymia that occurs before or after age 21. This may have some prognostic significance.

DSM-IV also includes alternative diagnostic criteria in the appendix, in which the depressive symptoms (criterion "B") are replaced with a different group. These alternative criteria focus more on cognitive symptoms than the current set (Appendix B) and may better describe the quality of mood symptoms described by dysthmic patients.

In ICD-10, the disorder is termed dysthymia and is described similarly to in DSM-IV (Appendix C).

2.4 Course and Prognosis

By definition, dysthymia is a chronic disorder. It usually waxes and wanes over time. In children, the average length of a dysthmic episode is about 3 years, which is much longer than that for a major depressive episode (Keller and Hanks 1995). In adults, the duration may range from 2 to 20 years, with a mean of 5 years' duration. An early onset of the disorder may imply a more chronic course: one study of dysthymia beginning in childhood or adolescence reported a mean duration of 30 years (Shelton et al. 1997).

The outcome is also problematic. Most patients with dysthymia go on to develop major depression (Keller and Hanks 1995). The disorder may show a high comorbidity with other psychiatric disorders, such as personality disorders. Similarly, comorbid medical disorders, such as chronic gastrointestinal complaints and neurological disorders, are common. One large-scale study in the United States followed depressed individuals for 2 years and found that functional outcome was worse for those individuals with dysthymia (with or without major depression) than for those with major depression alone (Wells et al. 1992).

3 Double Depression

3.1 Definition

Double depression refers to the concurrent presence of both dysthymia and major depression. In this disorder, the episodes of major depression are superimposed on a more chronic depressive disorder.

3.2 Epidemiology and Etiology

Double depression is common: between 25% and 35% of patients with a major depressive episode also have a more chronic depression (Keller et al. 1982).

It is not clear from an etiological perspective what would predispose an individual to double depression and another to dysthymia or unipolar major depression alone. One study examining inheritance patterns in depressed patients and their first-degree relatives was unable to (genetically) distinguish major depression, recurrent depression, minor depression, and double depression from each other (Remick et al. 1996). Another study used single photon emission computed tomography (SPECT) to compare individuals with major depression alone and double depression. The SPECT scans showed significant differences in the frontal and posterior regional cerebral blood flow ratio (Thomas et al. 1993). Such a finding suggests that the cerebral dysfunctions may be different for these two disorders.

3.3 Diagnosis

Currently, double depression is not considered an independent diagnosis by either DSM-IV or ICD-10. In both systems, the disorder would be recorded as two comorbid diagnoses.

This disorder should be distinguished from a minor depression that continues after partial remission from a major depressive episode. To make such a distinction, DSM-IV requires that the dysthymia must clearly precede the episode of major depression or, if it occurs after an episode of major depression, there must be a clear remission of major depressive symptoms for at least 2 months. In practice, it can be difficult to distinguish a chronic residual state of major depression from an return to dysthymia. A history of minor depression preceding the major depressive episode – often by years – is a key feature in differentiating the two.

3.4 Course and Prognosis

By definition, double depression is chronic. Compared with major depressive disorder alone, double depression has an earlier age of onset. Furthermore, double depression affects the outcome of depressive episodes. Keller and colleagues (1983) found that patients with double depression recovered more rapidly from episodes of major depression than those with major depression alone. However, the recovery tends not to be to a state of "normalcy," but to one of dysthymia. Relapse is more frequent in patients with double depression than those with major depression alone – almost twice as likely in one study of 32 double depressed subjects followed for 2 years (Keller et al. 1983).

Individuals with double depression may be more likely to have a personality disorder than those with major depression or dysthymia alone. Double depression also causes greater social morbidity than major depression or dysthymia alone. It may also be a risk factor for suicidality.

4 Recurrent Brief Depression

4.1 Definition

RBD is characterized by brief depressive episodes that do not meet the 2-week criteria for major depressive episodes. The longitudinal course is characterized by multiple and frequent recurrences.

4.2 Prevalence

The prevalence of this disorder in the community is not clear. Angst (1990), in an epidemiological survey of young adults in Switzerland, estimated the prevalence of RBD to be approximately equal to that seen for major depression (estimating a 1-year prevalence of about 4.5%; males, 3.9%; females, 4.9%). Amore and colleagues (1995) suggested a 1-year prevalence in the general population of about 5% and a lifetime prevalence of 16%. The Mood Disorders Field Trial for DSM-IV (Keller et al. 1995), using a clinical sample of depressed patients in the United States, found that 17% of the subjects met the criteria for RBD.

RBD may be more common in samples drawn from primary care or other medical settings. One study using a primary care sample found that almost 8% of primary care patients met criteria for RBD, with about 4% meeting strict criteria (Weiller et al. 1994).

4.3 Diagnosis

Definitions for this disorder vary: the most liberal describes the disorder as meeting all of the DSM criteria for major depressive episodes except the time criterion. Stricter definitions, used in some research studies, require an episode length of less than 1 week consisting of at least four depressive symptoms. Such episodes are required to occur at least monthly for 1 year, with evidence of social or occupational dysfunction (Angst 1990).

Currently, RBD is included in the appendix of DSM-IV under "Criteria Sets and Axes Provided for Further Study" as research criteria (Appendix D). Individuals having these criteria under DSM-IV would be diagnosed as having a depressive disorder, not otherwise specified. ICD-10 includes a category of recurrent depressive disorder, but patients must meet full criteria of major depression to be included in this category. RBD would be diagnosed in ICD-10 under the general category of "Other persistent mood [affective] disorders."

It remains open whether this diagnosis is necessary to capture individuals with debilitating disorders that do not meet the criteria for major depression or dysthymia. Studies comparing such clinical variables as family history, age at onset, and psychiatric comorbidity do not distinguish RBD from major depression, nor do such biological parameters as the

dexamethasone suppression test or thyroid-releasing hormone response. In the DSM-IV Mood Disorders Field Trial (Keller et al. 1995), the majority (91%) of the depressed patients met the criteria for either major depression or dysthymia. This suggests that additional diagnoses are not necessary.

There also remains some debate as to the validity of this diagnosis and its relationship to other diagnoses, such as personality disorders. In patients in which recurrence is frequent with brief interepisode recovery, distinguishing this disorder from dysthymia may be difficult. One study in a primary care sample, however, found that individuals with RBD had not had another affective disorder diagnosis within the last year (Maier et al. 1994).

4.4
Course and Prognosis

As implied by the name, the course of RBD is chronic and recurrent, and it may be particularly unresponsive to usual treatments for depression. The mean episode length is about 3–5 days, with a mean of 20 episodes in a year (Amore et al. 1995). Onsets are sudden, with rapid progression to peak symptoms. Episodes vary in their time to recurrence, averaging about 18 days. About a third of such episodes are sufficiently severe to meet all but the time criteria for severe major depression (Montgomery and Montgomery 1992). Angst (1996) reported that, in his Swiss cohort, RBD remitted in 41%, recurred in 35%, progressed to major depression in 22%, and progressed to bipolar disorder in only 7% of the group.

RBD may have a seasonal pattern, similar to seasonal depression, and subjects with RBD may be more likely to have certain medical complaints, such as functional gastrointestinal complaints. Studies of suicidality in individuals suggest that RBD is a risk factor for suicide. For example, Weiller and colleagues (1994) found that, among primary care patients with RBD, almost a quarter had a history of suicide attempts.

5
Seasonal Depression

5.1
Definition

Seasonal Depression, also called seasonal affective disorder, describes a mood disorder that occurs predictably at a certain time of year. Most commonly, the onset of a depressive episode occurs during the winter, but it can occur at other times of year (such as the spring) as well. With winter depression, the disorder is often associated with episodes of hypomania occurring in the spring.

Symptoms of depression in this disorder are often "atypical" or "reverse vegetative symptoms": hypersomnia, hyperphagia, and weight gain being common (Allen et al. 1993). Fatigue is often the most frequent complaint.

5.2
Epidemiology and Etiology

The prevalence of this disorder varies with age, gender, and location. It is most common (particularly the winter variety) in the young, and 60%–90% of those with this disorder are women. It is more prevalent at higher latitudes: one community survey reported a rate of almost 10% in Fairbanks, Alaska (Booker and Hellekson 1992).

Although the cause of seasonal depression is not known, an association with the diminished periods of daytime is presumed for winter depression. This is supported both by the fact that the disorder is more common at higher latitudes and by the successful use of light therapy to treat the disorder. A serotonergic role, involving rapid tryptophan depletion, has been suggested, but investigations of this hypothesis have had mixed results. Circadian rhythm disturbances have also been suggested as a cause, but hypotheses have disagreed on the exact nature of the disturbance. No consistent evidence exists to support a family predisposition for this disorder.

5.3
Diagnosis

Past diagnostic criteria differ in the degree to which depressive symptoms should be limited to a seasonal pattern (to the exclusion of other episodes during the year). In DSM-IV, seasonal depression is included as a longitudinal course specifier for major depression and requires a pattern of seasonal episodes for at least 2 years, without any other episodes of major depression during this period (Appendix E). Though included as a subtype of major depression, evidence exists for a subsyndromal variety of this disorder.

5.4
Course and Prognosis

The disorder usually has a chronic and remitting course. As many as a third of patients suffering from

seasonal depression also have symptoms typical of RBD.

It appears to vary in whether or not individuals continue to have exclusive seasonal depression. In one retrospective study (Schwartz et al. 1996), less than half the patients (42%) studied with a seasonal pattern had a recurrent disorder limited to the seasonal variety. In that study, a similar percentage of patients had episodes of nonseasonal depression over the same 8-year period, and only 14% had a full remission. Another study, carried out in Japan, reported that 22% of patients with seasonal depression continued to show a stable pattern over a mean of 10 years (Sakamoto et al. 1995).

6
Minor Depressive Disorder

6.1
Definition

Minor depressive disorder is, as the name implies, a more minor form of major depression - a subthreshold depression. It differs from major depression in having fewer symptoms and less functional impairment than the major disorder. Both disorders, however, share similar durations and are otherwise similar.

6.2
Epidemiology

The prevalence of this disorder is unclear, as little consensus exists on criteria for this disorder. It is thought to be at least as common as major depression. In the DSM-IV Mood Disorder Field Study (Keller et al. 1995), 4% of the sample met the criteria for minor depressive disorder. Estimates in primary care populations range from 6% to 10%.

6.3
Diagnosis

Currently, minor depressive disorder is included in the appendix of DSM-IV under "Criteria Sets and Axes Provided for Further Study" as research criteria (Appendix F). Individuals meeting these criteria would currently be diagnosed in DSM-IV as having adjustment disorder with depressed mood. There remains a reluctance to introduce a diagnosis that may be no more than a subthreshold form of an existing diagnosis. In ICD-10, the diagnosis would be included under "other mood [affective] disorders."

6.4
Course and Prognosis

The course of this disorder is not clear, but it is assumed to be similar to that for major depression. Patients with this disorder have higher medical comorbidity, medical costs, and multiple unexplained physical symptoms.

7
Mixed Anxiety-Depressive Disorder

7.1
Definition

Mixed anxiety-depressive disorder represents a disorder in which both anxiety and depressive symptoms are present, but do not meet the threshold for any clinical diagnosis. Although this disorder does not meet strict criteria for either anxiety or depressive diagnoses, it still causes substantial impairment (Zinbarg et al. 1994).

7.2
Epidemiology

In the DSM-IV field trials (Zinbarg et al. 1994), mixed anxiety-depressive disorder was common - at least as prevalent as standard mood and anxiety disorders - particularly in primary care settings.

7.3
Diagnosis

Currently, mixed anxiety-depression is included in the appendix of DSM-IV under "Criteria Sets and Axes Provided for Further Study" as research criteria. In the current nomenclature, individuals meeting these criteria would be defined in "DSM-IV as having anxiety disorder, not otherwise specified."

The presence of this apparently common syndrome may predict a poorer course of illness. It is not clear, however, whether such poor outcomes are simply an additive effect of the comorbid syndromes found in this group. Joffe and colleagues (1993) found a poor outcome to be related to the increased functional and symptomatic severity existing in patients with both anxious and depressive symptoms. Clayton and colleagues (1991), however, found the delayed treatment response to be independent of illness severity. Greater

use of this tentative diagnosis may help clarify these apparent discrepancies.

8
Treatment Issues

Perhaps the most interesting and controversial area of research on the "other affective disorders" is that of treatment. In the past, treatment of most of these disorders (particularly dysthymia and the subthreshold depressive disorders) was based more on theoretical understandings of the disease than on empirical studies. The result has been an undertreatment of these patients. In one study of depressed patients with a mean duration of 30 years of dysthymia, about 40% ever received pharmacotherapy, and only 56% received psychotherapy (Shelton et al. 1997). Excluding seasonal depression (which will be discussed separately), the bulk of data concerns the treatment of dysthymia.

8.1
Psychotherapy

Psychotherapy has been the traditional treatment for dysthymia and subthreshold depressive disorders. This is due more to a traditional understanding of dysthymia as the result of developmental and other personality factors rather than being "physiological" in nature.[a] There is little empirical research, however, to support this practice. The studies that do exist tend to have inadequate methodologies (small samples, lack of a control group; Markowitz 1994; Conte and Karasu 1992). In addition, there is some difficulty in the studies in defining what the goal of therapy is in this chronic population: should it be symptom reduction, improved psychosocial functioning, or relapse prevention? Most existing studies examine the first goal (symptom reduction). Not surprisingly, psychotherapeutic techniques that lend themselves to standardization, such as cognitive therapy, are the most frequent studied. In addition to cognitive therapy, a variety of other therapies have been studied, including interpersonal therapy, marital therapy, group therapy, and family therapy (Markowitz 1994; Conte and Karasu 1992; Paykel 1994). The majority report as least modest response; however, the methodological difficulties make any conclusions impossible.

[a]If only certain types of depression are physiological, what are the others? The philosophical concept of such a mind–body dichotomy is clearly flawed. However, in the opinion of the authors, this dichotomy still forms the basis of much of our clinical practice.

8.2
Pharmacotherapy

As noted above, for many years pharmacotherapy was not considered the treatment of choice for dysthymia, minor depression, and other affective disorders that did not meet the criteria for major depression. This was largely due to the conceptualization of dysthymia and other disorders as more akin to personality disorders than to major depression. This bias continues; even recent studies show that dysthymia is more likely to be treated with antidepressants if the patient has a history of major depression than if they have dysthymia alone (Shelton et al. 1997). There may be at least partial basis for this bias; Akiskal and others have suggested a subtyping of primary dysthymia into disorders that appear more "characterological" (i.e. a type of personality disorder) and those that appear to be a "subaffective disorder" (i.e. a less severe, but otherwise similar version of major depression) (Ravindran et al. 1994).

Similar to psychotherapy, there is a paucity of rigorous studies on the pharmacotherapy of dysthymia and other affective disorders not meeting criteria for major depression. Most available studies investigate the treatment of dysthymia. Most of the studies investigating the treatment of dysthymia show at least a modest response to medication (Howland 1991). Overall, randomized controlled studies exist to show efficacy for most available agents, including tricyclic antidepressants (Kocsis et al. 1985; J.W. Stewart et al. 1993), serotonin reuptake inhibitors (Hellerstein et al. 1993; Thase et al. 1996; Ravindran et al. 1994; Vanelle 1997), and such atypical agents as ritanserin (Bakish et al. 1994), moclobemide (Botte et al. 1992), and amisulpride (Boyer and Lecrubier 1996). Some attempts have been made to investigate whether some agents are preferentially efficacious, e.g. some earlier data suggested that monoamine oxidase inhibitors were more useful for dysthymia (Howland 1991). However, there is no definitive data to suggest that any one agent is more efficacious that the other – the bulk of data suggests, instead, that any available agent used for major depression is likely to be effective for these other disorders. As discussed above, it would appear that the major problem continues to be the undertreatment of these disorders rather than a lack of efficacy for any specific treatment.

8.3
Light Therapy for Seasonal Depression

A full review of therapy for seasonal depression will not be undertaken here, as the use of light therapy for

seasonal depression is widely known and reported. As with the discussion of possibility etiologies of seasonal depression, no proposed mechanism of treatment (such as circadian phase adjustments) adequately explains all empirical observations regarding this treatment. Several questions regarding light therapy are of interest:

1. Is light therapy specific to the treatment of seasonal depression?
2. What aspects of the procedure are necessary for effect?
3. Is it the treatment of choice for seasonal depression, or merely an alternative treatment?

Light therapy is difficult to study, given the challenges of designing a convincing placebo condition. A great number of studies having been done, however, with large sample sizes and reasonable methodology. The majority of these studies strongly support the efficacy of light therapy as a first-line treatment for seasonal depression (Lam et al. 1989). Whether light therapy is specific to seasonal depression is not as clear. The majority of studies seem to support a specificity for seasonal depression (Thalen et al. 1997), with less or no antidepressant response seen in patients with nonseasonal depression. In studies that do show a positive response to light therapy for nonseasonal depression (e.g. Mackert et al. 1990), it is notable that these studies do not show the dose (light intensity) - response effect that has been observed in seasonal depression studies, which raises the question of a placebo effect. Still, more studies need to be done, and light therapy may prove to have a role in nonseasonal depression, either alone or as an adjunct to pharmacotherapy (Lam et al. 1989).

Several aspects of the treatment appear to be directly related to a positive effect. The patient's eyes must be directly exposed to the light, as the therapeutic effect appears to be optically mediated rather then through some other organ (such as the skin) (Attar Levy 1997). Likewise, the duration of treatment and the intensity for the light appear to be directly related to the effectiveness of treatment. The effect does not seem to require the ultraviolet A wavelengths of light (Lam et al. 1992), a fortunate finding, given the potential side effects of chronic ultraviolet exposure. Broadband white light may be preferable to other narrower spectra (K.T. Stewart 1991); however, the intensity of light is of more importance than the spectra.

The proper timing of light therapy is controversial, and studies have conflicted greatly on whether morning or evening light is preferable (or whether it makes no difference). These discrepancies are usually blamed on the varying study designs or on the general difficulty of devising rigorous studies. Many use a crossover design, which may confound the results, as the order in which the treatment is introduced may affect the outcome. In a randomized controlled study using a parallel design on 40 patients with seasonal depression, Wirz-Justice and colleagues (1993) found no difference in the timing of treatment. No subsequent study has convincingly refuted this finding.

Little is known about the final question of how light therapy compares to other treatments for seasonal depression. As light therapy is usually more difficult to obtain and implement than medication treatment, it is an important question. Virtually no comparative studies exist. Research on the pharmacotherapy of seasonal depression is in a relatively nascent stage. A number of medications have been shown to be useful for seasonal depression (at least in open studies), including buproprion (Dilsaver et al. 1992), citalopram (Wirz-Justince et al. 1992), fluoxetine (Ruhrmann et al. 1993), d-fenfluramine (O'Rourke et al. 1989), and the natural remedy hypericum (Kasper 1997).

Appendix A. DSM-IV Diagnostic Criteria for 300.4 Dysthymic Disorder

A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years. Note: In children and adolescents, mood can be irritable and duration must be at least 1 year.
B. Presence, while depressed, of two (or more) of the following:
   1. Poor appetite or overeating
   2. Insomnia or hypersomnia
   3. Low energy or fatigue
   4. Low self-esteem
   5. Poor concentration or difficulty making decisions
   6. Feelings of hopelessness
C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in criteria A and B for more than 2 months at a time.
D. No major depressive episode has been present during the first 2 years of the disturbance (1 year for children and adolescents), i.e. the disturbance is not better accounted for by chronic major depressive disorder or by major depressive disorder, in partial remission.

Note: There may have been a previous major depressive episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the dysthymic disorder. In addition, after the initial 2 years (1 year in children or adolescents) of dysthymic disorder, there may be superimposed episodes of major depressive disorder, in which

case both diagnoses may be given when the criteria are met for a major depressive episode.

E. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder.
F. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder.
G. The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).
H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:
- Early onset: if onset is before age 21 years
- Late onset: if onset is age 21 years or older

Specify (for most recent 2 years of dysthymic disorder):
- With Atypical Features

Appendix B. Alternative DSM-IV Research Criterion B for Dysthymic Disorder

B. Presence, while depressed, of three (or more) of the following:
1. Low self-esteem or self-confidence, or feelings of inadequacy
2. Feelings of pessimism, despair, or hopelessness
3. Generalized loss of interest or pleasure
4. Social withdrawal
5. Chronic fatigue or tiredness
6. Feelings of guilt, brooding about the past
7. Subjective feelings of irritability or excessive anger
8. Decreased activity, effectiveness, or productivity
9. Difficulty in thinking, reflected by poor concentration, poor memory, or indecisiveness

Appendix C. ICD-10 Diagnostic Guidelines for Dysthymia

The essential feature is a very long-standing depression of mood which is never, or only very rarely, severe enough to fulfil the criteria for recurrent depressive disorder, mild or moderate severity. It usually begins early in adult life and lasts for at least several years, sometimes indefinitely. When the onset is later in life, the disorder is often the aftermath of a discrete depressive episode and associated with bereavement or other obvious stress.

It includes the following:

- Depressive neurosis
- Depressive personality disorder
- Neurotic depression (with more than 2 years' duration)
- Persistent anxiety depression

It excludes the following:

- Anxiety depression (mild or not persistent)
- Bereavement reaction, lasting less than 2 years (prolonged depressive reaction)

Appendix D. DSM-IV Research Criteria for Recurrent Brief Depressive Disorder

A. Criteria, except for duration, are met for a major depressive episode.
B. The depressive periods in criterion A last at least 2 days but less than 2 weeks.
C. The depressive periods occur at least once a month for 12 consecutive months and are not associated with the menstrual cycle.
D. The periods of depressed mood cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).
F. There has never been a major depressive episode, and criteria are not met for dysthymic disorder.
G. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria are not met for cyclothymic disorder.

Note: This exclusion does not apply if all of the manic-, mixed-, or hypomanic-like episodes are substance or treatment induced.

H. The mood disturbance does not occur exclusively during schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, or psychotic disorder not otherwise specified.

Appendix E. DSM-IV Criteria for Seasonal Pattern Specifier

Specify if with seasonal pattern (can be applied to the pattern of major depressive episodes in bipolar I disorder, bipolar II disorder, or major depressive disorder, recurrent):

A. There has been a regular temporal relationship between the onset of major depressive episodes in bipolar I or bipolar II disorder or major depressive disorder, recurrent, and a particular time of the year (e.g. regular appearance of the major depressive episode in the fall or winter).

Note: Do not include cases in which there is an obvious effect of seasonal-related psychosocial stressors (e.g. regularly being unemployed every winter).

B. Full remissions (or a change from depression to mania or hypomania) also occur at a characteristic time of the year (e.g. depression disappears in the spring).

C. In the last 2 years, two major depressive episodes have occurred that demonstrate the temporal seasonal relationships defined in criteria A and B, and no nonseasonal major depressive episodes have occurred during that same period.

D. Seasonal major depressive episodes (as described above) substantially outnumber the nonseasonal major depressive episodes that may have occurred over the individual's lifetime.

Appendix F. DSM-IV Research Criteria for Minor Depressive Disorder

A. A mood disturbance, defined as follows:

1. At least two (but less than five) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (a) or (b):
   a) Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g. feels sad or empty) or observation made by others (e.g. appears tearful)

Note: In children and adolescents, can be irritable mood.

   b) Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
   c) Significant weight loss when not dieting or weight gain (e.g. a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day.

Note: In children, consider failure to make expected weight gains.

   d) Insomnia or hypersomnia nearly every day
   e) Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
   f) Fatigue or loss of energy nearly every day
   g) Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
   h) Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
   i) Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
2. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
3. The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).
4. The symptoms are not better accounted for by bereavement (i.e. a normal reaction to the death of a loved one).

B. There has never been a major depressive episode, and criteria are not met for dysthymic disorder.

C. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria are not met for cyclothymic disorder.

Note: This exclusion does not apply if all of the manic-, mixed-, or hypomanic-like episodes are substance or treatment induced.

D. The mood disturbance does not occur exclusively during schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, or psychotic disorder not otherwise specified.

H.-U. Wittchen

Epidemiology of Affective Disorders

Translator: E. Taub

1 Introduction

The major forms of affective disorder with which this chapter is concerned, namely, major depression, bipolar disorders, and dysthymia, have been well studied epidemiologically on an international scale. Nonetheless, this is so only with respect to descriptive epidemiology, i.e. the quantitative measurement of disease prevalence, putative risk factors, and possible complications (e.g. comorbidity). Less is known about which risk factors are in fact relevant, as well as the epidemiological aspects of mental health care delivery, the natural course of disease, and the incidence of affective disorders in different age-groups. There is also a lack of knowledge regarding other illnesses that can be counted among the affective disorders, including adaptive disorder, mixed disorders, brief, recurrent depressive disorders, and "subthreshold" or "minor" depression – all of which, like the major affective illnesses, may be associated with major psychosocial impairment.

Only a few, mostly regional, studies from the 1980s and 1990s are available for the German-speaking countries; these do not allow any reliable conclusions on a national level, nor do they allow possible differences between the former East and West Germany to be reliably determined. The present review is limited to population-based studies of the prevalence of affective illnesses, as narrowly defined by means of structured and standardized diagnostic instruments according to the criteria of DSM-III, DSM-III-R, ICD-10, and DSM-IV. We have deliberately chosen not to discuss the older studies that were already dealt with comprehensively by Shepherd (1975) in the earlier (German) edition of this text.

ICD-10 and DSM-IV, the two diagnostic classifications currently in use, define affective disorders in very similar ways, not only at the level of disease manifestations, but also at the level of diagnostic classification. This convergence has the great advantage for epidemiologic studies that artificial differences related to the particular system of classification used are kept to a minimum, while core epidemiologic data can be obtained with reference to both systems through the use of the same diagnostic instruments.

2 Studies on the Prevalence of Depressive and Bipolar Disorders in the General Population

As shown in Table 1, five population-based studies have been carried out in the German-speaking countries in recent years. These are the Munich Follow-Up Study (MFS) of Wittchen and von Zerssen (1987), carried out between 1974 and 1981 in the federal states (*Länder*) of the former West Germany; the regional follow-up study performed by Fichter (1990) as a component of the Traunstein study (Upper Bavaria); the Swiss regional age-cohort study conduced by Angst et al. (1984); the Early Developmental Stages of Psychopathology (EDSP) study, performed in 1995, in which 3021 subjects drawn from the general population of Munich were investigated (Wittchen et al. 1998); and the Basel study carried out by Wacker et al. (1992).

Because all of these studies, with the exception of the MFS, were restricted to single regions, and most of them dealt with narrowly defined age ranges, they cannot be considered representative of the population of the German-speaking countries as a whole, or even of individual German states. A number of North American, South American, African, and Asian studies of disease prevalence are available for comparative purposes, of which the American National Comorbidity Survey (NCS; Kessler et al. 1994) is particularly comprehensive and carefully performed.

In the great majority of these studies, the affective illnesses were defined according to the diagnostic criteria of DSM-III, DSM-III-R, or DSM-IV, all of which are similar, and most of the studies employed the Composite International Diagnostic Interview (CIDI; WHO 1990; Wittchen and Semler 1990; Wittchen and Pfister 1997) or its precursor, the Diagnostic Interview Schedule (DIS; Robins et al. 1982; Wittchen et al. 1985), a standardized diagnostic instrument for case ascertainment whose reliability and validity have been well studied (Wittchen 1994a). There is thus a relatively homogeneous database available for the last two decades, although the interpretation of these data requires careful attention to a number of methodological differences between the studies.

Nearly all of these studies dealt not with the entire German population, but only with that of smaller regions (e.g. the Traunstein study; Fichter 1990). In addition, a considerable, artificial variation in findings may result from differences between the studies with respect to the population sample studied (e.g. age-groups), the diagnostic system used (DSM-III, DSM-III-R, DSM-IV, ICD-10), and the instruments and methods of evaluation applied (e.g. weighting procedures).

In Table 1, data are given regarding four prevalence figures: lifetime prevalence, i.e. the percentage of individuals who have had an affective illness at any time in their lives until the present, and three different types of cross-sectional prevalence (12-month, 6-month, and point prevalence, the last of which is defined in practice as prevalence over a period of 2–4 weeks, depending on the study).

Table 1. Prevalence (%) of affective disorders according to the DSM-III, DSM-III-R, and DSM-IV criteria

[b]DSM-IV.

2.1 Point Prevalence

As shown in summary form in Table 1, there is at first sight a remarkable variation between studies with respect to lifetime prevalence, but most of the studies, despite major differences in the age-groups studied, yielded a figure near 3.1% for the point prevalence of episodes of major depression (range, 1.7%–3.7%). This implies more generally that approximately 3.1% (conservatively estimated) of the population between the ages of 15 and 65 suffered from depression at the time the study was performed. The median value

across studies for the point prevalence of dysthymia was 2.1% (range, 1.0%–5.9%), and that of bipolar disorders, 0.4% (0.1%–0.6%). The latter figure concerns only bipolar I disorder, i.e. fully developed manic episodes.

2.2 Prevalence over Defined Intervals and Lifetime Prevalence

As expected, the lifetime prevalence of bipolar and dysthymic disorders (1.3% and 3.6%, respectively) is somewhat higher than their point prevalence, while the lifetime prevalence of major depression, estimated at 16.1%, is much higher than its point prevalence. Data obtained in the MFS and EDSP studies, which were broken down according to severity of illness and type of course, imply that nearly one third of all individuals suffering from major depression fulfill the criteria for recurrent disease. Furthermore, moderate and severe episodes are clearly more common than mild episodes.

Despite the apparent high degree of scatter in the findings on major depression across studies, a closer analysis reveals that nearly all of the variation can be accounted for by methodological differences, particularly the choice of age-group and the manner of ascertaining and evaluating disease manifestations; cultural factors account for comparatively little of the variation (Wittchen et al. 1994). Thus studies employing the DIS, whose criteria for disease manifestations are stricter, and those with a very wide age range extending into old age yielded the lowest prevalence figures. The studies in which the 6-month prevalence of affective illnesses was determined yielded median figures of 6.5% for major depression, 3.3% for dysthymia, and 1.1% for bipolar disorders.

It is also worthy of note that the more recent studies yielded higher prevalence figures than the older studies. All studies carried out in the 1990s yielded considerably higher rates of depression than older studies, for both men and women. Perhaps a small fraction of the increase in prevalence can be attributed to the more sensitive diagnostic criteria of DSM-III-R, ICD-10, and DSM-IV (inclusion of less severe depressive episodes), but there may also be a "real" increase in the prevalence of depressive illnesses, particularly in younger age-groups (see below).

If we consider the figures for prevalence in different age-groups, we find that, according to most studies, e.g. Epidemiologic Catchment Area (ECA) Study, NCS, MFS (Weissman et al. 1991; Kessler et al. 1994; Wittchen and von Zerssen 1987), the highest prevalence of both bipolar and depressive disorders was between the ages of 30 and 44. In a small number of studies, however, the highest prevalence of major depression was found in the somewhat younger 25- to 30-year-old group (Wells et al. 1989; Bland et al. 1988c; Wittchen 1988; Lee et al. 1990a; Wittchen et al. 1992). The EDSP, in which only 14- to 25-year-olds were studied, further revealed that major depression is very common in adolescents and young adults, with a lifetime prevalence of 11.8% and a 12-month prevalence of 5.3%.

In contrast, the prevalence of dysthymia differs little across age-groups up to age 64 according to the aggregate ECA data and those of most other studies. Past this age, the prevalence of dysthymia declines considerably (Weissman et al. 1991). There is evidence, however, that the ages of 45 to 64 may be a period of especially high risk for this disease; the elevated risk seems to be related to comorbid, chronic physical illnesses (Canino et al. 1987; Wittchen 1988; Wells et al. 1989; Lee et al. 1990a; Wittchen et al. 1992).

Subthreshold (minor) depression, which may be associated with significant psychosocial impairment even though not all of the strict criteria for major depression are fulfilled, and a number of other types of depressive disorder have only rarely been studied epidemiologically. Oldehinkel et al. (1999) estimate the prevalence of subthreshold depression at 5.3% on the basis of a new, carefully performed analysis. Adaptive disorders have been studied to date only in a few, mostly older studies employing the clinical criteria of ICD-9. Wittchen and von Zerssen (1987), in the MFS, arrived at a cross-sectional prevalence of 1.2% and a lifetime prevalence of 2.3%; a somewhat higher prevalence of 4.9% was found by Fichter in the Upper Bavarian study (Fichter 1990). Mixed states of anxiety and depression not fulfilling the criteria for any specific disorder are estimated to have a lifetime prevalence of approximately 1% (Wittchen and Essau 1993a) when only individuals who have never had major depression, dysthymia, or a bipolar disorder are counted. Brief, recurrent depressive disorders have a 12-month prevalence of 4.2%–7.2% according to the studies conducted by Angst et al. (1990).

2.3 Grades of Severity and Subtypes of Depressive Illnesses

Only a few reliable estimates of the prevalence of different grades of severity (mild, moderate, severe) and subtypes (single episode, recurrent) of the depressive disorders are available to date. The EDSP study of adolescents and young adults (Oldehinkel et al. 1999) showed that most individuals with major depression had either moderate or severe depression; mild depressive episodes were present in only 18%. Moreover, the EDSP study and the NCS revealed that 25% (EDSP, in 14- to 24-year-olds) to 46% (NCS, in

15- to 55-year-olds) of all depressive illnesses are of the recurrent type.

2.4 Prevalence of Depressive Disorders in General Medical Practice

General medical practice is an important venue for epidemiologic study, both because of the regular medical help-seeking behavior of the public and because of the opportunity to assess health economic stress indicators of a psychiatric nature. According to the findings of the WHO multicenter study (Üstün and Sartorius 1995), the point prevalence of affective disorders is actually considerably higher in general medical practice than in the population at large. This study was carried out in 15 regions in 14 different countries; two general medical practices in Germany (one in Mainz and one in Berlin) were included in the study. On the basis of clinical interviews employing the CIDI, it was determined that 10.4% of all patients visiting a general medical practitioner currently suffer from a depressive illness according to the ICD-10 criteria (Üstün and Sartorius 1995). As seen in Table 2, the specific figures for Mainz and Berlin are 11.1% and 6.1%, respectively.

An additional 5.4% of these patients fulfilled the ICD-10 criteria for neurasthenia, while 6.5% fulfilled the criteria for subthreshold depression with major psychosocial impairment. The prevalence of bipolar disorders was not assessed. Other noteworthy findings of this study included the high comorbidity rates with anxiety disorders and also with somatoform and addictive illnesses. This study serves to emphasize not only the high prevalence of affective disorders in general medical practice, and the burden of care they represent for the treating physicians (Sartorius et al. 1989), but also the fact that there is a major deficiency in the delivery of mental health care to such patients. Barely 50% of patients found to have current, verified major depression by the research psychiatrist had been diagnosed as such by the general medical practitioner, and only one in ten had received specific treatment for depression.

3 Risk Factors

3.1 Sex and Age at Onset of Illness

All relevant epidemiologic studies in all age-groups have consistently revealed that women are affected by depression much more commonly than men. In the relevant studies (Robins et al. 1984; Canino et al. 1987; Wittchen 1988; Lee et al. 1990a; Bland et al. 1988a; Wacker et al. 1992; Wittchen et al. 1992; Kessler et al. 1994), the lifetime prevalence of major depression has been found to be two to three times higher in women; the prevalence figures ranged from 4.1% to 21.3% for women and from 2.3% to 12.7% in men. The differences between men and women in the point and interval prevalence of depression are just as marked.

Dysthymia, also, has a higher lifetime prevalence in women (2.3%–10.3% in women, 1.2%–4.8% in men). This sex difference has been found to be statistically significant as early as puberty (Oldehinkel et al. 1999) and has been reconfirmed by the recent American representative study, the NCS (Kessler et al. 1994), which employed the more sensitive DSM-III-R criteria. The NCS revealed a lifetime prevalence of depression of 21.3% for women and 12.7% for men, while the corresponding figures for dysthymia were 4.8% for women and 0.8% for men. An even sex distribution has been consistently reported for the bipolar disorders.

The findings regarding the age of onset of illness are less consistent. The earlier studies all showed an earlier age of onset for bipolar disorders than for major depression. According to the findings of the ECA studies (Weissman et al. 1991), the average age of onset of bipolar disorders is 18 years, while hypomanic forms appear somewhat later on average (21.7 years) but still considerably earlier than the average age of

Table 2. Point prevalence of depressive disorders in general medical practice (weighted prevalence in percent) (WHO Cooperative Study after Üstün and Sartorius 1995)

Disorder	Findings in general medical practices	
	Berlin (n=400)	Mainz (n=400)
Depression (ICD-10: F32/33)	6.1	11.1
Dysthymia (ICD-10: F34)	0.5	0.9
Recognized cases	56.7	55.6
Treated cases		
With antidepressants	11.4	10.5
With sedatives	5.7	23.7

onset of major depression, which is 26.5 years. A bimodal distribution of bipolar disorders, with peaks in the third and fifth decades of life, has frequently been postulated (Angst 1987).

Studies have usually revealed a wide variation in the age of onset of depressive disorders. Periods of significantly increased risk for the onset of disease include late adolescence and early adulthood, with progressively increasing incidence up to the age of 45. The age of 30 is usually given as a typical age of onset, although more recent investigations imply that the average age of onset is considerably earlier. Kessler et al. (1994), using multivariate risk analysis, found that the relative risk of developing depression for the first time (compared to the over-45 age-group) is 1.7 between the ages of 15 and 24, 1.3 between the ages of 25 and 34, and 1.4 between the ages of 35 and 44.

3.2 Differences Between Age-Groups

Contrary to the traditional clinical conception that the highest rates of depression are found in older persons (over age 45), more recent studies have found the highest rates of depression in younger age cohorts.

The cumulative rates of a "major depressive episode" in different age cohorts, as found in various studies and listed in order of the age of onset, are shown in Fig. 1. Although the overall prevalence varies among studies, it is nonetheless clear that the youngest age cohorts have the highest prevalence, and the oldest age cohorts the lowest. The difference is considerable: the prevalence of depressive illnesses is barely over 2% in older cohorts, but approximately 10% in younger cohorts. Furthermore, the age of onset of the disorder is clearly earlier in the younger cohorts, i.e. an increasing number of young patients are developing depression at earlier and earlier ages.

Moreover, it is interesting to note that the older studies from the years 1980–1985 consistently revealed a lower prevalence than the more recent studies. This has been taken as an indication that the higher prevalence in younger age cohorts is continuing to rise. Taking the NCS (Kessler et al. 1996) as an example, we can see from Fig. 1 that a difference in prevalence between age cohorts is demonstrable, though not marked, while the age of onset of depression has clearly shifted more strongly toward the younger age cohorts. As the separate curves for men and women reveal, this difference between age cohorts holds regardless of sex.

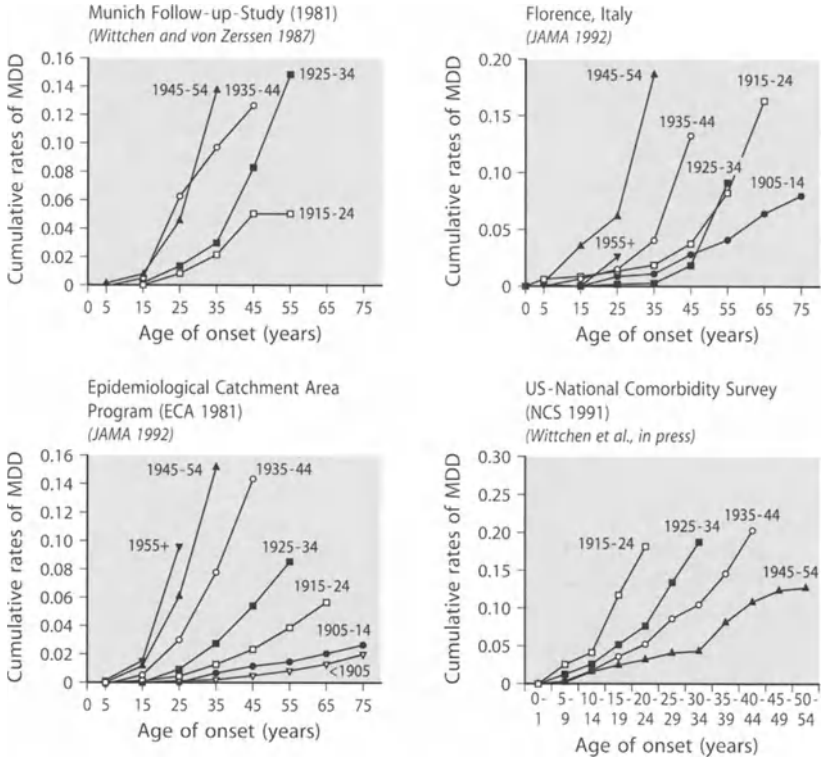

Fig. 1. Cumulative rates of major depressive disorder (*MDD*) in different age cohorts as a function of the age of onset of disease (data obtained from different studies)

These findings have been the subject of thorough review in a number of studies (Cross-National Collaborative Group 1992; Knäuper 1994; Wittchen et al. 1994; Kessler et al. 1996). Possible sources of statistical artifact were examined, including differential morbidity, institutionalization, selective migration, different diagnostic habits and criteria, varying age-specific attitudinal patterns, and methodological aspects of the study instruments. The ultimate conclusion of all of these studies, taken together, is that a large number of methodological artifacts might contribute to the observed differences in prevalence, but no single factor or combination of factors appears able to account for the size of the differences found.

It is of interest that the criticism of these findings from the clinical perspective has been primarily with respect to the lower prevalence among older individuals, rather than the high prevalence among adolescents and young adults. The latter finding appears to be adequately supported by repeated clinical observation and by special studies in childhood and adolescence; the studies carried out Lewinsohn et al. (1993), Garrison et al. (1992), and Klerman (1988) clearly reveal a high prevalence of more than 10%–18% in younger age-groups. As far as the older age-groups are concerned, the Berlin Old Age Study (BAS; Mayer and Baltes 1996) confirmed the absence of any notable increase of prevalence in old age. Studies in our own institution, however, revealed statistically significant evidence of a systematic generation of artifact (Knäuper 1994); thus it might be the case that our instruments for the assessment of depression lead to a systematic underestimation of its prevalence in older individuals.

3.3
Family Situation

Affective disorders, particularly depression, occur more commonly in subjects who are separated from their partners, divorced, or widowed (Wittchen et al. 1987; Bland et al. 1988a; Weissman et al. 1991). Major depression is 2.5 times more common in separated people living alone (Kessler et al. 1994), although living alone per se cannot be considered a risk factor (Weissman et al. 1991). The elevation of risk due to a separation of any kind is significantly higher in women than in men (relative risk, 4.2). The risk analyses performed in a number of studies already mentioned (the NCS, ECA, and MFS) also confirmed that married women are twice as likely as men to develop major depression and that this risk becomes even higher (relative risk, 4.8) if they are not regularly employed (Wittchen 1994b). Even after these factors are statistically controlled for, the main finding that women have a higher prevalence of depression than men remains valid.

3.4
Other Psychosocial Factors

People who were unemployed during at least 6 months out of the 5 years preceding assessment have a threefold elevation of the risk of developing an episode of major depression. Moreover, those with low income who are dependent on government financial aid have a threefold elevation of the prevalence of bipolar disorders or major depression. There are no significant differences between urban and rural areas in this respect (Weissman et al. 1991).

Critical life events with respect to interpersonal relationships, particularly the death of a person with whom the individual has a relationship, and physical illnesses in association with a paucity of social resources (e.g. inadequate social support) and personal resources (e.g. dysfunctional coping behavior) are found primarily in depressive cases (Wittchen 1987; Angst and Dobler-Mikola 1985) and have also been found in analytical epidemiologic studies with small sample groups and in clinical studies. Most of these findings were obtained retrospectively, and the causal relationships are still relatively unclear (see Katschnig 1980; Lin et al. 1986).

3.5
Psychopathological Indicators

Epidemiologic studies have also shown that psychopathological and treatment variables are closely associated with the risk of depressive episodes. For example, with respect to chronicity, Wittchen (1994b) stated, on the basis of the findings of the longitudinal MFS, that an earlier onset of illness, a slower rather than acute onset, the presence of dysthymia, the presence of chronic physical illnesses, and above all the presence of a chronic anxiety disorder (see Sect. 4) all seriously increase the risk of chronic depression.

4
Comorbidity

Although no comprehensive evaluation of comorbidity is yet available from the ongoing longitudinal studies (e.g. the EDSP), a preceding anxiety disorder seems to be one of the more important risk factors for major depression (Thompson et al. 1989; Wittchen and Essau

1989, Maser and Cloninger 1990; Wittchen 1996; Merikangas et al. 1996). Panic disorders are frequently associated with depression, but supposedly mild phobias have also been repeatedly found to be highly significant risk factors for depression (Stein et al. 1990; Vollrath et al. 1990; Merikangas et al. 1996; Kessler et al. 1996). It is worth noting that the association between dysthymia and anxiety disorders is also statistically significant, but of a much smaller magnitude.

There is controversy over the interpretation of these findings. They may be explained by the hypothesis that depression is a frequent secondary complication of chronic anxiety disorders or, alternatively, that other mechanisms are responsible for the association, such as familial genetic linkage, different stages of a single disease process, and so forth (for a review, see Maser and Cloninger 1990; Wittchen and Essau 1993b; Wittchen and Vossen 1995). A further important observation from the comorbidity perspective is that depression takes a different and less favorable course when it is clearly coupled with anxiety (see below).

There are also significant associations between the affective disorders and disorders involving psychotropic substances (abuse, dependency). In the ECA studies, 32% of those with affective disorders also had a disorder involving a psychotropic substance (Regier et al. 1990b). Although the diagnoses of substance abuse and dependency were common in individuals with all subtypes of affective disorder, they were especially common in those suffering from bipolar disorder (60.7%).

An association with somatoform disorders has also been found: 55% of patients with somatoform disorders meet the criteria for major depression at some point in their lives, and 19% meet the criteria for dysthymia (Swartz et al. 1991).

Comorbidity within the group of the affective disorders, particularly that of dysthymia with major depression, is difficult to evaluate because of methodological problems. The differential diagnosis of the affective disorders is based less on the clinical manifestations of disease than on the nature of disease course. It is therefore controversial at present whether dysthymic disorders represent an independent disorder, with a specific type of course, and can thus be considered a valid subtype (Bronisch 1990; Angst and Wicki 1991). Increased clarity on this point can perhaps be expected as a result of the DSM-IV criteria, with which finer distinctions can now be made.

5 Course

The course of the affective disorders is highly variable across the different disorders. Affective disorders may take a phasic course, but they may also be singular occurrences. The duration of episodes varies, but several prospective studies of disease course (the MFS, the ECA, and the Zurich study) have shown that the affective disorders remit completely much more often than the anxiety disorders (range, 32%–46%). As a rule, bipolar forms are thought to be of shorter duration than unipolar forms (Wittchen et al. 1991). A further difficulty in the study of disease course is that disorders initially diagnosed as dysthymia may turn out to be bipolar disorders on further follow-up, i.e. these diagnoses cannot be considered very stable (Angst 1987). Moreover, only a few longitudinal studies of disease course are now available.

Bronisch et al. (1985) found that patients with endogenous depression and with neurotic depression had different courses of disease. A total of 71% of the patients with endogenous depression, but only 37% of the patients with neurotic depression had a favorable course. The rate of remission (defined as 5 years without relapse), according to Angst (1986), is 29% for bipolar disorders and 42% for unipolar depressive illnesses. Robins et al. (1991) found that 42% of those who had ever been diagnosed has having major depression, but only 28% of those who had manic episodes in the preceding year, were asymptomatic at the time of investigation. Bland et al. (1988b), on the other hand, determined that 56% of those with manic episodes and 46% of those with at least one "major depressive episode" were asymptomatic for at least 1 year.

The risk of suicide has been estimated at 15% (Hautzinger and de Jong-Meyer 1994) and is thus considerably higher than in the normal population. More recent findings from the MFS (Wittchen 1993) and the EDSP (Wunderlich et al. 1998) further indicate that comorbid depressive episodes last significantly longer than non-comorbid depression and that they also have a considerably higher rate of relapse.

6 Use of Mental Health Care Services

Although most depressive individuals and most people suffering from a bipolar disorder in the general population report having discussed the symptoms of their disorder with a physician at least once in the course of the illness (Robins et al. 1991), more recent findings from Germany imply that only a third of such persons receive the medical diagnosis of depression or receive any kind of psychological or pharmacological intervention (Wittchen et al. 1999a,b). Nonetheless, among all mental illnesses, affective disorders are second only to the schizophrenic disorders in the rate

of utilization of mental health care services. According to one study, approximately three quarters of affected individuals had visited some type of public health care facility in the 6 months preceding questioning; among these, 31% had visited psychological, psychiatric, and psychosocial facilities, 14% general medical care facilities, and 18% psychiatric specialists (Shapiro et al. 1984). At all levels of mental health care delivery, the rate of treatment of bipolar disorders was somewhat higher than that of major depression (Weissman et al. 1991).

7 Concluding Remarks

The foregoing overview of the currently available epidemiologic studies has shown that depressive disorders are a common and geographically widespread phenomenon. Multivariate analyses have confirmed the existence of multiple risk factors of a sociodemographic nature, particularly age, sex, family situation, and employment; these factors may also interact with one another. Other types of risk factors have been studied only rarely to date, but one consistent and significant finding is that psychopathological precursor states allow considerably better prediction than sociodemographic predictors. Our own working group (Wittchen 1996; Wittchen and Vossen 1995; Kessler et al. 1996) has been able to demonstrate that primary anxiety disorders, in particular, can be considered an important and hitherto underappreciated risk factor for the appearance of depression. Odds ratios in the primary anxiety disorders are typically in the range of 7–12, i.e. subjects with primary anxiety disorders have a 7- to 12-fold risk of developing depression in comparison to the general population.

Another important and stable finding of epidemiologic research is that the highest prevalence of depressive disorders is not, as expected, in old age, but rather in the younger age-groups. Because studies performed in the 1980s yielded considerably lower figures for prevalence than more recent studies, especially in younger age cohorts, it may be concluded that the prevalence of depressive disorders has risen, particularly in the young, at least since the early 1980s. This surprisingly large increase has not yet been definitively explained. Proposed explanations primarily concern psychosocial factors and precursor states, as suggested by the increased prevalence of substance abuse and dependency over the same period.

This overview of the epidemiology of the affective disorders must inevitably remain incomplete. For example, because of space limitations, it has not been possible to discuss the perspectives of health psychology, public health, care evaluation and planning, and pharmacoepidemiology in detail or to pay greater attention to the recent findings of genetic and family genetic research. Nonetheless, we have been able to present some of the major contributions made by descriptive epidemiologic studies to the construction of theories and to the field of psychopathology, e.g. the identification of specific anxiety syndromes as significant risk factors for the onset and relapse of depressive illnesses.

As we have also discussed, there is a major lack of clear, current epidemiological reference data for the German-speaking countries; our knowledge of the epidemiology of affective disorders in this area is largely derived from studies performed in the early 1980s. We thus cannot show any clear secular trend toward an increasing prevalence of mental disorders, as has been found in the United States, although a number of studies make such a trend appear likely. Partly because of the lack of relevant data, it is also not yet possible to establish a rational plan for the delivery of mental health care, e.g. with respect to the demand for psychologists.

Genetics of the Affective Disorders

Translator: E. Taub

1 Introduction

The causation of the affective disorders is the subject of much speculation, but little secure knowledge. The most reliable and replicable findings on this topic to date are the following:

- Affective disorders occur with increased frequency in patients' relatives as compared with the population at large, which implies that familial factors play a role in their causation.
- Concordance rates for affective disorders are higher in monozygotic than in dizygotic twins, which implies that these familial factors are at least partly genetic.

Molecular genetic methods that have been available for the past decade now enable the study of single genetic mutations as putative causative factors for genetically determined disorders. More recently, it has also become possible to identify genomic candidate regions that may contain genes influencing the occurrence of affective disorders. The extremely rapid development of molecular genetic methods has given genetic research on the causation of mental illness a decisive push forward.

In this chapter, the classical methods of family genetics that do not rely upon genetic markers, i.e. family, twin, and adoption studies, will be discussed first. These methods serve to establish the fact of familial occurrence, identify familially determined subtypes, and test the relevance of putatively influential genetic factors. The elements of molecular genetic technique will be presented next, followed by a discussion of the present state of molecular genetic research in the affective disorders.

2 Familial Genetic Determination

All studies performed on the subject have revealed that affective disorders occur more frequently in patients' relatives than in the population at large. Table 1 shows the more recent family studies. These studies meet current methodological standards, i.e.:

- The majority of living first-degree relatives were personally studied with standardized interviews and compared with control subjects not affected by mental illness.
- All diagnoses were made in accordance with one of the current diagnostic manuals, which enable operational diagnosis based on well-defined criteria.

The familial lifetime risk of developing an affective disorder, i.e. the risk that a patient's first-degree relative will develop such a disorder at any time of life, varies considerably among studies, with figures ranging from 7% to more than 31%; a similarly wide variation of the lifetime risk of unipolar depression has been found in samples of the general population and in groups of control subjects (0%–23%). Patients with bipolar disorders have a stronger familial loading of affective disorders (of all types, considered as a single group) than patients with unipolar depression. The variation of the lifetime risk of unipolar depression is partly attributable to variable methods of identifying cases (for an overview, see Maier and Lichtermann 1993).

As shown in Table 2, the concordance rates for monozygotic twins are higher than those for dizygotic twins, which implies an at least partly genetic determination of the disease. The degree of heritability (i.e. the percentage of variance attributable to genetic factors) is 60%–80% for bipolar affective disorders and 28%–52% for unipolar depression. The latter figure varies depending on the definition used; maximal heritability is found when the definition requires an episode of unipolar depression to last a minimum of 2 weeks (Kendler et al. 1992b). A few studies support the hypothesis that heritability is lower for less severe degrees of unipolar depression (Torgersen 1986).

The concordance rate among monozygotic twins is 50% for unipolar depression and 80% for bipolar affective disorder. The fact that both of these figures lie under 100% indicates that nongenetic etiological factors are also at work. Putative nongenetic, or at least partly nongenetic, factors under discussion include perinatal complications (particularly for bipolar disorders; Kinney et al. 1993) and critical life events, as well as familial factors such as modes of upbringing, parental neglect, and parental conflict (mainly for unipolar depression; McGuffin et al. 1988; Angst and Wicki 1990; Murray and Sines 1996). The unusually large Virginia Twin Study revealed an interaction between genetic etiological factors and specific environmental factors. The environmental risks were not equally distributed; instead, it was found that the patients at elevated genetic risk for unipolar depression were more exposed to environmental risks and either sought out these risk-enhancing environmental conditions (critical life events) or contributed to them (Kendler and Karkowski-Shuman 1997).

All subtypes of affective disorder appear more commonly in relatives of patients. There are also subtype-specific patterns of familial occurrence, as will be discussed below.

Table 1. Age-adjusted lifetime prevalence of affective disorders in first-degree relatives, compared to control subjects from the general population

Diagnosis	Study	Lifetime prevalence of the illness of the index patient in first-degree relatives (%)	Lifetime prevalence in the general population (%)
Bipolar disorder	Gershon et al. (1988) RDC/DSM-III	7.2	0.3
	Maier et al. (1993) RDC/DSM-III-R	7.0	1.8
Unipolar depression	Gershon et al. (1988) RDC/DSM-III	16.7	6.7
	Kendler et al. (1993c) DSM-III-R	31.1	22.8
	Maier et al. (1993) RDC/DSM-III-R	21.6	10.6
	Winokur et al. (1995a) RDC	10.4	4.9

RDC, Research Diagnostic Criteria.

Table 2. Results of recent twin studies

Diagnosis of the index patient	Study	Pairs of twins studied (*n*)		Concordance rates for the illness of the proband (%)	
		MZ	DZ	MZ	DZ
Bipolar disorder	Bertelsen et al. (1977) ICD-7	32	37	79	19
Unipolar depression	Torgersen (1986) DSM-III	28	46	25%	11%
	McGuffin et al. (1991) DSM-III	62	79	53%	28%
	Kendler et al. (1992b) DSM-III	FGP	FGP	49%	42%
	Kendler et al. (1993a) DSM-III-R	*FGP	FGP	48%	42%

MZ, monozygotic; DZ, dizygotic; FGP, twin study in the female general population, not selected by diagnosis (MZ, 510; DZ, 440).

3 Diagnostic Subclassification of the Affective Disorders

3.1 Unipolar Depression Versus Bipolar Illnesses

The subclassification of affective illnesses into unipolar depressive and bipolar manic-depressive illnesses is highly relevant to patterns of familial occurrence and genetic determination. The great majority of published family studies document a major elevation of the lifetime risk of bipolar disorders in first-degree relatives of patients with a bipolar affective illness (3%–10%), while the lifetime risk of bipolar affective illnesses in relatives of unipolar depressive patients is merely 0.5%–2%, which is not significantly different from that of normal controls (0.5%–1%) (Angst 1966; Gershon et al. 1988; Maier et al. 1993; Winokur et al. 1995b); the relative risk (quotient of lifetime risks) is therefore approximately 7.

This relative diagnostic specificity of increased familial occurrence is found particularly in bipolar subtype I, in which manic episodes are fully developed (Winokur et al. 1995a). Among relatives of such patients, the risk of developing the disease is the same for both sexes (as it is in the general population). It was recently found in a sample of families with a strong history of affective disorders that bipolar affective disorder is preferentially transmitted by the mother of the index patient (McMahon et al. 1995), although this finding has been disputed (Kato et al. 1996).

In families of patients with fully developed bipolar affective disorder, all other variants of bipolar disorder are found more commonly than in the general

population: cyclothymia and hypomania, which are characterized by frequently recurring, but less than fully developed manic and/or depressive episodes (Winokur et al. 1969), and schizoaffective disorders with manic episodes (Maier et al. 1992a). The frequently replicated increased familial incidence of bipolar disorders indicates the validity of the diagnostic differentiation of affective disorders into two types, as found in the currently accepted diagnostic manuals (ICD-10, DSM-IV).

Unipolar depression also occurs more frequently in patients' relatives: while the lifetime prevalence of unipolar depressive episodes (major depression) in the general population is approximately 10%, according to recent epidemiological studies, the comparable figure for first-degree relatives of patients with unipolar depressive episodes is approximately 20% (relative familial risk, approximately 2). Families of patients with unipolar depressive episodes are also subject to a higher-than-normal frequency of less severe or shorter-lasting forms of unipolar depression (including recurrent, brief depression) (Maier et al. 1992b). In such families, as in the general population, all variants of unipolar depression occur approximately twice as frequently in women as in men. As male patients with depressive episodes do not have a stronger family history than female patients, these findings cannot be the result of the so-called Carter effect (sex-specific threshold values in diseases of polygenic etiology, e.g. pyloric stenosis; Merikangas et al. 1985a).

The familial transmission of the unipolar depressive subtype, unlike that of the bipolar affective subtype, is not highly specific. The lifetime risk of unipolar depression is elevated even in relatives of patients with bipolar disorders and is approximately 20%, just as in relatives of unipolar depressives. As far as is known at present, patients with unipolar depression in the familial genetic context of bipolar affective disorders have no distinguishing clinical features (Blacker et al. 1993). Particularly high rates of unipolar depression and suicidal behavior are found in adolescents with a parent suffering from a bipolar disorder (Merikangas 1993). Although bipolar disorders are not often seen before age 18 in the children of parents with bipolar affective disorders, a large fraction of cases of unipolar depression in these children are later transformed into bipolar affective disorder when manic episodes appear. Bipolar affective disorders do not occur more frequently in the families of patients with unipolar depression than in the general population. An analogous specificity for the relatives of patients with unipolar depressive illnesses cannot be demonstrated; the relatives of patients with bipolar affective disorders, as well as those of unipolar depressives, have an increased frequency of unipolar depression, and the lifetime risk in the two groups is practically identical (Gershon et al. 1988; Maier et al. 1993). As shown in Table 2, both subtypes, but particularly the bipolar affective disorders, are subject to genetic influences. As with bipolar depressive syndromes among the families of bipolar depressives, the families of unipolar depressives have an increased frequency of unipolar depressive syndromes of both greater and lesser degrees of severity – the more severe types including depressive episodes with melancholic traits, or somatic syndromes according to ICD-10 and DSM-III-R/IV, the less severe including "minor depression" according to the Research Diagnostic Criteria (RDC), dysthymia according to ICD-10 or DSM-III-R/IV, and repeated brief depressive episodes.

3.2 Subtypes of Bipolar Affective Disorders

The differentiation of bipolar affective disorders with fully developed manic episodes (bipolar I) from those with exclusively less pronounced, so-called hypomanic episodes (bipolar II, if these episodes alternate with depressive episodes) shows long-term interindividual stability (Coryell et al. 1995). Both subtypes occur more commonly in particular families (Endicott et al. 1985). Several studies have shown a surprisingly high subtype specificity of the pattern of familial occurrence of the bipolar II subtype: relatives of patients bearing this diagnosis had a higher risk than relatives of normal controls for the development of bipolar II disorders and unipolar depression, while their risk of developing bipolar I disorders was less markedly increased (see, e.g. DePaulo et al. 1990; Heun and Maier 1993a,b).

Frequent recurrence of the affective disturbance has been repeatedly discussed as a possible indication of familial, genetically transmitted etiology (see, e.g. Goodwin and Ghaemi 1998). This hypothesis is supported by prospective studies of the course of bipolar affective disorders (Winokur et al. 1994). Nonetheless, studies of the families of patients with frequently recurring bipolar affective disorder ("rapid-cycling" type) have repeatedly failed to confirm this hypothesis (Nurnberger et al. 1988; Coryell et al. 1992b; Lish et al. 1993): the relatives of such patients have neither bipolar affective disorders nor unipolar depression more frequently than the relatives of patients with bipolar affective disorders of other types. It is possible, however, that the relatives of rapidly cycling patients are at elevated risk for substance abuse (Lish et al. 1993).

Whether or not an association with rapid cycling can be confirmed, there does appear to be a secure associ-

ation with a positive response to the phasic prophylactic effect of lithium: several studies have shown that a positive response is associated with a stronger family history of bipolar affective disorders (see, e.g. Mendlewicz et al. 1973; Grof et al. 1994), while lack of response may be associated with a stronger family history of schizophrenia (Grof et al. 1994).

3.3 Subclassification of Unipolar Depression

According to a classical hypothesis, reactive or neurotic depression is more likely to occur sporadically, while endogenous depression and particularly bipolar affective disorders are associated with a strongly positive family history (Maier and Philipp 1993). More recent research shows that this hypothesis is probably not correct. None of the more recent family studies employing the current, operationalized diagnostic classifications (i.e. those of the RDC, DSM-III-R, and ICD-10) have shown a higher incidence of depressive illnesses in the relatives of patients with endogenous unipolar depression than in those of patients with nonendogenous unipolar depression.

A further hypothesis, that of subtype-specific homogeneity of the pattern of familial increased occurrence, has also failed to be confirmed. The relatives of patients with endogenous depression, for example, were found to be at increased risk not only for endogenous, but also for nonendogenous depression (Maier and Philipp 1993; Fanous et al. 1996). The same holds true for all of the possible definitions of endogenous or melancholic subtypes of unipolar depression that have been tested to date (RDC, DSM-III-R, ICD-10, Newcastle scales). Known risk factors for unipolar depression, such as elevated neuroticism values and critical life events, are themselves, in turn, subject to genetic influences.

Alongside major depression, the dysthymias are a second common subtype of unipolar depression. Major depression and the dysthymias are both associated with an elevated risk of depressive episodes, recurrent depression, and chronic depression in relatives; this fact indicates that they may share a common etiology, at least in part. Nonetheless, dysthymias, and particularly early-onset dysthymias, are found at significantly increased frequency in the families of patients with early-onset dysthymias, which implies that this subtype may be etiologically distinct (Klein et al. 1995; Donaldson et al. 1997). The combination of both diagnoses ("double depression") is also more commonly found in relatives of patients with this combination (Donaldson et al. 1997).

3.4 Affective Disorders with Psychotic Features and Schizoaffective Disorders

The familial association of affective and psychotic disorders is controversial. No controlled study has shown a significantly elevated risk of developing schizophrenia among relatives of patients suffering from affective disorders without psychotic features (Kendler et al. 1996). Nonetheless, the majority of controlled studies have shown that the relatives of patients suffering from affective disorders *with* psychotic features have an elevated prevalence not only of affective disorders, but also of all types of psychotic disorder (including affective disorders with psychotic features, and schizophrenia). Male relatives of female patients with schizoaffective disorders are at particularly increased risk (Goldstein et al. 1993).

Intrafamilial similarity is usually observed: the more severe the psychotic manifestations are in the index patient, the more likely mental illness will occur in relatives, and the more severe it is likely to be; but the more severe the affective disturbance is in the index patient, the less marked the psychotic manifestations are in the relatives. In general, bipolar disorders with psychotic episodes are more commonly found in relatives of index patients who also suffer from bipolar disorders with psychotic episodes, and less commonly in relatives of index patients suffering from unipolar depression with psychotic features (Maier et al. 1992a).

3.5 Age at Onset of Disease

The age at onset of bipolar affective disorders is usually between 18 and 30 years. Because this range is rather narrow, it is hard to make any firm and replicable statements concerning a possible association between the age at onset of the disease and family history of this or related diseases; furthermore, a well-documented secular trend in the age at onset of the disease (Gershon et al. 1987) makes it still more difficult to demonstrate any such association, if one exists. Unipolar depression, in contrast, may begin at any age, from childhood to advanced age. Several family studies have shown that the increase in the frequency of affective disorders among relatives of index patients with unipolar depressive episodes is inversely proportional to the age at onset of disease in the index patient. In particular, patients who had become ill before the age of 40 had a strongly positive family history, while patients with senile depression (age at onset greater than 60 years) had a negative or only weakly positive family history of affective

disorders (Maier et al. 1991). A number of studies have also shown a weakly positive intrafamilial correlation of the age of onset of unipolar depression (Weissman et al. 1984, 1986; Bland et al. 1986).

As mentioned, the age at onset of affective disorders is subject to a strong secular trend: all over the world, the age at onset of both unipolar depression and bipolar affective disorders is steadily decreasing (Gershon et al. 1987; Cross-National Collaborative Group 1992). Hypothetically, this might be explained by an increasing effect of nongenetic etiological factors. Within families with strongly positive family histories, a further secular trend may be observed: the reported age at onset of the disease decreases with each generation. If early onset of the disease can be regarded as a marker of severity, then this constellation of findings is consistent with the well-known genetic mechanism of anticipation (see below; Penrose 1948). It is generally interpreted in this way.

It is conceivable, however, that this intrafamilial downward shift of the age at onset of disease is merely a methodological artifact (Hodge and Wickramaratne 1995) resulting from retrospective ascertainment, faulty memory, the reduced availability of elderly relatives for questioning, and generation-specific stratification effects. The fact that a small number of families show a secular trend in the opposite direction seems to make this type of artifact less likely to be the cause of the phenomenon (Grigoroiu-Serbanescu et al. 1997).

4
Cosegregating Disorders and Traits

4.1
Nonaffective Disorders Cosegregating with Unipolar Depression

Families of patients with affective disorders have a higher frequency not only of affective disorders, but also of nonaffective disorders. Several family studies have shown that anxiety disorders (Kendler et al. 1992a; Weissman et al. 1997) and alcohol dependence (Winokur et al. 1971; Winokur and Coryell 1991) occur at increased frequency in families of unipolar depressive patients, without themselves being sequelae of unipolar depression. Above all, unipolar depression and anxiety disorders tend to occur in the same families more often than would be predicted by chance (Merikangas et al. 1985b; Weissman et al. 1997). Moreover, different subtypes of anxiety disorder have different patterns of cosegregation. Panic disorders are transmitted independently, or nearly independently, of unipolar depression (Weissman et al. 1993; Maier et al. 1995a). Unipolar depression and generalized anxiety disorder, however, seem to be alternative expressions of a single genetic predisposition: it has been shown in two groups of twin pairs that the genetic causative factors of depressive disorders and generalized anxiety disorders overlap to a considerable extent (Kendler et al. 1992a). The phenotypic differentiation of the two disorders depends primarily on the specific environmental conditions affecting the individual rather than on genetic factors.

The putative familial/genetic connection between unipolar depression and alcohol dependence and abuse is controversial (Merikangas et al. 1985b; Coryell et al. 1992a; Maier et al. 1994). A familial connection between a subtype of alcoholism in men and a subtype of unipolar depression (so-called spectrum depression) in women was postulated by Winokur, but could not be confirmed in the majority of subsequent studies. Family studies do, however, show that patients with chronic depression of early-onset type (dysthymia, particularly subaffective dysthymia) have a more strongly positive family history of alcoholism than patients with other subtypes of affective disorder (Anderson et al. 1996). A twin study employing younger female subjects revealed a moderately elevated cosegregation of unipolar depression of early onset and alcoholism, which implies a moderately strong correlation of the genetic risk factors for these entities (Kendler et al. 1992c, 1993d).

The familial relationship between unipolar depression and nicotine dependence has also been investigated. A twin study (Kendler et al. 1993b) revealed that these two disorders occur in the same families more frequently than would be predicted by chance. This finding implies that there are genetic risk factors common to the two disorders, which manifest themselves alternatively (or simultaneously) as unipolar depression and nicotine dependence.

The putative familial relationship between unipolar depression and eating disorders is controversial. The most recent family study (Lilenfeld et al. 1998), in contrast to earlier studies (Strober et al. 1990), yielded no evidence to support such a relationship.

The first-degree relatives of patients with unipolar depression of any clinical subtype have an elevated frequency of clinical personality disorders (Coryell and Zimmermann 1989; Maier et al. 1992c; Klein et al. 1995). This association is due in part to comorbidity of depression and personality disorders in the index patient. In some subtypes of unipolar depression, however, the association is particularly strong, implying the existence of common familial risk factors. This is true especially of the association between dysthymia and all of the cluster B personality disorders (borderline, antisocial, histrionic, and narcissistic personality disorders) (Klein et al. 1995; Riso et al. 1996). The hypothesis that borderline personality disorders (or

the subtype of borderline personality disorder characterized by lability of affect) are variants of affective disorders, for which most of the earlier evidence was derived from sleep-polygraphic studies (Akiskal et al. 1980), thus obtains limited further support from family genetic studies.

4.2 Nonaffective Disorders Cosegregating with Bipolar Disorders

Family studies have been performed to investigate the putative familial association of bipolar affective disorders with alcoholism, anxiety disorders, and childhood hyperkinetic syndrome (Winokur et al. 1993; Maier et al. 1995b; Wozniak et al. 1995; MacKinnon et al. 1997). All of these studies revealed that the latter disorders are transmitted largely independently of bipolar affective disorders, despite the occurrence of comorbidity more frequently than would be predicted by chance. It was also observed that the occurrence of two disorders in the index patient is associated with comorbidity of both disorders in relatives more frequently than would be predicted by chance. Thus comorbidity of bipolar disorders with the other illnesses listed seems to define an etiologically distinct subtype of bipolar disorder. Moreover, there is discussion over a possibly increased frequency of bipolar disorders in the biological relatives of children with fragile-X syndrome and Gilles de la Tourette syndrome (Jeffries et al. 1993; Kerbeshian et al. 1995).

The pattern of familial association of unipolar depression with other diseases is less diagnosis specific than that of bipolar affective disorders (with particular reference to nonaffective disorders). The morbidity of all types in families of unipolar depressive patients is, however, no greater than that in families of patients with bipolar affective disorders.

4.3 Cosegregating Personality Traits

A number of personality traits occurring more commonly in depressed patients also occur more commonly in biological relatives of depressed patients who have never themselves suffered from any mental disorder. Such individuals at risk have been found to have an elevated mean value for neuroticism (Maier et al. 1992c; Kendler et al. 1993a; Lauer et al. 1997; less marked: Ouimette et al. 1996), which was also found to be a risk factor for the later appearance of depressive disorders. Prospective twin studies in the general population have revealed that the genetic determination of unipolar depression is partly mediated by the genetic determination of the personality dimension of neuroticism or critical life events (Kendler et al. 1993a).

In addition to neuroticism, rigidity has also been found more frequently in the healthy relatives of unipolar depressives (Maier et al. 1992c; Lauer et al. 1997). The personality traits of healthy relatives of patients with bipolar affective disorders have not been studied as extensively. An elevated average value for rigidity, but not neuroticism, was found in a recent study (Maier et al. 1995c) as well as in the earlier study by Klein and Depue (1985).

Several aspects of personality subsumed under the concept of "temperament" may have a genetic relationship to the affective disorders. This term denotes, among other things, the basic energetic conditions for emotional behavior. Temperamental factors are strongly genetically determined, in contrast to character factors, which are subject to the influences of family environment and upbringing. Certain temperamental factors are under consideration as possible genetically determined risk factors (also termed "endophenotypes" or "intermediate phenotypes") that may confer a large part of the genetic risk for affective disorders. Temperamental factors such as depressivity and "harm avoidance" (the latter strongly correlated with neuroticism) have been discussed as possible intermediate phenotypes for unipolar depression, and hyperthymic temperament as a possible intermediate phenotype for bipolar disorders (Cassano et al. 1992); these relationships are implied by elevated mean values of these factors in the (still) healthy relatives of patients with these disorders. Analogous relationships were postulated long ago by Kraepelin (1921) and Kretschmer (1936). A further discussion of personality factors is found in Chap. 20 (Vol. 3, Part 1).

4.4 Cosegregating Normal Biological Variants (Vulnerability Markers)

Pathophysiological correlates of unipolar and bipolar depression also occur more frequently in the relatives of depressed patients who have never suffered from any mental illness themselves:

- Sleep patterns characteristic of depression (Lauer et al. 1995) – elevated "rapid eye movement" (REM) density, lesser percentage of "slow-wave sleep" – are more common in healthy individuals with a family history of depression than in the general population.
- Cholinergic supersensitivity: A greater than normal shortening of REM latency in response to the administration of cholinomimetic agents is seen in healthy individuals with a family history of affective disorders more commonly than in the general

population (Schreiber et al. 1992). This finding supports the hypothesis that a familial, genetically transmitted adrenergic or cholinergic imbalance is a marker of vulnerability to affective disorders (Janowsky et al. 1994).
- The healthy children of patients with affective disorders (unipolar-depressive and bipolar), like depressed patients themselves, react to certain stresses with overactivity of the autonomic nervous system; the children's reactions are, however, less intense (Zahn et al. 1989).
- The intensification of depression and dysphoria that may be induced in depressed patients by tryptophan depletion is also seen in the healthy relatives of depressed patients; this finding implies that the serotonergic system is dysfunctional not only in depressed patients, but also in individuals with an elevated risk of developing the disease (Benkelfat et al. 1994).
- Nonspecific disturbances of slow ocular pursuit appear to be present at higher than normal frequency in the healthy children of individuals suffering from affective disorders (Rosenberg et al. 1997). In addition, prolongation of the P300 latency, which is more frequently observed in patients with affective disorders, is considered a possible vulnerability marker cosegregating with bipolar affective disorders (Blackwood et al. 1996a).

These normal biological variants perhaps represent prodromal states of affective disorders that will later become clinically overt or, alternatively, attenuated forms of disease that are not severe enough to be clinically manifest because of favorable environmental factors, despite the presence of genetic risk factors. Follow-up studies are needed to determine which, if either, of these explanations is correct.

5 Affective Disorders as Genetically Complex Disorders

In monogenic diseases, a single gene or several variants at a single genetic locus are responsible for the occurrence of a disease. If this is the case, the gene is referred to as the causative gene. Such diseases are transmitted, according to the mendelian rules, in either a dominant or a recessive pattern. The observed patterns of familial occurrence of the affective disorders are, however, not compatible with mendelian inheritance.

In the polygenic transmission model, genetic variants at multiple loci may contribute to the severity of the disease phenotype. These "risk-modulating" genes may have cumulative (additive) or synergistic (mutually potentiating) effects, or their effects may be physiologically interchangeable. In this model, an abnormality of any single gene is neither necessary nor sufficient to produce the disease, and there is no single causative gene; rather, each of the contributing genes incrementally affects the probability of the individual's developing the disease, and they are therefore referred to as "susceptibility genes" (Greenberg 1993). It is thus entirely conceivable that such genes may be found in individuals not suffering from the given disease who lack the additional factors that would be necessary to produce the disease (i.e. further susceptibility genes or environmental influences). If both environmental and (poly)genetic factors are important for the generation of the disease, its transmission is said to be multifactorial. There may also be interactions among genetic factors or between genetic factors and nongenetic environmental factors.

Family studies have shown that no simple mode of inheritance can account for the pattern of familial occurrence of affective disorders:

- Biometric analyses of the pattern of familial transmission of bipolar affective disorders imply that monogenic transmission is unlikely. Several segregation studies suggest that some genes may account for a significant portion, though not all, of the genetic variance ("major genes") (Rice et al. 1987; Spence et al. 1995), but other segregation analyses make this seem implausible (Craddock et al. 1995c, 1997). Without using genetic markers, however, segregation analyses cannot adequately differentiate between competing complex models of transmission. The linkage analyses performed to date for the bipolar affective disorders indicate that genes influencing the risk of disease are located in several regions (see below). This finding suggests that the transmission is polygenic and that each of several genes contributes only a small amount to the total (thus a variant of complex genetic inheritance). The increased occurrence of unipolar depression in the families of patients with bipolar affective disorder may thus indicate a partial commonality of the genes contributing to the genesis of both types of disorder. There is, however, as yet no verified hypothesis concerning the mode of complex genetic transmission.
- Bipolar disorders and unipolar depression have imperfect concordance (well under 100%) in pairs of monozygotic twins, which implies that nongenetic factors have an influence on the occurrence of the disease.
- Biometric segregation analyses have determined that the patterns of inheritance of bipolar disorders and of unipolar depression are incompatible with

monogenic transmission (see above). Nonetheless, genetic heterogeneity of these disorders cannot be ruled out; it may be that they are indeed transmitted, in some of the multiply affected families, by a single, causative gene, in accordance with the rules of mendelian inheritance. It is also possible that different combinations of susceptibility genes are responsible for the development of illness in different families.

- A progression of disease severity across the generations may be observed in families with multiple cases of bipolar affective disorders (see below). The age at onset of the disease is taken as the most important indicator of severity (McInnis et al. 1993). This progressive pattern in affected families is hypothetically attributed to an anticipation mechanism (see below).
- The probability of familial occurrence may depend on the sex of the transmitting parent, particularly in affective disorders (see, e.g. McMahon et al. 1995), where the disorder is more likely to be transmitted maternally. This has been shown for families strongly affected by bipolar disorders (McMahon et al. 1995) and for unipolar depression in the families of patients treated for depression (Keller et al. 1986). In view of the fact that mothers influence familial environmental factors more strongly than fathers, it may be that this sex-specific mechanism of transmission is due to nongenetic factors.

A number of plausible human genetic models have been developed to explain complex genetic transmission (Lander and Schork 1994):

- Incomplete penetrance: some individuals bearing the mutation that leads to a given phenotype may not, in fact, possess that phenotype. A mutation of the BRCA1 gene, for example, leads to the development of breast cancer by age 80 in no more than 85% of women.
- Phenocopy: some individuals bear the phenotype, but not the mutation; thus the phenotype may be produced by other factors, e.g. nongenetic environmental factors.
- Genetic heterogeneity: different mutations at different genetic loci might produce the same phenotype. Mutations at different loci might thus lead to different patterns of familial occurrence: the different mutations giving rise to early-onset familial Alzheimer's disease (Van Broeckhoven 1995) are an example of this phenomenon. Alternatively, there may be allelic heterogeneity, i.e. different mutations of the same gene may produce the phenotype, e.g. β-amyloid precursor protein (APP) mutations (Fidani et al. 1992) and presenilin mutations in early-onset familial Alzheimer's disease (Van Broeckhoven 1995). In monogenic disorders, which are very rare, allelic heterogeneity generally does not induce a complex pattern of familial occurrence.
- Polygenic transmission: the simultaneous presence of several mutations at different genetic loci may be required for the production of a given phenotype. Each one of the genes involved makes only a small contribution to the production of the phenotype, and a mutation in any individual gene is not necessarily required. Genes that play a more important role than others are called major genes. Genetically determined quantitative phenotypic variations are generally the result of polygenic transmission (e.g. hypertension).
- Anticipation: most of the known mutations are stable and are transmitted according to the classical mendelian rules. There are, however, so-called dynamic mutations whose base-pair sequence changes during mitosis, with the result that parents and children may have different mutations. Multiply repeated base-pair sequences (usually triplets, such as CAG) with variable numbers of repeats are an example. Such mutations are stably transmitted when the number of repeats lies below a certain threshold; however, when there are more than this number of repeats, the number may change – usually with an increase ("expansion") – during mitosis. Unstable mutations have been found to date in several disease-conferring genes, e.g. Huntington's disease (Huntington's Disease Collaborative Research Group 1993) and fragile-X syndrome (Verkerk et al. 1991). The number of repeats beyond the critical threshold for the disease is correlated with disease severity. Thus so-called full mutations of the FMR-1 gene locus (more than 150 CGG repeats) lead to the full development of fragile-X syndrome in boys, with mental debility and severe behavioral disturbances; the presence of 60–150 repeats ("premutation") leads to reduced intelligence and mild behavioral abnormalities in adult men; and alleles with fewer than 60 repeats are stably transmitted. The progression of disease severity (i.e. progressive reduction of age at onset of disease; see above) in families affected with bipolar disorders over several generations has given rise to the hypothesis that these disorders, too, are produced by dynamic mutations (Petronis and Kennedy 1995).

6 Strategies for the Identification of Genetic Variants of Mental Disorders

For monogenic inherited diseases, there is a well-charted path to the discovery of the causative gene,

Table 3. Comparison of linkage and association analysis

	Linkage analysis	Association analysis
Purpose of investigation	Cosegregation, i.e. common transmission of "gene" and disorder in multiply affected families	More frequent occurrence of an allele in the presence of a disorder
Sample	Multiply affected families over several generations	Independent patients and independent control subjects
Strategy	Genome scan, candidate genes	Candidate genes
Genetic markers	Highly polymorphous; distributed throughout the genome with the shortest possible intervening distances	If possible, only biallelic markers within or immediately adjacent to candidate genes; polymorphism should be expressed, if possible, as functional variation
Product of investigation	Candidate region	Candidate gene or linkage imbalance
Dependence on sample ("ascertainment bias")	Low	High
Sensitivity for:		
Genes responsible for a high percentage of the variance	High	Less high
Genes responsible for a low percentage of the variance	Very low	Low

beginning with gene localization by means of linkage studies in different families and ending with the demonstration of mutations in the gene causing the illness. The causative gene is localized to a given chromosomal segment of the genome by means of linkage analyses. Once such a segment is identified, it is subdivided into smaller DNA fragments. These fragments are then searched for genes, which, in turn, are searched for mutations in patients with the disease (e.g. by sequence analysis). If corresponding changes are found only in patients with the disease and not in healthy subjects, then the gene in which they are found may be the causative gene for the disease.

In principle, the same route may be taken to determine the causative genes of more complex diseases, such as the psychiatric diseases under discussion here. It is much more difficult, however, to find genetic abnormalities associated with these diseases (see, e.g. Baron 1996), for the following reasons:

- The mode of inheritance is non-mendelian and not yet determined.
- The phenotype transmitted in families is not clearly defined, but rather has unsharp boundaries and may be heterogeneous.
- Complex disorders are usually common illnesses, so phenocopies may be common (i.e. an identical clinical picture may be the result of nongenetic causes; see above).
- The disease may be genetically heterogeneous.
- Nongenetic environmental factors may play a significant role.
- Common genetic variants may increase an individual's risk of developing the disease, while the commonness of these variants has the effect of reducing the information available to the investigator (Lander and Schork 1994).

There are two ways to search for disease-associated genetic changes at the level of the genome: association studies and linkage studies. Both approaches are used to search for susceptibility genes for complex illnesses. Both start from the assumption of a categorical designation of patients as having the disease. A side-by-side comparison of the most important aspects of the two approaches is given in Table 3. A more extensive discussion of these methods is found in Chap. 4 (Vol. 1, Part 1).

7 Results of Genetic Marker Studies

7.1 Linkage Studies

The results of initial linkage studies using DNA markers were published as early as 1987 (Table 4); these studies were of a large Old Order Amish family (Egeland et al. 1987; Kelsoe et al. 1989). Bipolar affective disorders in this family were found to be

linked to a region on the short arm of chromosome 11, in which not only the dopamine D4 receptor, but also the enzyme tyrosine hydroxylase (TH) are encoded. Nonetheless, further studies of this region in other families and in a more extensive sample of the initial family, including collateral branches, failed to replicate the finding of linkage.

Replicable findings concerning the genetic linkage of bipolar affective disorders have become available only in the last 2–3 years. The most important of these are listed below.

Chromosome 18

Berrettini et al. (1994) were the first to report a linkage of pericentromeric markers on chromosome 18 with bipolar affective illnesses in 22 families. This region and also the long arm of the chromosome were then intensively studied by several research groups. Both positive and negative findings were published; an overview of these studies is given in Table 4. It is particularly noteworthy that some of the research groups found clearer evidence for a predisposing genetic locus when the families were chosen in consideration of whether the illness was maternally or paternally transmitted (Stine et al. 1995). Evidence for a genetic locus on chromosome 18q was found mainly in families in which the transmission was largely paternal. This constellation of findings was replicated by a German research group (Nöthen et al. 1996). The genetic transmission of the risk-conferring gene may depend on the sex of the transmitting parent. If this is true, then "imprinting," a previously described mode of molecular genetic transmission, might be the mechanism by which it occurs, although the participation of an imprinting factor has not yet been demonstrated (Stine et al. 1995; Nöthen et al. 1996). A further susceptibility gene may lie on the long arm of chromosome 18 (18q23) (Freimer et al. 1996).

Chromosome 21

Straub et al. (1994) found a possibly predisposing genetic locus on chromosome 21q22.3 by means of a genome scan of North American and Israeli families. This finding was replicated in a separate family by Gurling et al. (1995) and then by Detera-Wadleigh et al. (1996). A region on chromosome 21q overlapping with this original region was found independently in a sample of North American twin pairs affected by the illness; this finding was made in the course of a genome-wide search for predisposing genetic loci (as

described further below), which was a component of the extensive NIMH Collaborative Study (Detera-Wadleigh et al. 1997). Negative linkage findings were obtained, however, in one North American (Byerley et al. 1995) and one Danish family sample (Ewald et al. 1996).

Chromosome 16

In 1993, Eiberg et al. reported the linkage of a phenotypic marker on chromosome 16p (phosphoglycolate phosphatase) with bipolar affective illnesses. This finding was replicated by two research groups using polymorphic genotypic markers (Ewald et al. 1995d; Edenberg et al. 1997), while two further groups (LaBuda et al. 1996; Adams et al. 1997) found no evidence for a predisposing genetic locus in this region. Further studies are needed before the significance of this region can be determined conclusively.

Chromosome 12

The 12q23–q24.1 region of chromosome 12 has been intensively studied. Craddock et al. (1994a) reported the cosegregation of bipolar illness and Darier's disease with markers in this region. Studies by two independent groups of investigators provided further evidence for a linkage of this region with bipolar illness. Weak evidence for a linkage was also provided by the genome-wide search for predisposing genetic loci for affective illness, which is described further below (Rice et al. 1997).

Chromosome 4

Blackwood et al. (1996b), studying a large Scottish family with affective disorders, found clear evidence for a predisposing genetic locus on chromosome 4p. This study was replicated by a German group (M.M. Nöthen et al. unpublished). No evidence for a linkage was found in the NIMH Collaborative Study of ill twin pairs, which employed identical markers (Detera-Wadleigh et al. 1997).

X Chromosome

X-chromosomal transmission is characterized in the formal genetic sense by the lack of father–son transmission of the disorder. This pattern is only rarely observed; in a subgroup of pedigrees with familial affective disorders, the pattern of inheritance is reportedly consistent with sex-linked transmission (Pekkarinen et al. 1995). A possible linkage of affective disorders with the genetic locus for red–green color blindness and glucose-6-phosphate dehydrogenase on chromosome Xq28 has been under study for three decades, but the findings to date have not been consistently positive. These families were first studied with clinically defined markers and later with molecular genetic markers (for a review, see Berrettini et al. 1990). Table 4 provides an overview of recently published reports.

The findings of Pekkarinen et al. (1995) are particularly noteworthy. Affective disorders in a large Finnish family were found to be linked to a candidate region overlapping with Xq28. The extensive NIMH Collaborative Study revealed further evidence for such a linkage in a group of ill North American twin pairs (Stine et al. 1997). Linkage to a gene in the Xq28 region thus remains possible for a subgroup of families with familial affective disorders, despite the numerous negative findings to date.

Furthermore, the region of genetic linkage appears to depend on whether the affected twin pairs consist of brothers or sisters. Stine et al. (1997), for example, reported a possible linkage with Xp22 for pairs of brothers and Xq26–q28 for pairs of sisters. Here, too, further analyses are needed before the question of linkage to these regions can be definitively answered.

The initial findings of a multicenter study involving a genome-wide search for genetic loci predisposing to bipolar affective illnesses were published in 1997 (NIMH Genetics Initiative Bipolar Group 1997; see Table 4). Four centers in the United States collected a total of 97 families (540 individuals) with affective illnesses for investigation, and 301 highly informative microsatellite markers, spaced an average of 10 cM apart, were used in the study. Both parametric and nonparametric statistical analyses were performed. A total of 34 regions of the genome were identified as possibly containing a genetic locus predisposing to affective illness. None of these regions, however, contained a locus accounting for more than 50% of the variance in bipolar affective disorder. The regions identified included segments of chromosomes 1p31, 7q21–31, 10p12, and 16p12.

This study revealed no evidence for a genetic locus for affective disorders on either chromosome 4 or chromosome 18; the regions on chromosomes 21, 16, and 12 mentioned in the above discussion were, however, among those identified as possibly containing a locus predisposing to affective illness.

A summary of currently available data on genetic linkage in the affective disorders is found in Table 5.

7.2 Association Studies

Recent genetic association studies have involved genes participating in both the dopaminergic and the serotonergic systems. Polymorphisms of the serotonin 2A receptor and of the serotonin transporter have been investigated for a possible association with bipolar illness (Table 6).

Tyrosine Hydroxylase

TH, the key enzyme in cathecholamine synthesis, may play a role in the pathophysiology of affective

disorders. From 1990 onward, a group of investigators in France found evidence supporting a possible association of TH alleles with bipolar affective disorders (Leboyer et al. 1990; Meloni et al. 1995). These studies all involved a comparison of patients with independent control subjects. A large number of other groups were unable to replicate this finding, which may actually have been an artifact produced by stratification effects (see, e.g. Körner et al. 1994; Rietschel et al. 1995; Turecki et al. 1997).

Serotonin Transporter

The serotonin transporter gene (5-HTT) is located on chromosome 17 and is known to have two sites of polymorphism:

- A site in the gene promoter region, where the shorter of two variant forms is associated with reduced expression of the transporter
- A highly variable site ("variable number of tandem repeats"; VNTR) in intron 2 of the gene

Both polymorphisms have been investigated by multiple groups for a possible association (see Table 6). No final conclusion can yet be drawn as to whether or to what extent the serotonin transporter participates in the generation of bipolar illnesses.

Serotonin 2A Receptor

The fact that the serotonin 2A receptor (5-HT-2A) participates in the mechanism of action of the newer antidepressants has led to intensive investigation of this receptor for a possible association with bipolar illnesses. No such association has yet been found, and it is thus not yet known whether 5-HT-2A plays a role in the generation of bipolar illnesses. The published findings to date are summarized in Table 6.

Tryptophan Hydroxylase

Tryptophan hydroxylase (TPH) is the rate-determining enzyme in serotonin synthesis and is thus regarded as a candidate gene with respect to affective disorders. A group of investigators in France (Bellivier et al.

+, positive finding; –, negative finding.

1998) recently reported an association between a noncoding variant and bipolar disorder. Replication studies are needed to determine whether this finding is merely an artifact produced by stratification effects. A way to counteract this possibility might be the use of internal controls. In this technique, not only the index subjects, but also their parents are studied. The alleles transmitted to the ill index subjects are used as the study sample, while the parental alleles that are not transmitted are used as a control sample.

Monoamine Oxidase A and B

The enzymes monoamine oxidase (MAO) A and B serve to degrade neurotransmitter substances; their pharmacologic inhibition has an antidepressant effect. The genes for both enzymes lie on the long arm of the X chromosome and are polymorphic. A nonsense mutation preventing the synthesis of MAO-A has been described. This mutation has been shown to be responsible for the occurrence of a form of mental retardation, along with a tendency toward aggression and manic behavior, in a Dutch family with many affected members (Brunner et al. 1993). A further restriction fragment length polymorphism (RFLP) of the MAO-A gene has been found to be associated with elevated MAO-A activity in vitro (Lim et al. 1995). This MAO-A gene polymorphism and a further one were found to be weakly associated with bipolar disorder in several British study cohorts and in one Japanese cohort (Kawada et al. 1995b; Lim et al. 1995; Rubinsztein et al. 1996), but these findings were not definitively replicated in a further British study (Craddock et al. 1995b).

All association studies of MAO genes yielding positive findings to date have employed groups of independent control subjects that were not shown to be sufficiently comparable to the patient group to rule out the possibility of a false-positive result (see above). The few studies employing internal controls (Nöthen et al. 1995; Parsian and Todd 1997), which are not subject to this criticism, revealed no positive association for alleles of either the MAO-A or MAO-B gene. It therefore seems unlikely that the MAO genes play a role in the generation of the illness.

Other Possible Associations

Several studies have concerned the catechol *O*-methyl transferase (COMT) gene on chromosome 22 and the phospholipase A2 (PLA-2A) gene on chromosome 12 (which lies in the region of the genetic locus for Darier's disease). Their findings have been inconsistent for the PLA-2A locus and uniformly negative for the COMT locus. No definitive conclusion can yet be drawn regarding the relevance of the PLA-2A gene to the generation of the disease.

7.3 Repeat Expansion Detection

A British group working mainly with the repeat expansion detection (RED) technique demonstrated, in two separate studies, that patients with bipolar illness have expanded trinucleotide repeat sequences more frequently than control subjects (O'Donovan et al. 1995, 1996). Oruc et al. (1997) arrived at the same result for familial cases, while Lindblad et al. (1995), too, found expanded trinucleotide repeats in patients. Vincent et al. (1996) attempted, but failed, to confirm these findings. O'Donovan and colleagues (see Guy et al. 1997) studied 50 specific loci containing trinucleotide repeats, but failed to find expanded repeats of any of them in patients. An American group employed a hybridization technique to search specific loci for polymorphic trinucleotide units and then look for corresponding expansions in patients and control subjects. By means of this method, an association of expanded trinucleotide repeats in 13 different loci with bipolar illness was ruled out (Jain et al. 1996), but a partly unstable CTG repeat on chromosome 18q21.1 was found, which is sometimes enormously expanded (Breschel et al. 1997). Unfortunately, no association of this site with bipolar illness has yet been demonstrated.

In the coming years, the extent to which expanded trinucleotide repeats participate in the generation of the disease will become clearer. An assessment of the findings obtained by RED will be possible only after the expanded trinucleotide repeats have been localized in the genome.

8 Concluding Remarks

Clinical epidemiological studies have shown that affective disorders occur more frequently in relatives of affective patients and that they are partly genetically determined, but the mechanism of genetic determination remains unclear.

To summarize the subclassification of affective disorders, it may be stated that the patterns of familial occurrence of the various subtypes of unipolar depression and of bipolar disorder have certain similarities: all subtypes of affective disorder studied to date are associated with a higher frequency of depressive episodes (major depression) in patients' relatives than in the general population. On the other hand, subtype-specific patterns of increased occurrence have also been observed: bipolar affective disorders occur more frequently only in families of patients with bipolar

affective and bipolar schizoaffective disorders. The latter fact distinguishes this group of diagnoses etiologically from all variants of unipolar depression and indicates that genetic factors play a major causative role.

While unipolar depressive episodes occur with increased frequency in relatives of patients suffering from any type of affective disorder, early-onset dysthymias are more common in relatives of patients with dysthymia, but not in relatives of patients without dysthymia who suffer from depressive episodes.

Bipolar I disorders occur more commonly in relatives of patients with bipolar I, and similarly for bipolar II disorders, although there is some overlap in both directions.

The earlier model ("multiple threshold model") of a familial and genetic continuum, in which schizomanic disorder is the most severe and most highly familial element, followed in sequence by bipolar I disorder, bipolar II disorder, and then unipolar depression (Gershon et al. 1982), is no longer plausible in view of the partial specificity of the subtypes of the affective disorders. Rather, it must be assumed that the familial and genetic risk factors of the various subtypes are partly subtype specific and partly overlapping. There is relatively little genetic overlap between unipolar depressive disorders and bipolar affective disorders.

The pattern of familial transmission of affective disorders, and of all of their known subtypes, is determined by both genetic and nongenetic factors. Bipolar I disorders are the type most strongly influenced by genetic factors.

The patterns of familial transmission of the affective disorders do not correspond to the known patterns of transmission of monogenic diseases, and they also make the existence of a single, major gene appear unlikely for the majority of multiply affected families. The affective disorders are, therefore, genetically complex disorders. Specification of the causative genetic factors of such disorders is obtained by the identification of susceptibility genes through linkage and association studies; the latter technique is more likely than the former to yield false-positive results. Present knowledge with regard to susceptibility genes is largely limited to bipolar affective disorders; only a few genetic association studies have been performed on the familially transmitted phenotype of unipolar depression, both because it is imprecisely defined and because it is more weakly genetically determined than bipolar disorder, as discussed above. No study to date concerning genetic markers in unipolar depression has yielded replicable positive findings.

Linkage studies have revealed several candidate regions for bipolar affective disorders, and findings have been replicated. The majority of the findings are consistent with polygenic transmission and thus accord with the findings of segregation analysis performed without genetic markers.

The linkage signal is sharply delimited and distinct in the case of monogenic diseases; therefore, as a rule, the candidate regions revealed by linkage studies can be narrowed down further by the study of critical recombinations located between the disease and marker genes (Kruglyak and Lander 1995). The replicable candidate regions emerging from linkage studies of complex disorders are rather broad (approximately 20 cM); further narrowing of candidate regions and the identification of susceptibility genes will therefore require either good fortune or a long-term, systematic search.

The candidate regions may contain candidate genes whose products play a role in the pathophysiology of the disorder. If these candidate genes are in fact susceptibility genes, decisive evidence for the fact can be obtained from mutation analysis of the candidate genes, suitable further linkage and association studies, and studies of the functional correlates of mutations. The study of the genetics of schizophrenia and the affective disorders has not yet reached this desirable state, but new candidate genes are continually being discovered as the pathophysiology of these disorders becomes better understood and the associated gene products are identified.

Under current conditions, candidate regions can be narrowed down by the following means:

- Enlargement of the family sample and thus of the number of recombinations; this enhances the power of the statistical analysis and enables a more precise definition of the region of the genome that might contain a susceptibility gene.
- Analyses of linkage to narrowly spaced, highly polymorphic markers (N.B.: the identification of susceptibility genes in this manner may require a very large sample).
- Determination of linkage disequilibrium between the marker and disease loci in nuclear family samples (ill index patient and both parents). Linkage disequilibrium represents the number of recombinations that occurred between the marker and disease loci in earlier generations. Linkage disequilibrium is more informative than linkage, insofar as it is more pronounced at the disease locus when the relative risk is low and falls off rapidly to insignificance as a function of the separation between marker and disease loci. This strategy is particularly promising in isolated or inbred populations, in which linkage disequilibrium is strong (Jorde 1995).
- Linkage disequilibrium of candidate gene loci in regions linked to the locus of the susceptibility gene.

This strategy may attain its objective rapidly if mutations of the candidate gene locus directly influence the risk of developing the disease (e.g. the fibrillin gene in Marfan's syndrome).

The advantages just mentioned of determining linkage disequilibrium, as opposed to determining linkage, will become particularly evident once the Human Genome Project has succeeded in its goal of mapping all genes on the genome and once alternatives have been developed to the relatively cumbersome electrophoretic sequencing techniques currently available (e.g. chip technology). All alleles of polymorphous genes (of which there are about 100,000) can then be studied for linkage disequilibrium. If certain assumptions are made as part of the model, the number of nuclear families (ill index patients and their parents) that will have to be enrolled or recruited for such studies will remain within practical limits (Risch and Merikangas 1996).

Genes shown by linkage analysis to possess mutations associated with an elevated risk of developing an affective disorder will certainly be accessible to identification, the more so in view of the steady progress being made in gene sequencing techniques and the speed at which the base pair sequence of the human genome is already being determined at present.

CHAPTER 19

F. Henn

Neurobiology of Affective Disorders

1 Introduction

The initial evolution of a biological explanation of mood and mood disorders came from accidental observations in internal medicine. Two observations resulted in the initial framing of the catecholamine hypothesis of affective disorders. The first came about when iproniazid was introduced for the treatment of tuberculosis. Patients at that time were sent to large sanatoriums and the initial trials of iproniazid were therefore carried out in these large clinic settings. It was noticed that patients on the new medication had pronounced mood elevation with increased sexual interest and had a picture which was essentially hypomanic. It was soon established that iproniazid was a monoamine oxidase inhibitor (MAOI) and could be expected to raise amine levels. The second observation was made in the treatment of hypertension. Reserpine was used in the 1950s and 1960s as the major drug in treating hypertension. Internists noted that up to 20% of the patients treated with reserpine developed severe depressions, and several suicides were reported. The mechanism of action of reserpine appears to be a depletion of catecholamines from storage vesicles, leading to decreased release of catecholamines. Putting these two observations together led to the catecholamine hypothesis of affective disorders, which in simple form stated that catecholamines were elevated in mania and decreased in depression. The initial focus was on the role of norepinephrine (NE), but very quickly interest in the role of serotonin grew, and evidence for this transmitter playing a role in depression accumulated.

The overly simplistic nature of a one-transmitter view of the affective disorders has gradually given way to a more integrative approach in which many transmitter systems and endocrine systems are seen to interact to produce mood disturbances. At present, there is no single accepted biological theory of depression. In this chapter, we will briefly review the evidence implicating major transmitter systems in depression and the role of the hypothalamic–pituitary–adrenal (HPA) axis in mediating stress and depression and will then attempt to show how these results can be integrated and where additional data is still needed. The concept which will emerge suggests that a variety of vulnerability factors may combine to lead to affective disorders.

2 Norepinephrine

We will begin our overview with NE. This system involves only about 15,000 cells in the central nervous system (CNS), located in the locus ceruleus and scattered in the lateral ventricle tegmental fields. This system has widely distributed projection throughout the limbic system, midbrain, cerebellum, and cortex. The distribution suggests a modulatory role for norepinephrine rather than the primary transfer of information. The system appears to play a role in regulating mood and anxiety, controlling the sleep–wake cycle, and even in memory and learning.

In an effort to support a basic role in depressive pathophysiology for NE, considerable effort has gone into looking at metabolite levels of NE in blood and plasma. One serious problem with this is that both urine and blood metabolite levels reflect predominantly peripheral rather than central levels of NE release. These studies have in general yielded conflicting results; there is a tendency to find lower urinary 3-methoxy-4-hydroxyphenylglycol (MHPG) in bipolar probands than in depressive probands. This appears especially true for bipolar I patients, whereas bipolar II patients show no differences (Schatzberg et al. 1989). Similar uncertainty exists with the response of metabolites to antidepressant treatment and with cerebrospinal fluid (CSF) metabolites of NE. Taken as a whole, the metabolite studies thus have significant limitations and do not provide strong support for the role of NE in depression. An alternative strategy has recently been used by Delgado et al. (1993) to look at the role of both serotonin (5HT) and NE in depressive illness. Basically, these studies involve depleting the precursors to NE or 5HT synthesis, presumably resulting in lower CNS levels. What is found is that patients who respond to desipramine worsen when tyrosine is depleted using alpha methyl tyrosine, suggesting that those patients who respond to a medication which targets the NE system are sensitive to changes in the level of NE. Alternatively, patients who respond to selective serotonin reuptake inhibitors (SSRI) do not worsen when NE is depleted, but do worsen when tryptophan, the precursor of 5HT, is lowered, suggesting a particular susceptibility to levels of 5HT. These data suggest a heterogeneity in depressive illness which is repeatedly seen in pharmacological and biological studies.

At the receptor level, two NE receptors have been examined, the α_{a2} receptor and β_b receptor. The presynaptic α_{a2} receptor, which plays a role in controlling the release of NE, has been the focus of a variety of functional and binding studies. The results are marked by inconsistency. There were reports of increased platelet binding of clonidine (Garcia Sevilla et al. 1986; Pandey et al. 1989), which could not be reproduced (Georgotas et al. 1987). Studies of platelet aggregation and cyclic adenosine monophosphate (cAMP) response also have yielded inconsistent results. In the case of the β_b receptor, the initial interest came from the observation made by Sulser et al. (1978) that antidepressants down regulate β_b receptors. This led to

an investigation of postmortem levels of β_b receptors in suicide victims with documented depression compared to controls. Here, the balance of studies support increased β_b receptor density in cortex and hippocampus (Mann et al. 1986). Studies on peripheral cells such as lymphocytes show inconsistent results. The β_b receptor theory of antidepressant action was called into question when newer medications which did not appear to interact with the NE β_b system were introduced, including mianserin and the SSRI. In both cases, administration of the medication chronically to animals does not result in β_b receptor downregulation. This suggests that β receptor downregulation may not play a central role in the action of antidepressants. Work using the animal model of depression, learned helplessness, suggested that perhaps a central role for β receptors in the action of antidepressants should be considered again. In this model, β_b receptors are upregulated when the animals become helpless, and even medications such as SSRI or mianserin will downregulate the β_b receptors which are pathologically elevated, while having no effect on the basal level of receptors. Thus it appears that the postsynaptic change in β_b receptors may be part of a common final pathway in depressive illness, although it appears unlikely that this is a causal factor in the etiology of the illness (Henn et al. 1993).

There appear to be interactions between the NE system and several other CNS systems which could play a role in depression. In particular, the balance between cholinergic activity and noradrenergic activity was postulated by Janowsky et al. (1974) to play a role in depression. The role of the HPA axis in depression has been the focus of a great deal of research following the early observations that cortisol is elevated in depression (Sachar 1967) and that this is often not suppressible using dexamethasone (Carroll 1982). There also appears to be a relationship between adrenergic activity and HPA axis activity (Stokes et al. 1987). This could also be due to the effect of CRF on both systems, since CRF overactivity has also been suggested as having a role in depression (Nemeroff et al. 1984).

3 Serotonin

5HT, like NE, has the distribution of a modulatory system. It arises from a group of midbrain cells located in the raphe and has a widespread distribution through limbic system, cortex, and midbrain. The synapses of 5HT involve a wide number of specific receptors; at latest count 15 have been cloned, and the boutons often appear to release their contents into extracellular spaces without a neuronal connection. Thus it clearly appears to function as a modulatory system in the CNS and has documented roles in the control of sleep, appetite, libido, cognition, and impulsivity. This alone suggests a role in affective disorder in which the vegetative functions of sleep, appetite, libido, and concentration are disturbed. In order to summarize the enormous data available on the role of 5HT in depression, we will look at metabolic studies, receptor studies, and interactions with the HPA axis separately and then attempt to develop an overview of the role of 5HT in affective illnesses.

3.1 Metabolic Studies

The initial studies focusing on blood looked at 5HT levels; however, since the platelets have a powerful uptake system for removing free 5HT from plasma, a characterization of the uptake system in platelets proved more reasonable. Initially, imipramine binding was studied as a measure of uptake sites, but this proved to be somewhat nonspecific since the ligand measures two different receptors. Several studies, but not all, showed a decrease in platelet imipramine binding sites. More recent studies using the more specific ligand paroxetine have not shown consistent differences. Thus the best studies have looked at 5HT uptake by platelets; these studies are numerous and give variable results. A majority suggest that the rate of uptake for 5HT is significantly lower in depression than in controls. However, about 30% of these studies find no difference between patients and controls. Taken together, these data show sufficient variability both within studies and across studies to preclude any reliable interpretation (Meltzer and Arora 1991).

The metabolic studies began with an examination of 5HT turnover looking at the major metabolite 5-hydroxy indolacetic acid (5HIAA) in CSF. This has been done by many groups with and without probenicid treatment, which prevents the reuptake of the 5HT. The most interesting data on 5HIAA levels came from Asberg et al. (1976), who reported that a subgroup of depressive suicides had very low 5HIAA levels. A variety of studies on low 5HIAA showed that very low levels were associated with impulsivity (Faustman et al. 1991) and with such acts as fire-setting and impulsive violence (Virkkunen et al. 1987) rather than depression per se. A summary of the 5HIAA studies in the CSF of depressed patients does not show a lower mean concentration in depression; however, as with the platelet studies, there is a high degree of variability.

Another way of looking at the metabolic control of 5HT is to look at the precursor levels, in this case the levels of L-tryptophan. Here, suggestions that 5HT may well be an important factor in the vulnerability to

depression gain strength. There are suggestions that L-trypophan is lower in depressed patients than in controls (Maes et al. 1990). Repeated studies have shown that depleting L-tryptophan leads to a lowering of mood (Heninger et al. 1992), and when using dietary lowering of L-tryptophan levels in remitted depressed patients, a relapse was seen which was correlated to the lowered levels of CSF 5HIAA, suggesting that this had lowered the levels of central 5HT in these patients. Interestingly, only patients who had responded to SSRI showed this response; if patients only responded to desipramine, lowering L-tryptophan had no effect on mood. When looking at patients still in a depressed state, lowering L-tryptophan levels does not result in a worsening of symptoms. These studies suggest that central levels of 5HT must be one of several factors which influence mood in depressed patients. Another interesting feature of precursor studies is the possibility that the system which leads to the catabolism of L-tryptophan in the liver is induced in depression; one study is consistent with this idea (Maes et al. 1987).

3.2 Receptor Studies

The family of 5HT receptors has become increasingly well defined through molecular techniques; cloning has revealed at least 15 distinct receptor subtypes in three major classes. This has made the interpretation of older binding studies somewhat difficult, since the identification of a class of receptors using pharmacological binding techniques often lacked the specificity to cleanly separate receptor subtypes. Nevertheless, receptor pharmacology of the 5HT system has contributed to understanding the role of 5HT in depression and reinforces the hypothesis that 5HT has a role in this illness.

The $5HT_{1a}$ receptors have been examined in postmortem tissue from depressed patients, and although there is some variability in the data, most well-controlled studies fail to find significant differences in this receptor level. In addition, specific $5HT_{1a}$ agonists are not consistently effective antidepressants, though they have been reported to either speed up antidepressant actions or increase the effectiveness of other antidepressant treatments (Jenkins et al. 1990).

The $5HT_2$ receptor binding has been measured in platelets, and the majority of studies have found increased binding. This is consistent with increased phosphoinositol turnover, which was also shown in one study (Mikuni et al. 1992). The postmortem studies of this receptor in general have found increased levels of receptor binding in frontal cortex (Arango et al. 1992). One problem in assessing the role of this receptor in depression are changes due to active treatments. Most antidepressant drugs induce a down-regulation of this receptor, with the exception of ECT, which induces an upregulation (Lerer 1987). This suggests that the $5HT_2$ receptor changes are probably not primary in causing depression, but rather a secondary consequence of other changes.

3.2.1 *Endocrine Interactions*

In general, HPA axis activity is increased in depression with increased cortisol secretion and decreased feedback control. 5HT has been shown to interact with the HPA axis through partial control of corticotropin-releasing hormone (CRH) secretion. In general, 5HT can be shown to increase CRH release and stimulate HPA axis activity. On the surface, this appears contradictory, since depression appears to be associated with lowered 5HT activity and this should not result in increased HPA axis activity. One hypothesis is that 5HT may regulate feedback control in the HPA axis. Decreased 5HT leads to decreased glucocorticoid and mineralocorticoid receptor function, and this in turn would result in higher cortisol secretion.

3.2.2 *Pharmacological Evidence*

Many tricyclic antidepressants have potent inhibitory effects on 5HT reuptake. This suggests that increasing 5HT centrally may have beneficial effects on depression. This is consistent with the action of MAOI and ECT and was the basis for the design of SSRI. While some antidepressants such as desipramine or specific NE reuptake blockers have little or no effect on 5HT, the majority of effective agents increase the availability of 5HT centrally, consistent with a major role of this transmitter system in depression.

3.3 Role in the Etiology of Depression

The evidence briefly reviewed above suggests two things. First, 5HT plays a major role in the CNS changes which result in depressive illness, and second, 5HT is probably not a primary etiological factor in the onset of depression. As with norepinephrine, this is a major modulatory pathway which clearly plays a role in the regulation of mood. In the case of 5HT, it appears that it may have a central role in control of impulsivity and, as such, dysfunctions in this system may be directly related to suicide. However, the

balance of the evidence suggests that either depression is etiologically heterogeneous with only some cases involving 5HT directly, and/or serotonin is involved in regulating the vulnerability of the CNS to other factors which directly result in depression.

4 Dopamine

Although not classically considered as part of the catecholamine hypothesis, much of the clinical data suggesting that norepinephrine plays a role in depression could equally well apply to dopamine. In view of the central role of dopamine in the neurobiology of psychosis, it has been less discussed in affective disorders. Dopamine is distributed in three primary tracts in the CNS, the nigrostriatal tract, the mesolimbic pathway, and the mesocortical pathway, and innervation of the pituitary. In considering affective changes, we are concerned with the mesolimbic pathway, which has been postulated to be the center of reward behavior and closely involved in mediating the effects of stimulants. Since stimulants can induce hypomania, it appears clear that the dopamine system is related to the control of mood.

4.1 Metabolic Changes

Dopamine turnover has been measured looking at levels of homovanillic acid (HVA) in the CSF of patients using probenicid to block HVA transport. These studies consistently show decreased levels of HVA in the CSF of depressed patients, particularly those with psychomotor retardation (Willner 1983). In view of this, HVA has been looked at in other situations having motoric slowing, such as Parkinson's disease and Alzheimer's disease (Wolfe et al. 1990). In these cases it was also decreased, but in view of the cellular loss and dopamine dysfunction this is no surprise. Nevertheless, it appears that dopamine turnover can best be correlated with activity levels.

4.2 Pharmacology

Stimulants which elevate dopamine clearly have a transient beneficial effect on depression. Both methylphenidate and amphetamine also can serve to predict the response to tricyclic antidepressants (Fawcett and Siomopoulos 1971). Interestingly, this is not true for response to SSRI (Little 1988). In addition, the dopamine reuptake inhibitor nomifensine, which was withdrawn from the market due to side effect problems, was an effective antidepressant. Data on dopamine agonists is also positive; in one study, bromocreptine was found to be as effective as imipramine (Willner 1983). Thus there is some suggestion that stimulation of the dopamine system can relieve depression.

In summary, it is clear that the dopamine system also plays a role in control at least of some aspects of affect. It may be that dopamine is particularly involved in psychomotor symptoms, anhedonia, and emotional blunting. The chronic stress model presented by Willner et al. (1992), which features anhedonia, clearly involves an alteration in the dopamine system. It may be that there is heterogeneity throughout the affective disorders, and certain neurotransmitters or modulators contribute more to the development of one set of symptoms than another.

5 Acetylcholine

The role of acetylcholine in affective disorders really entered the discussion through a study of bipolar disease. It was found very early that cholinergic antagonists could cause a short-term reduction in manic symptoms (Janowsky et al. 1973), and these findings led Janowsky et al. (1974) to propose a cholinergic–adrenergic balance hypothesis of affective disorders. The data in support of this hypothesis are relatively weak and consist mostly of observations concerning the effects on mood of drugs which affect the cholinergic system. The best clinical data on patients showing a relationship between depression and the cholinergic system come from sleep studies. The problem is that these studies depend on the shortening of rapid eye movement (REM) latency and increase in REM density which are seen in major depression, but unfortunately are not specific to this disease. The use of the long-acting muscarinic agonist RS-86 had a greater effect in shortening REM in depressive patients than in controls (Berger et al. 1989), and this appears to be a state phenomena. This is consistent with the report that mitotic response to a cholinergic agonist in eyedrops is greater in depressive patients than in controls.

While the clinical data in this area consist of observations on the effect on mood of drugs with cholinergic activity, strong anticholinergic drugs, while occasionally reported to have anti depressive activity (see Janowsky and Overstreet 1995), are not considered as effective antidepressant treatments. This

suggests that the cholinergic axis may modulate mood, but does not play a primary role in depressive illness. However, animal studies suggest that manipulation of the cholinergic system can lead to a model depression. The Flinders sensitive line of animals bred for sensitivity to an anticholinesterase has been proposed by Overstreet (1993) as an animal model of depression. The animals show decreased weight, learning problems, reduced activity, increased REM sleep with reduced REM latency, and an exaggerated response to chronic mild stress. All this points in the direction of cholinergic modulation of factors related to mood.

6 Hypothalamic–Pituitary–Adrenal Axis and Depression

The human organism is programmed with a variety of adaptive responses to stress, including the sympathetic nervous system and the HPA axis (see Chap. 8, Vol. 1), which regulates the release of hormones from the adrenal medulla. Since depression often appears to be associated with increased life events (see Chap. 21, this volume) which can be considered stressors, and the agents of the sympathetic nervous system appear to play a role in the control of mood, it was logical to look at the HPA axis function in this disorder. Early on, Sachar et al. (1970) showed that cortisol levels in depression appear significantly higher than seen in control subjects. It was found that over 50% of all depressed patients failed to suppress cortisol secretion following a dexamthasone challenge (Stokes et al. 1975). These data suggested that perhaps the stress response was overactive and not appropriately terminated in depression. That there is a loss of feedback control of the system was illustrated by the development of the combined dexamethasone–CRH challenge test, in which a subject receives dexamethasone to suppress cortisol release and later a dose of CRH, which should stimulate release. In normal subjects, there is a dexamethasone dose-related decrease in adrenocorticotropic hormone (ACTH) and cortisol release, but not in depressed patients, in which there is increased ACTH and cortisol release, in spite of the fact that when depressives are directly challenged with exogenous CRH, they show decreased ACTH responses and normal cortisol secretion (Amsterdam et al. 1988).

An additional factor which could play a role is endogenous CRH release. Nemeroff et al. (1991) showed that CRH is elevated in depression and decreased after ECT treatment. This suggests that increased CRH may be present in depression and was supported by postmortem studies looking at CSF CRH(5) and tissue levels of the CRH receptor, which appears to be downregulated in the frontal cortex (Nemeroff et al. 1988). The CRH changes appear to be state-dependent changes which revert to normal following a depressive episode. It is currently not possible to determine whether they reflect primary pathology in depression or a secondary compensation. The fact that some patients have a normal HPA system during a depressive episode suggests either heterogeneous causes or that these abnormalities reflect secondary changes in depression.

7 Hypothalamic–Pituitary–Thyroid Axis and Depression

The hypothalamic–pituitary–thyroid axis (HPT), like the HPA axis, is a hierarchical system in which the hypothalamus produces thyroid-releasing hormone (TRH), which acts in the anterior pituitary to release thyrotropin (THS); this in turn goes to the thyroid gland, where it induces the synthesis of triiodothyronine (T_3) and thyroxin (T_4). It has long been known that thyroid status can have profound effects on mood. Hypothyroidism is part of the differential diagnosis for depression with patients often showing low mood and lethargy. Hyperthyroidism can also be mistaken for mania, with anxious overactive patients presenting in the clinic. This prompted an investigation of the thyroid axis in depression and the development of the concept of subclinical hypothyroidism. Here, elevated TSH at baseline is seen with normal T_3 and T_4. When a TRH stimulation test is carried out on depressed patients, between 25% and 50% will show a blunted TSH response. This reverts to normal in most patients as the depression resolves. Those patients in which the TRH stimulation test does not normalize have an increased risk of relapse.

8 Other Peptide Systems

The first peptide system which should be considered is the opiate peptide system. Historically, this is one of the first systems identified as being associated with depression through the use of morphine to treat depressed patients. This work goes back to the initial use of opiates and was referred to by Kraepelin. Interestingly, it appeared to be a moderately effective treatment with little addiction developing as a result of

exposure to the drug during the illness. With the awareness of the addictive potential of the opiates, this treatment was soon abandoned.

The distribution and action of opiates suggests they may play some role in hippocampal activity and learning as well as an extensive role in the activity of noradrenergic systems. Opiates acutely inhibit locus ceruleus cell firing, and these cells quickly develop tolerance to the inhibitory effects of opioids. The substances appear to act through activation of the second messenger system involving cAMP, and activation of cAMP response element binding protein (CREB) leads to gene activation. These established activities of opiate receptors certainly suggest that they may be involved in the circuits which control affect.

Postmortem studies of suicide victims without history of drug abuse revealed remarkably elevated levels of the mu opiate receptor in young adults (Gross-Iseroff et al. 1990). These receptors showed a manyfold increase over controls, results which should be reproducible since they represent far larger effects than usually seen in biological psychiatry. Small studies of dynorphin in treatment-resistant depression have shown effectiveness, but large-scale replication trials are not available. In the learned helplessness model of depression, inbred helpless strains have been established (Henn et al. 1993). In these strains, mu opiate receptors showed an up to fourfold regionally specific increase over non-helpless animals. These results suggest that the opiate system probably mediated through the mu opiate receptor may also play a role in the control of mood.

Recent data on substance P suggests that this peptide may also play a critical role in the control of mood. Again, the distribution of substance P suggests activity not only in the well-known pain pathways of the spinal cord, but also colocalization with both noradrenergic containing neurons and 5HT neurons. Antidepressant treatment has been reported to result in a downregulation of substance P (Barden et al. 1983), and substance P is raised in inescapable foot shock (Lisoprawski et al. 1981). The substance P antagonist MK-869 at high doses of 300 mg/day was tested in a single reported trial of 70 patients. It had the same time course and efficacy as paroxetine, but neither were statistically better than placebo in this limited study. This suggests that more work on this new avenue for the treatment of depression is necessary.

9 Intracellular Targets

Ultimately, the signals which carry information about stress and mood must act at the level of the individual neuronal cells. Here, changes in function and possibly structure must take place which lead to the behavioral changes associated with mood disorders. This must obviously take place in defined circuits with defined functions, but ultimately individual cells must change. In this section, we will look at what happens intracellularly when signals from amines or peptides alter receptor activity at the cell surface. There are two broad classes of intracellular signal transduction pathways. The first, which we will consider in slightly more detail, are the pathways which are activated by neurotransmitters and neuromodulators. These involve the major classes of second messenger systems, cAMP, cGMP, inositol phosphate, Ca^{2+}, and nitric oxide (NO). The second large class involves neurotrophin and cytokine receptors acting through a series of tyrosine kinases; these have previously not been central to a discussion of the neurobiology of depression, but newer evidence suggests we should consider these pathways as well. The effects of signal transduction pathways in neurons is to initiate changes which underlie neuronal plasticity and hence all behavioral changes.

The second messenger systems activated by the amines and peptides include many such as cAMP activation which are initiated through G protein activation. G proteins are a large class of proteins, with at least 15 different forms, which couple receptor activation to cellular effector function. Receptors which, when stimulated, lead to an increase in the effector molecule, e.g. cAMP, such as the adrenergic β_b receptor, work through a stimulatory G protein know as G_s, while receptors such as the cholinergic muscarinic receptor which inhibit this process work through inhibitory G proteins known as G_i or G_o. There are several other G proteins some of which interact with the phosphinositol system. All the G proteins appear to be made up of three subunits, α_a, β_b, and γ_g. The α_a subunit contains the binding site for guanine nucleotides and has a catalytic site as well which hydrolyzes GTP to GDP plus P_i. When GTP binds with the α_a subunit, the G protein complex dissociates into α_a and $\beta_b\gamma_g$ subunits, both of which bind adenyl cyclase (see Fig. 1). This activates adenyl cyclase and increases cAMP, which then acts on downstream kinases.

One such kinase is the cAMP-dependent phosphokinase A (PKA), which when activated is translocated into the cell nucleus and increases; this initiates gene activity resulting in new protein synthesis. CREB may play a central role in the control of mood, since it can be activated by several of the neuromodulators mentioned above, including NE and 5HT. In addition, Ca^{2+}-dependent kinases can also activate CREB. Two of the intracellular systems which can regulate CREB appear to be altered in a state-dependent way in depression, suggesting this pathway is part of a final

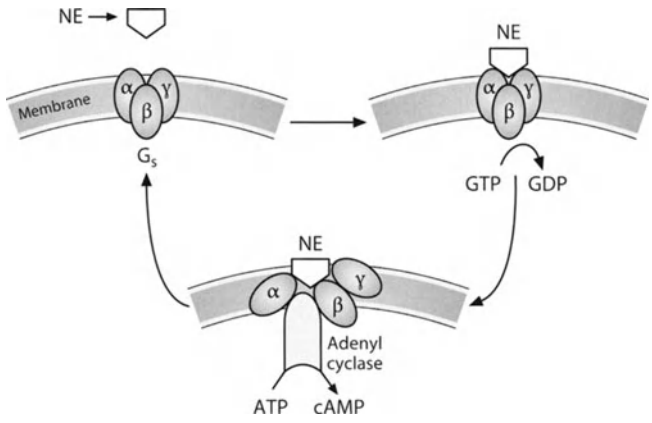

Fig. 1. G_s protein activation by norepinephrine (*NE*) and production of cyclic adenosine monophosphate (*cAMP*)

common pathway in the control of mood. Both changes have been measured in peripheral cells, mononuclear leukocytes, which could reflect similar changes in neurons. The first involves G proteins, which appear to be decreased in depression and elevated in mania, and the second involves internal Ca^{2+} flux in response to mitogen stimulation.

The G proteins have been investigated in mania (Schreiber et al. 1990) and depression (Avissar et al. 1997) and found to be increased in mania by about 25% using an immunoblot analysis and decreased in depression by about 20%. Looking at receptor-enhanced binding of a GTP analogue, depressed patients showed almost no overlap with controls when isoproterenol was used to stimulate binding. Under similar conditions, manic patients showed nearly a doubling of binding. A variety of antidepressant treatments including medication and ECT normalize the level of G_s in depression. In mania, the muscarinic G_i is increased, and this is normalized by lithium. Thus G protein function and level appear to be correlated with mood state.

Ca^{2+} flux also appears to be state dependent when looking at isolated lymphocytes. In general, when lymphocytes are stimulated with a mitogen, there is an increase in intracellular Ca^{2+}, which occurs with oscillating waves of Ca^{2+} appearing intracellularly. Recent studies have shown that, in depression, lymphocytes do not respond nearly as strongly to a standard mitogen challenge. When patients recover, even when treated with interpersonal psychotherapy, without medication, or when treated with a tricyclic medication, the Ca^{2+} response to mitogen normalizes (Aldenhoff et al. 1997).

The above data suggests that there are multiple intracellular state-dependent changes which occur in depression, all of which could work in the direction of less CREB activation. Consistent with this interpretation is the finding that chronic antidepressant treatment activates multiple components of the signal transduction pathway, including, in addition to G_s and cAMP, the cAMP protein kinases (42 Da) and phosphorylation of microtubules (43 Da). Long-term antidepressant treatment with fluoxetine directly has been shown to increase CREB mRNA levels in the hippocampus (D). Thus antidepressants appear to always work in the direction of increasing CREB and inducing gene activation. This suggests the possibility that the long-term plasticity which occurs with the development of depression is due to changes in gene expression leading to changes in neuronal function. The effected cellular pathways are shown in Fig. 2. What is clear is that a variety of inputs including NE, 5HT, and several peptides could react through signal transduction pathways to increase CREB, which may represent one step in a final common pathway necessary for the development of an effective antidepressant response. This suggests that, for depression to begin, some normally expressed pattern of gene activation must be inhibited. If this is a reasonable hypothesis, the next question is which gene expression is necessary to prevent the development of depression. To begin to look at this question, we need to look at those genes activated by CREB. Within the hippocampus, it has been shown that CREB plays a role in the control of some neurotrophin functions. This is of particular interest since the neurotrophins are natural candidates for regulating neuronal plasticity, this being merely an extension of their role in development. One neurotrophin induced by CREB is brain-derived neurotrophic factor (BDNF).

There is considerable information suggesting that changes in the level of BDNF may play a role in antidepressant action; thus, by implication, it may play a role in the initiation of depression. Studies of ECT and long-term administration of antidepressants, including SSRI, NE reuptake inhibitors, and MAOI, all show an upregulation of the expression of BDNF (Nibuya et al. 1995). In addition, the direct administration of BDNF in the learned helplessness model

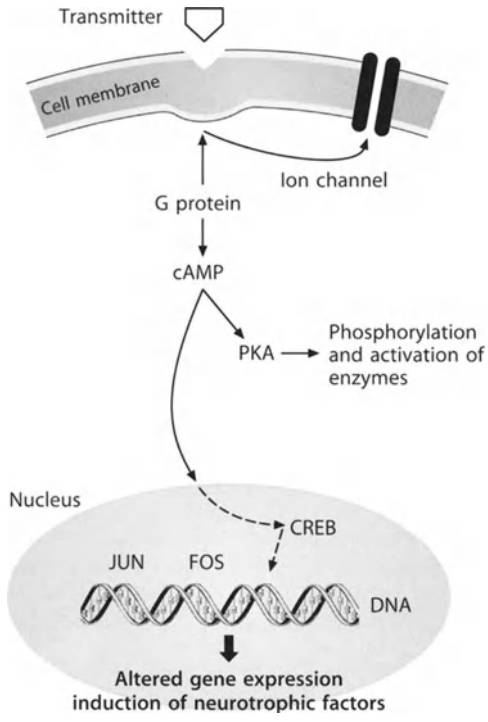

Fig. 2. Altered gene expression through receptor activation. *cAMP*, cyclic adenosine monophosphate; *PKA*, phosphokinase A; *CREB*, cAMP response element binding protein

of depression results in the reversal of depression (Siuciak et al. 1996). Stress also has a direct effect on BDNF levels, and restraint stress inhibits the expression of several neurotropic factors, including BDNF (Smith et al. 1995).

BDNF and other growth factors appear to play an ongoing role in neural plasticity in the fully developed brain, in addition to their more commonly studied role in development. That this plasticity has functional consequences which could play a role in the etiology of depression is suggested by the recent work by Korte et al. (1996), in which they were able to show that, in BDNF knockout mice, hippocampal long-term potentiation (LTP) was altered and could be normalized with the restoration of BDNF through virus-mediated gene transfer. Since LTP appears to be associated with learning in the hippocampus, this could be a relevant pathway for the induction of depression. Furthermore, it has been shown that BDNF can promote sprouting in 5HT (Mamounas et al. 1995) and NE neurons (Sklair-Tavron and Nestler 1995). Thus we can imagine a hypothetical pathway beginning with uncontrolled stress which leads to the activation and subsequent depletion of sympathetic pathways. Concurrently, we would expect that increased HPA axis activity leading to increased vulnerability of hippocampal neurons, the decreased production of cAMP, and changes in the activation of CREB with the subsequent change in neurotrophin levels could lead to subtle structural and functional changes which alter the perception of information, resulting in feelings of hopelessness and ultimately depression. This hypothesis suggests that a multifaceted pathway is possible involving multiple transmitter systems and is consistent with the variety of evidence presented above. It also suggests that, while there may be a final common pathway of changes leading to depression, the driving etiological factors may in fact be heterogeneous.

10 Conclusion

The above hypothesis suggests that alterations in how stress is perceived in the CNS or alterations in a variety of systems mediating input to the CNS, such as the aminergic modulatory systems, could lead to similar dysfunction in the maintenance of a balanced affective system. This system appears to control the processing of information in such a way as to allow the organism to formulate ways to control its environment; when this sense of control is lost, anxiety and helplessness take over. It appears likely that if this becomes chronic, a depressive state results. That this can occur through a variety of systems is not unexpected, and that a primary change in a given system, be it CRH production or control of the noradrenergic β receptor, will lead to compensatory changes in a wide variety of other CNS systems is also to be expected. It does appear that information is given its emotional coloring in the interplay between hippocampus, amygdala, hypothalamus, and frontal cortex and that the interactions between NE, 5HT, the HPA axis, and neuropeptides in this system are critical in establishing the set point for affective control. The data reviewed suggests that no single system appears to be etiologically responsible for all cases of depression and further suggests there may be new points for developing more effective therapies.

This chapter did not address one significant point which may have major neurobiological impact on the control of mood, and that is the issue of biological clocks. Clearly, depression is usually an episodic illness in which sleep patterns are disturbed and seasonal patterns of onset have been detected. Two therapies which have shown some utility, sleep deprivation and light therapy, appear to work in part through the mediation of biological rhythms. Much has been learned about the nature of biological clocks, but up till now no clear connection between the biology of rhythm control and mood disorder has been shown. This remains an area for future work.

In summary, depressive illnesses appear to result from a dysregulation of the systems which mediate the interpretation of stressful events, principally including the modulatory amine systems and the HPA axis. There may be a common final pathophysiological pathway involving these systems which results in changes in NE function, 5HT function, and the HPA axis such that a normal expression of gene products is interrupted. One possible final step which may allow integration of the variety of findings in depression is that patterns of neurotrophic factor production are altered. This hypothesis needs considerably more study, but offers a step beyond the previous amine theories of depression, in that it would reflect possible changes in a variety of modulatory systems. Though the vast amount of data collected on the various systems reviewed has not always been consistent, a general pattern emerges which is consistent with a group of illnesses with heterogeneous etiologies which for the most part effect a single final common pathway. Using the new tools of molecular biology and imaging, it is certain that considerable clarification in the details of such a pathway will emerge in the near future.

Personality and Affective Disorders

Translator: S. Davison

1 Introduction

This chapter examines the relationship between personality and affective disorders, the latter as described in ICD-10 (F30–39) (WHO 1992). Anxiety disorders will only be discussed in relation to their comorbidity with affective disorders. Schizoaffective disorder (Angst and Scharfetter 1990; Marneros et al. 1991; Sauer et al. 1989; Schützwohl et al. 1992; Thau et al. 1991) and suicidal behavior (Angst and Clayton 1998; Bronisch and Wolfersdorf 1996; Engström et al. 1997; Straub et al. 1992), including extended suicide (Marneros 1997; Okumura and Kraus 1996), will not be discussed at all. Finally, the role of personality disorders in affective disorders (e.g. Gunderson and Phillips 1991; see also Chap. 11, Vol. 3, Part 2) will only be dealt with peripherally in connection with the issue of comorbidity.

As in the previous edition of this textbook (see Möller and von Zerssen 1987), this chapter deals primarily with *pre*morbid patient characteristics, even though these may be difficult to distinguish retrospectively from morbid and postmorbid personality changes in patients who have already developed an affective disorder. We have chosen here to concentrate on studies which have contributed to progress in this field since the last edition. They represent significant changes in research methods, as well as in results and their interpretation. The reader is also referred to recent overviews by Akiskal (1996), Cloninger (1994), Hirschfeld and Shea (1992), Klerman and Hirschfeld (1988), Möller (1992), Nietzel and Harris (1990), Tölle (1987), and von Zerssen (1996a–c), specifically in relation to bipolar affective disorder to Goodwin and Jamison (1990, pp. 281–317) as well as Kröber (1988).

It is important to note some recent changes in the classification of affective disorders which are relevant to the subject under discussion. The classical division, in the earlier literature, of depression without an obvious organic basis into endogenous and neurotic forms has been largely abandoned. Instead, the term "major depression" is widely used (see APA 1994). This disorder is divided into depression with and without melancholic features. It is also often divided into primary depression (in the absence of a preexisting psychiatric disorder) and secondary depression (following a preexisting psychiatric disorder). In addition, the clinical picture of dysthymia has been elaborated upon. Both dysthymia and major depression without melancholic features are more commonly associated with personality disorders (Parker et al. 1998) and anxiety disorders (Parker et al. 1999) than is pure depression with melancholic features. The latter corresponds broadly to the clinical picture of endogenous depression. The other forms of depression such as secondary depression, depression without melancholic features, and dysthymic disorder all overlap to some extent with the older concept of neurotic depression.

These relationships explain why, even in more recent studies of patients with neurotic depression (e.g. Uluşahin and Uluğ 1997), questionnaire measures of neuroticism, which tend to be elevated in personality disorders (Assion et al. 1998; Davidson et al. 1985; Fiedler 1997; Pukrop et al. 1998; von Zerssen et al. 1988) and anxiety disorders (Alnæs and Torgersen 1990), are found to be raised in just the same way as they are in studies of the comorbidity of depression with anxiety disorders (Alnæs and Torgersen 1990; Bronisch and Hecht 1990). The reverse is also understandable: questionnaire scores relating to neuroticism, such as those measuring interpersonal sensitivity (Boyce et al. 1993), may not be elevated in major depression with melancholic features. However, they are raised in major depression without melancholic features, because this is the type of depression which is often associated with other mental disorders. Furthermore, a study of the validity of the operational definition of endogenous depression (Zimmerman et al. 1986), the form of depression most closely approximating to major depression with melancholic features, found a comparatively low rate of associated personality disorder (see also Parker et al. 1998). However, there have been some contradictory findings (Grove et al. 1987).

In recent years, there has been an effort to replace the classification of affective disorders based on Kraepelin's categorical concept by the concept of a spectrum, in which more emphasis is placed on the overlap between the recognizable clinical pictures than on their differences (e.g. Angst and Scharfetter 1990; von Zerssen 1996a). In particular, Akiskal (1988, 1989, 1992, 1996), starting from Kraepelin's concept of fundamental states of "manic depressive insanity" (Kraepelin 1913), has conceived a bipolar spectrum in which subclinical forms of an affective disorder are included as minor forms of a bipolar II disorder. According to Akiskal, the affective disorders overlap with four different temperaments (Kraepelin used the term "personal disposition" rather than temperament), namely, a depressive, a cyclothymic, an irritable, and a hyperthymic ("manic" according to Kraepelin) temperament.

2 Definition and Classification of Personality

Personality is defined implicitly in the majority of papers relevant to this chapter as a pattern of relatively persistent ways of experience and behavior, i.e. in the

Table 1. Classification of personality in psychiatric patients according to von Zerssen (in press)

The "pattern of characteristic thoughts, feelings, and behaviors that distinguishes one person from another and that persists over time and situations" (Phares 1988):	
over the whole lifespan or during the last part of it prior to the first symptoms of a mental state disorder	= premorbid personality or primary personality
during the prodromal or initial stages of a disorder	= initial change of personality or "preclinical" personality
during the course of a disorder	= intramorbid personality
after a mental disorder:	= postmorbid personality
with incomplete recovery	= pathological change of personality
with full recovery	= reconstituted personality
during largely symptom-free intervals of a relapsing illness	= intermorbid or interval personality

sense of a trait concept (Wiggins 1997), despite criticisms from certain psychologists (e.g. Mischel and Peak 1982). Phares (1988, p. 4) provides a good example of a definition of this kind: "Personality is that pattern of characteristic thoughts, feelings, and behaviors that distinguishes one person from another and that persists over time and situations." Developmental changes are not ruled out by this a definition.

The term "temperament" is currently used quite often in the U.S. literature. In contrast to the term "character," temperament is considered to be the "biological core" of personality and to be relatively independent of social learning. The term "temperament" is, however, used in different ways within different conceptual frameworks (von Zerssen and Akiskal 1998). It may refer to a personal predisposition to or a fundamental state of an affective disorder (Akiskal 1996). It is also used as a generic term for the predominantly genetically determined components of personality (Cloninger et al. 1993). Alternatively, it is applied to habitual patterns of experience and behavior that can already be observed in childhood (e.g. Merikangas et al. 1998).

It is particularly confusing that, in Cloninger's theory of temperament and character, the different types of temperament described in Akiskal's framework are derived from combinations of Cloninger's hypothetical character dimensions (Cloninger et al. 1998). In view of such discrepancies in the terminology, it is advisable to use the term "personality," which is neutral in relation to etiology, whether biological or social. This makes particular sense in view of research comparing monozygotic twins reared together and apart. The results suggest that it is hardly possible, at least with current research instruments, to distinguish between personality dimensions that are genetically determined and those which are acquired through social learning (Waller et al. 1990).

There are two conceptual classifications of personality which are specific for clinical psychiatry (von Zerssen, in press). One of them relates to the appropriateness of ways of thinking, feeling, and behaving in particular situations, with an emphasis on coping. This implies a ranking from normal, through accentuated, to abnormal personality. The latter includes the particularly maladaptive personality variants which, due to their dysfunctional lifestyles, are referred to as personality disorders. The other psychiatry-specific approach to the classification of personality is to consider the temporal relationship between personality and mental state disorders, such as an affective disorder (Table 1).

A third, more general way of classifying personality refers to typical constellations of personality traits which distinguish larger groups of individuals from one another (categorical classification), or to the common variation of such characteristics (dimensional classification, because the common tendencies in the variation derived by means of factor analysis relate to euclidean dimensions). Both categorical and dimensional classifications can be transformed into each other because categorical personality types usually refer to extremes in a dimensional system (von Zerssen 1994, in press). For the sake of simplicity, both forms of classification will be dealt with here as equivalent.

We have introduced a classification system which arose out of research into the premorbid personalities of patients with different types of an affective disorder, in particular: primary unipolar depression with melancholic features; predominantly manic form of bipolar affective disorder; so-called neurotic depression; anxiety disorders; and psychoses of the schizophrenic spectrum (Pössl and von Zerssen 1990a,b; von Zerssen 1996a). A series of studies on premorbid personality in affective disorders which were based on this classification have since been published (Hecht et al. 1997, 1998; von Zerssen and Pössl 1990; von Zerssen et al. 1994b, 1996, 1998b).

Personality types predominating in different forms of affective disorders were called "affective types." They consist of the "typus melancholicus" (melancholic type) as described by Tellenbach (Kraus 1991, 1996; Peters 1984); the "typus manicus" (manic type) (von Zerssen 1988, 1992), which corresponds to a large extent to

Akiskal's hyperthymic temperament; and a rarer variant of the manic type, called "happy-go-lucky" or "relaxed, easy-going type." In addition, there are the "neurotoid types," which are encountered frequently both in schizophrenic and neurotic disorders. They include an "anxious, insecure type," its rare variant, the "unrealistic, dreamy type," and, finally, a "nervous, tense type."

With the exception of the melancholic type, the names of the affective types give an indication of the most striking features of the personalities they describe (see also the descriptions of the affective types in table form in the articles cited above). They should not be confused with the "affective temperaments" described by Akiskal (1988; see above).

The affective types can be assessed operationally on the basis of biographical information about the premorbid development of psychiatric patients obtained from case notes or from an appropriate interview (von Zerssen et al. 1994a, 1996, 1998a).

The following dimensional personality models are currently given most weight within psychiatry:

- Eysenck's (1990) personality model consisting of three dimensions: extraversion, neuroticism, and psychoticism.
- The Five-Factor Model, consisting of the so-called Big Five: extraversion, neuroticism, conscientiousness, agreeableness, and openness to (new) experience (Wiggins and Trapnell 1997). (The negative of conscientiousness and agreeableness is combined in Eysenck's psychoticism dimension; see Eysenck 1992.)
- Cloninger's model of temperament and character. Temperament is conceptualized as being composed of four dimensions: harm avoidance, novelty seeking, reward dependence, and persistence. Character is conceptualized as consisting of three dimensions: self-directedness, cooperativeness, and self-transcendence (Cloninger et al. 1993).

It can only be briefly mentioned in this context that the dimensions from these three systems, even if named differently, may overlap to a considerable extent (Zuckerman and Cloninger 1996). The reader is referred to Chap. 11 (Vol. 3, Part 2) for a more extensive discussion of the recent personality classification systems.

3 Research Methods

3.1 Assessment Methods

The taxonomies described above are closely linked to the development of methods for the assessment of personality (von Zerssen, in press). Since the publication of the last edition of this textbook, a series of new approaches and techniques have been applied in the study of personality in individuals with affective disorders. In an improvement of previous methods (e.g. Marneros et al. 1991; Tölle 1988), the assessment of premorbid personality from case note data was systematized with the use of extracts from case notes relating exclusively to premorbid biographical patient information (von Zerssen and Pössl 1990). The raters were blind to clinical information about the patient, thus eliminating any diagnostic investigator bias. This procedure was later operationalized by using an extensive list of personality descriptors for the ratings, which could then be analyzed by means of a diagnostic algorithm (von Zerssen et al. 1994a). The findings thus obtained correlate well with the results of a global assignment to the types of premorbid personality (von Zerssen et al. 1994a). In addition to assigning patients to a category, a dimensional description of premorbid personality is also possible by using the scores for the different personality types (von Zerssen et al. 1994b).

This case note analysis served as a model for the development of an interview technique using the same principle of collecting biographical data. The data include demographic variables, family history (excluding psychiatric history of blood relatives), and patients' history prior to the onset of their disorder, subdivided into internal and external life history. The interview is conducted and documented in a verbal protocol by an investigator different from the one who then has to carry out the rating. After special training, the interviewer assesses patients in clinical remission, blind to their diagnosis and other clinical information, and/or normal controls.

This Biographical Personality Interview (BPI; von Zerssen et al. 1996, 1998a,b) has been used extensively in studies of patients with affective disorders in clinical remission, healthy controls (Hecht et al. 1997, 1998), and hitherto healthy close relatives of patients (Hecht et al. 1998). It was applied in conjunction with likewise newly developed personality questionnaires (von Zerssen 1994; von Zerssen et al. 1988) that had also been used in the validation of the BPI (von Zerssen et al. 1996, 1998a,b).

Just as the BPI assesses the affective types described above, as well as wider aspects of premorbid personality, so the semi-structured Affective Temperaments Interview (TEMPS-I; Akiskal et al. 1998; Placidi et al. 1998) has been used to assess the four Kraepelinian fundamental states of manic depressives (cyclothymic, depressive, hyperthymic, and irritable) according to criteria formulated by Akiskal and Mallya (1987). These are operationalized using a series of distinguishing characteristics that are inquired about in a

fairly direct manner. The instrument can be used in a modified form as a self-report questionnaire (Akiskal et al. in press). No findings from clinical studies applying either of these instruments had been published at the time of writing this chapter.

Cloninger's group has developed the Temperament and Character Inventory (TCI) (Cloninger et al. 1993) for the assessment of their postulated dimensions of temperament and character. It should be noted that the Kraepelinian fundamental states of manic depressive illness, called temperaments by Akiskal, are operationalized by particular combinations of values on the three character dimensions. It should also be mentioned that three of Cloninger's temperament dimensions, namely, harm avoidance, novelty seeking, and reward dependence, had formed the conceptual basis for designing the Tridimensional Personality Questionnaire (TPQ; Cloninger 1987).

Akiskal's instruments are based on clinical constructs, while Cloninger's questionnaires were derived from theoretical considerations. On the other hand, Costa and McCrae's (1992) NEO-Five Factor Inventory is based on the Five Factors derived from factor-analytic studies of healthy individuals. The academic origin of the NEO-FFI is clearly apparent from the content of some of the items and the complicated mode of answering.

For this reason, von Zerssen (1994) developed the Six-Factor Test (SFT) as a simple questionnaire to assess the "Big Five" as well as an additional factor of conventional piety. It has been shown to have higher construct validity than the NEO-FFI, particularly in psychiatric patients (Steinmeyer et al. 1996). In addition, a simple Visual Analogue Scale for Six Factors (VAS-SF) (the same factors as measured by the SFT) and a parallel version for use with an informant (VAS-SF) were designed, whose application and analysis are more economical, but whose reliability and validity are necessarily lower than those of the SFT.

The Munich Personality Test (MPT; von Zerssen et al. 1988), like Akiskal's questionnaire, was primarily clinically conceived, but was also developed on the basis of extensive item and factor analyses (as were the NEO-FFI and SFT) in accordance with the classical test theory. It exists in self-assessment and informant assessment forms and has already been applied in many hospital and outpatient studies (Bronisch and Hecht 1989, 1990; Hecht et al. 1997; Heerlein et al. 1996; Sakado et al. 1997; Sauer et al. 1997; Schäfer 1991, 1994; von Zerssen et al. 1996, 1997, 1998a,b) as well as in high-risk studies (Hecht et al. 1998; Lauer et al. 1997; Maier et al. 1992, 1995).

Interviews and questionnaires for the diagnosis of personality disorders are described in Chap. 11 (Vol. 3, Part 2).

In all retrospective studies, including those with patients in clinical remission, the possible relationship between symptoms of psychiatric disorders and self-reported personality traits must be taken into account. This particularly applies to scales for the assessment of neuroticism and similar constructs, as well as those measuring extraversion (Ouimette et al. 1996; Reich et al. 1987), but hardly at all for the rigidity scale of the MPT (Sauer et al. 1997). Older findings on this theme have been confirmed (von Zerssen et al. 1988). On the basis of a prospective study, Shea et al. (1996) concluded that values obtained postmorbidly by means of personality inventories in patients with depression could not be explained as "psychological scars," except possibly in patients with frequent or prolonged episodes.

One research approach, which has only been used once in the context of affective disorder and personality and which differs significantly from interview and questionnaire methods, is participant observation within the family settings of patients discharged from hospital (Peters 1991). The observation of marital interactions in the clinic (Mundt et al. 1994) presents an alternative to participant observation. In comparison, it balances the disadvantage of the unnatural research situation with greater economy and better opportunities for quantitative analysis. With both these methods, conclusions about *pre*morbid behavior can only be made with considerable reservations.

3.2 Research Design and Data Analysis

Clear progress has been achieved in the design of studies in this field. Recent retrospective investigations have nearly always been conducted with patients in remission. In some of these studies, the influence of residual symptoms on the personality measures has been statistically controlled for (e.g. Hecht et al. 1997, 1998; Sakado et al. 1997; Sauer et al. 1997). Moreover, an increasing number of prospective or prospectively designed high-risk studies of women prior to childbirth (Boyce et al. 1991; Marks et al. 1992) and in particular of first-degree relatives of patients with affective disorders have been performed (Hecht et al. 1998; Lauer et al. 1997, 1998; Maier et al. 1992, 1995; Nurnberger et al. 1988; see also Goodwin and Jamison 1990). Even whole families have been investigated (Merikangas et al. 1998). The participant observational study mentioned above falls into this category too (Peters 1991). High-risk studies of patients' close relatives have not yet been running long enough to reach firm and valid conclusions about the affective disorders which develop. However, there are longitudinal epidemiological field studies, some of which cover decades (Clayton

et al. 1994; Crow et al. 1995; Duncan-Jones et al. 1990). One particular type of prospective study was that conducted by a North American research group who investigated monozygotic twins (Kendler et al. 1993a,b). The authors were thus able to draw conclusions about the overall contribution of genetic factors to the variance of personality traits (neuroticism) and illness manifestation (depressive episodes).

Meta-analysis of published data has now also become an established method in the study of personality and affective disorders, in particular depression (Nietzel and Harris 1990). This has been made possible by the considerable increase in the number of original studies which have used quantitative measures of personality traits, in this case emotional dependence and achievement orientation. Increasingly complex statistical methods have also been applied in original studies. These have included so-called path analysis models, which are designed to elucidate causal relationships between variables, thus going beyond merely statistical interdependence. For example, this technique has been used to demonstrate causal relationships between neuroticism and major depression (Kendler et al. 1993b) or between scores on symptom and personality scales (Sauer et al. 1997).

Despite these methodological advances, the results produced do not form a completely consistent picture. The procedures for sampling patients, individuals at risk, and normal controls differ too greatly across studies, and some of the research instruments have too little validity to reach valid conclusions. The convergence of findings using different research approaches will always be the best evidence of their validity (von Zerssen, in press).

4 Results

4.1 Personality and Depression

Research into the relationship between personality and depression most often relates explicitly to unipolar forms of depression. It is usually not apparent whether primary or secondary depression or even so-called double depression (i.e. a major depression superimposed on dysthymic disorder) is being examined. This and other clinical differentiations will therefore only be made explicit below where it is essential in understanding the results, e.g. where particular subtypes of unipolar depression have been compared to one another. The controls in studies of unipolar depression have most frequently been patients with bipolar affective disorder (Hecht et al. 1997; Richter et al. 1993; Sauer et al. 1997; Tölle et al. 1987). Healthy individuals have sometimes been used in conjunction with bipolar patients (Hecht et al. 1997; Sakado et al. 1997) or alone as controls (Boyce et al. 1993; Sato et al. 1994). In contrast, other psychiatric patients have rarely been investigated as control samples (e.g. by Alnæs and Torgersen 1990; Heerlein et al. 1996; Sakado et al. 1997; von Zerssen et al. 1997). Thus results are often not directly comparable to one another. In addition, the clinical diagnostic terms, operationalization, and other methodological aspects differ between studies. The reader is strongly recommended to refer to the original papers where there is any doubt.

4.1.1 Retrospective Questionnaire Studies

Self-report questionnaires are by far the most commonly used tools for assessing personality traits. This is why results obtained by means of these methods will be dealt with first. The results will be discussed under the headings of the "Big Five" personality factors. Even though questionnaires which specifically and directly measure the Five Factors have only rarely been used (e.g. by Bagby et al. 1996a,b), these factors lend themselves most easily to an account which brings together the various studies, because of their similarity to the constructs underlying most of the personality inventory scales.

Neuroticism scores are raised in most retrospective studies of unipolar depression. Because of the well-recognized overlap between depressive symptoms and items on neuroticism scales (Duncan-Jones et al. 1990; von Zerssen et al. 1988), residual symptoms should be taken into consideration even following clinical remission and, whenever possible, controlled for statistically (Sauer et al. 1997). Scales measuring traits that are associated with neuroticism such as interpersonal sensitivity (Boyce et al. 1993), reduced tolerance to frustration (von Zerssen et al. 1997), self-criticism (Bagby et al. 1992), and emotional dependence (Bagby et al. 1992; Nietzel and Harris 1990) frequently show corresponding changes, in particular in comparison with healthy controls (Hecht et al. 1997, 1998) and to some extent also compared to patients with bipolar affective disorder (Richter et al. 1993).

However, no such deviation from the norm was found in a study of Japanese patients after residual depressive symptoms were controlled for (Sakado et al. 1997). In another similar study, also of Japanese patients, von Zerssen et al. (1997) observed a reduced tolerance to frustration but no raised neuroticism. It is difficult to determine whether these findings represent a transcultural difference compared with Western countries because, in at least one of these studies (von Zerssen et al. 1997), patients were specially

recruited who had experienced at least one episode of primary major depression with melancholic features. It seems generally less common to find elevated scores of neuroticism and similar characteristics in patients with than in those without such features (Boyce et al. 1993).

Measures of extraversion can be reduced even in remission from a depressive episode (Janowsky et al. 1998), probably due to residual symptoms (Sauer et al. 1997). However, there is no overall deviation from the norm. Nevertheless, lower scores on individual aspects of extraversion, such as sensation seeking, have been found in patients with unipolar depression (Carton et al. 1995).

There are no consistent findings with regard to aggressiveness. This may relate to the fact that patients in remission following a depressive episode with melancholic features show less marked outward-directed aggression than patients without melancholic features (Matussek et al. 1985). Here, too, the question arises as to the extent to which the results relate to comorbid disorders.

Openness to experience was found to be higher in seasonal depression than in other depressive disorders in one study (Bagby et al. 1996a). Because patients were not in remission and no healthy control group was included, these results may be state dependent. In addition, they might reflect a low degree of openness in other depressive disorders rather than a high degree in seasonal disorder.

Relatively consistent findings have been reported with respect to conscientiousness and other related constructs such as rigidity, orderliness, and obsessionality. Patients with unipolar depression, in particular those with melancholic features, obtain higher scores than healthy controls (Heerlein et al. 1996; Sakado et al. 1997; Schäfer 1991; von Zerssen et al. 1997), commonly also compared to other psychiatric patients (Sakado et al. 1997) and sometimes compared to patients with bipolar affective disorder (Sauer et al. 1997) or patients with depressive reactions (Bronisch and Hecht 1989). There are exceptions (e.g. Hecht et al. 1997, 1998), but the opposite finding, i.e. lower scores than comparison groups, has never been reported. These findings are also consistent with the reduced tolerance of ambiguity, which was postulated on theoretical grounds by Kraus (1988, 1991) and demonstrated empirically in studies of German (Heerlein and Richer 1991; Mundt et al. 1997) and Chilean patients (Heerlein et al. 1996). These findings are also concordant with earlier results relating to different aspects of orderliness referred to in the previous edition of this textbook (Möller and von Zerssen 1987).

The elevated or reduced scores on the traits mentioned so far build up a picture which corresponds by and large to the melancholic type of personality ("typus melancholicus"). Thus increased rigidity and conscientiousness in association with reduced aggressiveness (Furukawa et al. 1998), i.e. marked agreeableness, are correlates of this affective type. In this respect, the findings with regards to neuroticism and extraversion are contradictory and inconsistent (Furukawa et al. 1998; Hecht et al. 1997; Mundt et al. 1997). In contrast, low tolerance to frustration has repeatedly been found to be a correlate of this affective type (Hecht et al. 1997; Mundt et al. 1997; von Zerssen 1996a). Another correlate of the melancholic type is conventional piety as measured by the SFT (von Zerssen 1996a), a finding consistent with older studies of religiosity in patients with depression (Hole 1977).

A few older as well as more recent studies have found elevated scores on scales measuring social desirability (Mundt et al. 1997; von Zerssen et al. 1997). At present, it is not possible to determine whether such scales merely record a tendency to portray oneself in a socially desirable manner on questionnaires or whether they reflect an orientation toward social norms that is relevant to real behavior. The earlier term "lie scales" even suggested a conscious intention to deceive. This, however, is rather unlikely, especially as particularly low scores, thus suggesting "truthfulness," have been found in patients with personality disorders (Assion et al. 1998; von Zerssen et al. 1988). This is an argument that such scales are probably measures of a real orientation toward social norms. For this reason, the respective MPT scale is named accordingly (von Zerssen et al. 1988). Elevated scores in unipolar depressives seem to correspond to what Kraus (1991) has described as "hypernomia" of the melancholic type.

Orientation to social norms, orderliness, and rigidity are less marked, and neuroticism is more marked in patients with so-called neurotic depression (Uluşahin and Uluğ; 1997) or depression without melancholic features. As already mentioned, this subtype of unipolar depression tends to be associated with anxiety and/or personality disorders.

On the basis of clinical observation, Beck (1983) contrasts dependent depression with autonomous depression, which he equates more or less with endogenous depression. Accordingly, he describes the premorbid characteristics of patients with autonomous depression as strongly autonomous. This is, however, in clear contradiction to nearly all other studies in this area.

According to a meta-analysis by Nietzel and Harris (1990), the dependency of patients with depression is particularly well established, better even than achievement orientation, which was previously emphasized in the U.S. literature. The latter trait corresponds to the task orientation and high demands of one's own achievements seen in the melancholic type. A lack of assertiveness is supposedly characteristic of this form

of achievement orientation. This, in addition to the differences between the different types of depression in the prevalence of the melancholic type, might in part explain the contradictory findings in the literature. It is likely that the term "autonomy" does not describe a typical premorbid personality trait in any subgroup of depressive disorders and the postmorbid personality is more accurately described by an increased tendency to dependency. Akiskal (1988) even considers emotional dependency to be a direct consequence of the disorder, as prospective studies have not shown it to be a *pre*morbid personality characteristic (see Sect. 4.1.3).

The premorbid deviations from the norm of patients with so-called neurotic depression appear overall to be fairly nonspecific and at least partly explained by the comorbidity with anxiety and/or personality disorders. The greater specificity of the melancholic type for melancholic forms of primary unipolar depression is limited by the fact that the psychometric profile corresponding to this affective type has also been demonstrated in patients with migraine, albeit not in other pain patients, patients with neuroses, or patients with so-called psychosomatic disorders (Schäfer 1991, 1994).

4.1.2 Retrospective Studies Using Case History Analyses, Interviews, and Observational Methods

Analyses of premorbid developmental biographical data from case histories of psychiatric patients support Tellenbach's concept that the melancholic type is representative of the personality characteristics of a considerable proportion of patients with so-called endogenous depression (Marneros et al. 1991); so do studies blind to clinical diagnosis (Pössl and von Zerssen 1990a,b; von Zerssen and Pössl 1990) and others where the classification of personality types was even strictly operationalized (Ernst et al. 1996; von Zerssen et al. 1994b). There is no such close association with this personality type in neurotic depressive disorders (von Zerssen et al. 1994b). When Angst and Ernst (1996) examined childhood histories of depressives as recorded in Zurich case histories, the features which stood out were primarily those which represent the anxious, insecure and the nervous, tense (neurotoid) types. This is consistent with Söldner's findings (1994; see below).

On the basis of clinical interviews, Mundt et al. (1997) found that 50% of patients with endogenous depression could be classified unequivocally, and a further 25% with reservations (overall, approx. 75%), as being of the melancholic type, which agrees with earlier findings from case history analyses (von Zerssen 1991). This even applies to seemingly very different results (Tölle et al. 1987; see von Zerssen 1991). A method blind to diagnosis and strictly operationalized yielded similar figures (von Zerssen et al. 1998b). The results from a quantitative analysis of scores for the affective types concord with these findings.

One reason for discrepancies in the description of premorbid personality in patients with depression, other than differences in clinical classifications, could be that certain traits of the melancholic type, in particular the achievement orientation and obsessional orderliness, are not as marked at a young age as they are in later life. Thus Söldner (1994) found more similarities than differences in the childhood histories of patients with unipolar endogenous depression and those with neurotic depression on the basis of psychoanalytic interviews. Lack of independence, low self-confidence, high sensitivity, and low tolerance to frustration were predominant. These correspond largely to the anxious, insecure (neurotoid) type (Pössl and von Zerssen 1990b). However, excitability and a proneness to feelings of revenge and aggressive fantasies were also evident, i.e. features of the nervous, tense (neurotoid) type according to Pössl and von Zerssen (1990b). In general, the fantasy lives of the patients with neurotic depression were more strongly developed. Moreover, the patients who later developed unipolar endogenous depression spent more time at home working than playing. This could be an indication that they already had a stronger tendency to be achievement oriented. If this tendency becomes more marked in later life, they could eventually develop the full picture of the melancholic type of personality.

Marital interactions of patients with depression in clinical remission assessed by interview (Matussek et al. 1986) related to postmorbid personality. Such observations show that patients with endogenous depression often display a marked tendency toward autoaggressive processing of frustration. In the systematic observation of such interactions in patients of the melancholic type, it becomes evident that they try to avoid marital disharmony at any price (Mundt et al. 1994).

Participant observation of patients with endogenous depression discharged from hospital, in their natural home surroundings, demonstrates that their families are restricted by the patients' lifestyle intent on orderliness (Peters 1991). The author therefore speaks of a "familia melancholica" in analogy to the individual patients' melancholic type of personality.

4.1.3 Prospective Field and High-Risk Studies

The following types of study belong in the category of prospective field and high-risk studies: prospective epidemiological studies of individuals drawn from the general population who have not yet become ill

(Clayton et al. 1994); studies of female monozygotic twins in some of whom a major depressive episode has been diagnosed retrospectively (Kendler et al. 1993a,b); and prospective studies of individuals who have not yet become depressed but are at high risk because family members are affected or due to critical life events such as childbirth or death of partner. For economic reasons, questionnaire methods have predominantly been used to assess premorbid personality traits in such high-risk studies, whereas interviews have only rarely been applied (e.g. the BPI by Hecht et al. 1998).

The results agree broadly with those of retrospective studies. However, the conclusions that can be drawn about personality are less complex because the number and types of instruments used are limited, largely on economic grounds (exceptions to this include Hecht et al. 1998; Hirschfeld et al. 1989; Lauer et al. 1997). In addition, the breadth of research instruments has been further restricted by the fact that only a small number of studies have been conducted so far. In high-risk studies, global diagnostic categories such as major depression have to be applied, without considering features such as comorbidity and melancholic symptoms because of the relatively small number of patients who develop a clinical disorder. On the other hand, high-risk and prospective field studies have the advantage that the results do indeed relate relatively clearly to *pre*morbid personality. One limitation is that early subclinical disorders can hardly be ruled out with certainty, especially where the data is not collected by fully qualified psychiatrists or psychologists for economic reasons.

Most studies using neuroticism scales have shown elevated scores in individuals who later became ill (Boyce et al. 1991; Clayton et al. 1994; Hirschfeld et al. 1989; Kendler et al. 1993a,b; Marks et al. 1992) and in individuals with a genetically increased risk of developing a disorder (Lauer et al. 1997; Maier et al. 1992; exceptions: Hecht et al. 1998; Hirschfeld et al. 1989) compared with healthy controls or published test norms.

Obsessionality and rigidity of individuals at high familial risk have also been found in some studies to be increased (Lauer et al. 1997; Maier et al. 1992). Hecht et al. (1998), however, did not find this difference. Instead, they observed a reduced tendency to extraversion and a strong orientation to social norms compared with controls. Despite these differences, which are probably due to a selection bias (see above), the results fit in broadly with the picture of the melancholic type of personality. However, only a certain proportion of individuals at risk and individuals with a disorder fall within this category. Others exhibit predominantly "neurotoid" traits, as found in retrospective studies of patients with the diagnosis of major depression that has not been broken down into its subtypes (see above).

4.2 Personality and Bipolar Affective Disorder

4.2.1 Retrospective Studies

The results of recent studies on the relationship between personality and bipolar affective disorder are, as in the earlier literature (see Kröber 1988; Tölle 1987), in part very contradictory. Most retrospective studies of patients in remission using personality questionnaires reveal no, or very few, differences in scores between cases of bipolar affective disorder and unipolar depression (Angst and Ernst 1996; Hecht et al. 1997; Heerlein et al. 1996; Roy 1990; Tölle et al. 1987). Sometimes the scores of patients with bipolar affective disorder correspond more closely to those of healthy controls or to norms derived from the general population (Richter et al. 1993).

Differences from normal values are most likely to be found in terms of raised scores for neuroticism and related constructs. Sometimes they are found with respect to increased scores on measures of hysterical tendencies (Solomon et al. 1996), novelty seeking (Young et al. 1995), and extraversion in predominantly manic patients (von Zerssen 1988).

The results clearly depend on the sample studied. Thus Hecht et al. (1997) combined the scores from patients with unipolar depression and those with bipolar II disorder in their data analysis, as the two groups did not differ significantly on any of the questionnaire and BPI scales. On the other hand, Angst and Ernst (1996) separated out patients with pure mania from those with bipolar manic depressive disorder because, on one scale, their scores differed from the controls in opposition to the group with typical bipolar disorder and the group with unipolar depression – they showed an increased tendency to extraversion, as in the study by von Zerssen (1988). On other scales, they did not differ from healthy controls.

The size of samples studied, their comparability in terms of gender, age, stage of remission, the use or not of relevant statistics to control for confounding factors, and the type of scales used all have a considerable influence on the results obtained. For example, the study conducted by Sauer et al. (1997), which involved a large number of cases, found that even after careful statistical correction for sources of error, significant differences emerged between individuals with bipolar and unipolar disorders on three of the MPT scales. Individuals with bipolar disorder appeared more extraverted than those with unipolar depression or compared with normative values (see also Abou-Saleh

and Coppen 1984; Bagby et al. 1996b); von Zerssen (1988) and Angst and Ernst (1996) also found this with manic patients. Moreover, individuals with bipolar affective disorder also demonstrated less rigidity and orientation to social norms than subjects with unipolar depression.

Overall, the results described so far fit with the concept of a spectrum of affective disorders (von Zerssen 1996a). The individuals with unipolar depression who predominantly have features of the melancholic type of personality such as rigidity, orientation to social norms, a reduced tendency to extraversion, and certain neurotoid tendencies make up one pole of the spectrum. Patients whose illness has an entirely or predominantly manic course and who premorbidly display many features of the manic type of personality, such as a greater tendency to extraversion (von Zerssen 1988), make up the opposite pole. Between the two poles of the affective spectrum (i.e. from bipolar II cases through bipolar I cases with predominantly depressive phases, those with an approximately equal proportion of depressive and manic phases to cases with a slight excess of manic phases), features of the two extreme types of premorbid personality are mixed in a relation which is approximately proportional to the ratio of the manic and depressive components in the long-term course of the illness. The clearest differences from the norm could be expected at either end of the spectrum, namely in patients with unipolar depression or bipolar depression with almost exclusively manic episodes.

This concept is supported by studies using case history analysis blind to clinical diagnosis. As predicted, the proportion of representatives of the melancholic type and those of the manic type of personality does indeed range from unipolar depression of the endogenous type (with melancholic features) through bipolar II and classic bipolar I forms to the rare disorder with an almost purely manic course (von Zerssen and Pössl 1990). This is confirmed by an operationalized analysis of case history data (Ernst et al. 1996; von Zerssen et al. 1994b). Data published by other authors on this topic are by and large consistent with these findings (see von Zerssen 1991, 1992, 1996b).

Biographical data obtained from interviews with patients in clinical remission have led to similar findings (Hecht et al. 1997, 1998). These studies have also enabled a comparison with data from normal controls, which would not be possible with case history data. The scores of normal controls were most similar to those of patients displaying a balanced proportion of manic (M) and depressive (D) episodes in the course of their illness (i.e. $M \approx D$). However, they also did not differ significantly from patients with predominantly manic episodes ($M > D$). This could relate to the fact that the latter group accounted for the smallest number of cases and most of them did not actually fulfill the strict criteria ($M : D \geqslant 4 : 1$) set out by von Zerssen and Pössl (1990). In addition, the control group was not quite representative of the average population because of the exclusion of all cases with a lifetime diagnosis of any psychiatric disorder. This is probably one of the reasons why they tended toward the psychometric profile of the manic type with high scores on the MPT for extraversion and esoteric tendencies, often seen in manic patients (von Zerssen 1988).

In accordance with the results from case history analysis (Pössl and von Zerssen 1990a,b), among patients with affective disorders characterized by predominantly manic episodes, in addition to those with a tendency toward the manic type, there are occasional individuals with introverted, socially inhibited personalities. They can usually be distinguished from those with a melancholic or an anxious, insecure type by their rich fantasy life, which resembles that of the unrealistic, dreamy type. It can be inferred from observations of individual cases and a casuistic article from Japan by Sone and Ueki (1984) that in these manic patients, a constitutional expansiveness was suppressed at an early age by an excessively authoritarian upbringing and turned inward, i.e. introverted in the truest sense of the word. In any case, we are dealing here with a rare exception to the rule of a more extraverted manic type already described in similar terms in the older literature (e.g. Waters 1979; for overview, see von Zerssen 1988, 1992, 1996a).

A somewhat different picture of the premorbid personality of patients with bipolar affective disorder has emerged from studies by Akiskal (1988, 1996) and his Italian colleagues (Cassano et al. 1988, 1992), although these authors have also used a spectrum concept of affective disorders for their research. This concept, however, differs in a few relevant points from that described above (von Zerssen 1996a). Individuals with unipolar depression are not divided into those with and without melancholic features, but rather into those with so far only one episode and those with more than one. Patients with bipolar II disorder include unipolar depressive patients with premorbid hyperthymic personality traits (Cassano et al. 1988, 1992) and patients with cluster B personality disorders, i.e. cases of secondary depression (Akiskal 1988). In addition, patients with purely or predominantly manic episodes are not distinguished from other patients with bipolar I disorder. This grouping of disorders and the narrowing of the personality assessment to the Kraepelinian fundamental states of manic depressive disease makes it understandable why Cassano et al. (1988) only found a depressive temperament and not a temperament corresponding to the melancholic type in their patients with unipolar depression, and why the traits of the melancholic type were also not detected in

bipolar II disorder, a disorder described by Dunner (1983) without reference to premorbid personality characteristics. The broad definition of the bipolar II group, including clinically pure depression with hyperthymic temperament (which corresponds approximately to the manic type) as well as cluster B personality disorders, inevitably increases the prevalence of hyperthymics in bipolar II disorder. The close relationship between hyperthymia and the manic component of an affective illness was probably missed because patients with a clear predominance of manic phases were mixed with those developing only occasional manic and many depressive episodes. This did not allow a proper differentiation between the types of temperament and their relationships to different courses of an affective disorder.

4.2.2 Prospective Field and High-Risk Studies

According to Akiskal's concept, one would expect not only a high frequency of affective disorders, but also of cluster B personality disorders in the families of patients with bipolar affective disorder. This, however, is not the case according to two independent studies (Coryell and Zimmerman 1989; Maier et al. 1995). Coryell and Zimmerman (1989) found only a relative increase of personality disorders from cluster C, in particular obsessive-compulsive personality disorder, in comparison with a group of healthy controls. This fits with the increased rigidity, as measured by the MPT in the study by Maier et al. (1995) of individuals at risk for bipolar disorder. Clearly, features of the melancholic type are not only predominant in the families of patients with unipolar major depression, but also in relatives of individuals with bipolar disorder (see also the high-risk studies carried out by Hecht et al. 1998 and Lauer et al. 1997). This is consistent with the fact that, in this group, the risk of developing a unipolar depression is clearly higher than that of developing a bipolar affective illness (Maier et al. 1995), particularly a bipolar I disorder with a predominantly manic course, in which we would expect premorbid personality features of the manic type to be increased.

Nevertheless, there are indications of features of the manic type in individuals with a high familial risk of bipolar affective disorder (Nurnberger et al. 1988). They show higher scores than controls for hypomanic traits and sensation seeking, particularly so on a scale of disinhibition with respect to drug taking and sexual behavior. However, the possibility cannot be ruled out that subclinical symptoms of a cyclothymic disorder were measured. Yet these would have been regarded by Akiskal (1992, 1996) as part of the subjects' temperament.

Prospective field studies provide interesting information about the development of distinctive premorbid personality features in individuals who later suffer from a bipolar disorder. According to one study, these characteristics clearly do not increase continuously from childhood onward. It appears that it is the other way round, at least in 7-year-old boys. In comparison with probands who remained healthy, they presented similar signs of hostility and motor restlessness as probands who later developed schizophrenia. However, the features were less marked and were only present at this relatively early age (Crow et al. 1995).

This might explain why a study of young Swiss men eligible for military service who later developed a bipolar affective disorder found no significant differences from the norm on any of the scales of the Freiburg Personality Inventory (Clayton et al. 1994), in contrast to others who developed unipolar depression or schizophrenia. The age of the subjects in any psychological study may therefore considerably influence the results. This of course also applies to high-risk studies. Over short time periods, however, the psychometric profiles of individuals at risk of developing an affective disorder remain relatively constant, at least at the age of full maturity, as far as they are not influenced by a mental state disorder which develops during the follow-up interval (Lauer et al. 1998).

All in all, the findings described here from prospective field and high-risk studies are compatible with the concept that features of the manic and the melancholic types are combined premorbidly in bipolar patients or cancel each other out. Thus features of one or the other type of premorbid personality only become evident in those who later develop either a predominantly depressive or an overwhelmingly manic course of the illness (von Zerssen 1996a). The combination of traits of the contrasting affective types may have a positive effect on occupational success, as can be inferred from studies of the employment status of patients with unipolar and bipolar affective disorders (Kraus 1991) and their relatives (Coryell et al. 1989). The results of earlier studies on this topic are confirmed by these findings.

4.3 Personality and the Course of Affective Disorders

A considerable number of studies within the time-frame considered in this chapter have examined the extent to which personality traits can predict the course of illness in patients with affective disorders, and especially whether they predict the response to particular therapeutic measures. It has been repeatedly found that high scores on measures of neuroticism and related concepts, such as harm avoidance, as well as comorbidity with anxiety and personality disorders (which themselves

are typically associated with high scores on such measures; Davidson et al. 1985), worsen the prognosis of an affective disorder (Alnæs and Torgersen 1990).

These factors also worsen the response to therapeutic measures, including the following: acute treatment with antidepressants (Black et al. 1988; Carpenter et al. 1995; Joyce et al. 1994; Möller et al. 1987; Peselow et al. 1992; Shea et al. 1990), even if they only account for a small amount of the variance in outcome (Nelson and Cloninger 1997); psychological interventions (Shea et al. 1990); and the response of seasonal affective disorder to light therapy (Reichborn-Kjennerud and Lingjærde 1996). According to one study, this also applies to the long-term effectiveness of prophylactic lithium therapy (Abou-Saleh and Coppen 1990). The assumption that the compliance of patients, particularly with long-term therapy such as lithium prophylaxis, is dependent on personality factors needs to be tested in controlled therapeutic trials. It can be predicted that those who predominantly have features of the melancholic type of personality would be more compliant than those who tend toward the manic type. It remains unclear whether the usual personality questionnaires are sufficiently valid for this type of investigation. To date, they have not produced many convincing results in relation to the long-term prognosis of depressive disorders (Philipp and Maier 1988; Wittchen et al. 1988; exception: Alnæs and Torgersen 1990). On the other hand, Kröber et al. (1998), who had administered an adjective list to an informant, found that what they called "syntonia" (which probably corresponds to our relaxed, easy-going type; see Sect. 2) had a significant long-term protective effect in terms of relapse of a bipolar manic depressive disorder. These protective, or so-called salutogenic, aspects of personality variables should be given more attention alongside the pathogenic aspects in future research. Until now, there have only been a few isolated examples of studies looking at protective factors in the genesis of depression (e.g. Söldner 1994; see von Zerssen 1996b).

An American multicenter study (Akiskal et al. 1995) investigated whether it is possible, on the basis of personality traits, to predict which patients who have hitherto suffered from major depression will develop manic or hypomanic episodes in the long term. The results were surprising in light of the previously mentioned cross-sectional studies of the relationships between personality and the different courses of an affective disorder. It was not possible, on the basis of the postmorbid assessment of personality traits, to distinguish those who later developed a bipolar I disorder and those who continued to suffer from unipolar depression. On the other hand, those who changed from a unipolar depressive disorder to a bipolar II disorder had been more emotionally labile at index investigation. The authors interpreted this as a confirmation of Akiskal's concept of a close relationship between a cyclothymic temperament and bipolar II disorder. There is clearly an urgent need for research to clarify these nosological problems that are relevant to the prognosis of affective disorders.

5 Interpretation of the Relationships Between Personality and Affective Disorders

The following interpretations of the relationships between personality and affective disorders have been proposed (see Akiskal 1988; Angst 1988; Klerman and Hirschfeld 1988; von Zerssen 1996a):

1. Personality traits are risk factors for or protective factors against an affective disorder.
   a) They act as moderator variables, which either increase (Joffe and Regan 1991) or decrease (Kröber et al. 1998) the risk of developing an affective disorder in conjunction with preexisting vulnerability factors.
   b) They are a direct expression of vulnerability or lack of vulnerability (resilience). Only the pathogenic, i.e. vulnerability aspect will be discussed below. In this context, personality traits may be:
   - Nonspecific indicators of vulnerability whose existence does not allow any clear conclusion about the actual illness-specific vulnerability factors and therefore about the type of disorder to be expected (depressive, manic, or nonaffective; Angst and Ernst 1996; see von Zerssen 1996a in relation to "neurotoid" personality traits in patients with affective disorder).
   - Relatively specific indicators which allow such conclusions (see Akiskal 1996 in relation to the temperaments he derived from Kraepelin's work; von Zerssen 1996a in relation to traits of the manic and melancholic types in patients with different courses of an affective disorder).
   - The actual predisposing factor, in other words the actual illness-specific vulnerability factor itself, i.e. an indispensable precondition without which the affective disorder cannot develop, even if additional precipitating factors may be required. This corresponds approximately to the interpretation by Kraus (1991, 1996) of the role of the features of the melancholic type of personality in melancholia.
2. Personality traits are pathoplastic factors once the illness has developed. Thus personality traits may have nothing to do with the origin of the illness, but may influence features of the disorder and its consequences.

a) They color the symptomatology of the disorder in a personality-specific way, e.g. an anankastic depression in patients with a primary anankastic personality (Videbech 1975).
b) They modify the course of the illness, e.g. personality disorders worsening the prognosis (see Sect. 4.3).
c) They influence recovery, including issues such as compliance and rehabilitation (see Sect. 4.3).

3. Personality traits are an expression of the illness itself:
a) They represent preclinical "formes frustes," as is almost certainly the case in cyclothymic fluctuations seen prior to typical bipolar affective disorder (see Akiskal 1992, 1996; for case descriptions, see Waters 1979).
b) They are a sequela to the disorder in terms of a personality change brought about by the illness, whose nature is not recognized and is then falsely attributed to the patients' premorbid personality. This is accepted by several authors in relation to some of the postmorbid measures of particular personality traits in patients with depression, e.g. emotional dependency, low self-confidence, and low extraversion (see e.g. Akiskal 1996; Angst and Ernst 1996; Hirschfeld and Shea 1992).

These different possibilities are not mutually exclusive. They may be combined either in one type of disorder or in an individual case. Thus some characteristics that are present premorbidly, including autonomic lability and other dysthymic traits such as anxiety and depression proneness, become stronger postmorbidly and at the same time influence the course of the illness unfavorably (see Sect. 4). In any case, such dysthymic traits can often be traced back to childhood in patients with depression (Söldner 1994). When they reach the level of a personality disorder, or when a personality disorder develops in addition, there is a clear predisposition to an early onset of the affective disorder (for cluster B personality disorders, see Black et al. 1988; Brodaty et al. 1991; for clusters C and A, see Parker et al. 1998).

Whether dysthymic traits in patients who later develop a depressive illness are regarded as personality characteristics or as symptoms of a chronic disorder with an early onset that have become habitual, is probably merely a question of semantics (Lauer et al. 1998) and will not be elaborated on further here. It should, however, be emphasized that, according to the author's own observations, which are in agreement with those of Waters (1979), cyclothymic fluctuations in individuals who later develop a full-blown bipolar disorder can usually be differentiated from the individuals' primary personality, even by the patients themselves. This is much less often the case with the hypomanic traits as described as the manic type of personality. In these cases, it appears that the traits are more likely to represent a direct expression of their vulnerability to a predominantly manic course of a bipolar disorder (von Zerssen 1996a).

The role of genetic and environmental factors in the genesis of premorbid personality on one hand and affective disorders on the other can only be hinted at with reference to relevant studies (e.g. Kendler et al. 1993b). Psychoanalytically inclined authors direct their theoretical interpretations essentially toward the influence of early life experiences within the family (Söldner 1994). The considerable influence of genetic factors even on the development of attitudes and (e.g. religious) beliefs has, however, been convincingly demonstrated in recent twin studies (Waller et al. 1990). Molecular genetic studies have revealed associations between polymorphisms of individual genes (or, to be precise, their promoter regions) and personality dimensions as measured by means of questionnaires. Thus there are suggestions of a relationship between the dopaminergic system and extraversion, particularly novelty seeking (Benjamin et al. 1996), and between the serotonergic system and neuroticism (Lesch et al. 1996). A relationship between the monoamine system and extraversion, in particular sensation seeking, had already been postulated by Zuckerman (1985).

Cloninger (1987) suggested a relationship between three of his hypothetical dimensions of temperament and the activity of particular neurotransmitter systems. However, the only relationship that has been convincingly demonstrated so far is that between reduced serotonergic activity, as measured in cerebrospinal fluid, and increased impulsivity, which predisposes to aggressive and autoaggressive behavior, the latter in the form of suicide using "hard" methods (Coccaro 1989; Virkkunen et al. 1989). On the basis of cerebrospinal fluid and psychometric variables, a relationship has been suggested between the dopaminergic system and extraversion in patients with depression (King et al. 1986). There are many open questions left and areas in which research could be further expanded. These include the question of how individual predisposition and social relationships interact in the development of personality on one hand and mental state disorders on the other.

G.W. Brown

Role of Life Events in the Causation of Affective Disorders

1 Introduction

Life-event research has arguably proved to be the most effective way of gaining insights into how the external environment helps to generate and perpetuate depressive conditions. An early achievement was to make clear that concepts such as the amount of mere change in activity brought about by an event is largely irrelevant, and it was essential to deal directly with the meaning of events and their emotional impact (Brown and Harris 1978). It has also proved important to pay some attention to ongoing difficulties that can either be brought about by an event (the death of a husband leading to financial problems) or lead to an event (a marital difficulty eventually ending in a separation).

In dealing with meaning, two perspectives have proved productive. The first can be summed up by the statement that we cannot fully know the meaning of most life events until they can be related to the individual's relevant plans and concerns. However, while the mechanisms involved are clearly cognitive, they are not necessarily matters a person is either entirely conscious of or willing or able to report. Concerns "are largely dormant demons: They are dispositions that remain silent as long as conditions conform to the standard, within reasonable limits" (Frijda 1986, p. 336). One way of conceiving of these concerns is in terms of plans and purposes that typically stem from role activity and in that sense are clearly social in nature, e.g. a woman's wish to move from an overcrowded and damp flat to give children "a better start in life". A second perspective concerning meaning assumes that evolutionary-based response patterns that guide us in terms of what to want or to avoid are also likely to be involved. The woman planning to move from her damp flat may therefore experience shame on learning her plans have fallen through if this disappointment results from a friend's mistrust that she will repay the loan that has been planned. At the same time, she may experience increased anxiety if she perceives her child's asthma as likely to worsen again during the coming winter. There are therefore behavioural systems sensitive to a particular range of stimuli. Of course, such responses will be influenced by cultural display rules and individual differences of various kinds, but there is little doubt that such evolutionary-based behavioural systems need to be taken into account if we are to understand the role life events play in the aetiology of common psychiatric disorders such as depression.

The only life-event instrument to deal with both kinds of meaning has been the Life Events and Difficulty Schedule (LEDS) developed in London, and this review will be largely restricted to research based on it. It has been used to estimate *general* as well as various kinds of *specific* threats. It does this by the use of contextual ratings made by the investigator which take into account a person's likely plans and concerns of likely relevance for the event insofar as these can be indirectly assessed from a person's current circumstances and biographical detail. The use of such ratings is also methodologically important, as they go some way to rule out reporting artefacts since such ratings take no account of reported feelings about the event or difficulty or whether or not a disorder followed. This is achieved by means of consensus meetings in which the interviewer holds back from a team of raters such information when describing the event and its immediate context. It is possible to argue that this procedure rules out possible bias and, if anything, will result in a conservative estimate of any aetiological effect. General guidelines for rating severe threat are given in an extensive rating manual containing thousands of examples listed in terms of over 100 event categories (e.g. subject's demotion at work and subject's unplanned pregnancy). Only events having long-term threat in the sense of its presence some 10–14 days after its occurrence are considered for a severe threat rating. The LEDS has been used to study a variety of psychiatric conditions and has been successfully employed in a wide variety of cultural settings. Nothing has emerged from the employment of other life-event instruments that would seriously threaten the LEDS-based findings to be reviewed.

2 Three Key Early Findings

The first use of the LEDS to study depressive conditions occurred in the early 1970s and involved both a patient series seen at the Maudsley Hospital in South London together with a random series of women from the local Camberwell population (Brown and Harris 1978, 1989). All the women were aged between 18 and 65. The Present State Examination (PSE) was used to assess psychiatric state (Wing et al. 1974). The initial threshold of caseness for depression was settled by two psychiatrists (John Copeland and John Cooper) who had previously worked on the PSE. They went by their experience of affective disorder in out-patient practice (Brown and Harris 1978). Later work operationalised this threshold in terms of core symptoms of depression (Finlay-Jones et al. 1980). This has been found, if anything, to be somewhat higher than that of the computer algorithm (ID/CATEGO) of the PSE (Wing

and Sturt 1978) and the Research Diagnostic Criteria (Spitzer et al. 1978) which were developed somewhat later (Dean et al. 1983).

Three key findings emerged:

1. Most onsets of depression were preceded by a "provoking agent" (either a *severely threatening event* or a *major difficulty* lasting at least 2 years). As already noted, only long-term threat in the sense of being present some 10–14 days after the event raised the risk of a depressive onset, and this time element is built into the definition of a severely threatening event. Events with short-term threat alone did not raise the risk. These results emerged despite the use of contextual ratings of events that are approximate and probabilistic and based on a limited amount of information. Again, as already noted, in rating the severity of threat of life events, the investigator did her best to assess relevant plans and purposes by taking into account current circumstances and any biographical detail that appeared relevant. A woman, for example, experiencing a second miscarriage after persistent attempts to have her first child would probably have the event rated severe, but her first miscarriage shortly after marriage would have been rated contextually upsetting but not severely so.
2. However, despite events and difficulties playing a substantial aetiological role in the sense that the majority of onsets of depression in the general population were preceded by at least one such severe threat-provoking agent, the likelihood of a depressive episode was very low without the additional presence of one or more ongoing vulnerability factors of a psychosocial nature. One key vulnerability factor in the original Camberwell research was the lack of effective confiding in a core relationship, particularly where a partner or boyfriend was involved. While this particular result has to be treated with caution given that the material on which the rating was based was provided by the woman after the onset of depression, subsequent prospective enquiries have confirmed the central importance of such background psychosocial factors (Brown et al. 1990c).
3. There was no clear-cut link between the presence of a provoking agent in the Camberwell patient series and diagnostic type. Provoking agents were somewhat less common before onset in the patient series as a whole than onsets of depression in the general community not receiving psychiatric care and, while somewhat less common before endogenous-type depressive conditions when defined in clinical terms, there was little difference from the experience of those with "neurotic" depressive conditions, a result reported earlier by Paykel et al. (1971) and later in several studies (e.g. Katschnig et al. 1986; Bebbington and McGuffin 1989).

3 Subsequent Findings

In what follows, findings from research that has followed this first LEDS study of depression will be outlined. The original research reports (which will be cited) should be consulted for details concerning measurement and design.

3.1 Meaning of Severe Events and Onset

Table 1 deals with the role of severe events based on prospective enquiry carried out in the inner-city area of Islington in North London. It is a typical result. The research was based on 400 women with at least one child at home. They were largely working class, with one fifth living alone with their children. The women were followed up at 12-month intervals. The table deals with the 303 women who, at the time of first contact, did not qualify as patients with depression and who might therefore develop such an episode in the following year. Twenty-nine of the 32 onsets in the first follow-up year were preceded by at least one severe event involving long-term threat in the prior 6 months, most within some 8 weeks of onset. In terms of specific rather than general threat, research has shown that such events typically involved loss, if this was defined not only by a loss of person but loss of a role or cherished idea about oneself or someone close (Finlay-Jones and Brown 1981).

The relevance of the contextual ratings of long-term threat based on a crude assessment of relevant plans and purposes was confirmed by the use of a direct measure of emotional commitment to various role domains made at the time of first contact and therefore

Table 1. Onset rate among Islington women in terms of provoking agent status

Provoking agent status	Onsets (n)	Onset rate (%)
No provoking agent	2/153	1
Provoking agent		
Major difficulty only	1/20	5
Severe event	29/130	22
Total	32/303	11

$\chi^2 = 36.60$, 2 df, $p < .001$.

established before any event or onset occurring in the following year. Table 2 shows that, where a severe event in the follow-up year "matched" a prior area of high commitment (e.g. a child's delinquency in the context of a woman's high commitment to motherhood), the risk of an onset of depression was considerably increased.

However, although loss is typically present, it may not be the factor of central aetiological importance. Table 3 illustrates this by the use of a hierarchical scheme dealing with the likely meaning of each severe event (or a closely related sequence of such events) occurring in a 2-year period excluding any time spent depressed (Brown et al. 1995). Various types of specific meaning are considered. Events are only rated lower down the scale such as subcategory vii ("other key loss") if they have failed to quantify for a higher rating such as subcategory iii ("humiliation: put down"). The design of the rating scheme was influenced by an evolutionary perspective on depression (Gilbert 1989).

The first three subcategories (i–iii) concern possible types of humiliation. The ratings assume that one consequence of such events was likely to be either a sense of being put down or a marked devaluation of self. The first subcategory, for example, includes any separation from a partner or lover where he either took the initiative or where the woman was forced to leave or break off a relationship because of violence or discovery of infidelity.

Events associated with subcategory iv ("entrapment") had to have failed to meet criteria for the three humiliation subcategories. Such events underlined the fact of being imprisoned in a punishing situation that had gone on for some time. The table goes on to deal with four types of loss (in the absence of humiliation or entrapment) and finally danger, a residual group involving threat of a future loss (Finlay-Jones and Brown 1981).

The table as a whole deals with whether a particular severe event (or sequence) was followed by an onset. It shows that there were large differences in risk by category of event when those occurring to Islington women are considered. If those involving humiliation are combined with those involving entrapment, the risk of depression was three times greater than for other severe events (31% versus 9%). The relatively low risk associated with loss alone, except following a death rated severe, suggests that something more than loss is usually necessary to bring about a depressive onset.

The likely importance of devaluation of self and entrapment is seen in another result. Separations occurring to Islington women associated with humiliation (subcategory i in Table 3) were further divided into whether or not the woman took some initiative in bringing about the separation after learning of an infidelity or the experience of a partner's or lover's violence. When the further subcategory of a woman who clearly took the initiative in the separation (vi in Table 3) is taken onto account, Table 4 shows a clear gradient between the amount of control apparently exercised by the woman and risk of an onset.

Table 2. Onset of depression among the 130 women in Islington with severe event in terms of matching commitment

At least one severe event taking place in an area of marked commitment	Onset (%)
Yes	40 (16/40)
No	14 (13/90)
Total	22 (29/130)

$\chi^2 = 9.01$, 1 df, $p < .01$.

Table 3. Rate of onset by humiliation/entrapment/loss/danger following 377 event sequences during a 2-year period among Islington community women

Event sequence	Provoking onset (%)
1. Humiliation/trapped	31 (41/131)
i. Humiliation: separation	35 (12/34)
ii. Humiliation: other's delinquency	19 (7/36)
iii. Humiliation: put down	38 (12/32)
iv. Trapped	34 (10/29)
2. Loss alone	9 (14/157)
v. Death	29 (7/24)
vi. Separation: subject initiated	11 (2/18)
vii. Other key loss	7 (4/58)
viii. Lesser loss	2 (1/57)
3. ix. Danger alone	3 (3/89)
4. Total	15 (58/377)

3.2 Psychosocial Vulnerability

The second theme of the introduction concerned issues surrounding psychosocial vulnerability. Two background factors measured at the time of the first interview in Islington have proved highly predictive of onset during the following year (Brown et al. 1990a,b):

Table 4. Risk following separation in a core tie by degree of control on woman's part – Islington series

Type of separation/risk	Onset (%)
Other's initiative	53 (9/17)
Woman "forced" to act	25 (4/16)
Woman's initiative	11 (2/18)

$\chi^2 = 7.59$, 2 df, $p < .05$.

- Negative psychosocial (negative evaluation of self or chronic subclinical conditions)
- Negative environmental (negative interaction in the home or – for single mothers – lack of close tie defined by the women at the time of first contact as "very close" and seen fairly often).

The predictive power of the indices can be judged by the fact that, while only 23% of the 303 women at risk at the time of first contact had both risk factors, three quarters of all onsets recorded in the 12-month follow-up period occurred among them (Brown et al. 1990c). The findings concerning the importance of humiliation and entrapment, of course, fit well with these two background risk factors.

Figure 1 takes into account both type of provoking event and vulnerability. (Since self-esteem was measured only at the time of first interview, only the first follow-up year has been considered.) The size of the interactive effect is impressive. A severe event, however threatening, was never enough without a vulnerability factor to provoke depression, nor for that matter was vulnerability on its own. Where loss alone was concerned, risk of onset was negligible unless both of the two risk factors were present. (Subsequent research has indicated that onset can occur without such vulnerability following a severe event, but under these circumstances risk is low.)

4 Endogenous Conditions

So far, only depressive onsets in the general population, almost entirely of a "neurotic" kind, have been considered. The third introductory theme concerned the curious failure to obtain any clear differentiation between the presence of a provoking severe event and diagnostic type. At the same time, there can be no doubt about the presence of genuine "endogenous" conditions. A recent study of a London psychiatric patient series dealing with inpatients and outpatients seen over a defined period of time has thrown some possible fight on this puzzling set of findings. Table 5 shows, as expected, that those with melancholic/psychotic conditions were a good deal less common than those without. However, it also shows that only those who had a melancholic/psychotic diagnosis and a prior episode differed in having less chance of experiencing a severe event before onset. This difference between first and later episodes may well go some way to explain the general lack of a relationship. It might also help to explain the inconsistencies in published results, since the proportion of patients with both these characteristics is bound to vary by type of treatment centre, and traditional patient enquiries that have reported such differences have often been carried out in tertiary centres where the proportion of later episodes is likely to be greater. While numbers involved with a high melancholic/psychotic score are small, findings held for two other patient series (Brown et al. 1994a) and a series from Pittsburgh produced some consistent findings (Frank et al. 1994). Such a fall-off with episode number has been found to relate to the course of bipolar conditions (Post et al. 1986), and kindling and sensitisation phenomenon, as with such conditions, may play some part with the melancholic/psychiatric conditions as defined in the London and Pittsburgh enquiries. It is also of interest that this same London study suggested that, despite intensive interviews, as many as one tenth of patients with a "neurotic" depressive disorder were without a hint of being "provoked" (Brown et al. 1995).

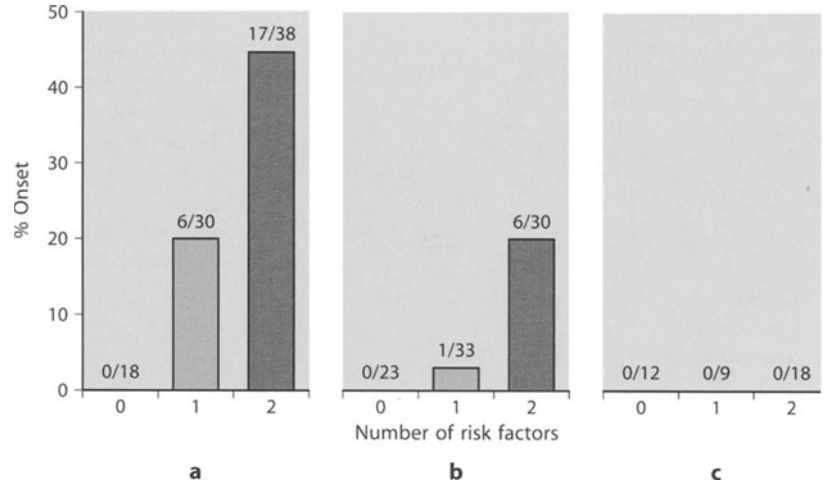

Fig. 1a–c. Rates of onset depression in follow-up year by severe event type and background risk among 130 Islington women. All onsets and severe events (or sequences) taken; only the event nearest onset considered provoking. **a** Any humiliation/entrapment event. **b** Loss event (and not any humiliation/entrapment event). **c** Danger event (and not any humiliation/entrapment or loss event)

Table 5. Ordinal number of adult episodes of depression in North London patients by melancholic/psychotic score and presence of a severe event within 6 months of onset

Melancholic/ psychotic score	Severe event rate (%)					Total excluding first episode	Total
	First episode	Second episode	Third episode	Fourth episode	Fifth episode or more		
Low	71 (25/35)[a]	70 (21/30)	83 (10/12)	60 (3/5)	80 (8/10)	74 (42/57)[b]	73 (67/92)
High	59 (10/17)[a]	15 (2/13)	33 (1/3)	100 (1/1)	0 (0/1)	22 (4/18)[b]	40 (14/35)
Total	67 (35/52)	53 (23/43)	73 (11/15)	67 (4/6)	73 (8/11)	–	64 (81/127)

[b]$x^2 = 13.18$, 1 df, $p < .001$.

5 Outcome

LEDS life-event research has opened up other issues. Perhaps most significant has been the question of outcome. Here, evidence is beginning to emerge that improvement or remission quite often involves the reverse of the psychosocial processes typically leading to the onset of an episode. For example, Table 6 takes account of the presence of positive events in the 20-week period before any significant improvement or remission. Such events on contextual grounds were seen as giving renewed hope about the future. In the Islington series, when episodes lasting 20 weeks or more were considered, 57% of such changes in symptomatology were preceded by such an event compared with an expected proportion of 15% (Brown 1993). No effect emerged for episodes lasting less than 20 weeks. In the patient series, the overall proportion was much the same at 51%; however, those patients recovering or improving on anti-depressant medication had only around half of this positive LEDS experience.

Table 6. Proportion with a positive event among North London patients recovering/improving from depression of at least 20 weeks' duration by medication (with overall Islington series results for comparison)

Patient group	Positive event (%)
North London patients recovering/improving[a]	
Anti-depressant medication	26 (12/47)
Other medication	62 (8/13)
No other medication	48 (28/58)
Total without anti-depressant medication	51 (36/71)
Islington community depressed patients recovering/improving	57 (28/49)

[a]$\chi^2 = 8.20$, 2 dfl, $p < .02$.

One type of "positive" event was defined by its heralding a significant reduction in an ongoing marked difficulty. It is therefore of interest that presence of such an interpersonal difficulty at the point of onset (but no other type) was an important predictor of the chronicity of an episode in both a community and patient series. The experience of a history of childhood abuse or neglect was about as equally effective as a predictor of chronicity. Table 7 gives the percentage of 101 episodes of depression in the Islington community series of women occurring over a number of years in terms of the proportion without improvement/recovery within 12 months by whether they had had either childhood neglect/abuse or an interpersonal difficulty throughout the episode (much the same result was obtained if presence of the difficulty at the point of onset was taken instead) (Brown and Moran 1994; Brown et al. 1994b).

6 Conclusion

There are two ways of looking at the findings that have been reviewed. Firstly, the study of life events has clearly been an effective facilitator, a way of opening up a series of issues concerning depression for study. Once a substantial causal link had been established, a platform was provided for the study of the role of a whole range of other current and biographical experiences. Moreover, as research has progressed, it has pushed back in time to consider the role of early experiences of neglect and abuse which often has event-like characteristics. In more general terms, the study of events has led to the consideration of issues of vulnerability and protection, event production, coping behaviour and issues surrounding chronicity and course of particular episodes. So far, this kind of extension has remained largely within the psychosocial realm, but clearly potential ramifications are much

Table 7. Percentage with chronic course (> 1 year) of 101 episodes of depression among Islington women by the risk factors of interpersonal difficulty and childhood adversity

Risk factor	Chronic course (%)		Odds ratio
	Risk factor present	Risk factor absent	
Childhood adversity	44 (17/39)	16 (10/62)	4.02*
Interpersonal difficulty during course	44 (18/41)	15 (9/60)	4.43*
Childhood adversity *or* interpersonal difficulty during course	44 (24/59)	7 (3/42)	8.91*

*$p < .0001$.

broader. In diagnostic terms, it has raised issues concerning the role of sensitisation and kindling in explaining the apparent lessening of the importance of stress in subsequent onsets of melancholic/psychotic depressive conditions. This is a possibility suggested by research on bipolar conditions (Post et al. 1986).

It has also been possible to isolate a small group of apparently endogenous "neurotic" depressive episodes. Such results call out for collaborative research in both biological and clinical terms. It also suggests that such areas of research are likely to be handicapped if they fail to take account of the now complex psychosocial aetiological models that have been developed around the event–onset link. Particularly significant, for example, for genetic research are findings from disparate cultures that have documented considerable differences in the experience of caseness of depression, e.g. on the one hand at one extreme 2.5% among women between 18 and 65 in a Basque-speaking rural community in a 12-month period (Gaminde et al. 1993) and on the other 30% among women in a black township in Zimbabwe (Broadhead and Abas 1998). Since there were comparable differences in the rates of severe events in the various populations studied, an obvious interpretation is that the differences in the experience of "neurotic" depression had been driven by such psychosocial factors. This argument would hold irrespective of the presence of substantial heritability indices (h^2) within each population (Brown 1996).

The second contribution of such research concerns the depression–event link itself. This is a highly complex issue, because depressogenic life events correlate with a whole range of factors ranging from genetic/personality (Owens and McGuffin 1997) to macrolevel/societal (Brown 1996). However, the findings concerning the role of events involving humiliation or entrapment do suggest that the issue of meaning cannot be entirely divorced from an evolutionary perspective – that in some way an evolutionary-based response pattern in group-living animals closely linked to issues surrounding defeat and exclusion is often involved (Gilbert 1989). However, it does not follow that depression-like states of clinical severity have ever been adaptive. An artificially created life event such as that resulting from the transfer of a dominant marsupial male sugar glider to another group with an accompanying loss of status can create an apparently severe depression-like response (Jones et al. 1995). However, this might largely be a function of captive conditions in which these responses have been documented, and such extreme states may well be largely avoided in natural conditions (M.J. Eales, unpublished work). Nevertheless, this view is fully compatible with such clinically relevant depressive conditions being a complication of essentially non-pathological evolutionary-based submission and appeasement responses to defeat in group-living mammals that are adaptive. Therefore, the high rates of clinically relevant depression that appear to be possible in some human populations may well be a result of our more highly developed cognitive development together perhaps with the event-creating potential of many societies experiencing periods of marked social changes due to factors such as war, industrialisation, urbanisation, changing sexual mores and the like. Such considerations suggest that the study of life events places aetiological research on depression firmly in the courts of social science, biology and clinical medicine, and interdisciplinary collaborative research is likely to prove vital.

General Principles of the Treatment of Depressive and Manic Disorders

Translator: E. Taub

1 Introduction

This chapter describes general guidelines for the treatment of affective disorders. It is thus more specific than Chap. 9 (Vol. 1, Part 2), which concerns the general principles of treatment in psychiatry, and more general than the discussion of specific methods of treatment for the affective disorders found in the following chapters of this volume (Part 1, Chaps. 23–25 and Chap. 31). The aim here is to delineate the role of various forms of treatment in the overall treatment plan, with an emphasis on common, overarching principles.

Depressive disorders are among the more common mental illnesses, with a point prevalence of 4%–8% and a lifetime prevalence of 10%–20% (Kessler et al. 1994; Angst 1995). They are characterized not only by high prevalence, but also by a pronounced tendency to recur and by a chronic course with considerable morbidity and mortality: 40%–80% of patients with unipolar depression suffer a recurrence within 2 years; the likelihood of a recurrence increases with the number of previous depressive episodes and the severity of the current episode; patients with more severe depression have a risk of approximately 15% of dying by suicide (Keller et al. 1986; Frank et al. 1990; Klerman and Weissman 1992; Prien and Kocsis 1995) and also have a higher mortality rate from cardiovascular causes (Glassman and Shapiro 1998; see also Chap. 14, Vol. 2, Part 2). Chronic treatment, involving prophylaxis against recurrence and suicide, is therefore of the greatest importance, in addition to acute treatment (Kupfer 1991; Kupfer et al. 1992; APA 1993).

A complicating factor is that the great majority of depressive patients present first not to the psychiatrist, but to the general practitioner or internist, and, therefore, not all of these patients are correctly diagnosed and properly treated (Keller 1988; Linden et al. 1996; Hirschfeld et al. 1997). In summary, depressive disorders are common, tend to recur, and are associated with considerable mortality.

As is true of other psychiatric illnesses, the etiology and pathogenesis of depressive disorders have not yet been elucidated. At present, it is assumed that their origin is multifactorial, involving not only genetic and biological, but also psychological and social determining factors (Akiskal 1995). The modern treatment of depression must thus take biological, psychological, and social aspects into account (APA 1993). A number of recent studies have shown that a diagnostic distinction between neurotic and endogenous depression makes little sense with respect to either etiopathogenesis or treatment. The two leading diagnostic classification systems have therefore dispensed with this dichotomy; they now list only the diagnoses of the depressive episode (in ICD-10; WHO 1992) or of major depression (in DSM-IV; APA 1994a). Primary distinctions with implications for therapy are now drawn according to degree of severity (mild, moderate, severe), type of disease course (single episode, recurrent), and, especially, the characterization of disease manifestations (e.g. psychotic manifestations, seasonal pattern) (see Chaps. 14, 15, Vol. 3, Part 1; Chaps. 2, 3, Vol. 1, Part 2).

Bipolar disorders are recurrent affective disorders with both depressive and manic episodes. Bipolar I disorder is characterized by one or more manic or mixed episodes, which are usually associated with episodes of major depression. Bipolar II disorder is characterized by one or more episodes of major depression and at least one hypomanic episode (APA 1994a).

Manic disorders are much rarer than depressive disorders. Epidemiologic studies have revealed a 1-year prevalence rate of 0.6%. The lifetime prevalence of bipolar I disorder in the general population has been determined to be between 0.4% and 1.6% (Robins and Regier 1991). In contrast to depressive disorders, which are more common in women, bipolar disorders occur with approximately the same frequency in both sexes. Bipolar disorders are characterized by a high rate of recurrence and thus also by a high morbidity, a high risk of suicide (in 10%–15% of cases of bipolar I disorder; APA 1994a), and many associated social and psychological problems (see Chap. 15, Vol. 3, Part 1).

2 Diagnosis and Indications for Treatment

A correct diagnosis and prognosis, leading to the establishment of proper indications for treatment, is a precondition for the successful therapy of a depressive or manic episode. Careful assessment of the patient's clinical findings, past psychiatric and medical history, and psychosocial stress factors is required. A specific family history with respect to affective disorders must be obtained, and an understanding of the patient's familial and cultural environment is also essential.

Potential organic causes of depressive or manic manifestations must be ruled out by means of a neurological and general medical examination and, when indicated, by appropriate additional diagnostic techniques, including electroencephalography (EEG), biochemical laboratory tests, and radiological and neuroradiological studies, i.e. computed tomography (CT) or magnetic resonance imaging (MRI) of the

head. A medication history is indispensable, as is screening for the covert use of medications and illicit substances when this is suspected (e.g. benzodiazepines, amphetamines, barbiturates, cannabis), both to rule out the possibility of a pharmacogenically induced affective disorder (Müller-Oerlinghausen 1997) and also because these substances may interact with antidepressant or antimanic medications. In particular, if the first manic episode occurs after age 40, a medical disease or substance ingestion must always be ruled out as the cause.

The current nosologic diagnostic classification of the affective disorders is based on two operationalized classification systems, ICD-10 of the World Health Organization (WHO 1992) and DSM-IV of the American Psychiatric Association (APA 1994a); in the German-speaking countries, the diagnostic categories of ICD-10 are in widespread use in the clinical field. The diagnosis of a depressive or manic episode is made when a particular pattern of manifestations listed in the diagnostic manual is present (WHO 1992). Moreover, the syndromal diagnostic evaluation of current clinical findings and the assessment of the severity of depression or mania are particularly important for specific aspects of decision-making relating to therapy. Finally, the possible presence of suicidality and of somatic and social complications of depression must be taken into account. In the case of mania, particular attention must be paid to the extent of self-endangerment (e.g. by large financial expenditures or unrestrained professional activities) and uncritical endangerment of others (e.g. in road traffic).

Treatment is indicated in all reliably diagnosed cases of depressive or manic disorder. Once the diagnosis has been made, a comprehensive and multidimensional treatment plan should be drawn up, taking account not only of the current clinical findings (e.g. the presence or absence of psychotic manifestations, inhibition or agitation in depression, dysphoric-irritative or mixed affective manifestations in mania), the severity of illness, and possible suicidality, but also of the patient's conceptions and preferences regarding specific forms of treatment. At this point, the question also arises as to whether inpatient treatment in a specialized facility is necessary or whether the treatment can be carried out in an outpatient setting.

The indications for inpatient treatment of depressive or manic disorders are summarized in Table 1.

If the patient refuses to be admitted to an inpatient facility, he or she can be committed involuntarily to a locked psychiatric facility if there is acute self-endangerment secondary to depression, according to currently applicable law, i.e. the PsychKG in the German federal states or the federal Care Act (*Betreuungsgesetz*, BtG) (see also Chap. 15, Vol. 1, Part 2). In cases of severe mania, financial or social self-endangerment or uncritical endangerment of others may also necessitate judicial commitment.

Table 1. Indications for inpatient treatment

Depressive episode	Manic episode
Suicidality	Presence of delusions or psychotic manifestations
Presence of delusions or psychotic manifestations	Financial or social self-endangerment
Lack of a favorable social environment	Uncritical endangerment of others
Family conflict constellations that tend to maintain depression	Intractability
Inability of the patient to care for him- or herself	
Intractability	

3 Goals of Treatment

The initial goal of treatment is the complete eradication of affective manifestations (complete remission), followed by the prevention of recurrences and chronification. Because there may be considerable overlap between the therapeutic measures used to achieve these different goals, attention must be paid to course-specific aspects of the illness even during the initial treatment of acute episodes. At the same time, it must be borne in mind that acute treatment and recurrence prevention are two different forms of therapy, each with its own indications.

The short-term, intermediate, and long-term goals of the treatment of a depressive or manic episode are given in detail in Table 2. After the acute affective episode has worn off, the goal of further treatment is to reduce the probability of recurrence (see Table 2).

4 Aspects of Course with Implications for Treatment

The typical course and the correspondingly structured treatment of a depressive illness (episode and recurrence tendency) may be represented graphically according to the model developed in the 1990s in Pittsburgh (USA) by Kupfer and colleagues (Kupfer 1991; Fig. 1). Three stages of treatment were described, corresponding to three stages of the illness:

Table 2. Goals of therapy for depressive and manic episodes and for the tendency toward recurrence

	Depressive episode	Manic episode	Tendency toward recurrence
Short-term goals (hours to days)	Acute alleviation of anxiety, agitation, and insomnia	Control of psychomotor agitation, logorrhea, and aggression	
	Prevention of suicidal behavior	Prolongation of sleep duration	
Intermediate goals (days to weeks)	Improvement of mood, motivation, and cognitive ability	Reduction of grandiose ideas and excessive self-esteem	
	Removal of psychosocial stress factors	Reduction of excessive activity in social, occupational, and sexual areas	
Long-term goals (weeks to months)	Prevention of rapid relapse in the vulnerable period after remission	Prevention of rapid relapse in the vulnerable period after remission	
	Prevention of chronification and resistance to treatment	Prevention of resistance to treatment	
	Regaining of social competence with reintegration into family, occupation, and society	Elimination of unfavorable consequences of excessive activity and reintegration into family, occupation, and society	
Very long-term goals (years)			Prevention of recurrence
			Prevention of rapid cycling, particularly in bipolar disorders

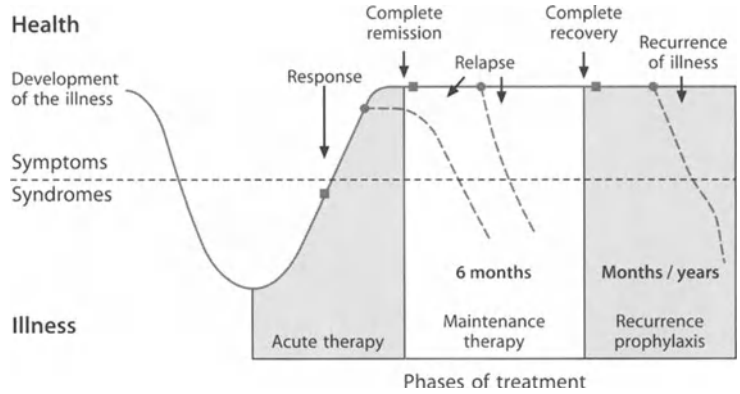

Fig. 1. Long-term course of a depressive illness. (After Kupfer 1991)

1. Acute therapy
2. Maintenance therapy
3. Prophylactic therapy against recurrence

If the premorbid level of functioning has been fully reestablished by acute therapy, we speak of a complete remission. The phase of acute therapy is followed by that of maintenance therapy, which lasts approximately 6 months. Antidepressant pharmacotherapy for the stabilization of remission should be carried out for 6 months with the same antidepressant used for acute therapy, at the same dose. This is also true of the successful augmentative use of lithium "add-on" treatment, as was recently shown in a 6-month,

placebo-controlled study (Bauer et al. 1999). If the depressive syndrome returns during the phase of maintenance therapy, we speak of a relapse. If no relapse occurs during maintenance therapy, a slow tapering (>3 months) of the antidepressant medication is recommended. Nonetheless, if this results in a symptomatic deterioration, the original medication should be given at the original dose for at least another 6 months before a cautious attempt at discontinuing medication is made again.

If the patient has been asymptomatic for approximately 6 months, it is presumed that complete recovery has taken place. This presumption remains to be confirmed by stable, continued freedom from symptoms (complete remission) after the cessation of medication. Moreover, the concept of recovery applies only to individual episodes of the illness, and not to their tendency to recur. A recovery in the latter sense can be spoken of only if the patient remains free of recurrences after the cessation of prophylactic therapy against recurrence.

Prophylactic therapy against recurrence in either mono- or bipolar disorders should be taken into consideration depending on the previous course of illness. A recurrence of disease is said to occur when an affective episode appears during the phase of prophylactic therapy, i.e. after a completely asymptomatic state has been achieved for some length of time (Kupfer 1991). Even though no definite recommendation can be given as to when prophylactic therapy should be initiated, it is clear that it is indicated in certain situations associated with a high risk of recurrence, as listed in Table 3.

For the depressive disorders, a high risk of recurrence is present in patients who have had two episodes within 5 years and in patients who have had more than three episodes overall. Bipolar disorders have a much higher recurrence rate than unipolar depressive disorders. Furthermore, there are a number of other risk factors for the recurrence of affective episodes (Brunello et al. 1995; Greil and Kleindienst 1997; Table 3).

Table 3. Risk factors for recurrence

Depressive disorders	Manic disorders
Two episodes within 5 years	Bipolar course of illness
More than three episodes	Two episodes within 3–4 years
"Double depression" (i.e. depression and dysthymia occurring simultaneously)	Presence of manic or bipolar disorder in first-degree relatives
Residual manifestations in the phase of maintenance therapy	Early age of onset of illness
Simultaneous presence of substance abuse or anxiety disorder	
Depressive episode in first-degree relatives	
First depressive episode before age 30	
Severe depressive episode with suicidality	
Direct transition from depressive episode to manic episode	

Even if only one of these features is present, it is recommended that acute therapy be followed by prophylactic therapy against recurrence, or at least that such therapy be considered, so that the type of maintenance therapy can be chosen partly with a view toward future prophylactic therapy. The medication of choice for recurrence prophylaxis in unipolar depression is either lithium or the antidepressant with which remission was achieved in the index phase (APA 1993). Lithium is also indicated for recurrence prophylaxis in bipolar disorders or unipolar mania, in which it may also be given – particularly in the presence of schizoaffective features – in combination with carbamazepine or, as recently proposed, valproate (see Chap. 23, Vol. 3, Part 1).

5 Spectrum of Options for Treatment of the Acute Episode

The origin of depressive illnesses is currently assumed to be multifactorial, and their treatment is therefore fundamentally multidimensionally oriented. The different forms of treatment available can be combined with one another in different ways; in particular, pharmacotherapy can be combined with supportive or specific psychotherapy. The established forms of treatment for depressive and manic illnesses are listed in Table 4.

The applicability of individual forms of treatment varies over the course of the disorder; in the acute phase, biological and supportive therapies are most important. Furthermore, the severity of illness also determines the choice of therapy. Mild depressive episodes, especially of a reactive type or in the setting of an adaptive disorder, can usually be treated adequately by supportive conversation with the physician or by conflict-centered short-term psychotherapy. Moderate and severe depressive illness, however, is treated primarily by medical therapy with antidepressants.

Nonetheless, according to current concepts, the so-called disorder-specific forms of psychotherapy, such as cognitive therapy, as described by Beck (1967), and interpersonal psychotherapy (IPT), as described by Klerman et al. (1984), play an increasingly important role in the treatment of depression, even in cases of

Table 4. Established methods of treatment for depressive and manic episodes

Depressive episodes	Manic episodes
Pharmacotherapy with antidepressants[a]	Pharmacotherapy with antimanic agents[a]
Supportive therapeutic conversation (supportive psychotherapy)[b]	Electroconvulsive therapy for intractable cases
Specific psychotherapy, e.g. behavior therapy, cognitive therapy, and interpersonal psychotherapy[b]	Accompanying therapeutic conversation (information about the nature and course of the illness, explanation of treatment options, provision of a feeling for and concept of the illness)
Other methods of somatic therapy, e.g. sleep deprivation treatment, phototherapy, and electroconvulsive therapy[c]	Sociotherapeutic measures, e.g. protection from the negative social and financial consequences of the illness
Sociotherapeutic measures, e.g. provision of social activities, protection from the negative social and financial consequences of the illness	Inclusion of family members
Inclusion of family members	Agreement on treatment if a tendency toward recurrence is present

[a]See Chap. 23, Vol. 3, Part 1.
[b]See Chap. 25, Vol. 3, Part 1.
[c]See Chaps. 24 and 31, Vol. 3, Part 1.

moderate severity, in both acute and long-term therapy (see Chap. 25, Vol. 3, Part 1).

The most important component of the treatment of mania is pharmacotherapy with antimanic agents, including neuroleptics, prophylactic agents against recurrence, and benzodiazepines. The recurrence-prophylactic agents lithium, carbamazepine, and valproate are indicated particularly in mild or moderately severe forms of the illness, as they have less serious side effects than the neuroleptics (see Chaps. 15, 23, Vol. 3, Part 1). The accompanying discussion with the physician should inform the patient about the illness, its course, and its treatment. Specific psychotherapeutic measures have no value in the treatment of acute mania. The environment of manic patients should be kept as devoid of stimulation as possible. The established modes of treatment for manic illnesses are listed in Table 4.

6 Medical and Psychotherapeutic Guidance of Depressive Patients

The basis of any treatment for depression is the therapeutic conversation between the patient and the physician, in which the physician must demonstrate empathy, acceptance, and understanding. Reliability and ensuring that the same therapist always treats the patient are especially important factors, because depressive patients are often very sensitive to change and loss. Furthermore, the physician may exert a supportive effect by communicating to the patient that the illness is treatable. Before the treatment is begun, the patient must be informed about the illness and its projected therapy; in particular, the patient must be informed of the latency of effectiveness of the antidepressants and their typical side effects. Thorough explanation of the treatment plan or, even better, an agreement between patient and physician concerning the treatment plan can improve the extent of the patient's cooperation and compliance in taking antidepressants.

It has been found useful for the physician to see the patient frequently at the beginning of pharmacological therapy and to evaluate the therapeutic effect together with the patient, perhaps with the participation of family members as well, over the course of treatment. The basic principles of the medical therapeutic conversation with depressed patients can be delineated as follows:

- Basic therapeutic behavior (provision of empathy, acceptance, and understanding)
- Thorough information provided to the patient about the nature, course, and prognosis of the illness
- Explanation of the multidimensional model of the cause of depression
- Explanation to the patient of the goals and temporal course of treatment
- Creation of a treatment plan
- Explanation of the latency of effectiveness and side effects of antidepressants
- Bringing family members into the discussion
- Common evaluation of the effect of treatment

7 Pharmacotherapy with Antidepressants

Since the introduction of the first tricyclic antidepressant, imipramine, in 1957, many new types of antidepressants have been developed; nearly 30 different antidepressants have been used clinically in Germany up to the present. Newer antidepressants were developed with the goal of finding substances that were as effective against depression as the tricyclic agents, but with fewer side effects, a more rapid onset of effect, and lesser toxicity (Rudorfer and Potter 1989; Leonard 1995). The classes of substances currently available differ little in their antidepressant effect; there is no convincing evidence that any class of antidepressants is more effective, or has a more rapid onset of effect, than the others. Nonetheless, there are important differences in their neurochemical activity profiles and thus also in their side effects. The newer antidepressants of the 1980s and 1990s generally have less serious side effects than the "classical" substance groups of the tricyclic agents and the irreversible monoamine oxidase (MAO) inhibitors (see Chap. 23, Vol. 3, Part 1).

Differential therapeutic considerations concerning the initial choice of an antidepressant are essentially based on various clinical features of, and specific previous experiences in, the individual patient. The antidepressant should be chosen according to the following criteria (Bauer and Berghöfer 1997):

- The clinical features of depression in the individual patient (e.g. a sedating antidepressant for an anxious-agitated depressive syndrome, or an activating and less sedating antidepressant for an inhibited, psychomotorically slowed depressive syndrome)
- Psychiatric comorbidity (e.g. serotonergic agents and MAO inhibitors for patients with comorbid obsessive-compulsive and panic disorders)
- Specific previous experiences (e.g. nonresponse vs. response, intolerance, allergic reactions) with individual antidepressant substances or substance classes
- The range of side effects of the antidepressant
- Accompanying medical and neurological illnesses
- Further specific features of the patient, e.g. age, particularly with regard to somatic comorbidity (Lebowitz et al. 1997); pregnancy (see Chap. 13, Vol. 2, Part 1)

Proper selection of an antidepressant requires a knowledge of the typical side effects of the individual substances, which, in turn, are determined by their pharmacological activity. The neurochemical effects of the antidepressants account for their clinical effectiveness against depression and also, in part, for their unwanted side effects (Leonard 1993; Richelson 1994). The presence of accompanying medical or neurological illness necessitates the choice of an antidepressant whose pharmacologic profile will have a beneficial, or at least not harmful, effect on the accompanying illness. An example of this is the use of substances such as mianserin or selective serotonin reuptake inhibitors (SSRI) in the presence of heart disease, as they have a much weaker effect than the tricyclic agents on the cardiac conductive system, for example (ECG monitoring for potential adverse effects is mandatory).

The use of substances with a strong anticholinergic effect should be considered with special caution in patients over age 70. Older patients are more sensitive to the central anticholinergic effects of these medications and may develop disorientation, confusion, or even delirium as a result. The newer antidepressants, which have fewer side effects (e.g. SSRI, nefazodone, venlafaxine), are preferred to the tricyclic agents in this age-group. The cardiovascular and renal changes usually associated with advanced age lead to an intensification of side effects as compared to those found in younger individuals (Lebowitz et al. 1997). Antidepressants should therefore be given to older patients in slowly increasing doses and in lower overall doses than those given to younger patients (Bezchlibnyk-Butler and Jeffries 1996).

Intoxications and delirious syndromes are considered absolute contraindications for the use of all antidepressants. Relative contraindications for the use of tri- and tetracylcic antidepressants include congestive glaucoma, cardiac dysrhythmia, bladder dysfunction, severe hepatic or renal injury, epilepsy, and blood dyscrasias. There are no relative contraindications for monotherapy with SSRI or reversible inhibitors of monoamine oxidase. If SSRI are used in combination with other substances having serotonergic effects, such as lithium, clomipramine, and especially MAO inhibitors, the possible appearance of a serotonin excess syndrome should be watched for. The use of antidepressants during pregnancy and nursing requires an especially careful assessment of risks and benefits, in view of the possibility of adverse effects on the fetus or infant (Altshuler et al. 1996).

Tri- and tetracyclic agents should be given in slowly increasing doses in order to minimize their anticholinergic effects and possible drug-induced orthostatic hypotension. The typically effective daily dose (150 mg of a tri- or tetracyclic antidepressant) should be reached in 4–7 days; monitoring of blood levels usually plays no role in the introductory phase of antidepressant medication. For antidepressants of the SSRI type, the initial dose (daily dose of 20 mg) usually has an

adequate antidepressant effect. If it does not, and if the medication is well tolerated, an increase of the dose can be attempted before switching to another medication or to combination therapy, if necessary. Inadequate dosing is a common reason for inadequate response to antidepressants (so-called pseudoresistance; Keller 1988). Under stable conditions, the dose may be raised as early as 2 weeks after the initiation of treatment (see Table 6).

Regular laboratory monitoring must be carried out both before and during antidepressant pharmacotherapy, because such treatment may, in rare cases, cause changes in a number of organ systems. The performance of blood tests, including a complete blood count with differential leukocyte count, hepatic enzymes, creatinine, electrolytes, and thyroid hormones, is recommended before and during therapy, so that any changes in these values with respect to the baseline may be detected. An ECG and blood pressure measurements, as well as an EEG in patients known to have epilepsy, should also be performed before treatment is begun. The frequency of monitoring over the course of treatment must be adjusted individually according to patient characteristics (age, accompanying illnesses) and the type of therapy administered (type of antidepressant, dose). At the beginning of treatment, the complete blood count and hepatic enzymes should be monitored biweekly, then monthly; the ECG should also be repeated at 2-week intervals.

8 Resistance to Treatment and Treatment Optimization

Clinical studies and observations in clinical practice have shown that approximately 30%–40% of depressive patients in either the inpatient or the outpatient setting fail to respond adequately to an initial 4- to 6-week treatment with an antidepressant (Möller 1997). As many as 10%–15% of patients fail to improve sufficiently even after several different treatments have been attempted (Nierenberg and Amsterdam 1990). A review of the literature reveals that 12%–15% of depressive patients are not yet asymptomatic 2 years after the onset of the illness, and the illness takes a chronic course in these patients (Scott 1988).

The lack of success of antidepressant or antimanic therapy is often due not to the illness itself, but to suboptimal treatment. Thus several possible means of optimizing the treatment should be considered before switching to another agent (Table 5).

9 Experimental Methods and Combination Therapy

If resistance to therapy remains intractable despite attempts at treatment optimization of the types

Table 5. Methods of treatment optimization

General treatment optimization	Treatment optimization for the depressive episode	Treatment optimization for the manic episode
Assured compliance (blood level monitoring)	Adequate duration of antidepressant medication (4–6 weeks)	Adequate duration of antimanic medication (usually more than 4 weeks)
Addition of neuroleptic agents in the presence of psychotic (delusional) manifestations	Adequate dose (tricyclic agents >150 mg/day, SSRI >20 mg/day)	Elevation of serum levels of phase-prophylactic agents (lithium, carbamazepine, valproate)
Treatment of psychiatric comorbidity (e.g. alcohol and substance abuse, including nicotine and caffeine abuse)	Serotonergic antidepressants (clomipramine, SSRI) for depression with marked obsessive-compulsive manifestations	Combination therapies
Diagnosis and treatment of somatic comorbidity (e.g. intercurrent somatic illness)	Trial of a high dose of the antidepressant (tricyclic agents 200–300 mg/day, SSRI 30–60 mg/day)	
Determination of negative drug interactions (e.g. with medications used to treat general medical illnesses)	Search for psychosocial stress factors that may maintain depression	
Exclusion of medications used to treat general medical illnesses as disease-inducing or disease-maintaining factors		

SSRI, selective serotonin reuptake inhibitors.

outlined, the use of augmentative or combination therapy, or of experimental therapies, should be considered. Experimental therapies for depressive disorders include the administration of thyroxine at high doses (Bauer et al. 1998a,b), psychostimulants, estrogens, MAO inhibitors at high doses, inhibitors of cortisol synthesis, and reserpine (Nolen et al. 1994; Heinz 1997; Nelson 1997). Among augmentative therapies, the addition of lithium to the conventional antidepressants has been found useful (Bauer and Döpfmer 1999; Bauer et al. 1999). Combination therapy with various antidepressants has been tried with variable success, as has so-called pindolol augmentation, a combination of the β-blocker pindolol with a SSRI (Nelson 1997). On the other hand, the combination of a neuroleptic with an antidepressant has proved useful in the treatment of depression with psychotic features (so-called double-rein therapy).

The usefulness of a combination of pharmaco- and psychotherapy in the treatment of depressive disorders is not yet fully clear, because studies on this question have yielded conflicting results (Schramm and Berger 1998). In most studies, this combination was found to be only moderately superior to either form of therapy alone. It should be pointed out, however, that combination therapy was associated with fewer terminations of treatment and with a greater acceptance of treatment than either form of therapy alone (Weissman and Klerman 1990).

Forms of treatment for refractory mania that should be considered experimental include the use of a double or triple combination of various phase-prophylactic agents; atypical neuroleptics (e.g. clozapine, olanzapine, risperidone); newer anticonvulsants (e.g. lamotrigine, gabapentin); augmentation with calcium-channel blockers; and electroconvulsive therapy (Post et al. 1997).

10 Sequential Treatment Strategies (Stepwise Approaches)

Failure of treatment is often attributable to the indiscriminate application and poor monitoring of antidepressant therapy. Clinical decision-making is a topic of major importance in medical research today, as the different modes of application of a therapy clearly account for a considerable portion of the variation in its clinical effectiveness. The unsuccessful treatment of depression is a clear example of the negative consequences of the lack of a clear treatment strategy, particularly with respect to the use of medications.

It thus seems reasonable to pay attention to the procedural elements of quality assurance while providing treatment and to apply them consistently. These elements include the standardized assessment of clinical findings at predetermined, regular intervals, using defined criteria for treatment success, and the decision either to continue effective treatment or to abandon ineffective treatment in favor of another form of treatment (Helmchen 1990). Within this formal framework, the large variety of possible treatments for depression can be applied in a reasonable and mutually compatible sequence.

Stepwise approaches to treatment have the following formal characteristics:

1. An established and rationally justified sequence of therapeutic steps
2. Regular monitoring of therapy
   - At predetermined intervals (biweekly)
   - In the form of standardized assessment of clinical findings, with the aid of established diagnostic assessment scales
3. After the success or failure or therapy has been assessed by means of well-defined criteria, decision between the following:
   - Continuation of antidepressant therapy (if the response to therapy is complete or partial)
   - Change of antidepressant therapy (if unsuccessful)
4. Pharmacologic monitoring (serum levels of antidepressants and lithium, compliance monitoring)
5. Consistent application of the individual components of therapy

In order to provide such a rationally based sequence of treatment steps, a number of so-called sequential treatment strategies (stepwise approaches or flowcharts) have been proposed, i.e. multidimensional decision trees that lay out a sequential problem-solving approach incorporating many individual medical therapeutic decisions. Such strategies are a special form of the heuristic approach to making decisions and taking action in providing treatment; they reduce the complexity of decision-making for the treating physician (Linden 1994). The treating physician may, nonetheless, choose to deviate from a treatment plan of this type, when indicated, to take account of particular features of the individual patient.

An operationalized, consistently performed, and well-monitored stepwise approach to antidepressant therapy is considered an essential component of the prevention or surmounting of resistance to therapy (Helmchen 1974, 1990), although this has not yet been confirmed empirically. Such confirmation can only be obtained from controlled studies and is indispensable for quality assurance in the somatotherapy of depression.

Table 6. Stepwise approach to the somatotherapy of depressive disorders[a]

Therapeutic and diagnostic steps[b]	Description	Durations
1. Discontinuation	Tapering of previously given, unsuccessful medication and undesired (multi-)medication	0–3 days
2. Baseline diagnosis and therapeutic sleep deprivation	Diagnostic classification, exclusion of organic causes, pharmacological "washout"	4–7 days
3. Antidepressant monotherapy	Tricyclic agent or SSRI (see text for initial selection of antidepressant)	2 weeks
4. High-dose antidepressant monotherapy	Increase of dose according to individual tolerance	2 weeks
5. Antidepressant and lithium (lithium augmentation)	Addition of lithium, reduction of the antidepressant to the dose of step 3; reduction of the target serum lithium level to 0.5–0.8 m*M*/l	4 weeks
6. Lithium monotherapy and diagnostic reassessment	Discontinuation of the antidepressant of step 5; reconsideration ("reassessment") of the diagnosis, additional laboratory testing, imaging procedures, neuropsychological testing	1–2 weeks
7. Lithium and MAO inhibitors	Addition of an MAO inhibitor (tranylcypromine)	2 weeks
8. High-dose lithium and MAO inhibitors	Increase of dose according to individual tolerance	2 weeks
9. Medication-free step	Discontinuation of all psychotropic medications; preparation for electroconvulsive therapy (anesthesiological consultation)	1 week
10. Electroconvulsive therapy	Three sessions of electroconvulsive therapy per week	2–4 weeks
Special case for the treatment of delusional (psychotic) depression: double-rein therapy	Additional administration of a neuroleptic agent (haloperidol or olanzapine, 5–15 mg/day)	

MAO, monoamine oxidase; SSRI, selective serotonin reputake inhibitor.

[b]Proceed to the next step if no response.

A number of stepwise approaches to the treatment of depressive disorders have been published in recent years (Helmchen 1990; Linden et al. 1994; Kasper 1997; Nelson 1997). Table 6 shows one such that has been in use for 10 years (Linden et al. 1994; Berghöfer et al. 1997). There is as yet no comparable experience with stepwise approaches for the treatment of manic disorders or the prevention of recurrences in the affective disorders, although treatment algorithms for both of these situations in the event of nonresponse to an initial trial of monotherapy have been published recently (Post et al. 1997; Goodwin 1997; Bauer and Ströhle 1999).

11 Treatment-Resistant Tendency Toward Recurrence and Rapid Cycling

Lithium is the agent of first choice in the prophylactic treatment of bipolar disorders, even though one third of all patients have a tendency toward recurrence despite adequate lithium therapy. The anticonvulsants carbamazepine and valproate currently enable more specific phase prophylaxis directed against individual types of disease course and clinical syndromes, but a sizable fraction of patients (perhaps 10%–20%) nonetheless remain refractory to treatment for the prevention of recurrence (Bauer and Ströhle 1999).

A particular form of resistance to phase prophylaxis is found in patients with "rapid cycling," a malignant type of disease course in which more than four affective episodes occur over a 12-month period; this type of course, as a rule, does not respond either to lithium or to other phase-prophylactic agents. The affective episodes arise in any combination or sequence and meet the criteria for a manic, mixed, or hypomanic episode or for an episode of major depression; they are not separated by a 2-month period of remission, nor are they typified by a transition to an episode of opposite polarity (APA 1994a).

Rapid cycling occurs in approximately 10%–20% of patients with bipolar disorders, of which 70%–90% are women. In addition to female sex, other factors that have been repeatedly found to be associated with a higher risk of rapid cycling include the use of tricyclic antidepressants and the presence of either overt or subclinical hypothyroidism (in as many as 50% of cases) (Bauer and Whybrow 1991). The treatment history of patients with rapid cycling is often charac-

terized by diverse, polypharmaceutic, and mostly unsuccessful attempts at treatment. No standard concept of treatment has yet been developed for this subgroup of the affective disorders, in which as many as ten or more cycles may be experienced per year ("ultra-rapid cycling"; APA 1994b).

The treatment of rapid cycling does not differ fundamentally from that of nonresponse to phase prophylaxis, except in that the use of antidepressants should be avoided in patients with rapid cycling for the reasons discussed. A number of authors have shown that a considerable percentage (72%–82%) of patients with rapid cycling do not respond to lithium treatment. Due to favorable observations made in individual cases, a question that is increasingly coming under discussion is whether patients with bipolar rapid cycling might not be better treated initially with valproate or carbamazepine.

Among experimental methods, adjuvant high-dose thyroxine treatment has been found to be of value in bipolar patients with a prophylaxis-resistant tendency toward recurrence, both with and without rapid cycling (Bauer and Whybrow 1990; Baumgartner et al. 1994; Bauer et al. 1998a; see also Chaps. 15, 23, Vol. 3, Part 1).

Pharmacotherapy of Affective Disorders

1 Overview

The pharmacological treatment of affective disorders has revolutionised the course of the illness with marked beneficial effects on the patient's social role and a reduction of the costs to society at large. The use of pharmacotherapy significantly improves the chance that a depressed patient will recover over a period of 3–6 weeks. However, pharmacotherapy itself cannot be seen outside the context of a therapeutic relationship and shared understanding of the illness. A therapeutic alliance is not only useful in minimising non-compliance, but also facilitates a thorough explanation of likely adverse effects of any drug treatment given and the anticipated time taken to respond to treatment, as well as the relevance and likely duration of drug treatment within an overall treatment plan.

Although there have been effective treatments for depression for over 40 years, it is only relatively recently that there has been a wide and growing choice of antidepressants acting on differing receptor subtypes with varying specificity. It will take some time, with more experience through widespread use, before the optimal niche for each of these different drugs is found. Meanwhile, the newer drugs in general are safer and have a more favourable side-effect profile than previously available drugs. Only a decade or so ago, for example, all available antidepressants were highly dangerous in overdose. A further factor to consider is the increasing range of indications being identified for many of the newer antidepressants. Some, for example, have been shown to be useful in obsessive-compulsive, eating or anxiety disorders.

The range of available treatments for bipolar affective disorders (BAD), especially in the treatment and prophylaxis of mania, have not expanded to nearly the same extent as treatments of depressive illness. Increasing evidence has, however, emerged for the efficacy of anticonvulsant medication such as carbamazepine and sodium valproate, both in the treatment of acute mania and as mood stabilisers in the prophylaxis of bipolar disorder. There has also been an increased interest in drugs such as verapamil (a calcium channel blocker), clonazepam (a benzodiazepine also used in the treatment of epilepsy) and the atypical antipsychotics such as clozapine, olanzapine and risperidone.

The following routine investigations are recommended before and during treatment, with suggested tests for different drugs:

- Physical examination
- Thyroid function tests
- Full blood count (FBC)
- Urea, electrolytes (U+E) and general chemistry screen
- Urine toxicology for substance abuse
- Electrocardiography (ECG) in patients over 40 years
- Pregnancy test if relevant
- Serum levels of lithium; monitor thyroid function, urinalysis and U+E
- Serum levels of valproate; monitor U+E, FBC and liver function tests
- Serum levels of carbamazepine; monitor FBC and liver function tests
- Serum levels of the following tricyclics: amitriptyline, imipramine, desipramine and nortriptyline

2 Depressive Disorder

2.1 Available Drugs

The serendipitous discovery of the antidepressant effect of imipramine in 1958 (Kuhn 1958) led to intensive testing of the group of drugs known as the tricyclics in depressive illness. The almost simultaneous and equally serendipitous observation of mood elevation in tuberculous patients treated with iproniazid (Bloch et al. 1954) led to the development of the monoamine oxidase (MAO) inhibitor (MAOI) family of antidepressants. These focused research interest on changes in the activity of the biogenic amine neurotransmitters noradrenaline and 5-hydroxytryptamine (5-HT, serotonin) as mediators in the treatment of depression. Despite early disagreements about the relative contribution of these two receptor systems, it is now generally accepted that there is a complex interrelationship between them and also the dopaminergic system (Moller and Volz 1996). In the light of this, the possibility of manipulating one system without compensatory changes in the others is very small. Models of antidepressant action based simply on changes in availability of one neurotransmitter are clearly overly simplistic.

The research emphasis on amine neurotransmitters has, however, led to the development of the closely related tetracyclic drugs, which together with the tricyclics and MAOI comprise the classic antidepressants. Subsequent progress has resulted in the availability of the serotonin-specific re-uptake inhibitors (SSRI), other atypical antidepressants such as bupropion (used more widely in the United States than in Europe), trazadone and nefazadone, the specific and reversible MAO type A inhibitor moclobemide, and more recently introduced drugs such as mirtazapine, reboxetine and venlafaxine.

These newer classes of antidepressant have varied specificity for the various neuroreceptors, shown in Table 1, (modified from Richelson 1996). This is reflected in their differing side-effect profiles. At the present time, all of these antidepressant drugs, despite their different modes of action, still show similar delays in response (around 2–3 weeks) and no improvement in overall efficacy to that found with classic antidepressants (Cohen 1997). However, they do demonstrate clear advantages in adverse effect profile (reflecting both safety and side-effects) and in particular tend to show significantly decreased levels of cardiotoxicity and sedation.

2.1.1 Tricyclic and Tetracyclic Drugs

The group of tricyclic and tetracyclic drugs includes amitriptyline, clomipramine, desipramine, imipramine, lofepramine, nortriptyline and trimipramine. These are indicated for the treatment and prophylaxis of major depression, the treatment of secondary depression (in association with dementia, Parkinson's disease, etc.) and the depressed phase of BAD. Other approved indications for specific drugs include clomipramine for obsessive-compulsive disorder and imipramine for childhood enuresis.

The short-term effects of these drugs are to reduce the re-uptake of noradrenaline and 5-HT. This has provided one of the cornerstones of the monoamine hypothesis of mood disorders. In addition, they block the muscarinic subtype of acetylcholine receptors and histamine receptors. Longer-term effects (with a time course similar to that of onset of antidepressant action) include down-regulation of β-adrenergic receptors and (possibly) a similar effect on 5-HT receptors.

These drugs are administered orally, and there is a large first-pass effect. They are highly plasma protein bound, with predictable interactions with other similarly bound drugs, and are metabolised primarily in the liver. They demonstrate linear pharmacokinetics, with an increase in dose reflected in the plasma concentration. They have long elimination half-lives (between 10 and 70 h) compatible with once-daily dosage once the steady state has been achieved (usually after approximately 5 days).

The side-effect profile within this group of drugs varies and is dependent on the affinity for the various neuroreceptors (see Table 1); the clinical effects of receptor action are shown below. The effects of acetylcholine muscarinic receptor antagonism include:

- Dry mucous membranes, mouth, eyes, etc.
- Blurred vision
- Constipation
- Urinary retention
- Excess sweating
- Confusion, disorientation, delirium, delusions and hallucinations

The histamine H_1 and α_1-adrenoceptor antagonism effects include:

1. Cognitive effects:
   - Drowsiness
   - Weakness, fatigue
   - Nightmares, agitation, restlessness and insomnia
   - Confusion, disorientation
2. Neurological effects:
   - Fine tremor
   - Akathisia
   - Tardive dyskinesia
   - Seizures
   - Paraesthesia
   - Parkinsonism, dystonia and gait disturbance
3. Cardiovascular effects (exacerbated by muscarinic and 5-HT_2 antagonism):
   - Tachycardia
   - Orthostatic hypotension
   - Increased conduction times
   - Arrhythmias, syncope
4. Gastrointestinal (GI) effects (exacerbated by 5-HT uptake inhibition and muscarinic antagonism):
   - Anorexia, nausea, vomiting and diarrhoea
   - Glossitis and peculiar taste
5. Sexual effects (exacerbated by increased dopaminergic D_2 activity and 5-HT_2 antagonism):
   - Decreased libido and impotence
   - Testicular swelling and retrograde ejaculation
   - Breast engorgement and enlargement
   - Anorgasmia
   - Amenorrhea
   - Galactorrhoea
6. Others:
   - Weight gain (common)
   - Blood dyscrasia (rare)
   - Jaundice, hepatitis and urticaria (rare)
   - Photosensitivity and skin pigmentation (rare)

The therapeutic window is narrow; toxic effects (as seen in overdose) largely reflect anticholinergic and antihistaminic effects culminating in central nervous system depression, altered consciousness, respiratory slowing and onset of seizures. The cardiac effects are the most hazardous; the severity of the toxicity can be monitored electrocardiographically in terms of prolongation of the QRS complex.

Tricyclic and tetracyclic antidepressants have not been shown to be teratogenic and may reasonably safely be used during pregnancy. As with all other drugs, their use in pregnant women should be avoided,

Table 1. Effects of antidepressants on neurotransmitters/receptors (dissociation constants)

	Amitriptyline	Clomipramine	Imipramine	Nortriptyline	Trazadone	Nefazadone	Bupropion	Venlafaxine	Fluoxetine	Sertraline	Paroxetine	Mirtazapine	Reboxetine

5-HT, hydroxytryptamine; DA, dopamine; ACh, acetylcholine; H_1, histaminergic; D_2, dopamine 2 receptor.

if possible, especially during the first trimester. They are also secreted in small amounts into breast milk (1%), although this is thought unlikely to represent much hazard to the baby. They should be used cautiously in patients with hepatic or renal disease.

All tricyclic and tetracyclic antidepressants are equally efficacious in the treatment of depressive disorder. However, the choice of drug and dosage regime must be tailored individually, taking into related effects such as sedation, propensity to hypotension and risk of overdose. More sedative antidepressants (such as amitriptyline or trimipramine) may be particularly suitable for agitated patients with poor sleep. Similarly, less sedating antidepressants, such as lofepramine, imipramine and nortryptiline, are indicated for more withdrawn patients. The less cardiotoxic drugs such as lofepramine should be used for patients at higher risk of taking an overdose and in the treatment of elderly patients. Clomipramine is the treatment of choice in patients presenting with concomitant obsessive-compulsive symptoms.

Treatment should be preceded by an ECG in patients over 40 years and routine physical examination, blood count and serum electrolytes and liver function tests. The dose of antidepressant should be increased gradually with a small initial starting dose and incremental raise every few days up to the therapeutic dose. In the case of amitriptyline, the dose should be raised to 150 mg and sustained for 2–3 weeks. In the absence of clinical improvement, the dosage should be increased towards 300 mg if side-effects permit. Recommended doses are usually between 150 and 250 mg a day, and the use of lower doses has been criticised (Quitkin 1985). The response rate to routine doses is approximately 70%. Common side-effects, such as sedation, postural hypotension, dry mouth, blurred vision, constipation and urinary retention, can be ameliorated by initially spreading the dose through the day, although this can be changed to once-daily dosage, for convenience, once the therapeutic dose is reached.

2.1.2 Monoamine Oxidase Inhibitors

The MAOI iproniazid was developed in the early 1950s from the finding that a closely related drug, isoniazid, caused euphoria in patients treated for tuberculosis. This group of drugs (which includes phenelzine, isocarboxazid and tranylcypramine) irreversibly inhibits both subtypes of MAO: MAO-A, which is responsible for degrading noradrenaline and 5-HT, and MAO-B, which is specific for phenylethylamine. Tranylcypramine has an additional direct effect on inhibiting re-uptake of noradrenaline and 5-HT.

Both MAO-A and MAO-B are involved in the metabolism of dopamine. Their efficacy added further support in the 1960s to the monoamine theory of depression and also led to the use of other MAOI compounds; they were subsequently shown to be effective in the treatment of depression.

MAO is widely distributed throughout the body, in the central nervous system, sympathetic terminals, liver, platelets and within the gastrointestinal system, where it is responsible for the metabolism of dietary tyramine. Inhibition of MAO results in passage of tyramine directly into the circulation and a resultant hypertensive crisis. Phenelzine, isocarboxazid and tranylcypramine are irreversibly bound and non-specific, acting on both types of MAO. Reports of potentially fatal interactions with tyramine-rich foods, such as cheese, in patients taking MAOI led to reduction in their usage and realisation of the need to avoid tyramine-containing foods if taking them.

The MAOI have similar indications to the tricyclic and tetracyclic antidepressants. They may be better than the tricyclics in the treatment of "atypical" depression (characterised by hypersomnia, hyperphagia, anxiety and without prominent somatic symptoms; Cohen 1997). They have also been used for the treatment of panic disorder with agoraphobia, post-traumatic stress disorder and social phobia.

MAOI are well absorbed from oral administration. Phenelzine and isocarboxazid are metabolised by acetylation, which is dependant on the patient's acetylation status. Approximately half of the European and a higher proportion of the Asian population are slow acetylators, which can lead to higher than expected serum levels and an increase in adverse effects, even at moderate doses. The half-life of these drugs tends to be around 2–6 h, and they require multiple doses during the day.

The tyramine reaction is an important feature of the side-effect profile of these drugs, and patients need to be warned about the need to avoid ingestion of large doses of tyramine-containing food. Foods to be avoided include the following:

- Alcohol (particularly Chianti and beer)
- Broad beans
- Cheese (especially mature cheeses; cream cheese does not interact)
- Liver (especially beef and chicken)
- Smoked or pickled fish or poultry
- Soups or pate (commercial preparations)
- Yeasts and meat extracts
- Green banana skins

The following should only be eaten in moderation:

- Avocados
- Aubergines
- Raisins
- Soy sauce

- Sour cream
- Spinach
- Yoghurt

In addition, the possibility of interactions with other medications should also be pointed out. The following drugs are contraindicated:

- Anaesthetics (particularly administered with adrenaline)
- Bronchodilators
- Adrenergic antihypertensives (methyldopa, guanethidine)
- L-Dopa or tryptophan
- Opiates
- Cold/flu preparations (containing sympathomimetics, especially dextromethorphan)
- Sympathomimetics (including illicit drugs containing cocaine and amphetamines)
- Serotonin specific re-uptake inhibitors (including clomipramine, trazadone and tricyclics)

The following drugs should be used with caution:

- Antihistamines
- Codeine
- Hydralazine
- Propranolol
- Tricyclic and tetracyclic drugs

Note: The half-life of any contraindicated drugs must be considered before changing to an MAOI, and an adequate washout time must be allowed before starting treatment. The most common antidepressant combinations are phenelzine with amitriptyline or trimipramine. The tricyclic is started before the phenelzine or both are commenced together at a low dose. The traditional MAOI inhibit the enzyme irreversibly; even after stopping the medication, its effects will therefore continue for about 2 weeks until adequate monoamine oxidase is formed. Thus a washout period is required before any contraindicated drugs can be commenced.

The commonest adverse effects are orthostatic hypotension, weight gain, sexual dysfunction and insomnia. Very occasionally, patients present with paraesthesia, secondary to pyridoxine deficiency. Phenelzine and isocarboxazid have been associated with hepatoxicity, and treatment requires monitoring of liver function tests. MAOI are less cardiotoxic and less likely to lower the seizure threshold in patients than tricyclics. They are contraindicated in pregnancy and pass into breast milk. They need to be used with caution in patients with renal, hepatic or seizure disorders.

Moclobemide is a newer drug which is relatively specific for MAO-A and is reversibly bound (an example of a novel class of drugs known as reversible inhibitors of MAO-A, RIMA); this enables it to be displaced by tyramine and makes it far less likely to precipitate a hypertensive crisis. Selegiline is a specific inhibitor of MAO-B used predominantly in Parkinson's disease which may also (in high and non-MAO-B-selective dosage) be effective in refractory depression (Sunderland et al. 1994).

There is no clear evidence to suggest that there are significant differences in the efficacy of any one MAOI over another. The side-effect profile dictates treatment choice. Moclobemide is least likely to precipitate a tyramine reaction, although being the most recently introduced MAOI, there is little long-term data on its effectiveness in a prophylactic or maintenance role. Tranylcypramine is a more "activating" antidepressant and has relatively low hepatotoxicity. Phenelzine is advocated as the safest of the three traditional MAOI, but, like isocarboxazid, it may be hepatotoxic. All MAOI require a slow build-up of dose initially and administration two or three times a day.

2.1.3 Serotonin-Specific Re-uptake Inhibitors

The serotonin specific re-uptake inhibitors (SSRI) are the fruits of the renewed interest in the early 1970 in the role of the 5-HT system in depressive illness. The family of SSRI now includes fluoxetine, paroxetine, fluvoxamine, sertraline and citalopram.

The main indication for treatment with the SSRI is major depression, within which their use (both for acute treatment and in prophylaxis) is similar to that of the tricyclics. They are also indicated for the treatment of obsessive–compulsive disorder, panic disorder and bulimia (fluoxetine). Outside their approved indications, they shown efficacy in dysthymia, agoraphobia and impulsive behaviour.

The exact mechanism of the antidepressant effect of the SSRI remains unclear. They inhibit serotonin re-uptake without direct effects on adrenergic or dopaminergic re-uptake. The result is a down-regulation of 5-HT receptors, e.g. 5-HT_2. This has ill-defined indirect effects on the other neurotransmitter systems. There is some variability between SSRI in their in vitro specific affinity for serotonin and their potency in blocking its re-uptake, but this does not appear to have any clinical significance. The absence of significant anticholinergic, antihistaminergic and anti-adrenergic effects is responsible for their relatively benign side-effects. The commonest adverse effects with SSRI treatment in the central nervous system are headaches, anxiety, insomnia and weight loss; in the gastrointestinal system, nausea, diarrhoea and anorexia are relatively often seen. Sweating is also sometimes reported. The initial reports of increased suicidal acts in patients being treated with fluoxetine have not been

supported. Less common side-effects include disturbances of sexual function (anorgasmia, delayed ejaculation and impotence) and rashes. The SSRI have very low toxicity in overdose.

The SSRI are rapidly absorbed orally, undergoing little first-pass metabolism. They are highly plasma protein bound and will displace other drugs from protein binding, serving to elevate their plasma level; fluvoxamine has the lowest plasma protein-binding affinity. They all undergo hepatic metabolism and to some extent affect the cytochrome P450-metabolising system. This may result in an increase in levels of other drugs metabolised by this route, including antipsychotics such as clozapine.

The SSRI have many clinically significant drug interactions; there are potentially fatal interactions with concomitant L-tryptophan and MAOI treatment. Caution should be exercised with administration of benzodiazepines, antipsychotics, other antidepressants and lithium. Cimetidine has been shown to increase levels of some SSRI.

Treatment with the SSRI can usually be initiated with the therapeutic dose, although some SSRI, e.g. fluvoxamine, paroxetine and sertraline (see the pharmaceutical data sheets provided with the respective drug by the manufacturers), require upward titration if effects are not seen within 4 weeks. They have relatively long elimination half-lives, allowing once-daily dosage. This is particularly the case for fluoxetine and its active metabolite norfluoxetine (70 and 330 h, respectively) and can cause difficulties if a change of medication becomes necessary, as interactions will occur up to 5 weeks after discontinuing treatment. Higher doses of SSRI have been suggested in the treatment of concomitant or "stand-alone" obsessive-compulsive disorder (paroxetine) and bulimia (fluoxetine). Their low level of side-effects makes them suitable for treatment of elderly patients. There have been reports of SSRI withdrawal phenomena (particularly with paroxetine); these include symptoms of anxiety, malaise, akathisia and dyskinesia. They should be distinguished from depressive relapse associated with poor compliance. If they occur during planned cessation, it is suggested that the drug should be re-introduced and withdrawn more gradually.

The ease of administration (standard, single daily dose) of the SSRI and their lack of severe adverse effects has led to their increasingly widespread use and may even have contributed to the shift of care of depressed patients from hospitals into the primary care services. Fluoxetine has had an enormous effect on the public awareness of antidepressant medication and has been requested and prescribed for symptoms falling short of significant depressive episodes, including sensitivity to criticism and low self-esteem (Barondes 1994). The relative expense of the SSRI compared to the tricyclics for essentially equivalent efficacy has resulted in considerable debate as to the financial implications of antidepressant prescription in general. Economic analyses are discussed later in this chapter.

2.1.4 Trazadone and Nefazadone

Trazadone and nefazadone are structurally unrelated to the tricyclics, tetracyclics, SSRI or MAOI but provide equally effective treatment of depressive illness. Nefazadone, a very recently introduced drug, is structurally related to trazadone, but has a different pharmacological profile. They have very little in the way of anticholinergic side-effects and differ from each other in their degree of sedation, with trazadone but not nefazadone having a marked sedative effect.

These drugs are indicated for the treatment of major depression. Trazadone acts as a specific inhibitor of 5-HT re-uptake and is also a post-synaptic 5-HT_2 antagonist. The list in Sect. 1 reflects its additional anti-adrenergic and antihistaminergic effects. Nefazadone also inhibits 5-HT re-uptake and acts as an antagonist at the 5-HT_2 post-synaptic receptors. It has less blocking effect on histaminergic and α-adrenergic receptors than trazadone.

Trazadone and nefazadone are both readily absorbed from the gastrointestinal tract with hepatic metabolism. Trazadone has a longer half-life (6–11 h) than nefazadone (2–4 h). The commonest side-effects with trazadone are sedation, orthostatic hypotension, dizziness and nausea. It is safe in overdose and has the rare side-effect of priapism. Adverse effects with nefazadone are nausea, headache, drowsiness and dizziness. It is relatively free of adverse sexual effects, and cardiotoxicity and orthostatic hypotension are also uncommon. Both drugs are contraindicated in the treatment of pregnant or breast-feeding women.

Nefazadone has been shown to reduce depression-associated anxiety and to improve sleep patterns. It may be particularly useful in patients experiencing intolerable sexual side-effects from other antidepressants. Unlike trazadone, it does however entail the relative inconvenience of twice-daily dosage. Trazadone has similar indications but is more sedative, benefiting patients with prominent insomnia.

2.1.5 Other Antidepressant Drugs

Bupropion

Bupropion is a unicyclic antidepressant drug, originally formulated in 1966 but not used for the treatment of depression until 1985. It was suspended from use in

the United States when it was associated with increased incidence of seizures in treated patients. This adverse effect was subsequently realised to occur at similar levels to other antidepressants, provided therapeutic doses were not exceeded. It was reinstated in 1989.

It is indicated for the treatment of depression. Its mode of action is unclear; it has low-grade re-uptake activity at noradrenergic receptors and possibly dopaminergic receptors. It is well absorbed orally, metabolised via the liver and has a half-life of approximately 12 h.

Bupropion has the rare benefit of being devoid of any pharmacologically distinct activity outside the central nervous system. It is virtually devoid of side-effects in terms of orthostatic hypotension, weight gain or sexual dysfunction. The most commonly reported adverse effects are headache, insomnia and nausea. The risk of seizures has been demonstrated to be dose related and comparable to treatment with tricyclic antidepressants at therapeutic doses. Risk of seizures does, however, rise significantly if high doses are given. Bupropion is contraindicated in patients with a history of brain trauma, seizures or other neurological disease; it should also not used in pregnant or breast-feeding women.

Mirtazapine

Mirtazapine is a recently introduced antidepressant with unique pharmacology. It is marketed as a noradrenergic and specific serotonergic antidepressant (NaSSA). It antagonises presynaptic α_2-adrenoceptors and thereby enhances serotonergic and noradrenergic transmission. It also acts to antagonise post-synaptic 5-HT_2 and 5-HT_3 receptors. This acts to increase the release of 5-HT to act on 5-HT_1 receptors, which may be relevant to its action in improving sleep and anxiety. It has a high affinity for histamine H_1 receptors but little effect on cholinergic or α_1-adrenoceptors.

Mirtazapine is indicated for the treatment of depression. It is extensively metabolised hepatically with a half-life of 20–40 h, permitting once-daily dosage. Prominent adverse effects are sedation, weight gain and dry mouth. It offers the advantage (in comparison with the SSRI) of less nausea and sexual dysfunction with more sedation and some weight gain, which may be of some benefit in suitable patients.

Reboxetine

Reboxetine was also recently introduced and is a selective inhibitor of noradrenaline re-uptake. It has minimal affinity for the serotonergic and dopaminergic systems and does not have major actions on muscarinic, histaminergic or adrenergic receptors. It is indicated for the treatment of major depression. It undergoes hepatic metabolism and requires twice-daily dosage. It is highly protein bound, with a potential interaction with imipramine, chlorpromazine, propranolol, methadone and other similarly bound drugs. The commonest adverse effects are dry mouth, constipation, insomnia and sweating; less common effects include tachycardia, vertigo, urinary hesitancy and impotence.

Reboxetine may be a useful drug for those patients intolerant of SSRI or tricyclic antidepressants. It may also be useful in patients with Parkinson's disease who are particularly sensitive to SSRI-induced extrapyramidal side-effects.

Venlafaxine

Venlafaxine is a bicyclic agent marketed as a serotonin and noradrenaline re-uptake inhibitor (SNRI). It is similar in action to other drugs soon to be released onto the market such as milnacipran. Venlafaxine is a potent inhibitor of 5-HT re-uptake and also causes some inhibition of noradrenaline re-uptake. It has a similar although weaker effect on dopaminergic re-uptake. It has negligible effects on muscarinic, α-adrenergic and histaminergic receptors.

Venlafaxine is indicated for the treatment of depression, and it has been claimed that it is effective in resistant depression. It is hepatically metabolised into another active compound (*O*-desmethylvenlafaxine, ODV). Venlafaxine and ODV possess half-lives of 5 and 11 h, respectively. The routine preparation required twice-daily administration, although a once-daily slow-release preparation is now available. The major route for excretion is via the urine, so doses need to be lower in patients suffering concomitant renal or hepatic disease. The commonest side-effect is nausea; this has been reduced by the introduction of the slow-release preparation. Other adverse effects are headaches, sweating, anxiety and sexual dysfunction. Venlafaxine should be used with caution in patients with hypertension and avoided in pregnancy and while breast-feeding. Abrupt withdrawal has been associated with insomnia, nausea, dizziness and nervousness, and it is recommended that the dose is tapered prior to withdrawal. No dose adjustment is suggested for treatment in elderly patients.

Venlafaxine appears to be a promising drug with a good effect on depressive illness. The use of a slow-release preparation has decreased the otherwise important disadvantage of a high incidence of initial nausea, which, with the original preparation, affected 25%–37% of treated patients. The claims of faster onset of action and effects in refractory depression require further confirmation.

2.2 Choice of Drug

As all antidepressants seem to be equally efficacious in the treatment of depression, other characteristics serve

to distinguish them from each other. While there is little disagreement that the newer antidepressants have a safer side-effect profile, there has been a debate whether the newer antidepressant drugs are as effective in severe depression. Perry (1996) reviewed the literature from controlled trials using the Hamilton Depression Rating Scale changes and suggested that tricyclic antidepressants are more effective in severe endogenous depression; Nierenberg (1994) reviewed the literature comparing SSRI and tricyclic antidepressants in the treatment of severe depression and concluded that the SSRI were equally effective. The latter view is probably a fair reflection of contemporary opinion. The previous dichotomy between psychotic and neurotic depressions is largely unhelpful in guiding treatment, and current thinking views psychotic depression as being at the extreme end of a spectrum. Adjunctive neuroleptic medication is often required in the treatment of severe depression accompanied by psychotic symptoms; this can be withdrawn once the psychotic symptoms are in remission and treatment with antidepressants is continued.

The choice of antidepressant can be guided by the receptor and consequent side-effect profile; in the elderly, significant antagonism of the α_1-adrenergic receptors should be avoided in order to prevent orthostatic hypotension and subsequent falls. Similarly, antidepressants with significant antimuscarinic activity should also be avoided in order to reduce the greater sensitivity to the associated effects of dry mouth, increased urinary retention and constipation. Toxicity in overdose would be a consideration in patients with prominent suicidal ideation treated as outpatients, and the less cardiotoxic drugs would be the drugs of choice. In a similar vein, attempts are made to identify features of the somatic presentation which can be ameliorated using the side-effect profile in an advantageous manner. This would, for example, suggest the prescription of more sedative medication for patients with prominent insomnia and agitation.

Interactions with other medications taken by the patient are a major consideration. It would be inadvisable to treat a patient with a prominent 5-HT re-uptake inhibitor if he or she is being treated with selegeline for Parkinson's disease, for fear of precipitating a serotonergic syndrome as a result of enhanced serotonergic activity. The serotonin syndrome consists of at least three of the following symptoms: confusion, hypomania, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhoea, incoordination and fever (Sternbach 1991). Interactions between the newer antidepressants involving their effects on metabolism of other drugs, particularly via the cytochrome P450 system, have been reviewed by Nemeroff et al. (1996). They found that each of the newer antidepressants inhibited a different cluster of cytochrome P450 enzymes. Fluvoxamine inhibited the cytochrome P450 $1A_2$ and caused interactions with theophylline and clozapine, among others. Fluoxetine, sertraline and paroxetine inhibited the cytochrome P450 2D6 enzyme and resulted in elevated levels of desipramine and nortriptyline. Fluoxetine, sertraline and fluvoxamine inhibited the cytochrome P450 2C enzyme and elevated levels of phenytoin and diazepam, among others; these and nefazadone inhibited the cytochrome P450 3A4 enzyme and increased levels of co-administered carbamazepine, terfenadine, alprazolam and other benzodiazepines. Overall, these findings emphasise the need to check known metabolic interactions and to phenotype patients who present as very sensitive to particular drugs.

2.3 Pharmacoeconomics of Antidepressant Drug Prescription

The importance of evaluating the financial aspects of clinical treatments is increasingly being recognised; drug treatments are no exception. An economic evaluation simply comparing costs of providing individual drug treatments for depression show an enormous financial advantage in prescribing older drugs such as the tricyclic antidepressants. This rather simplistic system, currently used by many agencies, has been heavily criticised for ignoring other fundamental treatment variables. These other considerations can be summarised as follows (after Burke et al. 1994):

1. Cost of providing treatment
   a) Medication price
   b) Professional services
   c) Medical tests
   d) Special dosing requirements
2. Likelihood of treatment success
   a) Efficacy (does it work?) vs. effectiveness (likelihood of success)
   b) Ease of dosing
   c) Tolerability and compliance
3. Toxicity
   a) Therapeutic index of medication
   b) Cost of treating adverse effects
   c) Lethality in overdose
4. Potential for drug interactions
5. Interpatient variability
6. Maintenance and prophylaxis

Several factors have been identified as relevant to service utilisation. Time to onset of drug action is clearly important, and this may possibly be reduced with venlafaxine (Guelfi et al. 1995). Dose titration may be labour intensive and cause delays in the case of the tricyclic antidepressants, for example. Some antidepressants require medical tests both prior to initiation

and during treatment monitoring, such as ECG in patients over 40 treated with tricyclics. Drugs may vary in likelihood of response – this can be affected by differences between "real-life" and clinical trial populations and the difficulty in attaining therapeutic dosages of drugs without the intensive support available during a drug study. Drug toxicity may be critical; economic aspects of this include the costs of treating adverse effects directly and the indirect medical costs, e.g. treatment of falls secondary to orthostatic hypotension after treatment with antidepressants with marked adrenergic blockade. Similar considerations apply to treatment of overdosage, factors such as number of days of bed usage being higher for the more toxic antidepressant medications. Tolerability will presumably affect compliance and treatment success and is largely dependent on the adverse side-effect profile. Economic factors are not static across treatment populations; factors such as age and gender may influence liability to particular adverse effects and need to be considered in guiding the optimal choice of drug.

Economic analyses seek to answer the question of which is the most cost-effective treatment for depression using different economic models (Stoddart and Drummond 1984) with varying degrees of complexity. There are two major approaches: partial and complete economic analyses. Partial economic analysis describes either the costs or the outcomes of a treatment. The full analysis examines costs and outcomes together. The interest in treatment of depression requires the use of the full analysis, as both outcome and cost are of concern. There are several different types, and the reader is referred to Chap. 16 (Vol. 1, Part 1) for a fuller discussion of pharmacoeconomics in general. Despite the limitations of individual methods of economic analysis, they provide valuable information on the economic impact of the major depressive disorders. A few examples of these types of analyses applied to treatment of depression are illustrated below.

Health Maintenance Organisations (HMO) in the United States can generate data for a partial economic analysis with relative ease, as they are aware of the direct costs not only for drugs but also for clinic visits and hospitalisation. Comparison of different SSRI (Sclar et al. 1995) illustrates the importance of dose titration even among these drugs. These authors found that dose titration with SSRI correlated with the per capita costs of treatment of depression. Thus patients prescribed paroxetine or sertraline (requiring upward titration in 28% and 40% of patients) were found to result in greater costs to the HMO than fluoxetine (16%). The authors emphasise that this is not an assessment of the cost-effectiveness of these treatments, but only a measure of direct expenditure. The debate over the economic benefits of using tricyclics or SSRI continues apace with research supporting both points of view (Jonsson and Bebbington 1993; Hotopf et al. 1996; Sclar et al. 1994). The discussion and correspondence following publication of these studies has highlighted the difficulties inherent in economic analyses. Priest (1996) reviewed the cost-effectiveness of venlafaxine and emphasised the fact that direct antidepressant drug costs only represent approximately 10% of the full economic costs. Using the various clinical treatment and outcome variables listed above, he concluded that venlafaxine offers financial advantages over treatment with both tricyclic antidepressants and SSRI.

2.4 General Clinical Guidelines for Treatment

The treatment of depression can best be conceptualised as occurring in three phases: acute treatment, continuation treatment and maintenance treatment. Acute treatment is given to achieve remission of the depressive symptoms as quickly as possible. Continuation treatment is to continue improvement through to complete recovery (usually 3–6 months), i.e. to prevent relapse. Maintenance treatment is designed to avoid the development of a new depressive episode.

2.4.1 Acute Treatment

There is ample evidence that treatment success is in large part dependent on an adequate dose of drug being given for an adequate time. Achieving this with the tricyclic and tetracyclic drugs was limited by the need to minimise their side-effects. Dosage adequacy with these drugs could best be achieved through gradual upward titration. Some patients may be unable to tolerate optimal doses but may show a partial response. The plan should be to achieve the highest tolerated dose; if this is ineffective, patients should be changed to a different class of antidepressant, and if there is an adequate response at a low dose, they should remain on this dose unless improvement ceases. If the patient does not respond after 4 weeks, a plasma level may be useful to ascertain adequate compliance and any unusual pharmacokinetic actions, allowing change of dose or drug.

There have been inconsistent findings from studies seeking to relate drug dosage, plasma levels and antidepressant effect; this is unsurprising given the ten-fold variation in the plasma level among individuals given an equal dose of tricyclic antidepressant (Asberg 1976). A review by an American Psychiatric Association Task Force (Task Force on the Use of Laboratory Tests in Psychiatry 1985) concluded that there was good evidence of a linear relationship

between plasma level of imipramine and clinical outcome. The task force suggested that the percentage of patients responding favourably increases with increasing plasma levels up to 250 mg/ml; lower levels may result in response in some patients, but higher levels were unlikely to produce further benefit. The review suggested that nortriptyline has a different response curve, with a therapeutic window of good antidepressant effect achieved at 50–150 mg/ml; this level is achieved by the majority of patients if treated with 150 mg a day (Kragh-Sorensen et al. 1973). Surprisingly, the task force found inconsistent evidence of any such window for amitriptyline, despite nortriptyline occurring as its major metabolite. The newer antidepressants provide what is usually a therapeutic dose from the onset of treatment. Dose increase may nonetheless be indicated in the absence of response after 3–4 weeks of treatment.

Intravenous administration of antidepressants for treatment of depressive disorders has been thought to achieve a more rapid onset of action than conventional oral dosing and has increased in usage (Laux 1993). Other advantages are assured compliance and the use of lower medication doses as there is no first-pass effect. There are relatively few controlled trials, but there is some evidence for the above hypothesis with the use of intravenous maprotiline (Gastpar et al. 1986), doxepin (Laux et al. 1989), clomipramine (Pollock et al. 1989) and citalopram (Bouchard et al. 1997). Loss of efficacy when patients are switched to oral medication was not a problem when adequate oral doses were commenced (Adler et al. 1997). Overall, there is still a paucity not only of studies separating out the psychological from the physical benefits but also ones identifying which patients are most likely to accept and respond to intravenous administration of antidepressants.

2.4.2 Continuation Treatment

Continuation treatment is based on the premise that antidepressant (and antimanic) drugs can suppress the symptoms of the illness while leaving an underlying psychopathological process continuing on its natural course (Prien and Kupfer 1986). Thus withdrawal of the drug before the natural cycle of the disease ends will result in a relapse of the illness. Several placebo-controlled discontinuation design trials have demonstrated the need for continuation treatment; these are reviewed by Prien (1992). The effectiveness of SSRI is suggested to be comparable with that of the tricyclics and tetracyclic drugs during this continuation phase. Prien and Kupfer (1986) suggest that the continuation phase should last at least 4 months from the time of remission of symptoms. The results from the studies carried out by Montgomery and Dunbar (1993) and Doogan and Caillard (1992) suggest that patients should receive 6 months of full-dose treatment from remission of symptoms. There is no overall consensus on the dose of treatment during the continuation phase. It would, however, seem prudent to continue full-dose treatment in patients with previous severe episodes of depression and to attempt a lower-dose strategy in patients with less severe episodes, the latter also receiving regular review and rapid re-establishment of the full dose if symptoms reoccur.

2.4.3 Maintenance Treatment

The chronic and recurrent nature of depressive illness is well recognised. Maintenance treatment should be initiated in patients with a history of three or more episodes of major depression, two or more episodes with rapid recurrence, patients with dysthymia and patients at risk of a life-threatening episode or severe disruption to their functioning (Hirschfield and Schatzberg 1994).

Patients treated with maintenance therapy should be given the same dose that was used to treat their initial episode (Kupfer et al. 1992; Hirschfield and Schatzberg 1994). Full-dose maintenance should be continued for 4–5 years or the equivalent of the duration of two episodes of illness. Patients with three or more episodes of depression should be considered for life-long maintenance treatment.

Lithium has been shown to be an effective maintenance treatment (Baldessarini and Tohen 1988) along with both the SSRI (Hirschfield and Schatzberg 1994) and the tricyclics and tetracyclics (Prien 1992).

2.5 Resistant Depression

Up to 30% of patients with major depression fail to improve with antidepressant treatment, and at least 60% may fail to achieve full remission (Roose et al. 1986). Nierenberg and White (1990) reviewed the literature and suggested that the term "resistant depression" be applied to patients having had treatment with a tricyclic or newer antidepressant for at least 6 weeks at an adequate dosage (e.g. 300 mg imipramine/day or equivalent) with blood level monitoring to ensure adequate exposure. The options at that stage are to augment treatment with lithium or thyroid hormone or to change to a different class of drug. The most robust evidence from placebo-controlled trials favours lithium augmentation (e.g. Katona et al. 1995) and triiodothyronine (T3) augmentation (Joffe et al. 1993). Surveys of psychiatric treatment preferences for refractory depression in the

United States (Nierenberg 1991) and Canada (Chaimowitz et al. 1991) and the United Kingdom (Shergill and Katona 1997) show that lithium augmentation is one of the most popular options. It is, however, only chosen by about one third of psychiatrists, and many psychiatrists prefer to change the class of antidepressant as a first-line measure. Augmentation with lithium or T3 offers the advantage that benefit may still accrue from the initial course of antidepressant treatment, even where this alone has failed to achieve an adequate response. Interestingly, Joffe (1998) has shown that response (to lithium or T3) is equally likely in non-responders and partial responders.

L-Tryptophan has also been used to augment antidepressants. Difficulties with a contaminant, causing life-threatening immunological reactions, led to widespread withdrawal of this tryptophan precursor, although it is now available again under more tightly controlled conditions. Subsequently changing medication to a different class (particularly an MAOI) would be the next step, again with a view to attaining an adequate dose for an adequate time. The MAOI can in turn be augmented with lithium, as above, or with tricyclic antidepressants, starting with a low dose to minimise adverse effects (Amsterdam and Hornig Rohan 1996).

SSRI are an increasingly frequent choice for initial antidepressant treatment. The main options following failure to respond to 6 weeks of high-dose treatment are to change to a tricyclic or tetracyclic antidepressant and follow the suggestions above or to augment the SSRI. Augmentation strategies are reviewed by Amsterdam and Hornig Rohan (1996), who recommend adding lithium (following the suggestions above) or a tricyclic antidepressant.

The place of the newer antidepressants in refractory depression is not clear at present. There is, however, a suggestion from an uncontrolled study (Nierenberg et al. 1994) that venlafaxine may have some benefit in resistant depression.

3 Bipolar Affective Disorder

3.1 Available Drugs

No new range of drugs for the treatment of mania in BAD has emerged to parallel the range available in depression. The main recent advance has been in the demonstration of efficacy of two anticonvulsants (carbamazepine and valproate) both in the treatment of manic phases and in the prophylaxis of manic and depressive phases. Areas that require attention are the treatment of bipolar depression, rapid-cycling disorder and alternatives to lithium for long-term maintenance (Prien and Rush 1996); the current optimal management of these is described below.

The short-term treatment of mania still requires the additional use of sedative medication in the form of antipsychotics such as haloperidol or of relatively short-acting benzodiazepines such as lorazepam or clonazepam. Other drugs available for second-line use in acute mania include the anticonvulsants clonazepam and lamotrigine, calcium channel blockers such as verapamil, and atypical antipsychotics such as clozapine and risperidone.

3.1.1 Lithium

Lithium salts were used for the treatment of gout some 100 years before the discovery (by Cade in 1949) of their therapeutic effect in the treatment of mania. Subsequent work between 1960 and 1970 suggested that lithium was also useful in the prophylaxis of BAD (Gelenberg et al. 1989). Within BAD, lithium is indicated for the treatment of acute manic episodes, prophylaxis of both manic and depressive episodes and treatment of depressive episodes.

Lithium is completely absorbed from the alimentary tract and achieves peak levels after 90 min with a standard preparation and 4 h for sustained-release preparations. It is not protein bound and is excreted unmetabolised via the kidneys. It cannot cross the blood–brain barrier and has a half-life of around 20 h. Equilibrium is reached after approximately 5 days of treatment. The mode of action of lithium is not entirely clear, but a putative mechanism may be through its action on inhibition of the enzyme inisotol-1-phosphatase, which reduces cellular responses linked to the phosphatidyl inositol second-messenger system. Lithium has also been shown to stimulate both sodium- and magnesium-dependent adenosine triphosphatase in cell membranes and to alter the distribution of calcium and magnesium across excitable membranes, serving to stabilise the cell membranes. Furthermore, both noradrenaline and 5-HT show an increased turnover and metabolism in response to lithium treatment in the short term, but a decrease in the longer term. Lithium also increases activity at the 5-HT uptake sites on platelets.

The commonest adverse effects of lithium are seen on the thyroid, heart and kidneys. Thirst, polyuria and gastrointestinal upset are relatively common. A fine tremor, diabetes insipidus, cardiac arrhythmias, weight gain and hypothyroidism may also be induced. Recommended precautions are assessment of renal function, thyroid status and baseline ECG before commencing treatment and regular monitoring (3-monthly for the first 6–12 months and then

6-monthly) of renal and thyroid function. Lithium impairs coronary sinus function and is contraindicated in sick sinus syndrome. Its use in pregnancy and while breast-feeding is not recommended; there have been reports of congenital malformations following exposure to lithium in the first trimester of pregnancy, although the extent of this has been disputed (Schou 1990). Lithium is excreted in clinically significant amounts in breast milk, and its use in breast-feeding mothers is contraindicated. There are case reports of renal failure associated with the use of lithium, but a review of the evidence by Schou (1997) concluded that there were no consistent findings to support a causal relationship.

Initiation of lithium requires low doses initially with blood level monitoring every 5 days until the therapeutic range is achieved; thereafter, it should be checked every 3 months. There is a well-documented narrow therapeutic range of plasma lithium levels (0.6–1.0 mM/l, blood levels being taken 12 h after the previous dose) within which the balance between efficacy and toxicity is optimal. Lower levels are subtherapeutic, and levels greater than 1.2 mM/l can cause toxicity (Gelenberg et al. 1989; Schou 1997). The common symptoms suggestive of lithium toxicity are coarse tremor, dysarthria and ataxia. Lithium toxicity should be regarded as a medical emergency and requires rehydration and, if severe, even haemodialysis. Antipsychotic drugs enhance the neurotoxic effects of lithium treatment, and their dosage should be carefully monitored. Most non-steroidal anti-inflammatory drugs, diuretics and angiotensin-converting enzyme inhibitors can increase lithium concentrations and, if used concurrently, mandate particularly close lithium level monitoring.

3.1.2 Carbamazepine

Carbamazepine is similar in structure to the tricyclic antidepressant imipramine. Though used primarily in neurological practice (especially temporal lobe epilepsy and trigeminal neuralgia), it is being used increasingly in BAD. It is indicated in prophylaxis and may be particularly useful in preventing relapse in rapid-cycling BAD. It has also been found to be effective in the treatment of acute mania (Post et al. 1987).

The mode of action of carbamazepine responsible for its antimanic effects is not fully understood. The efficacy of carbamazepine (and valproate, see below) is consistent with the "kindling" theory of BAD. Kindling refers to the electrophysiological observation that repeated subthreshold stimulations of a neuron may result in an action potential. The kindling model of BAD relies on the phenomenon that episodes tend to increase in frequency and severity. Within this model, BAD is seen as a form of limbic epilepsy, modifiable by anticonvulsants. There are, however, no consistent electroencephalographic (EEG) abnormalities in patients suffering from BAD responding to carbamazepine. Carbamazepine may act as an agonist on peripheral benzodiazepine receptors located on the γ-aminobutyric acid (GABA)-A receptor complex. This may enhance the inhibitory effects of GABA in many brain areas. Peripheral benzodiazepine receptors also act to regulate the calcium channels. This may be relevant in the light of the beneficial effects in BAD of calcium channel blocking drugs such as verapamil.

There is erratic absorption of carbamazepine from the gastrointestinal system, with increased absorption if taken with food. Peak blood levels are reached in 4–8 h, and the half-life varies from 12 to 17 h, depending on the induction of hepatic enzymes. Steady state is reached in 2–4 days. Carbamazepine is metabolised in the liver and excreted via the kidneys.

Carbamazepine commonly induces leucopenia (10% in the first 2 months), although the white cell count usually remains above 3000. Very occasionally, it can also cause agranulocytosis and aplastic anaemia. Patients need to be warned to beware of any symptoms of fever, bruising or easy bleeding. A pruritic rash can occur in 10%–15% of patients within a few weeks of commencing treatment. This can occasionally be the precursor of more severe dermatological conditions.

The most common side-effects of carbamazepine are nausea and gastric disturbance; these can be minimised by gradual upward dose titration. Adverse effects on the central nervous system (such as dizziness, ataxia and sedation) can be minimised by the same strategy. Carbamazepine is not recommended for use in pregnant or breast-feeding women. It is an inducer of catabolic hepatic enzymes and may thus affect the metabolism of multiple other drugs.

The starting dose of carbamazepine is usually 200 mg b.d. It should be taken with meals, and the dose should gradually be increased to between 600 and 1000 mg a day. The dose should be increased at approximately 200 mg every 2–4 days if possible to minimise adverse effects. It can be used alone or with an antipsychotic drug to treat manic episodes. A 3-week trial at therapeutic doses (trough blood levels, 8–12 mg/l) should be enough to assess its effect in the treatment of acute mania. Failure to respond should be followed by addition of lithium or valproate rather than by immediate withdrawal of the carbamazepine.

3.1.3 Sodium Valproate

Sodium valproate was used originally as an antiepileptic in France and is indicated for the treatment of BAD where lithium and carbamazepine are contraindicated or have failed. It is used in acute mania

(Bowden et al. 1994), especially mixed affective states, as well as in the prophylaxis of BAD. Sodium valproate is thought to have its effects by decreasing catabolism of the inhibitory peptide neurotransmitter GABA.

Sodium valproate is converted into valproic acid in the stomach and completely absorbed. It has a half-life of 8–16 h and is metabolised in the liver. Adverse effects are common in the gastrointestinal system; these include nausea (25%), vomiting (5%) and diarrhoea. It can also cause sedation and more rarely ataxia and tremor. Weight gain is common, and alopecia is reported in 5%–10% of patients. Hepatic enzymes can be elevated but rapidly return to normal levels after discontinuation of the drug. Rare cases of severe hepatotoxicity have been reported. Sodium valproate should not be used in pregnant or breast-feeding women. It can interact with other anticonvulsants and will raise levels of tricyclics and warfarin.

Sodium valproate should be given at a starting dose of 200 mg t.d.s.; this should be gradually increased to achieve trough plasma levels between 50 and 100 mg/l. Baseline and regular checks should be made of liver enzymes and the full blood count.

3.1.4 Clonazepam

The benzodiazepine clonazepam is used in the "second-line" treatment of BAD where lithium and/or other anticonvulsants have failed. It is used successfully both in the treatment of acute manic episodes (Chouinard et al. 1983) and as adjunctive therapy, with lithium, in the prophylaxis of BAD. In common with carbamazepine, it acts on GABA-A receptors to facilitate GABA-induced reductions in neuronal firing.

Clonazepam is rapidly absorbed orally, has no major metabolites and has a half-life of 34 h. It should be prescribed once daily, usually at night, with an initial dose of 0.5–1 mg, increasing gradually to 4–8 mg/day over several weeks. As it can cause abnormalities of liver enzymes, routine liver function tests are required. Common adverse effects are drowsiness, fatigue and dizziness; rare effects are irritability and aggression.

3.1.5 Other Drugs

Verapamil

Verapamil is a calcium channel blocker and is mainly used for the treatment of hypertension, angina and certain cardiac arrhythmias. However, it is also useful in the "second-line" treatment of acute mania and for BAD prophylaxis, where lithium and anticonvulsants have been ineffective, and in the treatment of mania (Garza-Trevino et al. 1992). It is thought to act by inhibiting calcium-dependent intracellular protein kinases.

Verapamil is well absorbed, is extensively first-pass metabolised by the liver and has a half life of 5–12 h. Its main adverse effects (as might be expected) are bradycardia, hypotension and atrioventricular heart block. Gastrointestinal complaints are also common. Verapamil can enhance the neurotoxicity of lithium and carbamazepine. It can be fatal if co-prescribed with beta blockers. It should not be used in pregnant or breast-feeding women. Verapamil should be initiated at 40 mg t.d.s. and increased to 120 mg t.d.s. over a period of weeks. Concomitant monitoring of blood pressure, pulse and ECG is required.

Clozapine

Clozapine is an example of an atypical antipsychotic drug which has been used in the treatment of patients with severe bipolar illnesses. In this context, it should be regarded as a "third-line" drug in patients with acute mania refractory to lithium, antipsychotics and second-line drugs (Calabrese et al. 1996). It has been suggested to have mood-stabilising properties in addition to its antimanic effect (reviewed by McElroy et al. 1996). Clozapine has actions at various receptors, and it is unclear which is essential for its action. It has low D_2 receptor antagonism and is a more potent antagonist of D_1, D_4, 5-HT_2 and α_1-adrenergic receptors. Although clozapine is free from extrapyramidal side-effects, it is associated with seizures and agranulocytosis and is currently licensed only for the treatment of resistant schizophrenia.

Lamotrigine

Lamotrigine is an anticonvulsant drug licensed for monotherapy of certain types of epilepsy. It acts by blocking the release of the excitatory neurotransmitters glutamate and aspartate through blocking sodium channels and stabilising presynaptic neuronal membranes. There are case reports and open studies suggesting that it has a beneficial effect in the treatment of BAD, usually in treatment-refractory patients and as an adjunct to more conventional pharmacological approaches (Sporn and Sachs 1997). The adverse effects associated with its usage are headache, nausea, vomiting and diplopia. Confusional states and rashes have also been reported. A gradual increase in starting dose is recommended to reduce adverse effects.

Gabapentin

Gabapentin is an anti-epileptic drug thought to potentiate intracellular GABA, with some evidence of effectiveness in the treatment of bipolar disorder (Schaffer and Schaffer 1997).

Risperidone

Risperidone is an atypical antipsychotic which has shown some efficacy in the treatment of both acute mania and psychotic depression (McElroy et al. 1996).

It has not been as extensively studied as clozapine, and there have been reports of risperidone-associated precipitation of manic episodes, especially in the absence of mood-stabilising medication. Its mode of action is predominantly via 5-HT_2 and D_2 receptor blockade.

Olanzapine

Olanzapine, another atypical antipsychotic agent, has been shown to result in a significant improvement in the symptoms of acute mania when compared to placebo (Sanger et al. 1998).

3.2 Choice of Drug

3.2.1 Acute Treatment

Manic Episodes

Antipsychotics are commonly used in addition to lithium or another antimanic agent to gain rapid control over symptoms in mania. In studies comparing the treatment of mania with lithium and with antipsychotics (reviewed by Gelenberg and Hopkins 1996), lithium appeared better at stabilising mood and ideation, while antipsychotics were more effective in reducing time to clinical response and particularly in reducing hyperactivity acutely. Approximately 80% of patients with acute mania will respond to treatment with lithium, although this may take up to 2 weeks to take effect (Bowden 1996). In the initial treatment of acute mania, the treatment of choice is lithium, which may be given alone or adjunctively at this stage; if it is used alone, management can be problematic in the first few days because, unlike antipsychotics or benzodiazepines, lithium does not have sedative-related effects on aggressive or disinhibited behaviour. Adjunctive medication can be added according to clinical need: high- or medium-potency antipsychotics to control psychosis and induce sleep and sedation or benzodiazepines for sedation in the absence of psychosis.

In conclusion, lithium or valproate are the treatments of choice in mania patients, except for highly aroused patients in whom more rapid control is necessary. In these patients, the choice is to add a neuroleptic, usually with a higher potency such as haloperidol in low doses (5–15 mg/day), or to add a benzodiazepine such as clonazepam or lorazepam to achieve an acute sedative effect. Antipsychotics can be used on their own if patients are intolerant or unwilling to comply with lithium treatment or if there is a chance that they may be pregnant. Valproate is licensed for use in the treatment of acute mania (Bowden et al. 1994) in the United States. Other individual drugs used to treat mania, with evidence of their efficacy, include carbamazepine (Post et al. 1987), clonazepam (Chouinard et al. 1983) and verapamil (Garza-Trevino et al. 1992).

Depressive Episodes Within Bipolar Affective Disorder

Lithium can be used in the acute treatment of the depressive phase of a bipolar illness, but antidepressant drugs (reviewed earlier in this chapter) are increasingly used, additionally, for this indication. There is a danger that antidepressants will precipitate rapid cycling and mania (Wehr and Goodwin 1987). The evidence for this particularly implicates tricyclics, especially in the presence of hypothyroidism (Bauer and Whybrow 1990). Overall, there is insufficient data on the newer antidepressants to assess their risk in this area. However, a meta-analysis comparing SSRI and tricyclics suggested that SSRI may be both effective and less likely to induce a treatment-emergent mania (Peet 1994). However, the length of follow-up in the studies analysed was short and most were treatment efficacy studies with no standardised criteria to assess mania. There is preliminary data that bupropion may also be effective in treating depressive episodes within BAD (Wright et al. 1985).

Overall, mood stabilisers are preferable to treatment with antidepressants in the treatment of mild depressive episodes in BAD (Expert Consensus Guidelines 1996). Non-psychotic but moderate to severe depression will require treatment with an antidepressant in addition to the mood stabiliser; a psychotic depression may require further addition of an antipsychotic drug (Expert Consensus Guidelines 1996). Sachs (1996) reviewed the treatment of treatment-resistant bipolar depression, and a modified version of his suggested treatment algorithm is shown in Fig. 1.

3.2.2 Maintenance Treatment

The decision to commence prophylactic or maintenance treatment is based on the assessment of several factors: the severity of previous episodes of illness, the risk of adverse effects from treatment, the likelihood of a recurrence in the near future and patients' willingness to commit themselves to treatment. Once the acute manic episode has resolved, maintenance treatment with lithium has been demonstrated to decrease the relapse rate of BAD from approximately 80% (with placebo) to 35% (Prien 1992). Best current clinical practice is to introduce lithium maintenance after the *second* episode of illness in BAD, which may be thought of as the first relapse (Expert Consensus Guidelines 1996). There is evidence that maintenance lithium should be continued for at least 2 years from relapse, as subsequent relapses may occur when lithium is discontinued and treatment with lithium may not be as effective in subsequent episodes. It is suggested that, if

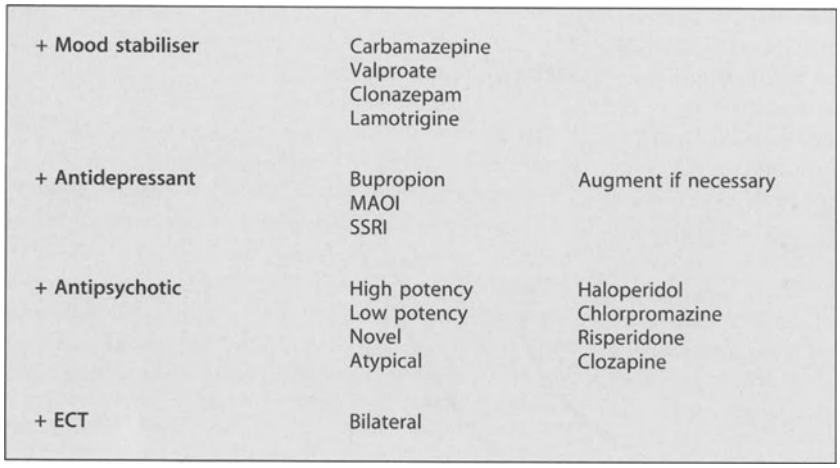

Fig. 1. Lithium treatment algorithm for bipolar depression. The options on the left-hand side should be initiated to control acute symptoms and the next choice on the right-hand side added or used as a substitute if cycling is unchanged for three cycles. MAOI, monoamine oxidase inhibitor; SSRI, serotonin-specific re-uptake inhibitor; ECT, electroconvulsive therapy

a further relapse occurs during lithium maintenance, the lithium should not be discontinued but augmented with carbamazepine or valproate.

Antipsychotics are not a treatment of choice for prophylaxis of BAD despite their common use as an adjunct to lithium (Gelenberg and Hopkins 1996). Antipsychotic treatment is associated with multiple side-effects with chronic use, including tardive dyskinesia, although there is little evidence of the long-term effects of using the newer antipsychotics. Their more favourable side-effect profile may lead to their increased usage in this area. It is generally advised that antipsychotics be used for as short a time as possible before mood-stabilising drugs are effective. They should be reserved for patients intolerant to or non-compliant with mood stabilisers (McElroy et al. 1996).

Lithium is the drug of choice in the prophylaxis of BAD in most patients. Maintenance treatment with lithium is most effective for patients with a history of previous good response, good inter-episode functioning and a history of bipolar illness in the family. General consensus suggests that treatment should be maintained for at least 2 years, and ideally for 5 years, before an attempt to discontinue treatment should be considered. Rapid-cycling illness, where there have been more than four episodes in the year, is less responsive to lithium treatment, and in such patients carbamazepine is probably more effective (Post et al. 1987). However, the results of a meta-analysis of selected studies highlighted the paucity of high-quality controlled studies and contended that there was insufficient data to support this view (Dardennes et al. 1995). A more recent review has supported the continued use of carbamazepine (Post et al. 1997). Similar arguments can be marshalled for the use of sodium valproate in the prophylactic treatment of BAD. Here, too, there are a number of clinical studies suggesting efficacy, but also a lack of good-quality controlled studies (McElroy et al. 1992). Valproate has been shown to benefit some patients with inadequate response to lithium and carbamazepine when used alone, as an adjunct to lithium or with both lithium and carbamazepine as triple therapy (Denicoff et al. 1997). These authors report the following response rates from their prospective randomised study: 33% with lithium, 43% with carbamazepine, 50% with carbamazepine and lithium, 60% with valproate and lithium and 62% with all three.

4 Other Mood Disorders

4.1 Atypical Depression

Atypical depression has been included in DSM-IV as a specifier of major depressive episodes and dysthymia; in ICD-10 it is classed under "other depressive episodes". Lam and Stewart (1996) concluded their review of atypical depression by supporting its diagnostic validity in terms both of clinical description and differential treatment response. In particular, atypical depression responds better to MAOI than to tricyclic antidepressants. Moclobemide also appears to be effective in the treatment of atypical depression and may be superior to fluoxetine in this context (Lonnqvist et al. 1994).

4.2 Dysthymia and Double Depression

The clinical significance of chronic mild depression (dysthymia) is well recognised, but until recently it was thought to be a form of personality type. This would

suggest that psychotherapy, rather than pharmacotherapy, was the treatment of choice. Howland (1990), however, reviewed the literature on the pharmacotherapy of dysthymia and concluded not only that was pharmacotherapy effective, but also that MAOI may be superior to tricyclic antidepressants. Subsequent studies, reviewed by the World Psychiatric Association Dysthymia Working Group (1995), have confirmed the effectiveness of a wide range of different antidepressants in dysthymia, including fluoxetine, imipramine, phenelzine and moclobemide. Long-term maintenance treatment is likely to be required. Sansone and Sansone (1996) recommend the use of SSRI in prophylaxis and suggest that such treatment should be continued for at least 2–3 years.

In patients with "double depression" (where dysthymia is complicated by discrete episodes of major depression), treatment of the major depressive episode also results in improvement of the dysthymia (Akiskal 1994). Continuation treatment should be given for at least 2 years. Where treatment fails, options for refractory depression (reviewed above) should be considered.

4.3 Cyclothymia

Cyclothymia, characterised by episodes of mild depression and hypomania, has a fluctuating course from onset in juvenile or early adult years and confers susceptibility to rapid cycling upon exposure to tricyclic antidepressants (Howland and Thase 1993). The treatment of choice is lithium or other mood stabilisers such as carbamazepine or valproate. Akiskal (1994) reviewed the treatment of depressive episode in cyclothymia, and suggested that such patients should be treated with bupropion, MAOI and low-dose SSRI in conjunction with mood stabilisers.

4.4 Recurrent Brief Depressive Disorder

Recurrent brief depressive disorder (RBDD) is characterised by repeated, relatively brief (less than 2 weeks) episodes of depressive symptoms, otherwise similar in range and severity to those found in major depression. There are limited data on the specific treatment of this disorder, but adoption of the general guidelines for antidepressant treatment is suggested. The value of maintenance treatment with mood stabilisers in RBDD is not yet known.

4.5 Seasonal Affective Disorder

Seasonal affective disorder is characterised by dysphoria and depressive symptoms with onset in winter. The depressive symptoms are classically "atypical" with prominent hypersomnia, hyperphagia and increased lethargy. Phototherapy has been shown to be beneficial in this condition. Pharmacological treatments with antidepressant drugs, such as tricyclic and tetracyclic drugs, MAOI, SSRI and lithium, at standard doses have been used to good effect (Oren and Rosenthal 1992).

Other Methods of Somatic Therapy for Depression

Translator: E. Taub

1 Introduction

Alongside pharmacotherapy with antidepressants, a number of other somatic therapies, including sleep deprivation, electroconvulsive therapy, phototherapy, and, most recently, repetitive transcranial magnetic stimulation can be used to treat depressive illnesses. These therapies are usually given in combination with antidepressants; the purposes of such treatment include giving the patient a degree of relief for several weeks before the effect of antidepressant medication sets in, potentiating the effect of medication once it is established, or, in case of medically refractory depression, providing a different means of brightening the patient's mood.

2 Sleep Deprivation Therapy

The systematic introduction of sleep deprivation for the treatment of depressive illnesses was based not on theoretical considerations, but on case reports from the 1960s. In 1969, Schulte, a psychiatrist in Tübingen (Germany), reported the following: "There are, indeed, melancholic patients who, having deliberately deprived themselves of nighttime sleep, are fresher and more productive the next morning than if they had slept undisturbed" (Schulte 1969, p. 415). This striking improvement of depressive manifestations after a night of wakefulness was unexpected, as it belied the general assumption among physicians, as well as laymen, that sleep has a restorative function, whether in normal individuals or in depressive patients.

2.1 Total Sleep Deprivation for One Night

Schulte's observations were confirmed in the initial study by Pflug and Tölle (1971). Total sleep deprivation for one night has an impressive antidepressant effect in the majority of patients so treated. An improvement of mood after sleep deprivation is often noted by patients as early as the second half of the night spent awake, but it may, in other cases, set in only in the course of the following day.

The effects of sleep deprivation therapy have since been examined in numerous studies. Wu and Bunney (1990), in a meta-analysis of some 60 studies involving a total of more than 1700 patients, concluded that total sleep deprivation for one night leads to a major improvement of mood in the following day in 59% of depressive patients. Patients with the melancholic subtype of depression had a response rate of 75%, while non-melancholic depressed patients had a response rate of only 48%. Wu and Bunney's meta-analysis also revealed, however, that 83% of patients treated with sleep deprivation alone fell back into a depressed mood after sleeping through the following night, in contrast to only 59% of patients who were simultaneously treated with medication.

It has long been known that sleep deprivation may induce a hypomanic mood or a manic episode in patients suffering from bipolar disorders. Nonetheless, in a recently published study involving more than 200 such patients, a transition from depression to hypomania or mania occurred in only 5% after treatment with sleep deprivation (Colombo et al. 1999).

2.1.1 Predictors of Efficacy

Factors predicting a positive response to sleep deprivation include the following:

- "Melancholic" subtype
- Bipolar disorder
- Hyperarousal before sleep deprivation
- Daily fluctuation with morning low
- High variability of mood changes
- Elevated metabolism in the limbic system

Other factors that have no effect on the sleep deprivation response include the following:

- Age
- Sex
- Number of depressive episodes
- Duration of episodes
- Number of hospitalizations
- Severity of depression
- Previous treatments
- Patient expectations

According to the meta-analysis by Wu and Bunney (1990), as already mentioned, 75% of patients with melancholic or endogenous depression respond to sleep deprivation, in contrast to only 48% of depressive patients not meeting these criteria (patients with "non-endogenous" depression). Earlier studies detected no difference in the efficacy of sleep deprivation between patients with bipolar and those with unipolar depression (Elsenga and Van den Hoofdakker 1987), but a more favorable response in bipolar patients has been reported in some more recent studies (Szuba et al. 1991; Barbini et al. 1998). The response rate seems not to depend on whether the patient is suffering from the first episode of depression or from one of many in a recurrent depressive disorder.

Similarly, the patient's age and sex, the duration and severity of the present episode, and the nature of previous treatment have no predictive value with respect to the effect of sleep deprivation therapy (Kuhs and Tölle 1991). Moreover, the effect of a previous attempt using sleep deprivation therapy in the individual patient cannot be used to predict the effect of a new trial (Gordijn et al. 1995): one quarter of all sleep deprivation treatments are successful even if a previous attempt failed to brighten the patient's mood. Only 9% of patients fail to respond to each of three separate attempts using sleep deprivation therapy.

The presence of typical daily fluctuations, with a morning low and a brightening of mood in the evening, has a high positive predictive value. On the other hand, patients with daily fluctuations of reversed polarity (mood low in the evening) and patients without daily fluctuations do not respond as well to sleep deprivation (Reinink et al. 1990; Haug 1992). Carefully performed studies have revealed that it is not the type of fluctuation immediately before sleep deprivation, but rather the variability of mood fluctuations over the preceding days, both over the course of each day and from day to day, that is a good predictor for the efficacy of sleep deprivation (Gordijn et al. 1995, 1998).

Studies of possible neurobiological predictors have mostly yielded conflicting results (for a review, see Kasper and Möller 1996). The response to sleep deprivation was found to be positively associated with "hyperarousal" and with a high level of vigilance (Bouhuys et al. 1989, 1995). Studies using single photon emission computed tomography (SPECT) and positron emission tomography (PET) have shown that patients with an elevated metabolic rate in the limbic system respond more favorably both to sleep deprivation and to pharmacotherapy given immediately thereafter (Ebert et al. 1991; Wu et al. 1992).

2.1.2 Influence of Medication on the Effect of Sleep Deprivation

Because its effect is usually no more than transient, sleep deprivation is not an adequate therapy when used alone; thus the question of its interaction with antidepressants is raised. It seems that the latter do not improve the rate of response to sleep deprivation, but they do reduce the risk of relapse after the following night of sleep. As mentioned above, the meta-analysis performed by Wu and Bunney (1990), involving more than 1700 patients treated with sleep deprivation, revealed that 83% of patients who had received no medication, but only 59% of patients treated with antidepressants, fell back into a depressive mood after a night of sleep. These data disprove the widespread assumption that successful sleep deprivation therapy is regularly followed by a relapse into depression. Simultaneous lithium therapy also reduces the risk of relapse after successful sleep deprivation (Grube and Hartwich 1990; Szuba et al. 1994; Benedetti et al. 1999).

Similar results have been reported for the combination of sleep deprivation and phototherapy. Although the application of bright light during sleep withdrawal does not potentiate its effect (Wehr et al. 1985; Van den Burg et al. 1990), phototherapy after sleep deprivation can reduce the probability of relapse (Neumeister et al. 1996).

A question of major clinical interest is whether repeated sleep deprivation therapy in combination with the administration of antidepressants is superior to the use of antidepressants alone over a treatment period of 4 weeks. A number of open, uncontrolled studies in patients refractory to drug treatment have yielded evidence that sleep depression may improve or accelerate the effect of antidepressants (Leibenluft and Wehr 1992; Van den Hoofdakker et al. 1994; Benedetti et al. 1997). In a controlled study, Kuhs and colleagues (1996) treated depressive patients, in randomized fashion, with amitryptiline either alone or in combination with six partial sleep deprivations over the course of 4 weeks. The combination of sleep deprivation with an antidepressant led to a significantly greater reduction of Hamilton depression scores than did treatment with an antidepressant alone.

2.2 Partial Sleep Deprivation in the Second Half of the Night

Sleep deprivation limited to the second half of the night is an alternative to total sleep deprivation that has a comparable antidepressant effect (Schilgen and Tölle 1980). This form of treatment involves waking up the patient, after several hours of sleep, at 1 or 2 A.M. and keeping him or her awake for the rest of the night and the following day. Sleep deprivation therapy of this type is suitable for patients who consider themselves incapable of undergoing total sleep deprivation or are used to going to bed early. The procedure can also be repeated several nights in a row, possibly with so-called recovery nights in between, to prevent a relapse into depression. In contrast, sleep deprivation in the first half of the night seems to be much less effective (Goetze and Tölle 1981). The superiority of partial sleep deprivation in the second half of the night as compared to the first half of the night was demonstrated in a crossover study by Sack et al. (1988).

General recommendations for the practical application of sleep deprivation in depression are as follows:

1. Sleep withdrawal (total or partial in the second half of the night, starting at 1 to 2 A.M.) should generally be used as *adjuvant* therapy:

a) In combination with the initial administration of antidepressant medication to counteract depression during the latency period of drug effectiveness.
b) In the case of resistance to pharmacological antidepressant treatment.
c) As a differential diagnostic instrument to distinguish between senile depression with pseudodementia and incipient dementing illnesses. Pseudodemented depressive patients often experience a marked, but transient, improvement after sleep withdrawal. Such a finding makes the diagnosis of an incipient dementing illness very unlikely, even if the affected individuals themselves complain of a loss of cognitive ability.

2. After successful sleep deprivation, either a series of sleep deprivation treatments or a treatment with shifting of the phases of sleep is recommended, depending on the preference of the patient, to maintain the therapeutic effect.

2.3 Theories on the Mechanism of Action of Total Sleep Deprivation

First of all, it must be noted that the effect of sleep deprivation in depressive patients can hardly be explained as a psychological or placebo effect. The improvement of mood by sleep deprivation and the relapse into depression after the following night of sleep are contrary to the general expectation of depressive patients. This was further confirmed in the studies conducted by Buddeberg and Dittrich (1978), which revealed the absence of a correlation between the patients' expectations and the objectively measurable effect. It must therefore be assumed that the mechanism of action of sleep deprivation is neurobiological, although there is no generally accepted explanatory model to date. This subject has been reviewed by Van den Hoofdakker (1997) and Kasper and Möller (1996).

A number of hypotheses are based on models of normal and disordered sleep regulation. According to the two-process model of sleep–wake cycle regulation, a homeostatic process S and a circadian process C are the major factors controlling the sleep–wake rhythm. Borbély and Wirtz-Justice (1982) postulated that depression may be associated with a deficiency of process S, which both increases the need to sleep and brightens mood. The therapeutic effect of sleep deprivation is attributed to a transient elevation of factor S. A further hypothesis is based on the disinhibition of rapid eye movement (REM) sleep in depressive patients: sleep deprivation is said to counteract depression primarily through the avoidance of REM sleep. In accordance with this hypothesis, Vogel et al. (1980) achieved an antidepressant effect in depressive patients by selectively suppressing REM sleep. REM sleep is associated with an inhibition of catecholaminergic and a stimulation of cholinergic neurotransmission, i.e. it intensifies the presumed imbalance of these neurotransmitter systems in depression (Berger and Riemann 1993).

Other theories favor a neurochemical explanation, by analogy to the mechanisms of action of the antidepressants. Thus, for example, a serotonergic mechanism has been proposed. This hypothesis is supported by studies in which the administration of serotonergic antidepressants such as clomipramine or fluoxetine was found to stabilize the effect of sleep deprivation. The serotonin system seems to play an important role in the mechanisms of action of lithium and phototherapy, and the administration of either of these was also found to stabilize the effect of sleep deprivation. F. Benedetti and colleagues (personal communication) recently reported that patients who have a functional polymorphism of the serotonin transport gene, and, therefore, a better therapeutic response to selective serotonin reuptake inhibitors (Smeraldi et al. 1998) also have a better response to sleep deprivation therapy.

Findings from neurochemical studies and experimental studies in animals suggest that the effect of sleep deprivation is comparable to that of the amphetamines (Ebert and Berger 1998). Imaging studies have revealed a reduction of limbic metabolism after the acute administration of stimulants (Volkow et al. 1997). As a good response to sleep deprivation was found to be associated with a reduction of limbic metabolism in other studies (Ebert et al. 1991; Wu et al. 1992), these findings are consistent with the hypothesis that sleep deprivation, like the psychostimulants, has a therapeutic effect by provoking neurotransmitter release.

2.4 Sleep Deprivation and Shifting of Sleep Phases

As early as the 1970s and 80s, single cases were reported in which brief daytime naps destroyed the beneficial effect of sleep deprivation therapy. Thus, in clinical practice, efforts are taken to ensure that the patient does not fall asleep after sleep deprivation.

The phenomenon of relapse into depression after brief episodes of sleep was studied systematically by our research group. We found that its occurrence does not depend on the length of the naps or the appearance of a particular stage of sleep, but the time of day does

have an effect: morning naps led to a relapse more frequently than afternoon naps (Wiegand et al. 1993; Riemann et al. 1993). This observation, combined with the fact that sleep deprivation is more effective in the second half of the night than in the first half, led to the hypothesis that there is a critical phase, beginning in the early morning hours and lasting until the early afternoon, in which sleep has a negative effect on mood in depressive patients. Avoidance of sleep in this critical temporal period seems to have an antidepressant effect.

A new method of treatment based on this hypothesis involves shifting the patient's sleeping hours into the noncritical period lasting from the late afternoon until the first half of the night.

The treatment begins with total or partial sleep deprivation for one night. The next day, the patients go to bed at 5 P.M. and are awakened 7 h later, i.e. at midnight. The day after that, the sleeping hours are advanced by 1 h, i.e. the patients go to bed at 6 P.M. and wake up at 1 A.M. Postponement of sleeping hours by 1 h per day continues for another 5 days until the patients have a normal sleep rhythm again, going to bed at 11 P.M. and waking up at 6 A.M. When this procedure is followed, sleep in the second half of the night is totally eliminated for a few days and reduced for a few days thereafter.

Studies to date have shown that the therapeutic benefit persists in two thirds of patients responding to sleep deprivation (Vollmann and Berger 1993; Riemann et al. 1996; Berger et al. 1997; Albert et al. 1998). A comparison of patients who did and did not take medication in addition to sleep deprivation therapy suggested that its therapeutic effect is independent of concomitant antidepressant treatment (Berger et al. 1997).

In an initial randomized and controlled study of 40 depressive patients, the effect of sleep deprivation followed by a shift of sleep phases to the late afternoon and first half of the night ($n = 20$) was compared with that of a control condition, in which sleep deprivation was followed by a phase shift in the opposite direction (from 2 A.M. to 9 A.M. in the first night, and so forth; $n = 20$). A total of 75% of patients in the first group, but only 40% in the second group, experienced a reduction of Hamilton depression scores by at least 30% at the end of treatment (Riemann et al., in press).

Sleep deprivation and the shifting of sleep phases may be used at the beginning of inpatient treatment for depression to carry patients over the latency period before the onset of efficacy of antidepressants, i.e. to brighten the patients' mood several weeks earlier than otherwise possible, with a beneficial effect in two thirds of all patients. As this mode of treatment alone is not expected to have a lasting effect, pharmacological maintenance therapy should be started simultaneously and continued for 6 months; phase prophylaxis should also be given, when indicated.

3 Phototherapy

Phototherapy has been used since the 1980s as a further method of somatic treatment, primarily in patients with seasonally associated depression. Patients generally sit for 1–2 h, in the morning or evening, with their eyes open in front of a lamp from which bright, white light at an intensity of 2500–10,000 lux (but no ultraviolet light) falls directly on the retina. The treatment is usually given for 14 days.

The development of phototherapy for the treatment of depressive illnesses was originally stimulated by the case of a patient with bipolar illness who had personally observed that his depressive and manic episodes varied with the seasons. During a depressive phase beginning in the winter months of 1980–1981, he received his first treatment with bright, white light, which led to a remission of his depressive manifestations (Lewy et al. 1982). This positive experience in a single case was the starting point for numerous studies over the following years of phototherapy at various light intensities. Exposure to light was carried out either in the morning or in the evening, or both.

The same group of clinical researchers that first used phototherapy in depressive patients defined, in the early 1980s, the diagnostic criteria for a new subtype of depressive illness called seasonal affective disorder (SAD; Rosenthal et al. 1984): depressive episodes beginning in the autumn or winter and remitting spontaneously in the following spring or summer, in at least 2 consecutive years. A further requirement for a positive diagnosis is that no relevant psychosocial factors should be present that vary seasonally themselves and might thus explain the seasonal pattern of the affective illness. The clinical manifestations of SAD differ from those of depression of the usual kind by the more frequent occurrence of atypical features such as severe loss of energy, hypersomnia, carbohydrate craving, and weight gain.

In the DSM-IV classification, seasonal depression can be used as a supplementary coding to designate the course of recurrent episodes of an affective disorder. The required criteria for seasonal depression include a pattern of seasonal onset of the episodes over 2 years and a clear predominance of seasonal depressive episodes over nonseasonal episodes in the long term.

Most studies of phototherapy to date have been performed on patients with SAD. Light intensities of 2500 or 10,000 lux were used. The success rates in the individual studies varied from 30% to 70%. The

Table 1. Rates of success of treatment in several studies of phototherapy (after Terman et al. 1989 and the Groningen studies of Meesters et al. 1995, Van den Hoofdakker and Gordijn 1997)

Light exposure	Patients (*n*)	HAMD baseline	HAMD after treatment	HAMD improvement (%)
Morning only[a]	172	17.8	8.1	54
Morning only[b]	16	18.1	8.9	51
Morning only[c]	14	16.9	4.7	72
Afternoon only[a]	34	21.2	12.4	42
Afternoon only[c]	15	15.9	8.4	49
Evening only[a]	143	18.0	10.1	44
Evening only[b]	11	15.8	7.1	50
Evening only[c]	12	17.5	5.5	68
Morning and evening[a]	136	21.1	9.2	56
Evening/morning[c]	14	16.2	8.2	49
Morning/evening[c]	13	19.0	6.5	67
Dim light (control condition)	77	23.4	20.0	15

HAMD, Hamilton depression scores.

[b]Groningen studies: data from 1989/1990.
[c]Groningen studies: data from 1990/1991, 1991/1992, 1992/1993; treatment with 10,000 lux. The other studies used 2500 lux.

percentage of improvement in various studies is given in Table 1. In contrast to studies of antidepressant drugs, the duration of treatment was only 14 days. Positive effects usually appeared a few days after the beginning of treatment.

These studies showed that the time of day at which the patient was exposed to light seemed to make no difference, despite original predictions on the basis of chronobiological hypotheses.

Unlike patients with seasonal depression, patients with typical nonseasonal depression seem to respond poorly or not at all to phototherapy; the rate of response among such patients is much lower than in those with SAD. Phototherapy therefore cannot be recommended as a standard treatment for nonseasonal depression. It should be pointed out, however, that there are fewer published studies of phototherapy in nonseasonal depression than in seasonal depression, and many studies do not satisfy strict methodological criteria (for a review, see Van den Hoofdakker and Gordijn 1997).

3.1 Critical Remarks

Many authors have correctly remarked that the positive effect of phototherapy on seasonal depression may be due to a placebo effect (Eastman 1990); it is known that the placebo effect plays a major role in studies of outpatient therapy in patients with mild to moderately severe depression. In many of the controlled studies of phototherapy, dim light at intensities of 50–500 lux was used as a control condition, a range in which artificial room light also falls. Patients can easily distinguish between dim light and bright, white light, so the difference in the effectiveness of the two intensities might be attributable to different expectations of therapeutic success on the patients' part.

Furthermore, it must be observed that the intensity of natural daylight out of doors in typical European and North American longitudes exceeds 1000 lux even on cloudy and rainy days and may be as high as 100,000 lux, while most phototherapy studies employed an intensity of 2500 lux, usually for 2 h. As the effect of phototherapy seems not to depend on the time of day, the patient might simply take a walk outside for an equivalent length of time instead of sitting in front of a lamp. Wirz-Justice et al. (1996) studied the effect of "natural phototherapy" of this type in seasonal depressives, compared with a control condition in which patients received a small dose of artificial light, which was expected to have no therapeutic effect. Natural phototherapy led to a significant improvement of mood compared to the control condition after 1 week of treatment.

3.2 Mechanism of Action

There is still no generally recognized hypothesis for the mechanism of action of phototherapy (Leonhardt and

Wirz-Justice 1995). Because of the known effect of light on the circadian system, which is mediated by the retina, the retino-hypothalamic tract, and the suprachiasmatic nucleus (the anatomical substrate of the biological clock), it was originally supposed that phototherapy might act by normalizing a disturbance of the circadian rhythm. Nonetheless, no such disturbance could be found in patients with SAD. Furthermore, the effect of phototherapy on disturbances of the sleep–wake cycle is known to depend on the time of day at which treatment is given, while the effect of phototherapy in SAD is independent of the time of day (Wirz-Justice et al. 1993). These facts do not support the hypothesis that the antidepressant action of light is based on an effect on the circadian system.

Other theories postulate an effect on neurotransmitter systems, e.g. the serotonergic system (Neumeister et al. 1997). The dose-dependence of the phototherapy effect and its independence of the time of day are both compatible with this hypothesis.

3.3 Practical Application

At the present time, phototherapy can be recommended as a single therapy against depression (i.e. not in combination with medications) only in milder episodes of seasonal depression. It can also be used in combination with medications in other forms of depression. Furthermore, the use of phototherapy to stabilize the effect of sleep deprivation and to treat sleep disorders in senile depression is also reasonable. The therapeutic effect can be expected to begin 3–4 days after the start of treatment. Recommendations for the application of phototherapy are as follows:

- The patient should look directly at a bright light with open eyes.
- 2500 lux for 2 h or 10,000 lux for 40 min.
- Every day for 2 weeks, in the morning or evening (whichever is more convenient for the patient).
- Maintenance of the proper distance to avoid overdose (according to the instructions of the manufacturer).

Side effects of phototherapy include occasional irritation of the eyes and headache. It should be used with caution in the case of: ophthalmologic illnesses (retinopathies, glaucoma, cataract); use of medications that increase ocular sensitivity to light (e.g. lithium, fluoxetine, propranolol).

4 Repetitive Transcranial Magnetic Stimulation

Repetitive transcranial magnetic stimulation (rTMS) is a new form of treatment in which a powerful magnetic field is used to cause electrical stimulation of brain areas. The possible antidepressant effect of this method is now being investigated in numerous studies; no firm conclusion regarding its clinical usefulness can be drawn at present. If the antidepressant effect of rTMS is confirmed, it will constitute a good alternative to electroconvulsive therapy (ECT), because, unlike ECT, it does not require general anesthesia.

TMS was originally developed for diagnostic use in neurology. In contrast to transcranial electrical stimulation (TES), TMS is painless and noninvasive. It is performed by externally applying a strong magnetic field (1.5–2 T) to the head, which then, penetrating the skull and subarachnoid space, induces an electrical current in the underlying brain structures. Stimulation of the motor cortex in this way with a sufficiently high current, for example, results in neuronal depolarization, which, if the motor pathway is intact, evokes a motor response detectable as electromyographic (EMG) activity in the corresponding muscles. In contrast to single-stimulus TMS, rTMS (repetitive or rapid-rate transcranial magnetic stimulation) employs high-frequency stimulus sequences (frequency >1 Hz, more than two consecutive stimuli, constant stimulus interval).

The initial case report by Höflich et al. (1993) was followed in the ensuing years by studies from a number of different research groups, involving a relatively small number of cases (for a review, see Haag et al. 1997), providing evidence for a possible antidepressant effect. According to the study by Pascual-Leone et al. (1996a,b), high-frequency left prefrontal stimulation was particularly associated with a therapeutic effect.

In a crossover study of 12 patients (George et al. 1997), a sham (placebo) treatment was used as a control. The patients treated with rTMS responded with a significant improvement of mood, while sham treatment resulted in a worsening of Hamilton depression scores. Figiel et al. (1998) treated 50 patients suffering from treatment-resistant depression with rTMS and obtained a response rate of 42%. A study of patients with mania (Grisaru et al. 1998) yielded evidence that stimulation of the right prefrontal cortex is an effective treatment for this illness. This contrasts with the above-mentioned finding that left prefrontal stimulation is effective against depression. In a more recent controlled study (Zwanzger et al. 1999), rTMS at an intensity of 90% and 100% of the motor threshold was compared to placebo treatment; rTMS at 100% intensity was found to be more effective than either of

the other two conditions. No randomized, controlled trial has yet been published comparing the efficacy of TMS and ECT.

4.1 Possible Mechanism of Action

Experimental studies in animals have revealed evidence that TMS and ECT exert similar effects on the behavioral level and lead to comparable biochemical changes in the central nervous system (Belmaker and Grisaru 1998). Multiple research groups have shown that rTMS produces a significant reduction of immobility in Porsolt's Forced Swimming Test (Zyss et al. 1997, 1999; Belmaker and Grisaru 1998). Thus animal models, too, provide evidence supporting an antidepressant effect of rTMS.

In rTMS, unlike ECT, the objective is not to induce an epileptic seizure. Seizures occur rarely during rTMS as an unwanted side effect. As for ECT, the induction of seizures is not necessarily its actual mechanism of action, but it is, apparently, a necessary precondition for a therapeutic benefit. Thus skepticism regarding the efficacy of rTMS as compared to ECT seems appropriate.

4.2 Indications, Side Effects, and Safety

Because there is a small chance that rTMS may induce an epileptic seizure, patients should undergo an EEG before they are treated, and those with evidence of elevated cerebral excitability should be excluded from treatment (Brandt et al. 1997; Wassermann 1998). Sleep deprivation should be avoided before rTMS. Caution is also indicated regarding the use of medications that significantly lower the seizure threshold. There is no evidence that rTMS leads to memory disturbances, as ECT does, nor does it require general anesthesia.

The potential side effects of rTMS are as follows:

- Focal and secondarily generalized epileptic seizures
- Change in auditory threshold (acoustic artifact up to 120 dB)
- Brief unpleasant sensation under the stimulating coil
- Headache
- Migraine attack in patients with known migraine (rare)
- Transient tinnitus

Important safety considerations in the performance of rTMS include the following:

- EEG before initial treatment
- Avoidance of sleep deprivation
- Caution in the presence of medications that lower the seizure threshold
- Hearing protection during TMS
- Not to be used in patients with metallic foreign bodies in the brain or cardiac pacemakers because of the strong magnetic field
- Not to be used in patients with tinnitus

In summary, no recommendation can be given at present for the routine use of rTMS as a treatment for depression. However, there is good reason to believe that rTMS might be a component of the spectrum of antidepressant therapies in the future, in particular as a simpler alternative to ECT, with fewer side effects, in the treatment of medically refractory depression.

Psychotherapy of Affective Disorders

This work was supported in part by grants MH49115, MH29618, MH30915, and MH41884 from the National Institute of Mental Health. Portions of this chapter have appeared previously in Frank and Spanier C (1995), Thase (1995), and Thase and Beck (1993).

1 Introduction

It is not mere coincidence that roughly contemporaneous with the development of the Research Diagnostic Criteria (Spitzer et al. 1978) there emerged in the United States a series of short-term psychotherapeutic approaches to the treatment of major depression. The move toward more specific categorization of nonpsychotic disorders undoubtedly facilitated the theoretical work necessary for the development of what have come to be known as the "depression-specific" psychotherapies, but also provided the atmosphere in which these theories could be developed into practical interventions that then could be tested empirically. Although this chapter is entitled "Psychotherapy of Affective Disorders," its major focus will be on the psychotherapy of unipolar depression and, in particular, on the treatment of acute major depressive episodes in adults. We emphasize this area for the simple reason that it is the area of the most consistent theoretical and empirical work.

This chapter will also focus on individual treatments as opposed to marital, family, or group interventions, again because the majority of data available are for individual interventions. The most prominent and empirically supported among these individual interventions have been interpersonal psychotherapy (IPT) as developed by Klerman et al. (1984), cognitive therapy (CT) as developed by Beck et al. (1979), and a variety behavioral therapies that were studied in the 1970s and early 1980s and that are finding a new place in the limelight as the field attempts to meet the demand for ever-briefer interventions. Recently, Shapiro et al. (1991, 1994, 1995) and others in the United Kingdom have examined the efficacy of psychodynamic-interpersonal psychotherapy (IP; Shapiro et al. 1994, 1995; Guthrie et al. 1998, 1999). Although the clinical use of more traditional psychodynamic psychotherapies in depressed patients is common, the multiple extant forms of this therapeutic approach (often provided without manual-based guidelines) and the lack of a coherent body of controlled research on the specific use of this therapy for depressed patients with rationally derived depression outcomes precluded further inclusion of psychodynamic psychotherapies in the current chapter.

As will become apparent as this chapter proceeds, there are a number of important commonalities among the depression-specific psychotherapies. Each was originally conceptualized as a time-limited intervention. They are all highly focused on the patient's depression and on the problems believed to be relevant to the onset and maintenance of the depressive episode. They are all present-oriented and highly pragmatic in their approach. While some provide much more explicit guidelines for therapists' behavior from beginning to end of treatment, and even from beginning to end of session, all share an emphasis on structuring the therapy to a greater or lesser extent. Each of these therapies, in addition, is likely to seem coherent and relevant to the depressed patient. Finally, and perhaps most importantly, each of the depression-specific psychotherapies provides a clear message of hope for the depressed patient.

2 Interpersonal Psychotherapy

2.1 Overview and Description

IPT examines the relationship between depression and problems in the interpersonal realm, making no attribution as to whether the interpersonal problems apparent in the context of depression represent causes of, or have been caused by, the depressive episode. IPT was initially designed to be practiced as a weekly, face-to-face, present-oriented, and relatively short-term therapy "that emphasizes the current interpersonal relations of the depressed patient while acknowledging the role of genetic, biochemical, developmental, and personality factors in the causation of and vulnerability to depression" (Klerman et al. 1984, p. 5). The techniques of IPT, while incorporating both psychodynamically oriented therapies (e.g. exploration, clarification of affect) and cognitive-behavioral therapies (CBT, e.g. behavior change techniques, reality-testing of perceptions), were, in fact, developed for the management of the four basic problem areas which distinguish IPT: (a) unresolved grief, (b) role transitions, (c) interpersonal role disputes (often marital disputes), and (d) interpersonal deficits. Accordingly, IPT is not considered to be unique in terms of its techniques, although the strategies used in IPT (e.g. relating symptom onset to overt or covert disputes with significant others with whom the patient is currently involved) *are* considered to be distinctive (Klerman et al. 1984).

The major goals of IPT are achieved by ascertaining with the patient which of the four types of problems described above was associated with the onset of the current episode of depression and, subsequently, by working with the patient to renegotiate interpersonal difficulties associated with the primary problem area. Rooted in the interpersonal school of psychoanalysis founded by Meyer (1957) and articulated by Sullivan (1953), and informed by Bowlby's attachment theory (Bowlby 1982), IPT recognizes the profound impact of

early developmental experiences and unconscious mental processes (i.e. intrapsychic wishes and conflicts) on later patterns of interpersonal relationships; however, during the actual practice of IPT, the clinician focuses on improving the patient's current social roles and interpersonal relations (Klerman et al. 1984). Rather than analyzing and reconstructing intrapsychic or cognitive events from the past, IPT focuses on improving current interpersonal relations. This emphasis on *current* relational dilemmas is based on the assumption that early childhood experiences will be reflected in current patterns of interpersonal relating and in the patient's current social roles. In the original conceptualization of IPT, it was assumed that interventions focusing on the current interpersonal context of a patient's life would both facilitate recovery from the acute episode as well as provide protection against reemergence of symptoms (Klerman and Weissman 1993; Klerman et al. 1984) as long as treatment was ongoing, and possibly even after treatment discontinuation. The first of these assumptions has been verified empirically, as will be elaborated below. The second assumption, of continued prophylactic benefit after treatment has been discontinued, has received inconsistent empirical support and only for continued improvement in social functioning, not for prevention of recurrence.

The therapeutic stance in IPT is one of warmth, support, and empathy. In other words, the role of the therapist in IPT is one of active patient advocate and not neutral commentator as in psychoanalysis, nor one of providing unconditional positive regard as in Rogerian client-centered psychotherapy. Accordingly, since transference is not facilitated, the therapeutic relationship is conceptualized to be based in reality, as are the patient's interpersonal perceptions of problems outside of therapy.

2.2 Maintenance Interpersonal Psychotherapy

The adaptation of IPT to a maintenance treatment was based extensively on IPT as developed by Klerman et al. (1984). While maintenance interpersonal psychotherapy (IPT-M; Frank 1991) preserves the four distinctive problem areas of IPT and implements the strategies (e.g. exploration of feelings associated with loss of a role) and techniques of IPT (e.g. elicitation of feelings, nonjudgmental exploration of the affective quality of relationships, facilitating the development of satisfying and adaptive interpersonal behaviors), it differs from IPT in terms of its goals and timing. The primary goal of IPT-M is to prevent recurrence, i.e. to sustain wellness in patients who are fully remitted; in contrast, the goal of IPT is to bring about remission from an acute episode of depression. Moreover, IPT-M is designed to treat patients in a maintenance format for several years. For example, patients were treated for up to 3 years with IPT-M in the Maintenance Therapies in Recurrent Depression (MTRD) study for which it was originally developed (Frank et al. 1990). Accordingly, the number of problem areas that are typically the focus of IPT-M is greater than in IPT for the acute treatment of depression.

Since the goal of IPT-M is prevention, the therapist is mindful of the early development of interpersonal problems similar to those associated with the onset of the patient's most recent episode as well as earlier episodes of depression (Frank 1991). The emphasis in IPT-M is on augmenting the patient's strengths and helping the patient assume much of the responsibility for the prevention of future episodes. Thus the patient is encouraged to be watchful for the appearance of early somatic and cognitive symptoms characteristic of prior depressive episodes. If symptoms are reported, preventative strategies are planned and implemented by the therapist and patient to avoid the onset of a new episode. Consistent with an interpersonal approach to the treatment of depression, these strategies are primarily interpersonal in emphasis and designed to improve the patient's mood and adaptive functioning (e.g. increasing supportive social contacts outside of a chronically conflictual marriage, attending to one's own emotional or practical needs, and focusing less on the needs of others). IPT-M, in contrast to weekly IPT for acute treatment, was scheduled once per month in the MTRD protocol (Frank et al. 1990). This modification in the timing of IPT sessions was justified in accordance with the nature of the study population, which consisted of asymptomatic patients with a history of recurrent episodes of depression.

The problem areas that become the focus of treatment in IPT-M usually involve a combination of role transitions, role disputes, and interpersonal deficits and less frequently grief issues, unless a significant loss-related event occurs during maintenance treatment (Frank et al. 1993). Identification of the problem area in IPT-M evolves over the course of acute treatment, in which a number of interpersonal themes surface but are not the focus. These themes, particularly ingrained interpersonal patterns that continue to be problematic for the patient during remission or as a result of remission, are noted by the therapist and explored in IPT-M. While the techniques used in IPT-M are similar to IPT, the time-frame of IPT-M places a greater emphasis on the future (e.g. developing adaptive coping strategies in preparation for an upcoming and potentially stressful interpersonal event).

2.3 Evidence for the Efficacy of Interpersonal Psychotherapy

A relatively small number of researchers have evaluated interpersonal psychotherapy as short-term (DiMascio et al. 1979; Elkin et al. 1989; Schulberg et al. 1996; M.M. Weissman et al. 1979) and long-term (Frank et al. 1990, 1991a; Klerman et al. 1974; Reynolds et al. 1999a; M.M. Weissman et al. 1974) treatments for depression. Although the absolute number of studies is small, they have consistently demonstrated IPT to be efficacious, not only in alleviating depressive symptoms, but also in extending the well interval in patients with recurrent illness.

2.3.1 Interpersonal Psychotherapy as an Acute Treatment for Depression

Three controlled trials have been completed which demonstrate the efficacy of IPT as an acute treatment for major depression. The first study, the New Haven-Boston Collaborative Study of the Treatment of Acute Depression, begun in 1973, was a four-cell, 16-week randomized trial of 81 depressed patients involving weekly IPT and amitriptyline either alone or in combination. The control treatment consisted of non-scheduled psychotherapy. Although there were no significant differences between IPT and medication in reduction of symptoms at the end of treatment, both treatments were more effective than the control treatment, and combined treatment was more effective than either treatment alone (DiMascio et al. 1979; M.M. Weissman et al. 1979). A reexamination of these data revealed that the advantage of the combination of IPT and amitriptyline was limited to the subgroup of patients with more severe endogenous depressions (see Thase, in press). This study also found that patients who had received IPT, either alone or in combination with pharmacotherapy, developed significantly better psychosocial functioning at 1-year follow-up than either treatment control patients or patients who received pharmacotherapy alone (M.M. Weissman et al. 1981). The researchers noted, however, that across the four treatment groups, many patients relapsed by the 1-year follow-up, thus indicating that higher social functioning did not appear to be of significant prophylactic benefit and suggesting that 16 weeks of treatment may be inadequate to maintain recovery from an acute episode of depression.

The second acute treatment study, the landmark National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program (NIMH-TDCRP, Elkin et al. 1989), also strongly supported the efficacy of IPT for the acute treatment of depression in outpatients. A total of 250 unipolar, nonpsychotic depressed outpatients were studied at three sites and were randomly assigned to 16 weeks of either imipramine plus clinical management therapy (a "minimally supportive therapy" provided by a psychiatrist involving regular meetings consisting of support, encouragement, and at times direct advice), IPT, CBT (Beck et al. 1979), or placebo treatment (i.e. pill-placebo plus clinical management, PLA-CM). In contrast to the Boston-New Haven study, a combined treatment condition consisting of medication and psychotherapy was not included. The primary analyses showed that, at termination of the 16-week treatment period, patients in *all* treatments, including PLA-CM, showed significant reduction in depressive symptoms and improved functioning. When aggregating across the multiple outcome measures, the three active treatments generally performed better than the placebo and clinical management; however, these differences typically did not reach conventional levels of statistical significance after adjustments for multiple comparisons. In addition, there was no evidence in the primary analyses that the efficacy of the psychotherapies was significantly different from tricyclic antidepressant treatment. Secondary analyses, in which patients were dichotomized according to baseline severity of depression, revealed no significant differences among the four treatments in the less severely depressed subjects, but consistently significant differences among the treatments for the group of patients who were more severely depressed. Less severely ill patients (baseline Hamilton Depression Score, HRSD < 20) improved with all treatments, including PLA-CM, while the more severely depressed patients (HRSD $\geqslant 20$) in PLA-CM did poorly. For the severely ill patients, IPT was comparable to imipramine in efficacy and both were superior to PLA-CM. IPT was not significantly more effective than CBT in this more severely depressed group, although there were suggestive trends. In a subsequent reanalysis stratifying the sample on the presence or absence of atypical depression, Stewart et al. (1998) found that IPT was equally effective among both typical and atypical patients.

In an 18-month naturalistic follow-up of the course of depressive symptoms (with follow-up data collected at 6, 12, and 18 months), Shea et al. (1992) found that the percentage of patients who both met a stringent criterion of recovery during the acute treatment and who did not relapse over the 18-month follow-up period did not differ significantly among the four treatments and was low, ranging from 19% to 30%. Moreover, the rate of relapse among patients who had recovered across the four groups was high, ranging from 30% to 50%. Similar to the results obtained by M.M. Weissman et al. (1981), these findings indicate

that the recurrence rate for major depression is high, despite effective acute treatment, and that 16 weeks of treatment is insufficient in many instances to maintain lasting remission. Thus it appears that short-term psychotherapy does not have enduring effects in many cases and thus cannot be considered effective in the long term. It is important to note that when the collaborative study was begun, data from the MTRD study (Frank et al. 1990) that demonstrate the efficacy of maintenance treatment were not available.

As a result of controversy surrounding the approach to data analysis, two reanalyses of the NIMH-TDCRP efficacy data have been reported (Gibbons et al. 1993; Klein and Ross 1993). Although the findings were generally consistent with those originally reported (Elkin et al. 1989), the reanalysis by Klein and Ross (1993) showed more distinct differences in efficacy among treatments, particularly among the more severely depressed patients. They found that medication was superior to psychotherapy, and IPT and CBT were superior to placebo, particularly in the severely ill group. Again, they found trends suggesting that IPT was superior to CBT among patients with severe illness.

In an effort to control for the effects of several problems common to longitudinal psychiatric data, including serial correlation, missing data, and person-specific effects, Gibbons et al. (1993) used random regression models (RRM) to reanalyze the NIMH-TDCRP longitudinal HRSD dataset. Gibbons and colleagues argued that the result of incorporating these so-called random effects was "a clear test of the primary hypotheses of the TDCRP study without compromises..." (p. 749). While their results were in agreement with those published earlier, the use of RRM allowed clearer inferences and more confidence in the major findings of the TDCRP. Results of the RRM analyses revealed significant improvement over all subjects ($p \leqslant q.001$) as well as a significantly faster rate of improvement for imipramine relative to placebo ($p \leqslant q.03$), with clearer differences from placebo in this analysis at 16 weeks than in the original analysis. In contrast to other analyses, no further differences were found among treatment groups at 16 weeks. In other words, none of the analyses provided evidence of significant differences in efficacy between the two psychotherapies (IPT vs. CBT) or between these groups and the placebo group (PLA-CM), or between the two psychotherapies (considered both separately and jointly) and IMI-CM. Inspection of trend lines, however, revealed some ordering of treatments; imipramine was superior to psychotherapy, and IPT and CBT were superior to placebo.

The original analysis coupled with the subsequent reanalyses of the NIMH-TDCRP dataset indicate that IPT is an effective acute treatment for depression, even for more severely depressed patients. In addition, based on HRSD recovery criterion scores (i.e. $\leqslant 6$), there is some evidence for the specific effectiveness of IPT as compared with PLA-CM, especially in terms of recovery rates for the more severely depressed patients.

The third major study (Schulberg et al. 1996) compared IPT ($n = 93$) with pharmacotherapy ($n = 91$; nortriptyline, plasma levels 190–270 n*M*) and a treatment as usual comparison group ($n = 92$). This study, which was conducted in four primary care clinics in the Pittsburgh area, included a 16-week acute-phase and 4-monthly continuation phase sessions. Results clearly favored both well-specified treatments over the usual care condition, and after 4 months remission rates were as follows: IPT, 46%; nortriptyline, 48%; and usual care, 18%. After 8 months of treatment, 72% of the IPT group had remitted, as compared to 67% of the patients treated with nortriptyline and only 20% of those in the usual care condition. Subsequent analysis confirmed that IPT was equally effective in more and less severely depressed patients (Schulberg et al. 1998).

Despite this seemingly consistent support for the short-term efficacy of acute IPT treatment, in one notable exception, Reynolds et al. (1999b) failed to find significant benefit for IPT monotherapy as compared to an attention-placebo control. This study of recently bereaved, older (>49 years) adults compared IPT plus nortriptyline ($n = 16$), IPT plus placebo ($n = 17$), medication clinic plus nortriptyline ($n = 25$), and medication clinic plus placebo ($n = 22$). Response rates following the 16-week trial were as follows: IPT plus nortriptyline, 69%; nortriptyline monotherapy, 56%; IPT monotherapy, 29%; and no-treatment control, 45%. Thus nortriptyline, either alone or in combination with IPT, was superior to both placebo and IPT. Notably, however, the combination of medication and IPT was associated with the lowest attrition rate, and thus the highest treatment completion rate, across all conditions.

2.3.2 Interpersonal Psychotherapy as a Continuation and Maintenance Treatment for Depression

Three randomized controlled trials have been completed that demonstrate the efficacy of IPT as a prophylactic treatment for major depression. In the original study of IPT, the New Haven-Boston Collaborative Study of the Treatment of Acute Depression, Klerman et al. (1974) assessed the effect of IPT in an 8-month six-cell trial in 150 depressed female outpatients who had responded with symptom reduction to 4–6 weeks of amitriptyline therapy. This trial would probably be considered continuation treatment rather

than a maintenance treatment study by today's standards. By *continuation treatment* we refer to the phase of treatment that is provided in the 4–6 months following remission of the depressive episode. A return of depressive symptoms during this treatment phase is typically referred to as a relapse of the previous depressive episode. In contrast, *maintenance treatment* refers to the phase of treatment provided after the patient has shown a full recovery of the depressive episode, i.e. a remission that is sustained for an adequate period of time, such as 4–6 months. Depressive symptoms that appear during this time frame are typically considered to represent the appearance of a new episode of depression or a recurrence. (For a full definition of these and related terms, see Frank et al. 1991b.) Thus, while the goal of continuation treatment is to prevent a relapse of the previous depressive episode, the goal of maintenance treatment is to prevent the recurrence of new depressive episodes or to extend the period of wellness between depressive episodes.

In the New Haven-Boston Collaborative Study, patients were randomly assigned to 8 months of weekly IPT, medication, or their combination, IPT and placebo, placebo alone, or no pill. At the conclusion of treatment, relapse rates were highest for patients receiving no treatment (36%) compared with the other three active treatment groups: medication alone (12%), IPT alone (16.7%), and the combined IPT/medication group (12.5%). Patients receiving IPT demonstrated improved social functioning, although these effects were not apparent for 6–8 months (M.M. Weissman et al. 1974). The investigators concluded that superior outcomes were produced by the combination of IPT with medication. However, the design of the study, in which medication was initially administered alone, restricts generalizations regarding the efficacy of IPT to patients who have already responded positively to amitriptyline.

The second study, the MTRD (Frank et al. 1990; Kupfer et al. 1992), is the longest randomized maintenance trial to date. In this 3-year outcome study in depressed patients who showed a clear history of repeated episodes of depression, we (Frank et al. 1990) contrasted maintenance IPT-M with maintenance pharmacotherapy (imipramine), combination pharmacotherapy/psychotherapy, and a control group in a five-cell design in order to determine whether IPT-M alone or in combination with medication would play a significant role in the prevention of recurrence. IPT-M was designed specifically to maintain recovery and reduce vulnerability to future episodes by improving social adjustment; thus the focus was on the interpersonal and psychosocial context of the *well* state. Accordingly, we hypothesized that the risk of recurrence would be reduced in IPT-M by improving social adjustment; the patient would be helped to cope more effectively with interpersonal and social problems associated with the well state which would, in turn, reduce the number and severity of stressful life-events. This, in turn, would reduce the risk of recurrence.

In this trial, all subjects were treated acutely with a combination of IPT and imipramine and continued on that combination until they had sustained a clear-cut remission (HRSD $\leqslant 7$) for 20 weeks. They were then randomly assigned to one of five maintenance treatments: (1) IPT-M alone, (2) IPT-M with placebo tablet, (3) IPT-M with imipramine, (4) medication clinic visits with imipramine, or (5) medication clinic visits with placebo tablet. In contrast to previous studies, imipramine was maintained at the highest dose of medication ever employed in a maintenance trial (mean dose, >200 mg/day), rather than being tapered from acute treatment levels, while IPT was administered monthly and thus at the lowest dose ever in comparison to other clinical trials (Klerman et al. 1994). We found that active imipramine, maintained at an average dose of 208 mg, provided a prophylactic effect to a larger proportion of patients over a longer period of time than in any previous study of maintenance therapy of recurrent depression (Frank et al. 1990). Survival analyses indicated that patients who received imipramine alone or in combination with IPT displayed the greatest mean survival time (124 weeks and 131 weeks, respectively), although these two groups did not significantly differ. The study also demonstrated that when patients received a combination of pharmacotherapy and IPT for the treatment of their acute episode, those who continued to receive IPT on a monthly basis following drug discontinuation remained well significantly longer than those who did not, thus indicating a clinically meaningful and statistically significant effect for IPT-M, i.e. the IPT-M alone and IPT-M plus placebo groups showed mean survival times of 82 and 74 weeks, respectively, which significantly differed from the 45 weeks displayed by patients with no active treatment. Thus this long-term outcome study clearly established the value of maintenance treatment in the prevention of recurrence in major depression and found IPT-M to have significant prophylactic capacity, even when used at a very low dose in patients at high risk for recurrence.

In a follow-up report from this study and in an effort to further understand the relationship between monthly psychotherapy and longer survival time, we (Frank et al. 1991a) examined the contribution of treatment quality and demographic and clinical variables to long-term survival in the IPT-M alone and IPT-M plus placebo conditions. Treatment quality was defined as the extent to which therapists conformed to specific principles, goals, and techniques of IPT psychotherapy, thus labeled "treatment specificity." While no demo-

graphic or clinical variables were related to long-term survival in the IPT-M conditions in this follow-up report, higher (i.e. above the median) specificity of IPT-M was associated with significantly increased survival time, with a median survival time of almost 2 years (102 weeks; SE, 8 weeks; $p < .001$). In contrast, patient–therapist dyads rated as having low treatment specificity of IPT-M or who, in other words, were unable to focus consistently on interpersonal concerns, had a median survival time of less than 5 months (18 weeks; SE, 4.6 weeks). Patients in the low-specificity dyads received no more protection from the IPT-M treatment assignment than was provided by the medication clinic plus placebo assignment (median survival time, 21 weeks). We concluded that, when patients are able to maintain a consistent focus on interpersonal issues, monthly sessions of IPT provide substantial protection against recurrence of depression.

The third study, the Pittsburgh Study of Maintenance Therapies in Late-Life Depression (MTLD; Reynolds et al. 1999a), extended the findings of Frank et al. (1990) regarding the value of IPT-M to include late-life depressed populations. In this 3-year outcome study, the first randomized, placebo-controlled study of maintenance psychotherapy in late-life depression, elderly patients (i.e. patients older than 59 years) with a clear history of recurrent unipolar depression were treated to full recovery with open treatment of nortriptyline and IPT. Recovered subjects ($n = 107$) were then randomized into one of four maintenance treatments: monthly IPT-M sessions alone (with placebo), nortriptyline alone (with monthly medication clinic), combined IPT and nortriptyline, or a no-treatment control (placebo and medication clinic). Results indicated that all three active treatments were better than placebo in preventing depression recurrence. While the preventive capacity of medication alone and IPT-M alone did not significantly differ, combined IPT and medication treatment showed a trend toward added benefit over either treatment alone in preserving recovery, an effect that was particularly notable in patients 70 years and older (Reynolds et al. 1999a).

Taken together, the results from the MTRD study, the MTLD study, the study by Schulberg and colleagues, the NIMH Collaborative Study, and the studies by Klerman, Weissman, and colleagues provide clear evidence of the efficacy of IPT in the treatment of major depression. The performance of IPT in these clinical trials consistently surpasses minimal treatment or placebo control groups in both acute and maintenance treatment of mid- and late-life outpatients with depression. The recent negative study by Reynolds et al. (1999b) does raise some concern about the utility of IPT alone for treatment of bereavement related depressions in later life.

3 Psychodynamic-Interpersonal Psychotherapy

3.1 Overview and Description

One model of psychotherapy that includes psychodynamic elements, is available in manual-based format, and has a growing empirical track record to support its efficacy in the specific treatment of adult depression is Psychodynamic-Interpersonal Therapy (PI). Previously known as *exploratory therapy*, the model for PI is based on Hobson's conversational model (Hobson 1985; Goldberg et al. 1984). Further developed in manual-based format by Shapiro and Firth (1985), PI utilizes psychodynamic, interpersonal, and experiential approaches to therapy. In line with IPT, PI views interpersonal difficulties as primary in the origins of depression. Yet, in line with psychodynamic and experiential approaches, PI places a greater emphasis on the patient–therapist relationship as a tool for revealing and resolving relevant interpersonal issues. There is, however, less emphasis on the interpretation of transference than in most formal dynamic therapies.

The PI model assumes that the patient's depression arises from or is exacerbated by problems within his or her interpersonal relationships. PI therapists seek to understand, with the patient, the bases of interpersonal problems through the exploration of the patient's feelings and mutual negotiation – where the therapist's views are expressed as tentative statements open to correction, elaboration, and feedback. Therapists take a tentative, encouraging, and supportive approach, helping the patient to link his or her distress to specific interpersonal problems. Finally, the therapeutic relationship itself is utilized to address interpersonal problems and to test solutions in the "here and now" (Guthrie et al. 1998, 1999; Shapiro et al. 1994).

3.2 Evidence for the Efficacy of Psychodynamic-Interpersonal Psychotherapy

As noted above, a manual for PI has been developed by Shapiro and Firth (1985), as have adherence rating scales (Shapiro and Startup 1990, 1993). As part of the Sheffield Psychotherapy Projects (see Shapiro et al. 1991), Shapiro and colleagues have implemented a programmatic series of studies regarding the efficacy of PI therapy for the treatment of adult depression. The first such project, which included both depressed and/or anxious patients, utilized a crossover design to compare PI (then termed exploratory therapy) with CBT (termed prescriptive therapy) and indicated

a marginal superiority of CBT over PI (Shapiro and Firth 1987). More recently, Shapiro et al. (1994) compared the effectiveness of PI and CBT in 117 depressed patients diagnosed with the Diagnostic Interview Schedule (DIS; Eaton and Kessler 1985) and stratified for severity with the Beck Depression Inventory (BDI; Beck et al. 1961), who were randomly assigned to one of four treatment conditions: 8 weeks of PI, 16 weeks of PI, 8 weeks of CBT, or 16 weeks of CBT. At post-treatment, CBT and PI did not significantly differ in effectiveness as assessed by the majority of the protocol's post-treatment outcome measures; however, a moderate effect size was obtained on the BDI, indicating some post-treatment advantage of CBT over PI on this outcome (Shapiro et al. 1994). No overall advantage of 16-session treatment over eight-session treatment was obtained at post-treatment, although severely depressed patients were generally found to improve more after 16 sessions than after eight sessions (Shapiro et al. 1994). Notably, however, results obtained at 1-year follow-up (with data collected for 89% of the original study patients) substantially differed from post-treatment results. Specifically, at 1-year follow-up, the eight-session PI treatment condition appeared significantly less efficacious than the other three treatment conditions across nearly all outcome measures. In addition, there was no longer a measurable benefit of 16-session CBT over eight-session CBT, even in the initially severely depressed patients (Shapiro et al. 1995).

Most recently, Guthrie et al. (1999) examined psychological, social, and economic outcomes for non-psychotic psychiatric patients (75.5% of whom had a depressive illness) who were unresponsive to 6 months of routine mental health treatment and who were subsequently randomized to either 8 weeks of PI or usual psychiatric care. Patients receiving PI treatment displayed significantly greater improvement in psychological distress and social functioning, as well as significant reductions in health care utilization in the 6 months post-treatment, as compared with usual care controls (Guthrie et al. 1999).

4
Cognitive Therapy

4.1
Overview and Description

The theoretical basis of cognitive therapy has been derived from three primary sources: (1) the phenomenological perspective, (2) the structural view of personality and psychotherapy, and (3) contemporary work in cognitive and behavioral psychology (Beck 1976; Beck et al. 1979). Cognitive therapy shares with the phenomenological approach an emphasis on concepts of self and the personal world as key determinants of behavior (Frankl 1985). This contribution dates to the ancient Greek school of Stoic philosophy (Beck 1976). The writings of the post-Freudian analysts such as Adler (1936), Horney (1950), and Sullivan (1953) stressed this viewpoint on personality and psychopathology.

Freud's structural theory that partitioned cognition (thought) into primary and secondary processes and recognized the role of conscious, preconscious, and unconscious mental activity was a second major influence. The psychoanalytic model also postulated the existence of personality constructs and defense mechanisms that, at times of distress or conflict, are central to the etiology of psychopathological reactions. George Kelly's (1955) formulation of personal constructs and Jean Piaget's (1954) studies of schemas (i.e. internalized and hierarchical sets of rules used for problem-solving) in the cognitive development of children and adolescents also helped to shape the cognitive model for psychotherapy.

The fundamental principles of cognitive therapy were outlined by Beck in a series of papers in the early 1960s (Beck 1961, 1963, 1964). Subsequently, a number of research studies solidified the importance of cognitive distortions in various psychopathological states (e.g. Beck 1967, 1976; Braff and Beck 1974; A.N. Weissman 1979; Nelson and Craighead 1977; Rizley 1978; Hollon and Kendall 1980). Another influence was the introduction of Albert Ellis' (1962) system of rational-emotive therapy. Ellis, who, like Beck, had been trained as an analyst, also emphasized the significance of irrational or distorted beliefs in the origin and maintenance of "neurotic" psychopathology and similarly advocated active and direct interventions in psychotherapy of depressed patients.

Beck's model of cognitive therapy continued to evolve during the 1960s and 1970s (Beck 1967, 1970) and was first published in a fully developed form in the text *Cognitive Therapy and the Emotional Disorders* (Beck 1976), which also described the use of behavioral methods such as activity scheduling (Lewinsohn et al. 1982), self-reinforcement and self-monitoring (McLean 1982), and social skills training (Hersen et al. 1984).

The cognitive therapy of depression posits that three types of problems in cognition are involved in the genesis and/or maintenance of depression. The first type of cognitive dysfunction derives from the fact that depressed individuals spend a disproportionate amount of time thinking gloomy or unpleasant thoughts about themselves, their world, and their future. Beck (1976) has referred to the content of thoughts in these three domains – self, world, and future – as the cognitive triad. Cognitions that are

particularly relevant to the depressed patients are those that occur almost instantaneously with the worsening of dysphoric moods. These cognitions are referred to as automatic negative thoughts, and they provide the gateway for the cognitive therapist to understand the depressed patient's phenomenological world.

The second type of cognitive dysfunction in depression involves errors in logic and information processing (Beck 1976; Burns 1980). For most patients, errors in information processing are primarily state dependent, i.e. only apparent when a person is in a state of depression or another dysphoric mood (Coyne and Gotlib 1983; Haaga et al. 1991; Robins and Hayes 1993). Information-processing errors associated with depression include overgeneralization, excessive personalization, selective abstraction, emotional reasoning, and all-or-nothing thinking (for an expanded description, see Burns 1980).

The third type of cognitive dysfunction in depression involves hypothesized or "deeper" cognitive structures, such as dysfunctional attitudes and a depressogenic schema (Beck 1976; Segal 1988; Young and Lindemann 1992). In cognitive therapy, both attitudes and schema are considered to be ultimately accessible through questioning techniques, as illustrated by the use of the Socratic method, or guided discovery (Beck et al. 1979).

Cognitive therapy is more traditionally oriented than behavior therapy in that pathological schemas are conceived of as "unconscious," nonobservable constructs. These depressogenic structures are presumed to result from adverse early experiences (Beck 1976; Segal 1988). In individuals prone to depression, pathological schemas in relevant areas such as excessive interpersonal dependence or perfectionistic expectations for success are proposed to be "silent" during times of a stable romantic relationship or a high vocational attainment (Persons and Miranda 1992). However, they are "activated" in response to specific, matching adversities (e.g. Hammen et al. 1989; Segal et al. 1992).

Early in the course of therapy, particularly with more severely depressed patients, cognitive therapists liberally employ behavioral techniques. For example, daily monitoring of moods and activities is used to increase participation in rewarding behaviors, as well as to help establish functional relationships between changes in moods and accompanying patterns of automatic thoughts. Similarly, stepwise graded task assignments are used to help patients begin to approach and overcome problems that are perceived as overwhelming.

Slowly, and in a manner directly tied to each patient's ability to use more abstract cognitive interventions, the therapy moves toward eliciting and testing the accuracy of automatic thoughts, developing rational alternatives, and identifying and modifying maladaptive schemas. Therapeutic strategies, such as the use of written responses to stereotypic automatic negative thoughts ("coping cards") and a printed, five-column form known as the "Daily Record of Dysfunctional Thoughts," are used to teach patients to begin to challenge their negative cognitions. Patients are also encouraged to keep their thought records as part of a journal or notebook so that a coherent summary of the course of therapy is readily available and can be drawn upon repeatedly. When properly performed, each session ends with a new homework assignment that builds logically on the material covered within that session.

It is important to distinguish more simplistic models of cognitive intervention, such as verbal persuasion or the notion that negative thoughts are "replaced" by more positive thoughts, from the actual process of Beck's model of cognitive therapy. In contrast to persuasion, in which the "expert" directly advocates a "correct position," cognitive therapy emphasizes the use of Socratic questioning in order to guide the depressed person's discovery that logical errors or distorted thinking influences his or her assessments and interpretations. These possibilities are then tested in vivo as experiments. That more positive alternative conclusions typically can be identified and validated is at the heart of cognitive therapy.

4.2 Evidence for the Efficacy of Cognitive Therapy

Beck's model of cognitive therapy is the best studied psychological treatment of major depression (Depression Guideline Panel 1993; Thase 1995). Cognitive therapy has been extensively studied in comparison with waiting-list control conditions and with other forms of psychotherapy, as well as pharmacotherapy. However, despite such intensive study, only two trials have compared cognitive therapy with a placebo-clinical management condition (Elkin et al. 1989; Jarrett et al. 1999).

There is little doubt about the efficacy of cognitive therapy as an acute-phase treatment when compared with waiting-list control conditions (Beach and O'Leary 1992; Neimeyer et al. 1989; Propst et al. 1992; Ross and Scott 1985; Rude 1986; Scott and Stradling 1990; Selmi et al. 1990; Thompson et al. 1987). In the meta-analysis conducted by the Depression Guideline Panel (1993) of the Agency for Health Care Policy and Research (AHCPR), cognitive therapy had an overall efficacy rate of 46.6% (±6.9%), with an advantage of 30% (±22%) when compared with waiting-list control conditions.

With respect to comparisons with pharmacotherapy, results of four studies indicate that cognitive therapy is

superior to low-contact or "treatment-as-usual" medication control conditions, whether cognitive therapy is administered alone (Blackburn et al. 1981) or in combination with treatment as usual (Ross and Scott 1985; Scott and Stradling 1990; Teasdale et al. 1984). Each of these studies had a primary care provider or family practitioner prescribe the pharmacotherapy. Results from studies utilizing more rigorous pharmacotherapy conditions, as are provided in psychiatric outpatient clinics (the psychiatric clinic setting of Blackburn et al. 1981; Elkin et al. 1989; Hollon et al. 1992; Jarrett et al. 1999; McKnight et al. 1992; Murphy et al. 1984), have yielded more consistent evidence of parity. Of note, there is little evidence that the combination of cognitive therapy and pharmacotherapy routinely delivers an added benefit when compared to cognitive therapy alone (e.g. Blackburn et al. 1981; Hollon et al. 1992; Murphy et al. 1984), although the methodological limitations of these smaller outpatient studies may obscure detection of more additive benefits (see Thase, in press).

In a reanalysis of the TDCRP study conducted by Stewart et al. (1998), cognitive therapy did quite well among patients with features of atypical depression, and relatively poorly among those with more "typical" symptom profiles. A recent placebo-controlled study by Jarrett et al. (1999) confirmed the utility of cognitive therapy for patients with atypical depression.

Cognitive therapy generally has been found to have an efficacy comparable to that of other active psychotherapies, including behavioral marital therapy (Beach and O'Leary 1992; Jacobson et al. 1991), individual or group behavior therapy (Gallagher and Thompson 1982; Rude 1986; Shaw 1977; Thompson et al. 1987), IPT (Elkin et al. 1989), brief dynamic therapy (Gallagher and Thompson 1982; Thompson et al. 1987), pastoral counseling (Propst et al. 1992), and nondirective group therapy (Hogg and Deffenbacher 1988). In the study by Jacobson et al. (1991), individual cognitive therapy appeared to be more effective than behavioral marital theory in a subset of patients with satisfactory marriages, whereas the latter treatment produced greater gains on measures of marital satisfaction in maritally distressed couples. Interestingly, a combination of individual cognitive therapy and behavioral marital therapy was no more effective than the individual modalities (Jacobson et al. 1991).

4.3 Cognitive Therapy as a Continuation or Maintenance Form of Treatment

During naturalistic follow-up, patients who were treated with cognitive therapy generally have fared better over 1- or 2-year follow-ups than patients who were treated with treatment-as-usual interventions (Ross and Scott 1985; Scott and Stradling 1990) or those who were typically withdrawn from antidepressant pharmacotherapy (Blackburn et al. 1986; Evans et al. 1992; Kovacs et al. 1981; Simons et al. 1986). However, in the TDCRP study, no appreciable difference in relapse rates was found among patients who responded to cognitive therapy, IPT, imipramine, or placebo (Shea et al. 1992). It should be noted that acute-phase cognitive therapy was not significantly more effective than clinical management and placebo condition in this trial (Elkin et al. 1989) and that, in the absence of evidence of acute-phase efficacy for cognitive therapy, the assumption of prophylaxis may not hold true. Comparability in survival rates among several forms of active psychotherapy has been observed in two other follow-up studies (Gallagher-Thompson et al. 1990; Jacobson et al. 1993).

Cognitive therapy is being increasingly studied as a continuation- or maintenance-phase therapy. In one early controlled trial, treatment with monthly cognitive therapy alone achieved the same level of prophylaxis over 6 months as was achieved by continuation pharmacotherapy (Blackburn et al. 1986). Blackburn and Moore (1997) subsequently replicated this finding in a larger study comparing continuation forms of cognitive therapy and pharmacotherapy. Two other early studies, employing relatively small samples and a type of CBT not entirely consistent with Beck's model of treatment, failed to find any prophylactic value for continued "booster" therapy sessions after termination of acute treatment (Baker and Wilson 1985; Kavanaugh and Wilson 1989). This may be because only the subset of patients with incomplete remissions are at increased risk for relapse after acute-phase cognitive therapy (Thase et al. 1992). More recently, Fava and colleagues (1994, 1996, 1998) have found that a short course of cognitive therapy focused on residual symptoms after acute-phase pharmacotherapy significantly reduced the risk of relapse even after discontinuation of medication.

The results of the NIMH-TDCRP study have raised some concerns about the suitability of cognitive therapy for treatment of more severely depressed patients (see, e.g. American Psychiatric Association 1993). Persons et al. (1996) have challenged this contention and pointed out that the TDCRP results are not consistent with the bulk of evidence comparing cognitive therapy and pharmacotherapy (see also Thase 1995). Nevertheless, results from a series of studies conducted at the University of Pittsburgh do suggest that patients with abnormal electroencephalographic sleep profiles (Thase et al. 1996a) or hypercortisolism (Thase et al. 1996b) are less responsive to cognitive therapy than patients with more normal

neurobiological profiles. A similar association between sleep abnormalities and IPT response also has been observed in two studies (Buysse et al. 1999; Thase et al. 1997a). We suspect that these neurobiological abnormalities may be associated with dysregulation of affect, diminished hedonic capacity, and/or impaired information processing that could, in turn, interfere with productive psychotherapy. Such patients may be better treated with antidepressants, either alone (Thase et al. 1997a) or in combination with psychotherapy (Thase et al. 1997b).

5 Behavioral Therapies

5.1 Overview and Description

The conceptual basis for behavioral approaches to psychotherapy originated from two main sources: (1) increasing attempts to understand human behavior on the basis of experimental learning theory, as evident in the early work of Thorndike (1931) and Skinner (1953), and (2) a general dissatisfaction with intrapsychic theories of psychopathology that were difficult to test in an empirical fashion (see Hoberman 1990). In response to this latter "philosophy of science" critique, behavior therapy is often conceptualized as a general scientific approach to the study of human behavior change, rather than a single theoretical model or set of therapeutic techniques. As described by Kazdin (1982), this methodological approach to behavior therapy is characterized by a focus on the maladaptive behaviors for which the patient seeks treatment, a reliance on empirical findings from general psychology (and, particularly, the psychology of learning), and a focus on current rather than historical determinants of behavior. Moreover, behavioral approaches rely heavily on behavioral assessment techniques, including detailed functional analyses of environmental determinants and consequences of behavior, as well as ongoing monitoring of target behaviors and utilization of assessment data to guide treatment implementation (Kazdin 1982).

Most behavioral theories of depression draw from one or more basic tenets of social learning theory. Social learning theory posits that psychological functioning is best conceptualized as a set of ongoing, reciprocal interactions among personal factors (e.g. cognitive sets or expectancies), behavioral factors, and environmental factors (Bandura 1977). Accordingly, behavioral approaches to depression often view people and their environments as reciprocal determinants of each another.

Skinner (1953) and Ferster (1966) were among the first to conceptualize depression as a behavioral extinction-related phenomenon, resulting from an interruption or reduction in behavior caused by decreased positive reinforcements in the social environment. Lewinsohn and colleagues (e.g. Lewinsohn and Shaw 1969; Lewinsohn 1974; Lewinsohn et al. 1979) further refined this position, describing depression as the result of a lack of response-contingent positive reinforcements in one's social environment. According to Lewinsohn, low response-contingent positive reinforcement may be due to a number of causes, including an inability to obtain positive social reinforcements because of social skills deficits, a lack of available positive reinforcers (or surplus of aversive or stressful experiences) in one's environment, and/or a decreased capacity to enjoy positive experiences (Lewinsohn et al. 1973; Lewinsohn and Gotlib 1995). Taking a cognitive-behavioral approach, Rehm's (1977) self-control model postulates that depression arises from deficits in self-monitoring (e.g. a tendency to attend to negative feedback and the immediate versus delayed outcomes of behavior), self-evaluation (e.g. setting unrealistic or perfectionistic standards for evaluating oneself), and self-reinforcement (characterized by low rates of contingent self-rewards and high rates of self-punishment). In contrast, Nezu and colleagues (Nezu 1987; Nezu et al. 1989) have implicated ineffective problem-solving skills in the onset and maintenance of depressive episodes.

At the heart of behaviorally based treatment approaches to depression is the attempt to alter dysfunctional interactions between the patient and his or her social environment and to increase the frequency and effectiveness of contingent positive reinforcements received by the depressed individual for adaptive, nondepressed behaviors. Toward this end, specific interventions may be aimed at changing aspects of the patient's environment, increasing social skills required for the patient to elicit positive reinforcement from the environment (such as positive social interaction, effective communication, or problem-solving skills), increasing the pleasantness and decreasing the aversiveness of patient–environment interactions, and/or increasing rates of self-reinforcement (Foa et al. 1989; Hoberman 1990).

Behavioral treatments of depression share a number of common strategies (see Hoberman and Lewinsohn 1985; Lewinsohn and Gotlib 1995). These typically include monitoring patients' activity level, moods, and/or thoughts, as well as the use of functional analysis to determine environmental stimuli that may predispose, trigger, reinforce, or maintain depressive (versus nondepressive) responses *for the particular individual.* Patients are aided to identify pleasant or reinforcing events or activities, and to increase these events, and,

similarly, to identify and reduce aversive or stressful events or activities. Patients are commonly encouraged to set small and achievable goals early in treatment and to reinforce themselves for graded therapy successes, in order to increase the patient's use of positive self-reinforcement, to obtain early reductions in depressive affect and, thereby, a sense of hopefulness, and to strengthen the patient's sense of self-efficacy. Social skills training is another common component of behavior therapies and may include interventions designed to increase interpersonal skills and improve social interaction, communication, assertiveness, decision-making, and/or problem-solving abilities. Finally, behavioral approaches to psychotherapy are typically time-limited, commonly designed to be implemented in 4–12 weeks (Lewinsohn and Gotlib 1995).

5.2 Evidence for the Efficacy of Behavioral Therapies

Lewinsohn and colleagues (e.g. Lewinsohn et al. 1980) were among the first to develop and test a predominantly behavioral intervention for the treatment of unipolar depression. This structured, 12-session program was specifically designed to increase patient's engagement in pleasant activities, and reduce the intensity and frequency of aversive activities, and included a variety of behavioral and cognitive intervention strategies such as training in assertiveness, relaxation, self-control, decision-making, problem-solving, communication, and time management. Lewinsohn and his group have demonstrated in a randomized clinical trial that, relative to various control groups, behavioral therapy increased pleasant experiences and reduced aversive experiences, which led to subsequent decreases in depression severity (for a comprehensive review of this work, see Lewinsohn and Gotlib 1995).

Based on the rationale that depressed individuals lack the skills necessary to elicit positive reinforcements from the social environment, a number of investigators have utilized behavioral treatments for depression that are explicitly designed to provide social skills training. Bellack et al. (1980) describe one such behavioral treatment program comprising four major components: (1) social skills training, (2) social perception training, (3) practice (including homework), and (4) self-evaluation and self-reinforcement (see also Becker and Heimberg 1985; Becker et al. 1987). Bellack et al. (1981, 1983) and Hersen et al. (1984) demonstrated that social skills training was as effective as amitriptyline in an acute, 12-week clinical trial. Moreover, treatment effects were maintained with six to eight booster sessions provided over a 6-month follow-up period. Similarly, McLean and Hakstian's (1979) behavioral intervention designed to improve social skills, problem-solving, and self-control was found to be equal or superior to insight-oriented psychotherapy, relaxation therapy, and amitriptyline in a 10-week clinical trial. Furthermore, data at a 27-month follow-up showed behavioral therapy subjects to be less depressed and more socially active and productive than patients in the other treatment conditions, particularly as compared with patients in the relaxation therapy condition (McLean and Hakstian 1990). Thus the efficacy of social skills training for depression has received support through a number of sources.

Rehm's self-control therapy is typically administered in six to 12 group sessions and includes structured interventions designed to remediate deficits in self-monitoring, self-evaluation, and self-reinforcement. Evidence supports the superiority of this intervention to no-treatment controls and nonspecific psychosocial treatments, yet suggests that self-monitoring tactics represent the most essential component of this intervention program (see Rehm 1990; Craighead et al. 1998). Finally, Nezu and Perri (1989) have provided preliminary evidence of the efficacy of a 12-week problem-solving intervention in reducing depressive symptoms at post-treatment and 6-month follow-up, and Arean et al. (1993) have reported the superiority of problem-solving therapy to both waiting-list control and reminiscence therapy in the treatment of older adults with depression.

Recent support for the effectiveness of behavioral therapy is evident in the work of Jacobson and colleagues. In a recent component analysis of Beck's cognitive therapy for depression, Jacobson et al. (1996) found that the behavioral activation component of cognitive therapy was itself as effective as either a partial or full cognitive therapy intervention program. Behavioral activation interventions were limited to those strategies specifically designed to "activate people in their natural environment." These included daily activity monitoring, assessing the pleasure and mastery associated with engagement in various activities, assigning increasingly difficult activities selected to increase both pleasure and mastery experiences, imaging behaviors to be performed to identify potential obstacles to pleasure and mastery experiences, identifying specific problems and behavioral solutions to problems, and social skills training (Jacobson et al. 1996, p. 297). Jacobson et al. (1996) found this behavioral activation intervention to be as effective as the entire cognitive therapy protocol following treatment completion (at 12–20 weeks), as well as in evaluations of survival times, relapse rates, and number of well weeks obtained at 6-, 12-, 18-, and 24-month follow-ups (Gortner et al. 1998). Thus, although purely behavioral interventions for depression have been overshadowed

by cognitive (or cognitive-behavioral) and interpersonal psychotherapies over the past 15 years, these preliminary data underscore the potential efficacy and endurance of positive treatment outcomes using behavioral therapy for unipolar depression.

6 Conclusions

Clearly, the body of high-quality research on psychotherapeutic treatments of unipolar depression is far outweighed by parallel clinical trials of pharmacologic antidepressant agents. Nonetheless, evidence gleaned from select, well-controlled outcome studies indicate that IPT, cognitive therapy, and behavior therapy represent useful treatments of unipolar depression in adults. In addition, emerging programmatic research on certain manual-based forms of short-term psychodynamic psychotherapy, such as PI, appear promising and certainly warrant further research.

Psychotherapy may fulfill a number of roles in the treatment of major depression, such as a first-line treatment option in sequential treatment algorithms (i.e. to be followed by the addition of, or substitution by, antidepressant medication in nonresponders), an effective alternative to medication therapy, or as an important adjunctive therapy for patients taking medication (e.g. elderly patients with recurrent depression). Indeed, we suggest that psychotherapy be considered the preferred first-line treatment option for certain patient populations, such as patients with comorbid medical conditions that may contraindicate medication therapy or young patients for whom clinician providers may not want to initiate what could become a lifelong course of pharmacologic treatment.

IPT, PI, cognitive, and behavioral therapies, although differing in their theoretical approach to the problem and treatment of adult depression, at times overlap in both the general and specific strategies utilized in the therapy process. Each, for example, may help the patient to identify and conceptualize their depression and to monitor and change important aspects of their cognitive, behavioral, and/or interpersonal functioning. Each provides elements of psychoeducation, as well as interpersonal support and a clear message of hope. Further research regarding the most essential components of these psychotherapeutic treatments, the process by which change occurs in psychotherapy, and the identification of individual differences associated with psychotherapy treatment response will be important to further advance our understanding and application of effective psychotherapies for depression.

Catatonia

> ... the patient remains entirely motionless, without speaking, and with a rigid, mask-like facies, the eyes focused at a distance; he seems devoid of any will to move or react to any stimuli; there may be fully developed "waxen" flexibility, as in cataleptic states, or only indications, distinct, nevertheless, of this striking phenomenon. The general impression conveyed by such patients is one of profound mental anguish ...
>
> Karl Ludwig Kahlbaum, 1874 (Kahlbaum 1973, p. 8)

1 Overview

Catatonia has been associated with neurological, medical, and psychiatric disorders since its initial description in 1874 by Kahlbaum (1973). In his seminal monograph of 1874, he conceived of catatonia as a distinct entity by "[grouping] together the symptoms that were most frequent and often coincided ... purely by empirical classification."

Contemporary authors view catatonia as a syndrome of motor abnormalities in association with disorders of mood, behavior, or thought. The syndrome may be subtle and unrecognized by the untrained observer, possibly accounting for reports that its incidence is declining, although systematic screening studies of acute psychiatric admissions reveal an incidence of 4%–9% (Francis et al. 1996).

2 Nosological Status

Kahlbaum believed he had identified a distinct clinical syndrome, which presented with certain distinct clinical features and evolved over time in recurrent cycles with an affective component to a progressive dementia. After Kahlbaum, later workers such as Kraepelin (1904) associated catatonic behavior with dementia praecox, and Bleuler (1950) perpetuated this notion in his conceptualization of schizophrenia. This formulation was accepted in DSM-III-R (American Psychiatric Association 1987), which included catatonia only as a subtype of schizophrenia (295.2x) or as a nonspecific criterion for brief reactive psychosis (298.80) and psychotic disorder not otherwise specified (298.90). This classification was adopted despite the reports by Abrams and Taylor (1976) and Barnes et al. (1986), who found catatonia to be most frequently associated with affective disorder, and Gelenberg (1976) and Wilcox and Nasrallah (1986), who described catatonia in association with an array of systemic disorders.

DSM-IV (American Psychiatric Association 1994) recognized catatonia due to a general medical condition (293.89) as well as catatonia secondary to mania or major depression, although the latter two conditions lack specific diagnostic codes. In DSM, the number of motor signs required to meet criteria for catatonia varies between these categories. In the case of catatonia secondary to a medical condition, only one motor sign is needed; for the other diagnoses, two signs are required. The formal motor criteria for DSM-IV diagnosis of catatonia are shown in Appendix A.

The ICD-10 diagnostic criteria (World Health Organization 1992) are similar to those of DSM-IV, in that they now recognize an organic catatonia as well as catatonic schizophrenia. The formal motor criteria for ICD-10 diagnosis of organic catatonia and schizophrenia are shown in Appendix B. Unlike DSM-IV, the enumeration of required catatonic signs differs between organic and nonorganic diagnoses, and only one motor sign suffices for diagnosis. For organic criteria, the sign need only be present, while for catatonia schizophrenia the motor sign should "dominate the clinical picture."

Although ICD-10 notes that catatonic signs can appear in affective disorders, this diagnostic system follows DSM-IV in lacking specific coding for these forms of catatonia.

A nosological issue relates to the diagnostic classification system of Leonhard, which recognizes several types of catatonic disorders, including episodic and chronic forms, with detailed psychopathological descriptions (Ungvari 1993). Some of these clinical syndromes are subsumed within schizophrenia, and others are defined according to specific clinical presentations and clinical courses. These subtypes of catatonia have not been utilized in American and British texts or in most modern reports on diagnosis and treatment. Some recent work using Leonhardian classifications suggests these clinical syndromes may be useful in psychiatric genetics, e.g. in a strikingly higher rate of familial aggregation for periodic as opposed to systematic catatonia (Beckmann et al. 1996).

A contrasting theme in some recent reports is to revive Kahlbaum's idea of catatonia as a discrete clinical disorder, to be considered separate from affective or schizophrenic groupings. Two recent studies using contrasting methods offer some support for this aim. Peralta et al. (1997) used clinical criteria based on Kahlbaum's case descriptions and found a group of newly admitted psychotic patients that differed on a variety of demographic and clinical variables from DSM schizophrenia and affective disorder. Van Os et al. (1996) used factor analysis methods on new-onset psychotic patients and found evidence for a clustering of symptoms, including catatonia, that predicted illness course and treatment response.

3 Diagnostic Assessment

Catatonia is diagnosed according to the presence of certain motor features, some of which are classic but

Table 1. Standardized examination for catatonia (adapted with permission from Bush et al. 1996a)

Procedure	Examines
Observe patient while trying to engage in conversation	Activity level Abnormal movements Abnormal speech
Examiner scratches head in exaggerated manner	Echopraxia
Examine arm for cogwheeling. Attempt to reposture, instructing patient to "keep your arm loose" – moving arm with alternating light/heavy force	Rigidity Negativism Waxy flexibility Gegenhalten
Ask patient to extend right arm; place one finger beneath hand and try to raise slowly after stating, "Do NOT let me raise your arm"	Mitgehen
Extend hand, firmly stating, "Do NOT shake my hand"	Ambitendence
Reach into pocket and state, "Stick out your tongue, I want to stick a pin in it"	Automatic obedience
Check for grasp reflex	Grasp reflex
Check records for past 24 h re oral intake, vital signs	Autonomic signs
Attempt to observe patient indirectly, at least for a brief period each day	

infrequent. Others are common in psychiatric patients (e.g. agitation, withdrawal) and become significant because of their duration and severity. Some debate exists in the research literature as to the number of signs necessary and sufficient to diagnose catatonia, with different groups recommending one to four signs (Bush et al. 1996a). In addition, operational definitions for catatonic motor phenomena have not been well described.

The diagnosis of catatonia can be difficult in routine practice, since DSM-IV offers a list of only 12 motor signs in the criteria for catatonic schizophrenia. These signs are not well defined, there are no guidelines as to the severity required for diagnosis, and the list of signs is probably incomplete. Our group has recently developed a 23-item rating scale (Bush-Francis Catatonia Rating Scale; Appendix C), which operationally defines each catatonic sign, rates its severity, and provides a standardized schema for clinical examination. The presence or absence of the first 14 items on this scale serves as a screening tool, in that a case is ascertained by the presence of at least two of these 14 signs. Severity of the catatonic state is determined by rating each of the 23 items on a 3-point scale to provide a summary score.

Systematic application of this scale to psychiatric inpatients revealed that the classical signs such as waxy flexibility are in fact uncommon in catatonia (occurring in less than 25% of the sample). The presence of at least two signs (e.g. mutism and stupor) identified a distinct group of catatonic patients with a mean of 8.6 of the 23 motor signs on the scale. Thus this new instrument may aid recognition of catatonia, facilitating appropriate and prompt treatments. This rating scale has been applied to several populations of patients with a variety of comorbid diagnoses.

Reliability of the Bush-Francis Catatonia Rating Scale depends on the use of its companion standardized examination procedure (Table 1). This protocol allows systematic examination of patients within several minutes and facilitates repeated observation to monitor the course of illness and the response to treatments which may occur in a brief time period.

4 Differential Diagnosis and Diagnostic Examinations

A variety of systemic, neurological, and toxic conditions may produce the syndrome of catatonia (Taylor 1990), and the clinician should consider a psychiatric basis as a matter of exclusion, especially with unfamiliar patients or new onset of illness. Recent systematic studies show a similar pattern and severity of catatonic signs for both catatonia arising from psychiatric illness and from catatonia secondary to a general medical condition (Carroll et al. 1996). A recent review summarized 261 published cases of catatonia as to the types of medical and neurological

Table 2. Medical and neurological conditions underlying catatonia in 261 published cases (adapted with permission from Carroll et al. 1996)

Condition	Cases (*n*)
Drug-induced/toxic conditions	45
Encephalitis	40
Cerebrovascular	31
Seizure disorder	25
Metabolic conditions	24
Neoplasm	13
Typhoid delirium	13
Wernicke's encephalopathy	12
Post-traumatic	11
Other neurologic conditions	11
Miscellaneous CNS infections	9
Systemic lupus erythematosis	8
Degenerative	8
Neurosyphilis	5
Multiple sclerosis	5

CNS, central nervous system

disorders revealed by examination. These data are shown in Table 2.

Some authors view neuroleptic malignant syndrome (NMS) and serotonin syndrome as forms of toxic catatonia. These syndromes share many motor features such as rigidity and mutism with catatonia, and recent reports show that autonomic disturbances are common in prospectively identified catatonic patients, highlighting the clinical overlap. A recent systematic study of NMS using operational criteria showed 15 out of 16 patients with catatonia, and severity indices for NMS covaried with the number of catatonic signs (Koch et al. 2000).

Differentiation of catatonia from other motor disorders has also been addressed, particularly for parkinsonism. Two reports found that catatonia could be discriminated from extrapyramidal motor symptoms in elderly patients diagnosed with either schizophrenia (Bush et al. 1997) or depression (Starkstein et al. 1996). Of note in the latter study, apomorphine improved parkinsonian symptoms without affecting catatonic symptoms.

Recommendations for routine examinations in a catatonic patient include common procedures and tests to rule out the medical and neurological conditions such as those in Table 2. These include routine physical and neurological examination, cerebral imaging, serum chemistries and hematology, electroencephalography (EEG), and toxicology and may extend to lumbar puncture. The breadth of these possible clinical investigations can be adjusted depending on the prior psychiatric history, age of the patient, severity and duration of the catatonic state, and the promptness of response to treatment.

5 Neurobiology

No confirmed specific genetic, pathologic, neurochemical, or structural mechanisms have been elucidated in catatonia, although promising information is becoming available.

Some evidence exists for familial clustering of catatonia, suggestive of a genetic component which lacks classical mendelian inheritance. For example, the report by Barnes et al. (1986) on 25 catatonia cases found familial clustering in probands with overt psychiatric disorders as well as in patients whose catatonia appeared organic or idiopathic. A recent report determining family risk in periodic catatonia diagnosed according to Leonhard showed a risk of catatonia in first-degree relatives of 27% and a pattern of illness onset that was suggestive of genetic anticipation across generations (Beckmann et al. 1996).

Neurochemical studies in catatonia have primarily focused on dopamine and γ-aminobutyric acid (GABA). Attention has been directed to these neurochemicals because of analogy between the motor features of catatonia with basal ganglia disorders where these systems are prominent, as well as the known direct or indirect actions of effective biological treatments such as benzodiazepines and electroconvulsive therapy (ECT) on the activity of these neurotransmitters (Fricchione 1989). Northoff et al. (1995) measured plasma levels of the dopamine metabolite HVA in a series of patients with catatonia on admission to the hospital. Levels of HVA were generally elevated, and higher levels predicted a positive initial response to lorazepam during the first 24-h period of treatment. Case reports of a positive treatment response to zolpidem, which shares strong GABA-A agonism with lorazepam, led Carroll (1999) to hypothesize a role for GABA-A receptor dysfunction in catatonia.

One recent study examined the cortical GABA-A receptor binding by single-photon emission computed tomography (SPECT) using radiolabeled iomazenil in catatonic patients compared to matched psychiatric controls with similar comorbid illnesses. The results showed diminished receptor binding in the left sensorimotor cortex, while parallel estimates of cerebral blood flow showed reduced activity in the right frontal and parietal cortices (Northoff et al. 1999). This is the first imaging neurochemical study to link the hypothesized mechanisms of lorazepam on GABA receptors to an abnormality of the distribution of GABA receptors in the brains of patients with catatonia. The reduced blood flow in the right cortex confirms other reports (Satoh et al. 1993; Galynker et al. 1997)

showing asymmetry of metabolic activity, which at present is of uncertain significance.

A separate line of biochemical investigation relates to the similarities between NMS and catatonia, both of which are associated with reduced serum iron. Catatonic patients with low serum iron were most likely to have excited forms of catatonia, poor response to benzodiazepines, and increased likelihood of the condition evolving into NMS (Lee 1998).

6 Treatment

With respect to treatments of catatonia, both benzodiazepines and ECT are effective modalities in current usage. Amobarbital has a longer history of clinical use, dating from the early 1930s. Amobarbital has been subjected to a placebo-controlled trial, where none of ten patients with catatonia responded to saline infusions, while six of ten patients responded acutely to intravenous amobarbital (McCall et al. 1992). Amobarbital has not been directly compared to benzodiazepines for initial treatment of catatonia, although arguments favoring benzodiazepines include a narrow therapeutic index for barbiturates and the availability of flumazenil, a specific reversal agent for benzodiazepines. Of interest, the salutary effect of lorazepam was reversed by flumazenil in a patient with catatonic stupor and mutism (Wetzel et al. 1987).

Benzodiazepines are much more familiar than barbiturates in contemporary psychiatric practice, which often includes parenteral administration of agents such as such as lorazepam. A parenteral benzodiazepine challenge has been encouraged as initial treatment for catatonia (Bush et al. 1996b). Reports of the favorable outcome of benzodiazepines for catatonia have been accumulating since the early 1980s. These agents appear effective for catatonia attributed to psychiatric illness, neuroleptic toxicity, and a variety of other conditions. Age, sex, comorbid psychiatric diagnosis, and severity of catatonia do not appear to predict treatment response (Bush et al. 1996b). Comorbid psychotic and affective disorders are not typically responsive to benzodiazepines. These disorders are commonly unable to be assessed in mute catatonic patients; specific treatments may be initiated after resolution of the catatonic state. An advantage of ECT in the initial treatment of catatonia is that this form of treatment is likely to be effective for both the catatonic syndrome and the frequently associated affective or psychotic illness.

Recent prospective studies show that marked improvement or complete resolution of catatonia will occur in 60%–75% of patients within hours or a few days after administration of lorazepam and related benzodiazepines. Most studies of benzodiazepine response in catatonia have included solely or primarily retarded rather than excited presentations of illness. The treatment response of patients with excited catatonia is not well studied. In any case, prolonged trials of benzodiazepines are not advised for severe catatonia, where complications such as dehydration, pressure sores, embolic events, etc. have been reported.

Convulsive therapy has both a historical tradition and modern support as a treatment for catatonia. In 1934, the first patient with dementia praecox treated by Meduna with camphor-induced seizures was suffering from catatonia, with mutism and withdrawal that required tube-feedings for 4 years. Cerletti and Bini first used ECT to treat a catatonic patient in 1938. Since then, retrospective case series have shown that ECT was successful in producing remission. ECT was found effective in two recent studies for catatonia resistant to lorazepam, as it had previously been for patients failing to respond to amobarbital (Francis et al. 1996). In addition, clinical evidence from case material suggests that ECT and lorazepam are synergistic for treatment of catatonia (Petrides et al. 1997).

For these reasons, initial treatment with lorazepam and consideration of ECT for refractory or severely compromised patients based on clinical status remains a reasonable practice.

Appendix A. DSM-IV Criteria for Catatonia

The clinical picture is dominated by at least two of the following:

(1) Motoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor
(2) Excessive motor activity (that is apparently purposeless and not influenced by external stimuli)
(3) Extreme negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism
(4) Peculiarities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing
(5) Echolalia or echopraxia

Appendix B. ICD-10 Criteria for Catatonia

ICD-10 Diagnostic Guidelines for Organic Catatonia Disorder F06.1

The general criteria for assuming organic etiology, laid down in the introduction to F06, must be met. In addition, there should be one of the following:

(a) Stupor (diminution or complete absence of spontaneous movement with partial or complete mutism, negativism, and rigid posturing)
(b) Excitement (gross hypermotility with or without a tendency to assaultiveness)
(c) Both (shifting rapidly and unpredictably from hypo- to hyperactivity)

Other catatonic phenomena that increase confidence in the diagnosis are: stereotypies, waxy flexibility, and impulsive acts.

ICD-10 Diagnostic Guidelines for Catatonic Schizophrenia F20.2

The general criteria for a diagnosis of schizophrenia (see introduction to F20 above) must be satisfied. Transitory and isolated catatonic symptoms may occur in the context of any other subtype of schizophrenia, but for a diagnosis of catatonic schizophrenia one or more of the following behaviors should dominate the clinical picture:

(a) Stupor (marked decrease in reactivity to the environment and in spontaneous movements and activity) or mutism
(b) Excitement (apparently purposeless motor activity, not influenced by external stimuli)
(c) Posturing (voluntary assumption and maintenance of inappropriate or bizarre postures)
(d) Negativism (an apparently motiveless resistance to all instructions or attempts to be moved, or movement in the opposite direction)
(e) Rigidity (maintenance of a rigid posture against efforts to be moved)
(f) Waxy flexibility (maintenance of limbs and body in externally imposed positions)
(g) Other symptoms such as command automatism (automatic compliance with instructions), and perseveration of words and phrases

Appendix C. Bush-Francis Catatonia Rating Scale (adapted with permission from Bush et al. 1996a)

Use the presence or absence of items 1–14 for screening.

Use the 0–3 scale for items 1–23 to rate severity.

1. Excitement:
Extreme hyperactivity, constant motor unrest which is apparently non-purposeful. Not to be attributed to akathisia or goal-directed agitation.

0 Absent
1 Excessive motion, intermittent
2 Constant motion, hyperkinetic without rest periods
3 Full-blown catatonic excitement, endless frenzied motor activity

2. Immobility/stupor:
Extreme hypoactivity, immobile, minimally responsive to stimuli.

0 Absent
1 Sits abnormally still, may interact briefly
2 Virtually no interaction with external world
3 Stuporous, non-reactive to painful stimuli

3. Mutism:
Verbally unresponsive or minimally responsive.

0 Absent
1 Verbally unresponsive to majority of questions; incomprehensible whisper
2 Speaks less than 20 words/5 min
3 No speech

4. Staring:
Fixed gaze, little or no visual scanning of environment, decreased blinking.

0 Absent
1 Poor eye contact, repeatedly gazes less than 20 s between shifting of attention; decreased blinking
2 Gaze held longer than 20 s, occasionally shifts attention
3 Fixed gaze, non-reactive

5. Posturing/catalepsy:
Spontaneous maintenance of posture(s), including mundane (e.g. sitting/standing for long periods without reacting).

0 Absent
1 Less than 1 min
2 Greater than 1 min, less than 15 min
3 Bizarre posture, or mundane maintained more than 15 min

6. Grimacing:
Maintenance of odd facial expressions.

0 Absent
1 Less than 10 s
2 Less than 1 min
3 Bizarre expression(s) or maintained more than 1 min

7. Echopraxia/echolalia:
Mimicking of examiner's movements/speech.

0 Absent
1 Occasional
2 Frequent
3 Constant

8. Stereotypy:
Repetitive, non-goal-directed motor activity (e.g. finger-play; repeatedly touching, patting or rubbing self); abnormality not inherent in act but in its frequency.

0 Absent
1 Occasional
3 Constant

9. Mannerisms:
Odd, purposeful movements (hopping or walking tiptoe, saluting passersby or exaggerated caricatures of mundane movements); abnormality inherent in act itself.

0 Absent
1 Occasional
2 Frequent
3 Constant

10. Verbigeration:
Repetition of phrases or sentences (like a scratched record).

0 Absent
1 Occasional
2 Frequent, difficult to interrupt
3 Constant

11. Rigidity:
Maintenance of a rigid position despite efforts to be moved, exclude if cog-wheeling or tremor present.

0 Absent
2 Moderate
3 Severe, cannot be repostured

12. Negativism:
Apparently motiveless resistance to instructions or attempts to move/examine patient. Contrary behavior, does exact opposite of instruction.

0 Absent
1 Mild resistance and/or occasionally contrary
2 Moderate resistance and/or frequently contrary
3 Severe resistance and/or continually contrary

13. Waxy flexibility:
During reposturing of patient, patient offers initial resistance before allowing himself to be repositioned, similar to that of a bending candle.

0 Absent
3 Present

14. Withdrawal:
Refusal to eat, drink and/or make eye contact.

0 Absent
1 Minimal p.o. intake/interaction for less than 1 day
2 Minimal p.o. intake/interaction for more than 1 day
3 No p.o. intake/interaction for 1 day or more

15. Impulsivity:
Patient suddenly engages in inappropriate behavior (e.g. runs down hallway, starts screaming or takes off clothes) without provocation. Afterwards can give no or only a facile explanation.

0 Absent
1 Occasional
2 Frequent
3 Constant or not redirectable

16. Automatic obedience:
Exaggerated cooperation with examiner's request or spontaneous continuation of movement requested.

0 Absent
1 Occasional
2 Frequent
3 Constant

17. Mitgehen:
"Anglepoise lamp" arm raising in response to light pressure of finger, despite instructions to the contrary.

0 Absent
3 Present

18. Gegenhalten:
Resistance to passive movement which is proportional to strength of the stimulus, appears automatic rather than willful.

0 Absent
3 Present

19. Ambitendency:
Patient appears motorically "stuck" in indecisive, hesitant movement.

0 Absent
3 Present

20. Grasp reflex:
Per neurological examination.

0 Absent
3 Present

21. Perseveration:
Repeatedly returns to same topic or persists with movement.

0 Absent
3 Present

22. Combativeness:
Usually in an undirected manner, with no or only a facile explanation afterwards.

0 Absent
1 Occasionally strikes out, low potential for injury
2 Frequently strikes out, moderate potential for injury
3 Serious danger to others

23. Autonomic abnormality:
Circle: temperature, blood pressure, pulse, respiratory rate, diaphoresis.

0 Absent
1 Abnormality of one parameter (exclude pre-existing hypertension)
2 Abnormality of two parameters
3 Abnormality of three or more parameters

Delusional Diseases

Translator: E. Taub

1 Introduction

Ever since the publication of Esquirol's study on the "monomanias" (Esquirol 1838), monosymptomatic delusional disorders have confronted the psychiatric profession with special diagnostic and therapeutic problems. Paranoia, the "pure" delusional condition, indeed possesses special psychopathological significance, but has not always been able to retain its separate status in relation to the two large categories of the affective and schizophrenic illnesses. After a long history of controversy over the independence of paranoia as a diagnosis, the concept of the delusional disorders has been incorporated into the current diagnostic systems as a rather broad, etiologically nonspecific nosological category, which has, however, been empirically confirmed as valid by numerous family studies and studies of disease course. This review builds on the discussion of paranoid processes by Retterstøl (1987) in the third (German) edition of this text and further presents the findings of more recent research on delusional disorders.

2 Nosology

The following changes with respect to the delusional disorders are evident in DSM-IV (Saß et al. 1996; Kendler et al. 1989) and ICD-10 compared with the earlier diagnostic classification systems:

- *Change of concept.* Kraepelin's etiological conception of paranoia has been replaced by the descriptive designation "persistent delusional disorder" (ICD-10: F22.0). This step was taken not least because of the ambiguity of the term "paranoid," variously used in the past to designate the presence of delusions, a particular delusional content (e.g. persecution), a type of schizophrenia, or a personality disorder. The abandonment of this term also leads to the loss of the concept of paranoia as a specific delusional structure narrowly interwoven with individual development, and to the loss of the corresponding distinction between paranoid and paranoiac processes (Schmidt-Degenhard 1998).
- *Broadening of the category.* The central feature of persistent delusional disorder is the presence of a delusion that is usually systematized and typically confined to a single subject and is not associated with an underlying schizophrenic, affective, or organic illness or with a major impairment of personality. The disorder is thus a monothematic and monosymptomatic delusional psychosis. In DSM-III, the corresponding category was restricted to persecution mania and morbid jealousy, but it has now been extended to include delusions of other, non-bizarre content (megalomania, erotomania, delusions related to the body). The major reason for this innovation was the finding in large-scale, long-term studies in Scandinavia that the particular type of delusional content has no predictive specificity for the outcome of paranoia or schizophrenia (Opjordsmoen and Retterstøl 1987; Retterstøl 1991a,b). The possible types of delusional content thus now include the following:
  a) Delusion of being harmed, persecution mania
  b) Morbid jealousy (Othello syndrome)
  c) Erotomania (Clérambault syndrome)
  d) Megalomania (e.g. inventive mania)
  e) Litigation mania
  f) Hypochondriacal psychosis
  g) Delusional parasitosis
  h) Olfactory delusional disorder
  i) Body-dysmorphic delusional disorder (delusional dysmorphophobia)
  j) Induced delusional disorder (*folie à deux*)
- *Inclusion of hallucinations.* The diagnostic criteria also now include clearly manifest hallucinations, as long as they are not visual or auditory; tactile, olfactory, and other vivid body-associated hallucinations are quite common in some forms of delusional disorder (e.g. delusional parasitosis, olfactory delusional syndrome).
- *Persistence.* The delusional disorder is required to be present for 1 month according to DSM-IV, and 3 months according to ICD-10; when it is present for shorter times, it must be classified as an acute, predominantly delusional psychotic disorder (F23.3). The long-term findings by Opjordsmoen and Retterstøl (1991) and Opjordsmoen (1993) indicate that there is a fairly large subgroup of acute delusional disorders, frequently of reactive origin, which remit within 6 months and do not recur, while patients with delusions lasting more than 6 months can expect a significantly worse course of illness. The authors therefore advocate a division of diagnostic categories according to a 6-month criterion, in analogy to the differentiation made between schizophreniform and schizophrenic illnesses.
- *Residual category.* Finally, ICD-10 lists other or not otherwise specified persistent delusional disorders as a residual category (F22.8, F22.9), as well as induced delusional disorder, the so-called *folie à deux* (F24).

As early as the initial studies by Winokur (1977) and Retterstøl (1966, 1970), it was found that first-degree

relatives of patients with delusional disorders had a frequency of paranoid illnesses only slightly higher than that of the general population. Since then, the nosological independence of the delusional disorders has been confirmed by further family studies (Kendler and Hays 1981; Kendler et al. 1985; Watt 1985), which revealed an elevated incidence of paranoid personality disorders in patients' relatives, but no increased occurrence of schizophrenic or schizotypal disorders, as is found in the families of schizophrenics. For the paranoid psychoses of old age, too, family studies indicate that there is no genetic link to schizophrenia (Howard et al. 1997). The hypothesis of a continuous "paranoid spectrum," ranging from non-paranoid and paranoid schizophrenias to paranoia and paranoid personality disorder (Magaro 1981; Munro 1982), has thus not been confirmed: "Most delusional disorders probably have no link to schizophrenia" (Dilling et al. 1993, p. 103). Despite the frequent occurrence of secondary depressive mood alterations in the course of the delusional disorders, the studies referred to above also provide evidence against their belonging to the class of affective disorders.

3 Etiology

3.1 General Considerations

As already mentioned, the studies available to date fail to provide evidence for any significant role of hereditary factors in the causation of delusional disorders. Neuropathological causes are also usually not found, except in the case of paranoia of old age (see below). According to our present state of knowledge, most cases result from a combination of abnormal personality development, unfavorable environmental conditions, and a triggering situation of conflict; the delusion often bears an understandable relation to these preconditions. Thus a continuous growth of the biographically determined delusional theme is often found through the intermediate stages of an overvalued idea and of a delusion-like reaction to the final stage of an irreversible, chronic delusion.

Two major themes continually recur in studies or descriptions of the primary personality of delusional patients: problems of self-confidence and of self-esteem. Thus most patients have personality disorders, usually of the paranoid or sensitive-narcissistic type (see, e.g. Enoch and Trethowan 1979; Opjordsmoen 1988b). According to Kretschmer (1966), a sensitive character is typified by high demands on oneself and corresponding susceptibility to impairment, with a simultaneous tendency toward introversion and affect retention. This structure is now usually subsumed under the further concept of the narcissistic disorder, which may thus also include delusional patients with rather expansive features. Obsessiveness and rigidity are further features of many delusional patients; these are characteristics that impair the ability to gain distance from oneself and that may promote the development of an overvalued idea.

Most patients can also be presumed to have a fundamental disturbance of self-esteem regulation and insecurity in their social relationships, whether because of genetic personality predispositions or because of developmental impairments in early childhood (Retterstøl 1987). Even in youth, these patients often manifest contact disturbances, inhibitions, affect retention, and tendencies toward distrust and withdrawal; supposed or actual slights are perceived in hypersensitive fashion, and deep-seated feelings of inadequacy are formed, along with resentment of others. Injurious or stigmatizing life experiences and conditions such as physical impairment, forced migration, loss of social class, and minority status may further reinforce such tendencies, even in later periods of life (Tölle 1987; Fuchs 1994a,b, 1998a).

Thus, in comparison to schizophrenic or affective disorders, delusional disorders are particularly prone to appear in individuals of low social and educational status and in immigrants (Kendler 1982). In Winokur's study (1977) of 29 delusional patients, more than half had an intelligence quotient below 90. Further factors favoring the development of delusions include social isolation (e.g. in incarceration psychoses), foreign-language environment, sensory deficits leading to an impairment of communication (Fuchs 1993b), impairment of critical ability and affect processing of organic cerebral causes, and persistent substance abuse (Retterstøl 1966; Munro 1988).

When these conditions are present, the delusional theme may gradually come to the fore or, indeed, appear suddenly. The immediate provoking factor is usually the threatened or actual failure of a central personal concern, such as a sexual or marital conflict, a severe narcissistic insult, shame, or loss of social standing, which can no longer be compensated for. In this situation, the individual abjures personal responsibility by paranoid outward projection ("the others are against me") or by inculpation of his or her own body, nature, or disposition ("my body is against me"). Delusions thus often represent a recognizable, projective, and denying defense against feelings of inferiority and inadequacy, against the feared lack of fulfillment of needs for intimacy and dependency, and even against the individual's own aggressive tendencies, fueled by feelings of resentment and revenge. Projective identification can be seen as a reversal of

shameful and degrading experiences: the supposed malevolence of others is used as a cover for one's own supposed inferiority (blame instead of shame; Morrison 1987).

Kretschmer's conception of the sensitive relational delusional state is still of paradigmatic significance for the psychodynamic interpretation of the origin of delusions, even if this conception is primarily concerned with moral and sexual/ethical conflicts as decisive triggers of the disorder. This type of problem seems to have faded in importance in liberal, pluralistic societies; the sensitive relational delusional state is still very much in evidence in Japan, but has receded into the background in the West and is actually entirely unknown in the United States (Rasmussen 1978). Nonetheless, it may be presumed that the change of social values has redirected the central narcissistic problem of relational delusions onto the theme of physical appearance and attractiveness, so that they now typically manifest themselves as body-dysmorphic disorder or olfactory delusional syndrome. Now as before, the battle for self-esteem seems to be the real theme of most delusional patients, who, by displacing it onto the neighboring battlefield of the delusion, "acquire an unconscious pretext by means of which their potential or supposed defeat in life can be covered up, justified, or indefinitely postponed" (Adler 1927, p. 191).

The functionality of the delusion, seen against this background, consists of a compensation for feelings of inadequacy or rejection (as in erotomania), a conviction of one's own greatness, or an enhancement of one's ability to wage battle against the imaginary opponent, with whom the delusional patient forms a "pseudo-community" (Cameron 1959). To this extent, chronic delusions also imply a self-stabilizing defense against a realistic confrontation with one's own life situation. Thus Roberts (1991) compared 17 patients with systematized delusions to a corresponding group of delusional patients in remission. The actively delusional patients attached a significantly higher degree of meaning to their lives and were less depressive, primarily because of the subjects of their delusions.

3.2 Contributions from Phenomenological Anthropology

Phenomenological anthropological research has also made a major contribution to our understanding of the paranoid disorders by attempting to explain delusions as an abnormality of the fundamental structures of the relationship of human beings to the world (Matussek 1963; Glatzel 1981; Blankenburg 1991, 1992). It is assumed that delusions generally consist not of false ideas about neutral and objectifiable states of affairs, but rather of interpretations and assessments that patients attach to a situation in relation to themselves. Delusional content is thus primarily composed of "second-order realities" (Watzlawick 1988), which cannot be directly and objectively tested. Normal, correct judgments in this area can only be made if the individual is basically familiar with the world and capable of assessing it reliably; in Blankenburg's phrase, the experienced world must possess a natural self-evidence (*natürliche Selbstverständlichkeit*; Blankenburg 1971), with respect both to the individual's relationships with others and to his or her own corporeal nature. Delusional disorders develop precisely in the areas where reliable orientation in our environment depends not on rational knowledge and empirical evidence, but on this type of familiarity with the world and emotional soundness. This basic safeguarding mechanism is lacking in individuals predisposed to paranoia; distrust and control are used in its place.

The paranoid individual is on the alert for possible injuries or malevolence and vigilantly scans his or her environment for signs of threat, deception, or betrayal. His or her social perception is thus directed toward hidden meanings, the possible use of pretenses by others, and the hidden "other side" of their behavior. In ambiguous or limited communication structures (e.g. neighborhood gossip, deafness, foreign-language environment), the uncertainty of social perception rises, and room is left for self-referential interpretations in which the greatest attention is paid to the least conspicuous matters – a fleeting gesture, undertones, or words left unsaid. If the paranoid individual further feels him- or herself to be threatened in a central personal concern, the tension of anxious distrust may become unbearable, until a new consistency is achieved by the construction of a delusional interpretation – the certainty of the contempt, betrayal, or malevolence of others, subjectively experienced as a seeing-through or unmasking of their real nature.

This delusional "insight" reduces the previously overwhelming cognitive-emotional complexity of the situation (Luhmann 1973); the tormenting ambiguity of social perception gives way to a subjective emotional certainty, which, despite its negative meaning, is associated with relief and, not least, with the possibility of taking measures of caution or of opposition. Once constructed, the delusional paradigm progressively establishes itself, both by the self-confirming distorted selection of information and ignoring of contrary evidence and by the patient's self-fulfilling behavior, as when enmity toward the supposedly malevolent others eventually provokes an actual rejection by them.

The essentially ambiguous nature of the second-order realities described above implies that any

subjective assessment of them is necessarily aspect bound and provisional. Social relationships are, therefore, based on constant, mutual reassessment of behavior patterns and their interpretation; to be continued, they required one's own view of the shared situation always to be correctable by that of the other person. It is characteristic of delusional individuals to foreclose the possibility of correction and stand by their own interpretations with apodictic certainty, without any intersubjective modulation, as if they were statements about their own inner states (Spitzer 1989).

In the anthropological literature, this phenomenon is known as the lack of assumption of another perspective (Glatzel 1981; Blankenburg 1991; von Baeyer 1991). A delusional condition can thus be construed as an unsuccessful, surrogate-like encounter with others, which securely shields itself against the possibility of doubt: by refusing to switch perspectives, the delusional individual protects him- or herself from becoming burdened once again by the inner conflicts that have been projected onto others. At the same time, the lack of assumption of another perspective brings the delusional individual into an egocentric position: the notion of being observed or threatened by others arises together with the inability to take the point of view of an uninvolved, neutral third party and thereby eradicate the self-referential, delusional perspective (Fuchs 1994b).

On the linguistic/semantic level, these models are reflected in the theory of concretism, according to which a delusion is to be understood not as a symbolic statement about an intersubjectively constituted state of affairs, but as a non-declarative, as it were "exclamatory" expression by the patient of his or her mental state, in a manner analogous to an interjection such as "Help!" or "Ouch!" (Holm-Hadulla 1982; Spitzer 1989; Mundt 1996). The matter troubling the patient is brought to expression, not as such, but masked, in concretistic fashion (e.g. lack of self-esteem as bodily disfigurement in body-dysmorphic disorder, guilt as sexually transmitted disease in hypochondriacal psychosis). Because the topic can no longer be reformulated in symbolic language, the expression of the delusion is also inaccessible to correction by reasoned argument.

3.3
Cognitive Research on Delusional Disorders

The findings of recent cognitive experimental research on the delusional disorders further add to our understanding of this subject. Patients with delusional disorders have been found to be characterized by abnormal attributive and cognitive styles, which may be demonstrated during the performance of specific tasks. Typically, premature conclusions are drawn from limited, ambiguous, or selectively perceived information; too much certainty is attached to one's own judgment in the assessment of probabilities; there is a tendency to ascribe a special significance to coincidental events; and, finally, unfortunate events tend to be blamed on others (Huq et al. 1988; Bentall and Kaney 1989; Bentall et al. 1991; Garety et al. 1991). This would imply that delusional patients lack the ability to see themselves objectively or to assume an attitude of "healthy skepticism" toward their own judgments and thus cannot put events affecting themselves in an overarching, neutral context – or, as expressed elsewhere (Minkowski 1947; Berner 1978), that the thought processes of these patients are characterized by "the exclusion of coincidence."

Although the tasks performed by the subjects in these studies were not related to the themes of their delusions, it should be borne in mind that these findings need not be interpreted as implying a preexisting vulnerability; they may, conceivably, indicate a feature of the course of the disorder. Nonetheless, these findings help to explain the cumulative origin of uncorrectable convictions: when the capacity for self-questioning and intersubjective correction is absent, social perception enters a vicious circle in which there is a progressively severe distortion of reality. The findings discussed above have now been incorporated into techniques of cognitive therapy in the delusional disorders (see below).

4
Individual Forms

The forms of delusional disorder listed in Sect. 2 may be broken down in terms of their basic areas of reference as follows:

1. Delusions primarily with respect to relationships with others:
   a) Injury, aggression (persecution mania, morbid jealousy, litigation mania)
   b) Self-aggrandizement, grandiosity (megalomania, erotomania)
   c) Shame and rejection (olfactory delusional disorder, body-dysmorphic disorder)
2. Delusions primarily with respect to one's own body:
   a) Delusional parasitosis
   b) Hypochondriacal psychosis

The types of delusional disorder listed under item 1 above have in common that the central experience is often one of shame, inadequacy, or inferiority. This becomes explicit only in subitem (c), while it is made almost unrecognizable by defense mechanisms in the

other two groups – by aggressively toned projections (blame instead of shame) or by self-aggrandizement. The primarily intersubjective reference of these forms of delusional disorder is expressed in the patient's frequent self-referential perceptions and delusional ideas.

Distinct from these forms of delusional disorder are the anxious-hypochondriacal forms, referring to the patient's own body, which are listed in item 2; in these forms, ideas of reference occur only rarely. The patient lacks trust not in other people, but in his or her own body and its functions. Admittedly, the excessive stress placed on the patient's own body is generally secondary to a disturbance of the capacity for interpersonal relationships (Küchenhoff 1985).

This dichotomy implies that not all forms of delusion regarding one's own body should be called hypochondriacal, as is usual in the Anglo-American literature. The hypochondriacal conviction of being ill is hardly the only form of disturbed and alienated corporeality; indeed, in the course of a person's life, very different themes may come to bodily expression, including shame, guilt, inferiority, and fear of death (Fuchs 1992). Body-dysmorphic delusional disorder, a pathological process of the social or "external body," thus has little in common with hypochondriacal psychosis per se. Furthermore, body-dysmorphic delusional disorder usually begins in adolescence, while the forms of delusional disorder primarily relating to one's own body usually begin in middle age or old age (Musalek et al. 1989).

The ensuing description of selected individual forms of delusional disorder is intended as an extension of, and supplement to, earlier treatments of the subject (see especially Retterstøl 1987).

4.1 Morbid Jealousy

Morbid jealousy is, along with persecution mania, one of the commoner delusional disorders (approximately 40% of all cases, according to Winokur 1977; Crowe et al. 1988). It predominantly affects men in late adulthood (Musalek et al. 1989). Only a minority of these patients are alcoholics; the supposed close relationship of this disorder to alcoholism is no longer postulated (Enoch and Trethowan 1979; Soyka et al. 1991). Alcoholic morbid jealousy is no longer counted among the delusional disorders in ICD-10, but rather among the disorders caused by psychotropic substances (F10.5). The differential diagnosis must exclude underlying schizophrenic or organic (e.g. dementing) illnesses.

The delusional theme of jealousy is related exclusively to the patient's partner. The patient is incorrigibly convinced of the partner's unfaithfulness and attempts to obtain evidence for it by constant questioning, checking, spying, and searching of the intimate sphere. This usually leads to severe marital conflicts. Typically, the supposed rival remains a rather obscure figure, and the possibility of "catching the partner in the act" tends to be avoided (Enoch and Trethowan 1979), which reflects the reluctance to confront reality that is inherent in the delusional disorders. Instead, the patient's aggressive impulses are directed entirely against the partner; morbid or delusional jealousy is therefore associated with a particularly high risk of violence, including homicide (Soyka 1992).

Narcissistic, latently insecure, and compulsive-controlling personality traits are thought to be predisposing factors for the development of this type of delusional disorder (Enoch and Trethowan 1979). It is often triggered by persistent partnership conflicts or by failures that are painful for the patient, e.g. in the occupational sphere, which are displaced onto the relationship. Feelings of inferiority and inadequacy, fears of loss (possibly secondary to sexual impotence), and also, not uncommonly, the patient's own repressed tendency toward infidelity are projected onto the partner and typically progress from excessive to delusional jealousy. Morbid jealousy exhibits a typical circular structure of intrusive thoughts, distorted perception, and intense feelings of anxiety or rage; this structure has recently proved accessible to cognitive behavior therapy (Tarrier et al. 1990; Dolan and Bishay 1996).

It can be inferred from the findings of several long-term studies that morbid jealousy has a favorable prognosis in comparison to other delusional disorders and only rarely converts to another type of psychotic illness (Crowe et al. 1988).

4.2 Erotomania

Erotomania (Clérambault syndrome) consists of the conviction that one is loved by another person, generally of higher social status, publicly known or held in high regard, who makes his or her passion known through secret signals or messages. The patients are predominantly women of modest social circumstances, in their fourth to sixth decades, who have not established lasting partnerships. They often pursue the admired person (who is usually married) through innumerable letters, telephone calls, or even public scenes and are not discouraged in these activities even by nearly insuperable obstacles, in accordance with the avoidance of confronting reality that is typical of the delusional disorders (see

Sect. 3.1). These patients succeed in reinterpreting their supposed admirers' acts of rejection, no matter how vigorous they may be, as expressions of love ("tests of devotion" etc.). Legal measures taken by the harassed victim of the delusion lead, not uncommonly, to the patient's involuntary commitment to a psychiatric institution.

The contrast between the generally not very successful, erotically unsatisfied, and lonely existence of the patients and the glamour of their supposed admirers suggests that the essential causative factor of erotomania is narcissistic wish-fulfillment (Segal 1989). In accordance with this hypothesis, these patients usually have an inhibited-sensitive or paranoid primary personality and are often notably physically unattractive (Hollender and Callahan 1975). It should be borne in mind, however, that similar manifestations may appear in the setting of schizophrenia or organic delusional syndromes (Signer and Cummings 1987; El Gaddal 1989). The prognosis of pure erotomania is thought to be rather unfavorable; treatment with neuroleptic medications usually has only a palliative influence on the chronic course of the disorder (Opjordsmoen and Retterstøl 1987). Directed reality confrontation or permanent separation from the loved person may have a beneficial effect (Segal 1989), but in many cases leads merely to a change of the "delusional object."

4.3 Body-Dysmorphic Disorder

Dysmorphophobia denotes the subjective perception of one's own body as ugly or deformed, combined with the conviction that others perceive one's body in the same way. As a rule, the supposed defect is located in a specific, usually exposed part of the body, such as the face, ears, nose, jaw, teeth, hair, etc., but it may also be in the limbs or genitalia. These patients develop ideas of reference, imagine that they are being discriminated against or ridiculed by others, and withdraw increasingly from social contact. They consult plastic surgeons, otorhinolaryngologists, or dentists and importune them for an operation that will change their appearance.

The designation "phobia" indicates the close relationship of this syndrome to the social phobias; in view of these patients' environmental anxieties and disturbed contact behavior, the rejection of this previously used term by DSM-IV and ICD-10 is not necessarily appropriate. The new division into separate categories (F45.2: body-dysmorphic disorder; F22.0: somatoform delusional disorder) is not in line with clinical experience, which suggests a continuum extending from excessive preoccupation with one's own appearance, to a neurotically overvalued idea, to the delusional certainty of one's own deformity (Phillips 1991). The assignment of delusional disorders to the category of the schizophrenias, as was customary in the past (Zaidens 1950; Connolly and Gipson 1978), has no proponents today, even if the dysmorphophobic syndrome, like obsessive-compulsive manifestations, can be conceived of as a defense against further psychotic disintegration. Bizarre delusional ideas about physical changes or experiences of being physically influenced from without are evidence for an underlying schizophrenic illness; moreover, dysmorphophobic convictions may also appear in the context of the affective disorders. The classification of the milder forms of dysmorphophobia, however, is still ambiguous in the current systems of classification.

In psychodynamic terms, the connection to the themes of shame and self-esteem is evident; it is a matter of showing oneself and being seen by others. Excessive observation of oneself and an idealized conception of beauty, combined with feelings of inferiority and contact anxieties, characterize these patients (Küchenhoff 1984). As one would expect, sensitive-narcissistic, insecure, and compulsive personality disturbances are also often found in this patient group. The initial manifestation usually appears, not surprisingly, in adolescence, when the individual's body image, concept of self, and interpersonal relationships all come to a crisis. In this situation, the projection of deep-seated feelings of inadequacy, particularly sexual inhibitions, onto a biological bodily defect may perform a self-protective function (Fuchs 1993a): it frees the individual from the need for confirmation, e.g. in competition for partners, and allows negative aspects of the self to be concretized and externalized in a single part of the body, a *pars pro toto* that becomes accessible to repair by cosmetic surgery.

Body-dysmorphic disorder usually takes a chronic course lasting several years or decades and is associated with an elevated risk of suicide (Phillips 1991). Surgical intervention can be expected to produce an improvement, if at all, only in milder forms of the disorder and should be firmly discouraged in more severe forms: when surgery is performed, patients often continue to complain of the supposed deformity because of unrealistic expectations from surgery, or else the symptom migrates to another part of the body, because the underlying conflict concerning the patient's self-esteem remains unresolved (Hay 1970; Andreasen and Bardach 1977; Strian 1984). A marked affective or compulsive component, however, calls for the application of serotonin reuptake-inhibiting antidepressants, which have been repeatedly reported to yield good results (Hollander et al. 1989; Phillips

1991), while the outcome of neuroleptic therapy is usually unsatisfactory.

4.4 Olfactory Delusional Disorder

Olfactory delusional disorder is characterized by the conviction that the sufferer emits a repellent odor (e.g. of sweat, bad breath, or flatus). The primary experience is mainly in the area of perception, i.e. there are abnormal olfactory sensations which, however, are experienced in an "environmentally dependent" fashion, usually only in the presence of other people. There are corresponding ideas of reference, in which words or actions of others that are insignificant in themselves are interpreted as expressions of disgust and aversion. These patients combat the supposed odor by washing or applying perfume, without success; they usually resort to a more or less total social withdrawal. They not uncommonly develop hypochondriacal explanatory delusions of odor-producing diseases of the skin or gastrointestinal tract (Gattaz and Haas 1982).

Olfactory phobia and olfactory delusional disorder have received the greatest amount of attention in psychopathology in Japan, where Morita (1947) grouped them together with dysmorphophobia, erythrophobia, and eye contact phobia as *taijin-kyôfu* syndrome ("fear of mankind," or anthropophobia). The common features of these disorders are the underlying feeling of shame and inferiority, the manifestation of ideas of reference and contact phobia, and social withdrawal (Yamashita 1993; Kimura 1995). Morita believed that the basis of the syndrome lay in the so-called *shinkeishitsu* personality ("constitutional nervous temperament"), characterized primarily by introversion, hyperreflectivity, neurasthenia, and disturbance of self-esteem, and developed a specific form of treatment known as Morita therapy (Kora 1999).

Because olfactory hallucinations also appear frequently in the settings of depression and schizophrenia, these differential diagnoses must be considered (Malasi et al. 1990). The presence of a pure delusional disorder is supported by the development of the delusion on the substrate of a sensitive-narcissistic personality and an existing relationship conflict, with experiences of inadequacy, insult, or exclusion. The perceived inferiority and self-contempt are concretistically projected by the delusion onto the physical sphere, aided not least by the special relationship of the sense of smell to emotional atmospheric experiences, sympathy, and antipathy. Such delusional conditions have a continuous transition into neurotic developments with delusion-like reactions, which are more accessible to psychotherapeutic intervention (Moesler 1992).

4.5 Delusional Parasitosis

Delusional parasitosis, first described by Ekbom (1938) under its German name *Dermatozoenwahn* ("dermatozoal delusion" or epidermozoophobia), consists of the unshakable certainty of being infested by intra- or subcutaneous parasites, usually accompanied by itch. These patients often subject themselves to extensive grooming rituals and bring small collections of skin particles to dermatological clinics or government health departments requesting that they be studied for the presence of parasites ("match-box sign"). The affected individuals, usually women in their fifth to seventh decade, feel severely tormented and socially stigmatized by their supposed condition. Tactile sensations (itching, paresthesia) are a major feature of this delusional disorder, for which the name "chronic tactile hallucinosis" has also been suggested (Bers and Conrad 1954), but they are not always present. A comparative study revealed that delusional patients with tactile phenomena, compared to non-delusional patients with tactile phenomena of other origin, were more often socially isolated and less frequently married, placed higher hygienic demands on themselves, and more commonly had a history of dermatological and mental illness (Musalek 1991).

The nosology of this delusional syndrome has always been particularly difficult; it has been found in association with practically all types of underlying illness. In the diagnostic study carried out by Musalek et al. (1990), approximately 40%–50% of all cases were attributable to organic delusional disorders, usually secondary to arteriosclerosis; Marneros et al. (1988) found this figure to be as high as 70%. Rarer entities to be considered in the differential diagnosis include cocaine- or amphetamine-induced psychoses ("cocaine bugs"), vitamin B_{12} deficiency, diabetes mellitus, lymphoma, and uremia accompanied by pruritus (Morris 1991). The supposed parasitic infestation may also be a delusional expression of feelings of guilt or punishment in the setting of melancholia, while a paranoid attribution of the infestation to another person (contamination delusion) is indicative of schizophrenia. Thus only a minority of cases can be considered pure delusional parasitosis. These cases are usually in the setting of a compulsive personality structure and social isolation. The partners of these patients relatively frequently develop an induced delusion (*folie à deux*) (10%–20%; Musalek and Kutzer 1990).

The prognosis of delusional parasitosis is relatively favorable: intensive application of pharmacological, psychotherapeutic, and sociotherapeutic measures leads to improvement, or even remission, in two thirds of these patients (Musalek 1991; Trabert 1993).

4.6 Hypochondriacal Psychosis

The concept of monosymptomatic hypochondriacal psychosis (Munro 1988) has been used to subsume several disorders, such as olfactory delusional disorder, delusional parasitosis, and body-dysmorphic delusional disorder, that are treated as distinct in this review. As mentioned above, however, the term should be reserved for the hypochondriacal delusional disorders per se, corresponding to the earlier "paranoia hypochondriaca" (Serieux and Capgras 1909), in which patients imagine that they are suffering from an incurable or fatal illness. Hypochondriacal psychosis must also be distinguished from neurotic hypochondriases, which present as diffuse states of ill-being or neurasthenic exhaustion and in which the fear of suffering from a physical illness does not have the same uncorrectable character (Dilling et al. 1993). The so-called circumscribed hypochondriases may, however, assume a character similar to that of a delusion (Hallen 1970); they are characterized by persistent abnormal sensations and foreign-body sensations in particular areas of the body, e.g. in the mouth, which often lead these patients to consult dentists or otorhinolaryngologists.

The affected patients are distinguished by the persistence with which they demand radical diagnostic and operative procedures, usually from multiple physicians. There are often painful dysesthesias in several organ areas, in the skin, or in the sense organs; when these are especially bizarre, the differential diagnosis of coenesthetic schizophrenia should be considered. On the other hand, the fact that the delusion concerns the patient's own state of health, rather than features of the external environment interpreted with reference to the self, suggests the possibility of a depressive disorder, and hypochondriacal delusions may indeed often persist at attenuated levels after the actual depressive phases have passed. It may also be necessary to exclude underlying disorders such as pernicious anemia, uremia, lead poisoning, endocrine diseases, or cerebrovascular disease by specific diagnostic testing, even though this may reinforce the patient's fixation on a somatic cause.

Hypochondriacal psychosis, like hypochondriacal syndromes in general, is typified by a loss of confidence in the corporeal basis of existence and an attitude toward the environment narrowly centered on bodily complaints. The patients' primary personality often exhibits anancastic features and a tendency toward somatization (Munro 1988). The overemphasis of the body is an expression of a loss of the capacity for interpersonal relationships; against this background, the demanding, hostile, and disempowering behavior of these patients toward physicians is to be seen as a surrogate for interpersonal relationships (Fuchs 1992; Küchenhoff 1985). The content of the delusion is not uncommonly of a sexual nature (delusional syphilis or AIDS; Mahorney and Cavenar 1988); this may indicate a sensitive or erotic-conflictual experiential reaction as the origin of the illness. If the disorder takes a chronic course, as it usually does, the frequently occult depressive mood alterations should be watched for, as these are accompanied by an elevated risk of suicide (Bebbington 1976; Opjordsmoen 1988a).

4.7 Delusions Accompanying Physical Impairment

Delusions as consequences of actual physical impairment must be distinguished from hypochondriacal and body-dysmorphic delusional themes. Gaupp (1942) first described such delusions in the case of a teacher named Hager, who felt that he was no longer taken seriously by others, especially women, after an amputation in the war, developed a progressively severe persecution mania, and finally killed a young woman. According to Tölle (1987, 1993), it is primarily amputations and other invasive operations, deformities, or illnesses that lead to social disadvantage and discrimination and are therefore perceived as shameful deficiencies. The resulting delusion of interpretation (delusion of being harmed), which not uncommonly remains hidden for very long periods, bears an important projective, ego-sparing function and is thus in keeping with the etiological concepts presented in Sect. 3.1 above. Clearly, a psycho-organic disturbance of information processing and critical ability plays an additional role in many cases.

4.8 Delusional Disorders in Old Age

Paranoia beginning at age 60 or above occurs with a prevalence of approximately 1%–2% (Christenson and Blazer 1984). Typical delusional contents include those of injury, threat, or persecution by people near the patient's home, although fantastic or confabulatory delusional contents are not uncommon. The nosological classification of the disorders first described by Kay and Roth (1961) as late paraphrenias remains controversial; the existence of a continuous spectrum of transitional forms, from pure delusional disorders with or without hallucinations to unambiguously schizophrenic phenomena, makes it impossible to differentiate delusional disorders of old age with certainty from late-onset schizophrenia (i.e. arising between the ages of 40 and 60) or to establish a clear

diagnostic distinction between schizophrenic and delusional disorders (Howard et al. 1994; Riecher-Rössler et al. 1995). In ICD-10, senile paranoia is assigned to the delusional disorders (F22.0); the presence of persistent auditory hallucinations constrains a classification as persistent delusional disorder of other type (F22.8), as long as the criteria for schizophrenia are not fulfilled (Dilling et al. 1993).

Independently of these problems of classification, certain risk factors and provoking conditions for the onset of dementia in old age have been repeatedly described:

- Female sex (female-to-male ratio typically 7:1; Almeida et al. 1995).
- Paranoid or schizoid premorbid personality traits (Kay et al. 1976; Fuchs 1998b).
- Social isolation (Naguib and Levy 1987; Almeida et al. 1995), in accordance with Janzarik's (1973) concept of contact deficiency paranoia.
- Sensory impairment, particularly deafness (in as many as 40% of cases), which may favor a paranoid misperception of social situations (Cooper et al. 1974; Fuchs 1993a).
- Discriminating, injurious, or threatening life events such as forced migration from one's homeland (in as many as 50% of cases), birth out of wedlock, physical impairments, etc. (Fuchs 1994a, 1998a).
- Mild cognitive disturbances that often can be detected only by neuropsychological assessment; patients with pure delusional disorder tend to have more severe cognitive deficits than those diagnosed as schizophrenic (Naguib and Levy 1987; Howard et al. 1994).

Studies using computed tomography and magnetic resonance imaging have demonstrated organic brain disturbances in a majority of patients; patients of this type generally belong to the category of delusional disorders without schizophrenic manifestations of the first rank (Förstl et al. 1991; Howard and Levy 1992). It is therefore assumed that at least a large fraction of senile paranoid illnesses are caused in part by neurodegenerative processes. This finding is of comparable significance to that of the mainly temporal and prefrontal cerebral abnormalities often found in younger schizophrenics, which probably reflect a disturbance of central nervous system maturation (Häfner 1997).

The course of the senile paraphrenias is usually chronic, although hospitalization is only rarely required. In the study by Howard and Levy (1992) of 64 patients, one third responded partially, and one quarter completely, to long-term neuroleptic treatment. The most effective form appeared to be a depot medication in a rather low dose (e.g. 14 mg fluphenthixol or 9 mg fluphenazine decanoate every 2 weeks). Nonetheless, even when neuroleptic therapy is effective, patients rarely gain insight into their illness. Most patients require permanent maintenance therapy (for a review, see Eastham and Jeste 1997).

5 Therapy

Building a relationship of trust is the indispensable foundation of successful treatment, regardless of what further measures are taken, and this is especially true for the delusional disorders. The physician must thus avoid a direct confrontation with reality, at least at the beginning, but should also take care not to render additional support to the patient's delusional system by an excess of benevolent understanding or even assent.

5.1 Somatotherapy

There is a serious lack of empirical studies, particularly controlled studies, which is not surprising in view of the deficient insight and compliance of this group of patients. There are, however, a number of relatively frequently replicated observations that may be of heuristic value in individual cases. Neuroleptic therapy is often only moderately successful, but if a therapeutic relationship of trust is present, a treatment should be attempted in all cases, at adequate doses and over a sufficiently long period of time. This may be justified to the patient by explaining that the purpose of medication is to heighten inner stability and to protect against the stresses caused by the (supposed) threats or injuries. Despite such assurances, however, the medication itself or any side effects that may occur are not infrequently viewed by the patient in paranoid fashion.

In a number of studies involving relatively few patients, pimozide at a dose of 2–6 mg was found to be an effective agent (Munro 1984, 1988; Pollock 1982; Kaschka et al. 1991); a combination of clomipramine and pimozide may also be useful in depressively colored delusional syndromes (Chiu et al. 1990). Nonetheless, it has not been demonstrated that these agents are fundamentally superior to other highly or intermediately potent neuroleptics. Pimozide may also have cardiotoxic effects in therapeutic doses, which may restrict its indications, particularly for older patients.

The frequent association of delusional disorders with latent or manifest depressive mood alterations (64% according to Munro 1988; 51% according to Marino et al. 1993) makes it seem reasonable to try

antidepressants in many cases. In particular, in both delusional and non-delusional dysmorphophobia, serotonin reuptake inhibitors have been found to be effective in as many as two thirds of all patients (Philips 1996).

5.2 Psychotherapy

Psychotherapeutic approaches to the treatment of delusions have aroused interest only in recent years (Torch and Bishop 1981; Teusch et al. 1987; Nelki 1988; Mundt 1996). A durable, long-term relationship of trust is basic to any psychotherapeutic treatment of delusional patients. According to Mundt (1996), focusing directly on the delusion should therefore be avoided whenever possible, and explorations in this direction should not be too frequent. Instead, the delusional theme should be circumvented and thereby deactualized, in a manner similar to behavior-therapeutic extinction. If treatment is based on the conception that the delusion is a concretistic manifestation of a central life concern that has come turned badly for the patient (see Sect. 3.2), then the therapist's task is to direct his or her efforts to the concern underlying the delusion, without naming it as such. An interpretation of the delusion that is unacceptable to the patient should thus be avoided. Instead, the promotion of new experiences in emotionally neutral fields, and acceptance of the patient by the therapist, can implicitly and covertly help to satisfy the patient's existential needs (e.g. for contact and esteem).

It is important in both the pharmacological and the psychotherapeutic treatment of delusional disorders to recall their compensatory function, i.e. the safe removal of topics that cannot be otherwise processed by means of projection or grandiosity. Structural deficits often manifest themselves as depressive syndromes provoked by a sense of emptiness and loss of meaning when the delusion remits, particularly after successful treatment. The treatment should therefore be directed toward topics of practical importance for the patient's life, the mobilization of resources and preserved abilities, and the recognition of the patient's coping capacity, so that the stabilizing function of the delusion can be replaced by a gradual strengthening of the ego. Once this process is in place, reality confrontation can slowly begin.

When this stage is reached in patients with delusions, or in milder cases with overvalued ideas, cognitive therapy strategies employing directed experiments in perception and behavior may be beneficial; such strategies are currently being developed and tested in connection with cognitive theories of the origin of delusions (see Sect. 3.2). Although the cognitive approach at first seems contradictory to the principle of not arguing with the patient, it can be carried out using careful strategies of circumvention and has been reported to influence the course of the illness favorably in as many as half of all patients (Chadwick and Lowe 1990; Kuipers et al. 1997).

6 Course

Ever since Kraepelin's time, delusional disorders have been held to be chronic, nearly irreversible diseases: "No case of genuine paranoia ever comes to a cure" (Kraepelin 1899). Yet Retterstøl and Opjordsmoen, in their partly prospective, partly retrospective long-term studies of a total of 334 patients, were able to document a much more favorable prognosis of the paranoid psychoses, including the pure delusional disorders. In the study by Opjordsmoen (1988b) of 41 patients with delusional disorders (according to DSM-III-R) followed up after an average of three decades, 15 (37%) had gone into remission. Patients with delusional disorders also differed significantly from schizophrenics with respect to coping with life: they were more frequently married (76% vs. 47%), more frequently had children (73% vs. 37%), and were more frequently employed (46% vs. 26%). Even among 26 patients with classical paranoia in the narrow sense, Retterstøl found that more than one third had gone into remission (Retterstøl 1991a,b). This accords with the finding by Winokur (1977) of a social cure in one third of patients after several years of follow-up; 60% worked in their occupations, and 53% lived in stable marriages. It is to be hoped that the prognosis of the delusional disorders will improve still further as newer, more effective forms of treatment are developed.

Cycloid Psychoses and Their Differentiation from Affective and Schizophrenic Psychoses

Translator: E. Taub

1 Introduction

An understanding of the causes, prevention, treatment, and rehabilitation of the endogenous psychoses has been a major goal of research for decades, not only in psychology and the allied humanities, but also in biology and the natural sciences. Nonetheless, despite the tremendous progress of basic science research, knowledge in this area has remained sparse. The slow pace of developments in this field is frequently attributed to the genetic heterogeneity and multifactorial etiology of the endogenous psychoses, yet efforts to identify valid subgroupings of these diseases are still being made today.

Leonhard's (1999) concept of the cycloid psychoses can be traced back to the historical beginnings of scientific clinical psychiatry. This group of diseases is well characterized clinically, narrowly circumscribed, and reliably diagnosable. In the following sections, the heuristic significance of the cycloid psychoses will be discussed on the basis of both older and newer research findings.

2 Exceptional Position in Psychiatric Nosology

By subdividing the endogenous psychoses into manic-depressive disorders and dementia praecox, Kraepelin (1898, 1923) seemed at first to have introduced a certain order into the chaos that had previously reigned in the classification of mental illnesses. Psychoses with a favorable long-term prognosis were assigned to the group of manic-depressive disorders, while those with an unfavorable long-term prognosis were termed dementia praecox. Nonetheless, it was often impossible to determine the long-term prognosis of a psychosis from its momentary clinical manifestations, and it was found that psychoses resembling each other in the initial stages could either partly regress or result in more or less severe states of mental deficiency.

Kraepelin's concept of dementia praecox was, therefore, soon replaced by that of schizophrenia, or "splitting insanity" ("*Spaltungsirresein*"). Bleuer introduced a new designation, "the group of schizophrenias," with the following rationale:

It soon became clear ... that many diseases that could not be distinguished, in their psychopathological appearance, from psychoses leading to 'imbecility,' have a good prognosis, as does manic-depressive insanity. A term needed to be devised that would link together the disease forms with like symptomatology, even though some of them end in recovery, others in mental deficiency, and yet others in imbecility (Bleuler 1911, p. 47).

Bleuler's concept of schizophrenia has remained current until the present day, although it met with criticism from the beginning (Gruhle 1932) and has proved to be less than fully adequate for the purposes of either clinical practice or research. In this context, Schneider's famous remark on the diagnosis of schizophrenia seems to express resignation on his own part:

Among the numerous varieties of experience [i.e. disease manifestations] that arise in schizophrenia, there are some that we call symptoms of the first rank, not because we think of them as fundamental disorders, but because they have special importance for this diagnosis, in distinction to either nonpsychotic mental abnormalities or cyclothymia. Their value is, therefore, only with respect to diagnosis. Nothing is thereby said about the theory of schizophrenia. ... Wherever such varieties of experience are determined to exist, and no underlying physical diseases are to be found, we speak in all modesty of schizophrenia (Schneider 1967, p. 135).

Kurt Schneider's "atheoretical" view is also that of the currently used operationalized classification schemes, which are revised at regular intervals in accordance with expert polling and consensus and are intended to produce high interrater reliability, as they indeed do, though not uncommonly at the expense of clinical validity.

Independently of this development, Leonhard (1999) continued to pursue the type of clinically and empirically oriented research initiated by Kahlbaum (1863) and Kraepelin. Building on the earlier work of Wernicke (1900) and Kleist (1926), he created a differentiated nosology of the endogenous psychoses that went far beyond Kraepelin's prognostic dichotomy. Leonhard subdivided the two major groups of disease into further, nosologically independent diseases, on the basis of longitudinal studies, some of which extended over the patients' lifetime (Fig. 1).

As Fig. 1 makes clear, it must have been mainly the cycloid psychoses that led Bleuler to abandon prognostic diagnosis. These "atypical psychoses" fell into the manic-depressive disease group of Kraepelin, but they belong to the schizophrenic group according to Bleuler, Schneider, and the modern operationalized classification schemes (APA 1994; WHO 1991), because patients present with symptoms typical of schizophrenia in the momentary clinical view.

Fig. 1. Prognostic dichotomy of the endogenous psychoses

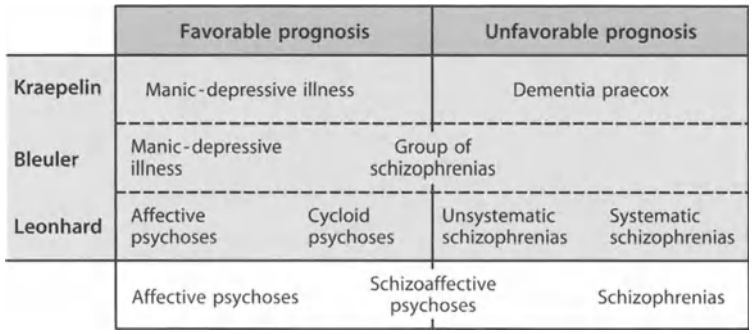

Table 1. Kraepelin's manic-depressive group of illnesses as subdivided by Leonhard (1999)

Phasic monopolar affective psychoses		Bipolar phasic psychoses	Cycloid psychoses
Pure mania	Pure melancholia	Manic-depressive disease	Anxiety-happiness psychosis
Monopolar euphorias	Monopolar depressions	–	Motility psychosis
–	–	–	Confusion psychosis

Table 2. Bleuler's group of schizophrenias as differentiated by Leonhard (1999)

Cycloid psychoses	Unsystematic schizophrenias	Systematic schizophrenias
Anxiety-happiness psychosis	Affective paraphrenia	Systematic paraphrenias
Motility psychosis	Periodic catatonia	Systematic catatonias
Confusion psychosis	Cataphasia	Hebephrenias

Table 1 shows Leonhard's differentiated subdivision of Kraepelin's manic-depressive group of diseases, and Table 2 shows Leonhard's differentiation of Bleuler's "group of schizophrenias."

3 Clinical Aspects

The bipolar cycloid psychoses had already been distinguished from manic-depressive illness and the schizophrenias as a nosologically independent group of diseases by Kleist (1926) and by Fünfgeld (1936), but Leonhard was the first to lay down precise symptomatological criteria for their accurate diagnosis. He distinguished three clinical forms:

- Anxiety-happiness psychosis
- Excited-inhibited confusion psychosis
- Hyperkinetic-akinetic motility psychosis

The characteristic manifestations of these individual subtypes are detailed in Tables 3–5, and three brief case presentations will serve to illustrate them:

1. *Anxiety-happiness psychosis.* The patient first became ill at the age of 27. She was referred to a psychiatric clinic with the diagnosis of "paranoid-hallucinatory psychosis." On admission, she was tense and very mistrustful and had no insight into her illness. She complained of fatigue during the day and derealization phenomena. She stated that she had been feeling happy at times, but very anxious at other times, for 4 weeks. She was discharged in an asymptomatic condition after a 1-month inpatient stay. One year later, she was hospitalized a second time when she suddenly ran around naked, said she was afraid of being poisoned, and told her husband to look her in the eye, because she was God. During the psychiatric examination on admission, she was very lively and alert. She said that she felt the power of God within herself and believed that all people would love each other from now on and that there would be no more war. This time, too, she was discharged in good health, but she soon required rehospitalization because she had developed the delusion that she was both God and "the archangel" and had attempted to prove it by laying her hand on a hot stove. Her mood in the hospital alternated between elevated and anxious, and she had

Table 3. Manifestations of anxiety–happiness psychosis

Anxiety pole	Happiness pole
Severe anxiety with ideas of reference and delusional perceptions	Ecstatic mood with ideas of mission, happiness, and salvation
Anxious, paranoid ideas of being threatened, persecuted, and annihilated	Affect-congruent illusions and hallucinations (often as visions)
Affect-congruent illusions and hallucinations	Ecstatic facial expression, pathetic movements and gestures
Anxiety-colored physical misperceptions	–
Ideas of self-sacrifice for the salvation of others	
Rapid fluctuations between anxiety and happiness	

Table 4. Manifestations of excited–inhibited confusion psychosis

Excited pole	Inhibited pole
Incoherent thoughts with logorrhea	Inhibition of thought with perplexity
Incoherent choice of subject (digressiveness)	Perplexed ideas of significance (delusional perceptions)
Transient misidentification of persons	Delusions of interpretation with perplexity
Delusions of interpretation	Illusions and hallucinations
Transient hallucinations	–
Anxious and ecstatic fluctuations of mood, of much lesser intensity than in anxiety–happiness psychosis	

Table 5. Manifestations of hyperkinetic–akinetic motility psychosis

Hyperkinetic pole	Akinetic pole
Increase of expressive and reactive movements	Loss of expressive and reactive movements
Senseless, purposeless compulsive movement	Flaccid or rigid akinesia
Severe distractibility by environmental stimuli (hyperreactive distractibility, hypermetamorphosis after Wernicke)	Slow, sluggish or absent voluntary movement
Occasionally incoherent speech	Loss of spontaneous speech, up to mutism
Illusions, hallucinations, and delusions of interpretation	
Rapidly alternating affect (elevated–anxious–irritated–depressed)	

delusions of interpretation and poverty delusions. She again recovered completely. The next phase of the illness occurred when she was 36 years old. This time, she expressed multiple ideas of a religious nature, claiming, among other things, that the Pope had appeared to her. She then complained again of severe anxiety, fearing that a world war and the end of the world were approaching. After discharge, she remained healthy and able to manage her household for 6 years. She became ill again at age 42, when she developed severe anxiety and felt threatened and persecuted by a man in her neighborhood. She also heard threatening voices. This time, too, she was discharged in good condition and had good insight into her illness.

2. *Confusion psychosis.* The patient was first hospitalized at age 17 because of a depressive mood disturbance. After being discharged, he passed an examination for a sales position. Three years later, he occasionally became very depressed and spoke extremely little. He was hospitalized a second time at age 23. He was anxious and had severe cognitive inhibition. He had recovered fully by the time of discharge. One year later, he had to be rehospital-

ized because of "thoroughly disordered" thinking associated with a "cheerful and silly" mood. Over the course of the hospital stay, times of excitement, in which he continuously "talked nonsense," alternated with states of perplexed inhibition. He regained mental balance and was discharged. In the ensuing years, he was hospitalized repeatedly. A severe formal cognitive disorder was always at the center of the psychopathology. Frequently, there was logorrhea of incomprehensible and incoherent content. On the other hand, there were also repeated occurrences of severely inhibited, perplexed, mutistic states. His mood was either euphorically elevated or depressed and anxious. Threatening, frightening voices and misidentification of people occurred at varying degrees of severity. He was well between the individual disease phases and was able to assist his elder brother with farm work.

3. *Motility psychosis.* This patient first became ill at age 19. She made "silly, clownish" gestures, stood in place with a facial expression of "quiet rapture," and held her hands, arms, and trunk in "peculiar, bizarre postures." She suffered from auditory hallucinations and sometimes misidentified people. According to her hospital record, she lay in bed moving her arms about constantly and waved her upper body and head back and forth "with a certain degree of grace." She continually repeated words that she heard being spoken around her. Later, she was "silly and in high spirits" and constantly in motion, threw slippers and pillows all over the place, and poured coffee on the floor. After 4 months, she was calmer and was discharged in good condition. Three years later, she became ill again. This time, according to the hospital record, she threw herself back and forth in bed and made noises expressing pleasure. There were accompanying auditory and visual hallucinations. On being discharged 3 months later, she was well again. There were six more inpatient hospitalizations until she reached the age of 60. Psychomotor abnormalities were prominent during all of these. The daily progress notes document, among other things, that she breathed in a mannered fashion and twitched in a comical, clownish way whenever she was touched. She displayed considerable psychomotor agitation, and she sang in a high soprano pitch. She spoke confusedly, with logorrhea, and was in a state of psychomotor excitation; she slammed doors, her face was rigid like a mask, and all of her movements were slowed. She always recovered fully between phases. On an outpatient visit at the age of 64, she was found to be mentally balanced, friendly, and able to modulate her affect. She had been widowed shortly before and lived alone in a well-kept detached house.

All three subtypes of cycloid psychosis are characterized by bipolarity, a phasically remitting course, and a lack of residual mental abnormalities. Leonhard conceded that a certain degree of impairment of internal energy might develop after multiple phases and hospitalizations, but considered this to be a reactive phenomenon. Several more recent studies have confirmed that the long-term prognosis is favorable (Beckmann et al. 1990; Maj 1990; Perris 1974).

These diagnoses are made in accordance with hierarchical clinical conceptions, and each of them has its own characteristic manifestations. If these manifestations are lacking, the diagnosis must be questioned. The diagnosis of a cycloid psychosis according to Leonhard is, in this sense, highly operationalized (as are all of Leonhard's diagnoses). After careful observation for a sufficiently long time, a precise diagnosis of one of the subtypes can usually be made. Leonhard repeatedly stressed that the illness of a given patient belongs to the overall group of cycloid psychoses only insofar as it can be confidently and precisely diagnosed as one of the recognized subtypes and that it is therefore not sufficient to diagnose a case of "cycloid psychosis." Misdiagnoses are particularly likely to occur if a diagnosis is constructed out of incomplete syndromes or if a diagnosis of cycloid psychosis is made only because the course is favorable.

As the above remarks will have made clear, the grouping together of diagnostic criteria into an overall complex called "cycloid psychosis," as was advocated by Brockington et al. (1982) and, in fact, carried out in ICD-10 under the synonymous term "acute polymorphic psychotic disorders," leads to a loss of clinical validity. The cycloid psychoses as originally described by Leonhard are found in all diagnostic categories of the operationalized classification systems, depending on their particular manifestations (Franzek et al. 1996; Franzek and Beckmann 1998a,b) and, despite some overlap, are not identical to any of the defined categories; in particular, they are not identical to the schizophreniform psychoses of DSM-III and DSM-IV or to the acute transient psychotic disorders of ICD-10 (Franzek et al. 1994; Pfuhlmann 1998).

4 Important Considerations in Clinical Practice

Ever since Bleuler's time, the diagnosis of schizophrenia has been associated with an uncertain prognosis. Neuroleptic prophylaxis is therefore recommended for nearly every case of psychosis with schizophrenic symptoms, not limited to acute psychotic episodes (DGPPN 1998). We know from our own clinical experience, however, that neuroleptic phase

prophylaxis often fails to prevent relapses of the cycloid psychoses. Perris (1978, 1986) stated emphatically that neuroleptics are useful for the acute therapy of cycloid psychoses, but he also found that they were significantly less effective than lithium when administered chronically for phase prophylaxis. Indeed, it was the effectiveness of lithium for relapse prevention in affectively colored intermittent psychoses with schizophrenic manifestations that led to the removal of these entities from the broad group of schizophrenias as defined by Bleuler and contributed to the ascendance of the term "schizoaffective psychoses," a vague diagnosis of little clinical utility.

A question for future study is whether low doses of "atypical" neuroleptics of the current generation, which have considerably fewer side effects, might be superior to classical neuroleptic treatment for phase prophylaxis or relapse prevention in the cycloid psychoses. Comparative studies with lithium, carbamazepine, or valproate would be desirable.

Franzek et al. (1994) reported that both malignant neuroleptic syndrome and life-threatening catatonic syndrome tend to occur preferentially in the course of cycloid psychoses, especially motility psychoses. Careful analysis of their own data and of the extensive literature on the subject led these authors to postulate that these two syndromes, when they complicate the course of acute cycloid psychoses, are very likely to be identical. They therefore recommend that no time be wasted on the pointless task of differential diagnosis, that neuroleptics be discontinued as the first step in the treatment of every patient, and that all other necessary therapeutic measures be initiated immediately afterward. The authors warn that the continued administration of highly potent neuroleptics, on the assumption that the patient's condition is the result of pernicious catatonia, will not only fail to improve this syndrome, but will actually make it worse.

Lastly, it is a great relief when a good prognosis can be delivered, and such is the case in postpartum psychotic illnesses, the great majority of which are cycloid psychoses (Pfuhlmann et al. 1998). The psychological comfort that a good prognosis affords the patient's entire family is inestimable.

5 Research Findings

Leonhard himself repeatedly stressed that a hereditary predisposition to disease plays only a small role in the cycloid psychoses. In his family studies, he found that only 4%–5% of patients' first-degree relatives were affected with these conditions – a figure considerably smaller than those for manic-depressive illness (20%–21%) and the unsystematic schizophrenias (13%–22%), which are more clearly hereditary. Only the figure for the systematic schizophrenias was lower (2%–4%) (Leonhard 1999).

New family studies performed to a high methodological standard have since confirmed a number of Leonhard's findings. Affective psychoses were found in 6.6% of the first-degree relatives of patients with cycloid psychoses, while there were no cases of schizophrenic psychoses in these families (Franzek and Beckmann 1998b). More than 20% of the first-degree relatives of patients with periodic catatonia (a clinical subgroup of the unsystematic schizophrenias) were similarly affected, while fewer than 5% of the first-degree relatives of patients with systematic catatonia had that condition (Beckmann et al. 1996; Stöber et al. 1995, 1997).

Another focus of recent investigation is the question of the relative importance of genetic and environmental factors in the causation of the cycloid psychoses. Twin studies, in which pairs of twins with at least one affected member are systematically recruited, are the most appropriate method for addressing this issue, but such studies are rarely performed today because of their strict methodological requirements.

The classical twin-study method is based on a comparison of monozygotic and dizygotic twin pairs and assumes that both kinds of twins are subject to the same environmental influences. According to Galton's rule, which remains valid today, heritability is implied if monozygotic twins are concordant for a particular trait more often than dizygotic twins. Conversely, monozygotic and dizygotic twins should not have significantly different rates of concordance and discordance for nonheritable traits. All phenotypic differences between monozygotic, and therefore genetically identical, twins are assumed to be due to environmental factors. Twin studies must always take possible complications of pregnancy and delivery into account, because the prenatal "environments" of twins, and particularly monozygotic twins, may be markedly different – the well-known twin transfusion syndrome is an extreme example.

Franzek and Beckmann (1998a,b) performed a systematic twin study meeting all of these methodological requirements. They investigated 12 monozygotic and 11 dizygotic twin pairs in which at least one twin suffered from a type of cycloid psychosis. A comparison of the proband-associated concordance rates of monozygotic and dizygotic twins clearly disproved the hypothesis of a primary genetic disposition. A total of 36% of affected monozygotic twins, and 31% of affected dizygotic twins, had an affected partner; these figures are not significantly different. This negative finding is quantitatively reflected in the low calculated heritability index of 0.14 (the maximum

possible value is 1) and the low monozygotic-to-dizygotic ratio of 1.16 (the minimum expected value is 1).

For the unsystematic schizophrenias, however, the findings were entirely different, in that significant differences between monozygotic and dizygotic twin pairs were found. The proband-associated concordance rate was 89% for monozygotic twins and only 25% for dizygotic twins. Accordingly high values were obtained for the heritability index (0.72) and the monozygotic-to-dizygotic ratio (3.56). Thus, according to Galton's rule, there is a major primary genetic predisposition for the unsystematic schizophrenias, but not for the cycloid psychoses. A further, remarkable finding of this twin study was the lack of monozygotic twins with systematic schizophrenia, despite systematic recruitment. The explanations proposed to date for this observation are all speculative, and a further discussion would be beyond the scope of this chapter (Leonhard 1999; Franzek and Beckmann 1998b).

Because genetic factors apparently play little or no role in the causation of the cycloid psychoses, predisposing environmental factors must be sought. Twin studies may give evidence for such factors in the form of environmental differences between affected and unaffected monozygotic twins; this is a situation in which the individual's genetic constitution is held constant, while the environment is the variable under study. The study referred to above involved 12 pairs of monozygotic twins in which the index twin had a cycloid psychosis. Three of these pairs were concordant and nine were discordant, i.e. the co-twin in nine pairs was unaffected. It was found that the index twins of the discordant pairs had had more frequent and more severe perinatal complications than their unaffected co-twins, to a high level of statistical significance ($p < 0.01$). This finding is in accordance with the conclusion of earlier studies of discordant twin pairs, to the effect that "schizophrenic" monozygotic twins had severe perinatal complications more frequently than their healthy co-twins.

Consideration of the case histories of the patients in the latter studies reveals that most of the "schizophrenic" probands were probably suffering from cycloid psychoses, according to Leonhard's definition (Pollin et al. 1965, 1966). It is also known today that perinatal complications probably represent only the last stage of damage sustained over the course of pregnancy (Nelson and Ellenberg 1986; Kuban and Leviton 1994) and that prenatal insults may affect only one of a pair of twins, even if they are monozygotic (Davis et al. 1995). Thus, in many cases, perinatal complications may be an expression of preexisting disorders of fetal development.

Of course, developmental disorders of the central nervous system might occur without any necessary association with severe perinatal complications. Figure 2 shows the magnetic resonance images (MRI) of a pair of 26-year-old male twins whom we recently had the opportunity to study. Twin A had acutely developed a cycloid psychosis (confusion psychosis) that fully resolved after a few weeks of treatment with perazine. His brother, twin B, was psychologically normal and had been healthy his entire life. According to their mother, the twins had been born by cesarean section (birth weights: twin A, 3000 g; twin B, 3100 g). There had been no other complications perinatally,

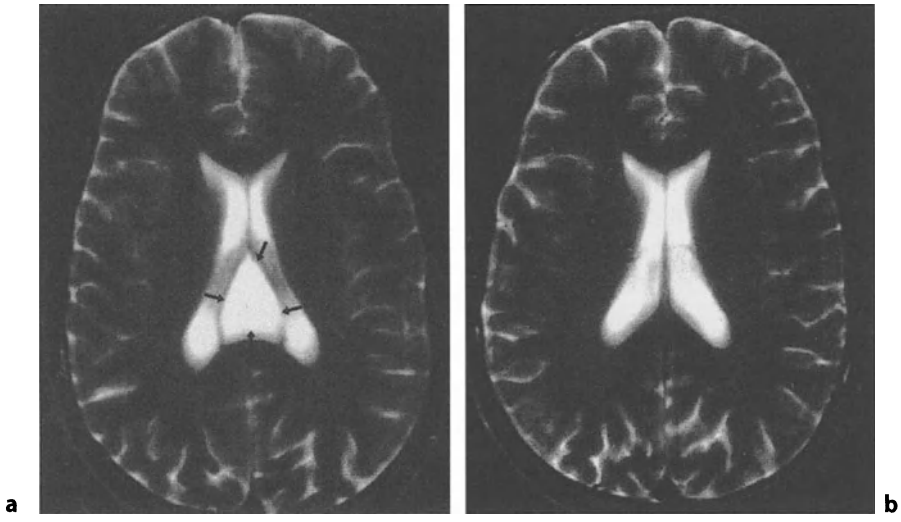

Fig. 2a,b. Magnetic resonance imaging (MRI) at the level of the lateral ventricles in two 26-year-old monozygotic twins. **a** Twin A: cycloid psychosis (confusion psychosis). *Small arrow*, cavum velum interpositum. **b** Twin B: normal

postnatally, or in early childhood development. Both twins passed the *Abitur* (high-school graduation examination qualifying for university) and were studying at the university level at the time of twin A's hospitalization.

As seen in Fig. 2, twin A, who suffered from an acute confusion psychosis, had a septal anomaly in the form of a cavum velum interpositum. This abnormality most likely reflects a developmental anomaly of cerebral maturation. The MRI of the healthy twin, twin B, is wholly unremarkable. For twin A, the septal anomaly itself had had no adverse consequences, neither perinatally nor in later development.

Unfortunately, the more recent studies of discordant twins contain no case histories, but merely speak in global terms of "DSM-III(-R) schizophrenia." We know from our own experience, however, that the index cases in pairs of monozygotic twins discordant for DSM-III(-R) schizophrenia suffer mainly from cycloid psychoses. Discussion of these studies is therefore appropriate here. Reveley et al. (1982) found a considerable difference of ventricular width between monozygotic twins discordant for "schizophrenia": the "schizophrenic" probands had significantly wider ventricles than their own healthy co-twins or than other, healthy, monozygotic twin controls. This is all the more remarkable as ventricular width is known to be largely genetically determined (Bartley et al. 1997).

Similar findings, i.e. wider ventricles in the affected twin, were reported by both Casanova et al. (1990) and Suddath et al. (1990). The latter study is of particular interest, because the neuroradiologist, who was blinded to the psychiatric diagnosis, was able to identify the affected twin in 12 of 15 cases merely by visual inspection of the MRI images for enlargement of the cerebrospinal fluid spaces. In accordance with these findings, Franzek et al. (1996), in a comparison study of psychiatric patients with unspecified abnormalities on cerebral computed tomography (CT) and a matched control group with normal CT scans, found a disproportionately high number of patients with cycloid psychoses in the group with abnormal CT scans. This observation was statistically significant. The abnormalities on CT consisted mainly of ventricular asymmetry and/or enlargement and were said by a neuroradiologist to be the likely result of pre- or perinatal insults.

The question naturally arises as to what the nature of these insults might be. An observation directly relevant to this question has been replicated by independent groups more often than any other in schizophrenia research and has given rise to much speculation: schizophrenics are significantly more likely than the general population to have been born in the winter or spring months (Bradbury and Miller 1985). A detailed discussion of all of the proposed explanations for this phenomenon would be beyond the scope of this chapter. The favored hypothesis at present is that insults arising preferentially in the colder seasons may affect a vulnerable phase of fetal cerebral development in such a way that the individual is predisposed to develop a schizophrenic psychosis in adulthood (Torrey 1987).

It has been repeatedly reported in recent years that excess births in the winter and spring months are found particularly among schizophrenics without schizophrenic relatives (D'Amato et al. 1991; O'Callaghan et al. 1991). Franzek and Beckmann (1992) studied the phenomenon of birth seasonality in a large group of patients diagnosed by Leonhard as having cycloid psychoses and unsystematic and systematic schizophrenias. There was an excess of winter and spring births in the overall group as compared to the general population, as expected. Consideration of the individual diagnostic groups, however, led to the surprising result that the excess was limited to patients with cycloid psychoses and systematic schizophrenias (both types of psychoses that tend not to be familial), while patients with the more familial unsystematic psychoses actually manifested a deficit of births in the months in question (Fig. 3).

The birth deficit among patients with unsystematic schizophrenias was interpreted as implying that individuals whose cerebral development is already impaired by a genetic defect may be less likely to survive if they sustain a further, exogenous insult to the central nervous system (Beckmann and Franzek 1992). The individuals that do not survive do not appear in later birth statistics, of course. On the other hand, if there is no primary genetic defect, the precise moment and anatomical location of the insult are probably what determine whether the individual will be predisposed to developing a cycloid psychosis or a systematic schizophrenia. Both of these hypotheses are entirely consistent with the "neurodevelopmental concept" of schizophrenic psychoses (Jakob and Beckmann 1986); evidence for disturbances of cerebral development has been found in both familial and sporadic forms of schizophrenia (Beckmann and Jakob 1991).

Maternal viral illnesses such as influenza A are considered likely to be a cause of these exogenous insults, as it is now known that they may damage the fetus directly or indirectly through a number of mechanisms (e.g. receptor-mediated endocytosis, axonal retrograde transport, transcytosis, overshoot of the maternal immune response; Franzek and Beckmann 1996). Attention was first drawn to the influenza A virus by the observation by Mednik et al. (1988) that significantly more schizophrenics had been born in the wake of an influenza A epidemic than in the periods immediately before and after. Although this finding has been disputed (Crow and Done 1992), more precise

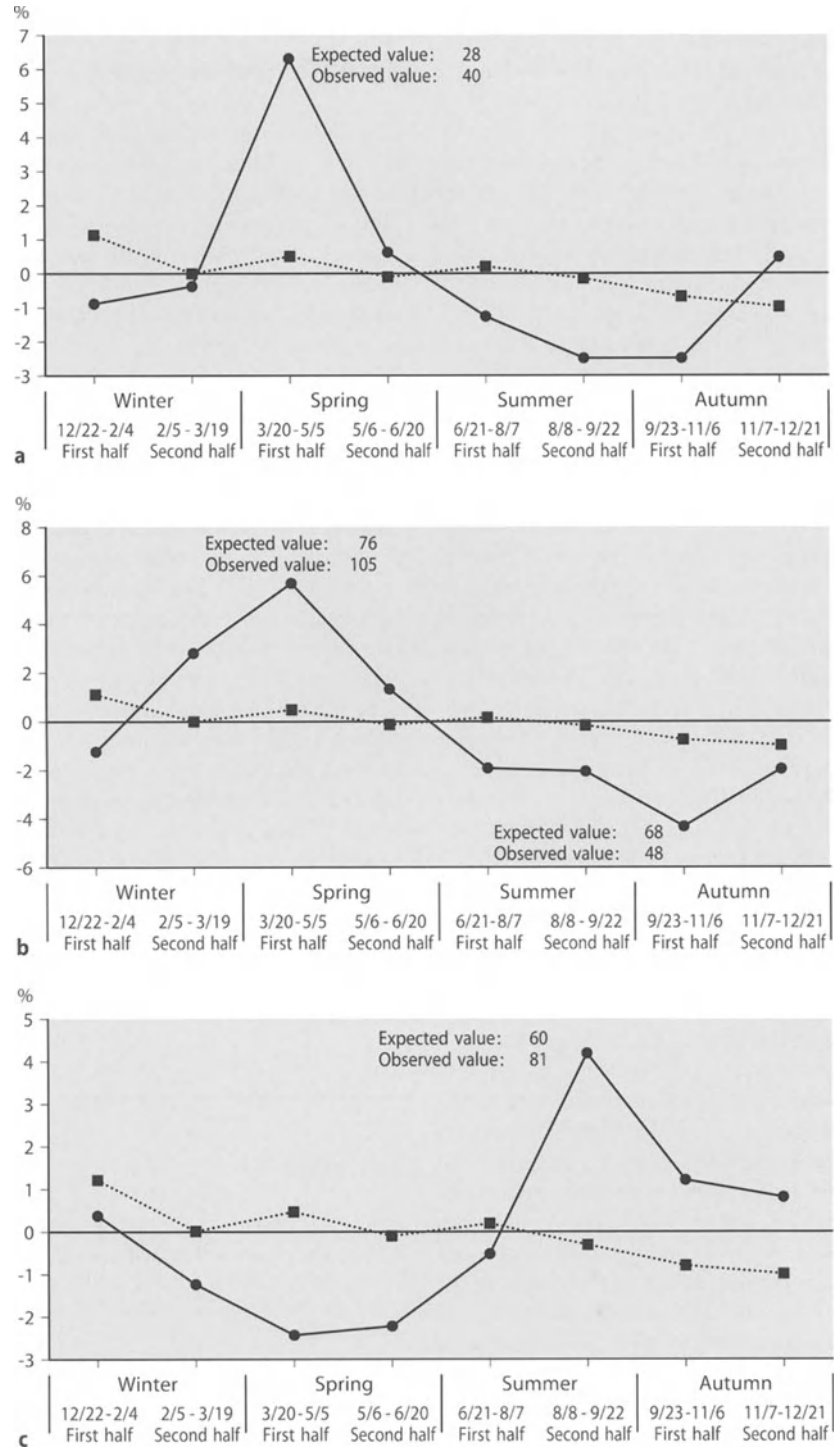

Fig. 3. Seasonal distribution of births in patients with **a** cycloid psychoses, **b** systematic schizophrenias, and **c** unsystematic schizophrenias as compared to the general population. *Dotted lines*, distribution of births in the normal population; *solid lines*, distribution of births among patients with psychosis/schizophrenia

analysis of the data reveals that an increased frequency of schizophrenia was always found among individuals living in densely populated areas. Negative findings, in contrast, were predominantly obtained in thinly or variably populated areas. The effect of an epidemic on the population is known to be more severe wherever people live more closely together, and less severe where there is more space between affected areas; thus the negative reports do not necessarily belie a causal relationship between the influenza A epidemic and the elevated frequency of schizophrenic psychoses.

Stöber et al. (1992, 1997) were the first to document a direct relationship between maternal infectious diseases and the later occurrence of cycloid psychoses and systematic (sporadic) schizophrenias. When questioned retrospectively, the mothers of patients of cycloid psychoses reported that they had flu-like and febrile illnesses in the first trimester of pregnancy more frequently than control mothers. Among mothers of patients with systematic schizophrenia, an elevated occurrence of viral illness as compared to control mothers was found in the second trimester of pregnancy. In contrast, the mothers of patients with manic-depressive illness or any form of unsystematic schizophrenia did not differ significantly from the control mothers. These findings have yet to be confirmed by prospective studies, and they can therefore be interpreted only in a preliminary and hypothetical fashion. It has been proposed that viral (or other) insults affecting the prenatal development of certain parts of the brain are involved in the causation of cycloid psychoses and systematic schizophrenias. The timing, localization, and extent of cerebral damage apparently determine the degree to which the individual then becomes vulnerable to the different forms of psychosis.

Lastly, functional investigative methods such as the measurement of P300 have revealed significant differences between patients with cycloid psychosis and patients with either manic-depressive illness or schizophrenic psychoses (Strik et al. 1996). The topography of P300 in patients with cycloid psychoses did not differ from that of controls, while a displacement to the right was observed in schizophrenics (both systematic and unsystematic). The P300 amplitude, compared to that of control subjects, was lower in schizophrenics, no different in manic-depressives, and elevated in patients with cycloid psychoses. The latter finding probably reflects an elevated state of arousal of the central nervous system. These results are in accordance with the finding by Warkentin et al. (1992) that patients in the acute phase of cycloid psychosis have a significantly elevated mean hemispheric blood flow. Schizophrenics, on the other hand, are known to have regionally decreased cerebral perfusion (hypofrontality).

6 Conclusion and Overview

The division of endogenous psychoses into affective and schizophrenic types, which still prevails today, has failed to bring about a decisive breakthrough either in clinical practice or in the scientific study of these diseases. Psychoses that do not fit neatly into either category are designated as atypical, schizophreniform, schizoaffective, or (more recently) transient polymorphic disorders and are assigned to either the affective or the schizophrenic category, depending on which of the two basic orientations is preferred, that of Kraepelin or that of Bleuler.

Leonhard's classification of the endogenous psychoses, whose roots extend back to the earliest days of psychiatry as a medical specialty, offers a promising alternative for the resolution of this dilemma. His concept of the cycloid psychoses as an independent nosological category distinct from both manic-depressive illness and the schizophrenias has proved especially useful in recent years.

Leonhard's original conception of the cycloid psychoses has been largely confirmed by current research. Indeed, modifications of his concept, especially those toward greater simplicity, have been found to result in a loss of heuristic value. A renewed emphasis on the precise characterization of individual manifestations and syndromes, as in the works of Wernicke, Kraepelin, Kleist, and Leonhard, holds great promise as a means of reviving progress in the scientific understanding of the etiology, genetics, prognosis, and differential treatment of the endogenous psychoses.

Schizoaffective Disorder

Preparation of this chapter was supported in part by grants R37-MH43518, U01-MH46318, and R01-DA04604 from the National Institutes of Mental Health and Drug Abuse and by a Veterans Affairs Research Merit Review Grant to Dr. Tsuang.

1 Introduction

When we refer to the diagnosis of "schizoaffective disorder," we think of a disorder which is a mixture of schizophrenic and affective (depressive or manic) symptoms. Efforts to clarify the boundary between schizophrenia and affective disorders have resulted in a number of terms proposed to label such patients, but no single definition has met with widespread acceptance. The inclusion of the term "schizoaffective disorder" in DSM-IV (American Psychiatric Association 1994) has substantially improved the situation and has allowed clinicians and researchers to use consistent definitions. Even with these written criteria, there still remains some controversy as to precisely where schizoaffective disorder falls between the major categories of schizophrenia and affective disorders.

In this chapter, we will survey the widely differing views regarding the diagnosis and treatment of schizoaffective disorder in the light of recent empirical research and refer to interesting findings from phenomenologic, genetic, epidemiologic, and follow-up studies. We will begin with a selective historical review of the concept of schizoaffective disorder.

2 Historical Overview

Confusion over the classification of those patients who share schizophrenic and affective features has existed at least since the time of Kraepelin, who wrote in 1919 that he believed differential diagnosis was most difficult when confronted by a "mingling of morbid symptoms of both psychoses" (Kraepelin 1971). The "acute schizoaffective psychoses," a phrase first employed by Kasanin (1933), expresses the problem succinctly. Kasanin applied this term to a group of patients characterized as having a sudden onset in a state of marked emotional turmoil, distortion of the outside world (including false sensory impressions in some), and recovery following a short-lived psychosis of a few weeks to a few months.

This type of patient, who when viewed cross-sectionally appeared schizophrenic but who fully recovered, attracted increasing attention in the 1960s. Vaillant (1964), relying heavily on the work of Langfeldt and Kant (Kant 1937; Langfeldt 1939, 1956), derived a group of prognostic features which he used to predict remission in schizophrenic patients. Stephens et al. (1966) generated a longer, but analogous list of prognostic features also used to predict recovery in such patients. Both of these investigators were able to predict remission in approximately 80% of their patients by combining various prognostic features, including affective symptoms and affective heredity (or absence of schizophrenic heredity) as predictors of remission. By referring to their patients as having "remitting schizophrenia," however, these authors implied their belief that mixed cases nonetheless remain schizophrenic.

Other investigators have argued that mixed cases are better thought of as variants of affective disorder. Evidence in support of this viewpoint has primarily come from studies of schizoaffective patients with a predominantly manic affective picture (e.g. Abrams and Taylor 1976; Pope et al. 1980; Rosenthal et al. 1980).

The final major three ways in which schizoaffective disorder has been viewed are (1) that it is a heterogeneous mixture of disorders, (2) that it is a distinct disorder separate from schizophrenia and affective illness, and (3) that it represents an artificial categorization of clinical phenomena lying on a continuum between schizophrenia and affective disorder. Family and outcome studies (which are discussed below) have been the primary focus of efforts to evaluate these alternative positions. At this point, we merely note that the continuum hypothesis assumes a dimensional as opposed to a categorical perspective and that, although dimensional nosologic approaches can have certain advantages (e.g. see Widiger and Frances 1985), when applied to psychoses conceptual (and clinical) confusion could arise if the continuum hypotheses is taken to suggest that the psychoses can be divided into a limitless number of categories for the purposes of prognosis and treatment. If, on the other hand, the heterogeneous view of schizoaffective disorder is adopted (e.g. see Levitt and Tsuang 1988), it suggests the usefulness of the strategy of subdivision into a few major homogeneous subtypes.

The latter approach raises the issue of how best to subtype schizoaffective disorder. For example, can schizoaffective disorder be most profitably subtyped into depressive and bipolar types, as in DSM-IV (American Psychiatric Association 1994), or should it initially be divided into schizo-dominant and affect-dominant types, as suggested by M.T. Tsuang et al. (1986), or should both approaches be used as in the Research Diagnostic Criteria (RDC) of Spitzer et al. (1978)? We shall see that empirical evidence from long-term outcome studies appears to support distinctions based upon polarity, but not to the exclusion of other subtyping schemes. Unipolar and bipolar subtypes have also proved useful for clinical purposes, e.g. in guiding cross-sectional pharmacologic treatment, but the evidence from family studies is not conclusive. It has also been pointed out that,

longitudinally, the course of schizoaffective disorder can often be described as polymorphous (Marneros et al. 1986), which could make any dichotomy an oversimplification. Because of these complexities, this remains a very active area of schizoaffective research.

Additional interest in schizoaffective disorder has been stimulated by a recent trend to conceptualize schizophrenia in terms of negative and positive symptoms (Crow 1980; Andreasen et al. 1991). For example, Cuesta and Peralta (1995) showed that, although both positive and negative symptoms were relevant to differential diagnosis between schizophrenia and other psychotic disorders, negative symptoms presented higher significant differences between diagnostic groups (including schizoaffective disorder) than positive symptoms. Such findings indicate the need to distinguish between the depressive component of schizoaffective disorder and the negative syndrome of schizophrenia. This distinction can be difficult cross-sectionally in view of the similarity of the two syndromes. One potential way to disentangle these two overlapping sets of symptoms is to follow patients longitudinally, as negative symptoms are thought to persist over the long term (Pfohl and Winokur 1983; Andreasen et al. 1991), whereas depressive symptoms tend to remit. An additional complication is that negative symptoms themselves are not homogeneous and can result from such diverse causes as drug-induced akinesia, institutionalization, positive symptoms, depression (Andreasen et al. 1991), or as an emotional response to psychosis itself, e.g. postpsychotic depression or demoralization.

In summary, the question that arises is whether schizoaffective disorder shares its unknown etiology with schizophrenia, with affective disorder, or with neither, or whether schizoaffective disorder simply labels a genotypically mixed group made up partly of affective disorder patients and partly of patients with schizophrenia (Coryell 1986).

3 Diagnostic Criteria for Schizoaffective Disorder

The term "schizoaffective disorder" has been widely used, but with considerable differences in meaning and application (Brockington and Leff 1979). However, most definitions of schizoaffective disorder do have in common that they identify patients who concurrently share characteristic and pronounced schizophrenic and affective features and hence do not qualify for typical diagnoses of schizophrenia or affective disorder (Levitt and Tsuang 1990). In particular, such patients have sufficient affective symptoms to exclude an uncomplicated diagnosis of schizophrenia or, alternatively, sufficient schizophrenic features to exclude an uncomplicated diagnosis of affective disorder. It follows that the concept of schizoaffective illness will be directly influenced by how broadly or narrowly schizophrenia and affective psychosis are defined (Kendell 1986).

Despite Kasanin's original description of schizoaffective disorder as characterized by very sudden onset followed by recovery after a few weeks or months (Kasanin 1933), not all subsequent definitions have emphasized the course of the illness. For example, the criteria of Welner et al. (1974), Brockington et al. (1980a,b), Abrams and Taylor (1976), and the proposed clinical criteria of M.T. Tsuang et al. (1986) are primarily or exclusively cross-sectional. However, in view of the complexity of schizoaffective syndromes, involving various mixtures of schizophrenic and affective features over time, it should not be surprising that there has been an increasing emphasis on the use of longitudinal features to define schizoaffective disorder.

The most widely used criteria for studies of schizoaffective disorder have been the RDC of Spitzer et al. (1978), which specify (but do not necessarily require) periods of time when schizophrenia-like symptoms clearly dominate the clinical picture. This concept – the persistence of psychotic symptoms in the absence of affective symptoms – is also important in RDC for distinguishing between "mainly schizophrenic" and "mainly affective" subtypes of schizoaffective disorder, and several major studies have demonstrated the predictive validity of this clinical feature (Brockington et al. 1980a; Himmelhoch et al. 1981; Coryell et al. 1990a,b).

At the same time that the RDC were introduced, an influential review paper by Pope and Lipinski (1978) forcefully argued that "schizophrenic" symptoms occur with some regularity in affective disorders, and by themselves (e.g. cross-sectionally) should not be the basis for differential diagnosis. In consequence of these several developments, there appears to have been a shift in the core concept of schizoaffective disorder from the co-occurrence of psychotic (and in particular, mood-incongruent) symptoms and affective symptoms to one that represents "patients whose psychotic symptoms are not clearly linked to their affective episodes" (Blacker and Tsuang 1992, p. 1476). In 1985, Maj and Perris proposed a set of diagnostic criteria distinguished by their emphasis on course to subclassify schizoaffective disorder. Subsequently, the DSM-III-R criteria required the persistence of delusions or hallucinations in the absence of prominent mood symptoms for at least 2 weeks; this is essentially

a modified version of the RDC criteria for schizoaffective disorder, mainly of the schizophrenic type. This longitudinal criterion was carried over into DSM-IV (American Psychiatric Association 1994), with the additional limiting requirement that this 2-week (or longer) period should occur during the same period of the illness characterized by the concurrent expression of affective or schizophrenic syndromes. Specifically, the essential feature of schizoaffective disorder, as defined by DSM-IV, is an uninterrupted period of illness during which, at some time, there is a major depressive, manic, or mixed episode concurrent with characteristic symptoms that meet the symptom criterion for schizophrenia. In addition, during the same period of illness, there should have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms. Moreover, the mood symptoms should be present for a substantial portion of the total duration of the illness. Finally, the symptoms must not be due to the direct physiological effects of a substance (e.g. cocaine) or a general medical condition. To meet the DSM-IV criteria for schizoaffective disorder, the essential features must occur within a single uninterrupted period of illness.

One effect of these requirements could be to reemphasize somewhat the cross-sectional picture in diagnosis by, for example, not including in schizoaffective disorder a hypothetical patient who had a mixed clinical picture in one episode followed in a separate episode by 2 weeks of predominantly schizophrenic symptoms. It appears that the prognostic and nosologic significance of longitudinal features will be an active area of research for some time to come.

At present, the criteria most commonly used to define schizoaffective disorder for research purposes include the RDC and the similar DSM-IV criteria. In addition, investigators have often modified these criteria (e.g. Marneros et al. 1992) or proposed their own criteria (e.g. M.T. Tsuang et al. 1986) as a means of studying course, family data, and other potentially important defining characteristics of these patients. Doubtless there will continue to be a variety of ways used to define schizoaffective disorder, and given the controversial status of the illness, this is to be preferred to settling prematurely on any one set of criteria. In fact, it is perhaps best explicitly to label all current diagnostic criteria for schizoaffective disorder as provisional. To emphasize this point (which can tend to be overlooked with repeated use of the phrase "schizoaffective disorder"), it could be helpful to use alternative terms such as "schizoaffective syndrome," "RDC schizoaffective disorder," or "DSM-IV schizoaffective disorder" in appropriate contexts.

4 Epidemiology

In contrast to schizophrenia, which has been the subject of innumerable epidemiologic investigations, relatively little is known about the epidemiology of schizoaffective disorder, e.g. regarding incidence, prevalence, demographics, mortality, and associations with socioeconomic variables and other potential risk factors. Most community surveys have not described rates of schizoaffective disorder. This is probably due largely to the uncertain nosologic status of schizoaffective disorder and to the resulting difficulty in reconciling across studies results that can be greatly affected by how the disorder is defined. To minimize this problem, we have emphasized in this review those studies that used objective diagnostic criteria.

4.1 Incidence

Only a few studies have examined the incidence of schizoaffective disorder. Brockington and Leff (1979) reported that patients meeting three or more definitions of schizoaffective disorder (out of eight definitions examined) comprised 4.5% of first-admission psychiatric patients in the Camberwell catchment area of London in 1973–1974. "Schizomanic" patients (manic patients with schizophrenic or paranoid symptoms) had an incidence rate of 1.7 per 100,000 population per year, which was considerably smaller than the rate of 4 per 100,000 population per year for "schizodepressive" patients. The numbers of schizoaffective patients identified in this sample exceeded the number of manic patients and were roughly half the number of incident schizophrenic cases, indicating that schizoaffective patients comprise a clinically significant population.

Additional evidence on this point can be obtained from an analysis of Epidemiologic Catchment Area Study data, obtained from Diagnostic Interview Schedule (DIS) interviews with randomly selected cases in five U.S. communities (Tien and Eaton 1992). These authors compared incidence rates in three non-overlapping groups of patients with delusions and hallucinations: individuals with the diagnosis of schizophrenia; patients with only delusions and hallucinations; and a "psychotic affective syndrome" group who also had manic or depressive episodes. The latter group is similar to, but not identical with most definitions of schizoaffective disorder, because 59% of the group experienced delusions and hallucinations only when they had a mood disturbance. Despite this limitation, the study is

important because it found that 1-year incidence rates for the psychotic affective group were approximately the same as for schizophrenia, namely, 1.7 per 1,000 population per year versus 2.0 per 1,000 per year for schizophrenia. Even if only 40% of the psychotic affective group were to meet criteria for schizoaffective disorder, this result still exceeds the earlier estimates made by Brockington and Leff (1979) by at least one order of magnitude. In part, the difference can be attributed to the difference between a community sample and a treated sample. However, the difference between the incidence rates for schizophrenia is just as large and not readily explainable.

4.2 Prevalence

Most of the information regarding the prevalence of schizoaffective disorder has been obtained from clinical samples. An exception is Torrey's prevalence study of schizophrenia in a rural area of western Ireland (Torrey 1987). Using key informants, Torrey estimated the 6-month prevalence rate for broadly defined schizophrenia to be 12.6 per 1,000 population. The actual numbers of patients included 21 with DSM-III schizophrenia and 11 with schizoaffective disorder; as with the incidence study by Brockington and Leff (1979), the ratio of schizophrenia to schizoaffective disorder is roughly 2 to 1.

Prevalence estimates of schizoaffective disorder in clinical populations have varied widely, as can be expected given the multiple factors affecting selection for treatment and duration of treatment. For example, Rosenthal et al. (1980) reported that 35% of the manic patients in a lithium clinic were RDC schizoaffective manic. Müller-Oerlinghausen et al. (1992) found that the prevalence of schizoaffective disorder in lithium clinics varied widely from city to city: 7% (Aarhus), 15% (Berlin), 23% (Vienna), and 32% (Hamilton). Junginger et al. (1992) found that 14% of the delusional patients in a chronic and highly selected population of inpatients and outpatients met DSM-III-R criteria for schizoaffective disorder, compared to 60% for schizophrenia, 17% for bipolar disorder, and 4% for major depression. In the Cologne Study on long-term course and outcome, Marneros et al. (1991) applied longitudinal criteria adapted from DSM-III-R to a large sample of patients with major psychoses and found that the number with schizoaffective disorder (28.5%) was about the same as the number with affective disorders (30%), and less than the number with schizophrenia (42%). Taken together, these studies validate current interest in schizoaffective disorder as being a clinically significant population of psychiatric patients.

A number of investigators have compared the prevalence of the manic and depressive subtypes of schizoaffective disorder. Clayton, in an influential review, concluded that the manic type is more frequent (Clayton 1982). A subsequent first-admission study by Berner and Lenz (1986) supports this conclusion in a comparison of subtypes of RDC schizoaffective disorder (12.5% schizoaffective manic vs. 8% schizoaffective depressed). However, a broader sample of first-admission patients in the study by Brockington and Leff (1979) showed substantially more schizodepressive patients (3.7%) than schizomanic patients (1.5%). Two recent studies of consecutive inpatient samples also indicate that the depressive subtype is more prevalent: Kitamura and Suga (1991), using RDC criteria, and Marneros et al. (1991), using modified DSM-III criteria. In view of these inconsistent results, we can hypothesize that selection factors largely determine the relative numbers of schizoaffective manic and schizoaffective depressed patients who are treated. More definitive findings will have to await information from future epidemiologic studies of schizoaffective disorder.

4.3 Demographic Factors

Given the variability in how schizoaffective disorder is defined and the evident influence of selection biases in prevalence studies, it is not surprising that studies of demographic factors such as gender and age at onset have produced widely varying results. Nevertheless, some general conclusions are possible.

With regard to gender, there appear to be as many or more females than males, e.g. 71% in the sample of M.T. Tsuang et al. (1986) and 63% in that of Marneros et al. (1990a). Berner and Lenz (1986) reported that the male to female ratio ranged from 0.3:1 to 1:1 depending on the definition of schizoaffective disorder employed. In their general population study, Tien and Eaton (1992) reported higher 1-year incidence rates for females with DIS psychotic affective syndrome (a heterogeneous group that probably includes schizoaffective disorder) for all age groups examined and computed a relative risk of 6.8 for developing this syndrome in females compared to males. Clayton (1982) hypothesized that the results also depend on polarity, e.g. with approximately equal numbers of males and females in the manic subtype, compared to almost two-thirds female patients in the depressive subtype. Kitamura and Suga (1991), however, found approximately equal numbers of males and females in both schizoaffective manic and schizoaffective depressed subtypes.

Age at onset is one of the basic characteristics that reliably distinguishes major subgroups – e.g. male versus female schizophrenic patients (Goldstein et al. 1989) and bipolar versus unipolar affective disorder (Smeraldi et al. 1983) – and for that reason is also of interest in schizoaffective disorder. First, age at onset appears to be a discriminating factor in comparison with other disorders. For example, in her 1982 review, Clayton concluded that most studies found the average age at onset to be youngest for schizoaffective disorders compared to unipolar and bipolar disorders. Similarly, M.T. Tsuang et al. (1986) reported that the mean age at onset of schizoaffective disorder (29 years) was significantly younger than for manic and depressed groups defined using Washington University criteria (34 and 44 years, respectively); however, there was no difference between schizoaffective disorder and schizophrenia. Marneros et al. (1990a) reported that the median age at onset for schizoaffective disorder (29 years) was younger than the median age for affective disorders (35 years) and older than for schizophrenia (24 years). Berner and Lenz (1986) showed that the age at onset depends largely on the diagnostic criteria employed; for example, DSM-III identified a schizoaffective patient population that was older than the RDC schizoaffective depressed subtype and substantially older than the RDC schizoaffective manic subtype of schizoaffective disorder.

Within schizoaffective disorder, there might also be a substantial effect of gender on the age at onset, namely, that women tend to be older at onset of the disorder (Angst 1986). To the extent that their DIS psychotic affective syndrome includes schizoaffective disorder, the results presented by Tien and Eaton (1992) also support this generalization: 1-year incidence rates for females were substantial for age groups greater than 34 years, whereas incidence rates for males declined sharply after age 34.

Information on marital status is available in a few studies (e.g. Clayton 1982; Marneros et al. 1990b), but confounding by gender makes the available results difficult to interpret or compare across studies.

4.4 Mortality

Several factors combine to make premature mortality a special concern in schizoaffective disorder. Schizoaffective patients share some of the symptoms and other characteristics of schizophrenic and affective disorder patients, who have repeatedly shown to be at increased risk of death, principally (but not exclusively) from suicides and accidents (Simpson 1988). Buda et al. (1988) directly compared the mortality experience of DSM-III schizophrenics with a heterogeneous group that included patients with schizoaffective disorder, schizophreniform disorder, and atypical psychotic disorder using follow-up data beginning with index hospital stays between 1934 and 1945. Excess mortality for the atypical group in this historical sample was observed for specific causes of death including infections, neoplasms, cardiovascular disease, and suicides. Furthermore, suicide occurred in excess among the other psychotic groups compared with schizophrenia and with the general population. Angst et al. (1990) compared suicides in patients with affective disorder and schizoaffective disorder using data from Zurich, Bonn, and New York and found that the suicide risk for schizoaffective patients closely resembled that for patients with affective disorders. In particular, the risk of suicide was constant over a lifetime and did not increase or decrease with age. Marneros et al. (1989a), in a long-term follow-up study of schizoaffective patients, reported suicide attempts over a lifetime in 43% of the unipolar subgroup and in 29% of the bipolar subgroup, usually by drug overdose. Clearly, the suicide risk in these patients is substantial and enduring.

Fortunately, there is evidence that suicide in psychiatric patients is to some extent predictable and preventable, largely in response to standard psychiatric interventions (M.T. Tsuang et al. 1992). Evidence in support of the view was gathered by Müller-Oerlinghausen et al. (1992) in a study of the long-term effect of lithium treatment (average duration of treatment, 7 years) on the mortality of patients with schizoaffective and affective disorders. That study, which included clinic samples from Canada and three European countries, found that mortality was not significantly increased in lithium-treated schizoaffective patients compared with the general population, although the mortality risk in the bipolar and unipolar comparison groups was actually somewhat less than for schizoaffective disorder.

5 Clinical Picture

Most definitions of schizoaffective disorder depend entirely on the clinical picture, and since these definitions vary so greatly, the associated clinical picture will also vary depending on the label (Coryell 1986). Because these patients suffer from psychosis, an associated loss of insight, and often severe psychomotor disturbance, many have problems remembering historical events in their lives. At the time of admission, affective symptoms may be altogether overshad-

owed by the patient's delusional preoccupation, hallucinations, or bizarre behavior. In fact, at this point, such patients often deny affective symptoms that they later recall. The distinction between affective, schizoaffective, and schizophrenic psychosis, therefore, must not depend on the patient interview alone. The clinician should seek knowledgeable informants to learn whether affective symptoms preceded the psychotic ones.

One recent study (Taylor and Amier 1994) attempted to discriminate the psychoses by their classic symptoms. Three groups were statistically compared, including chronic schizophrenia, schizoaffective disorder, and affective disorder. Their analysis discriminated chronic schizophrenia from affective disorder, but schizoaffective disorder overlapped both groups. In addition, the unipolar subtype of schizoaffective disorder resembled chronic schizophrenia, and the bipolar subtype resembled affective disorder. However, these discriminations also substantially overlapped, and among nonaffective positive features, formal thought disorder was best at discrimination. The findings of this study did not fully support the classification system and suggested that the emphasis on hallucinations and delusions is overvalued.

A later study (Kendler et al. 1995) sought to determine whether the DSM-III-R category of schizoaffective disorder differs meaningfully from schizophrenia and affective illness in terms of clinical features and other validators. On the basis of these various clinical validators, they found that schizoaffective disorder defines a syndrome that differs from both schizophrenia and affective illness. The division of schizoaffective disorder into bipolar and depressive subtypes was, however, not validated.

In order to evaluate the basic symptom differences of schizophrenia, schizoaffective disorder, and bipolar disorder, a consecutive series of 72 outpatients was recruited for another study (Ricca et al. 1997), including 28 with a diagnosis of schizophrenia, 29 with bipolar disorder, and 15 with schizoaffective disorder. Data obtained suggest that perception and thought disturbances are the most characteristic experiences of schizophrenic patients in comparison with bipolar patients. The analysis did not highlight a characteristic basic symptom profile of schizoaffective disorder when compared with bipolar affective disorder and schizophrenia. Cognitive features were also compared, by Manschreck et al. (1997), among patients with schizophrenia, schizoaffective disorder, major depression, and normal controls. The results indicate that schizophrenic subjects attain smaller gains in verbal recall when context is increased compared to depressed and normal controls. Schizophrenic and schizoaffective subjects, however, did not differ in recall gain on this task. The authors concluded that schizoaffective subjects could not be distinguished from schizophrenic subjects on this cognitive feature (verbal recall when context is increased).

Blehar et al. (1996) identified clinical variables that increased the diagnostic differentiation among three groups: schizoaffective bipolar disorder, bipolar disorder, and schizophrenia. Based on the clinical diagnostic interview, the schizoaffective bipolar disorder group was more clearly differentiated from the bipolar disorder group than from the schizophrenic group. The primary difference between the schizoaffective bipolar disorder group and the bipolar disorder group was with measures of psychosis, including specific hallucinations and delusions, ratings of the bizarre and fragmented nature of psychosis, catatonia, thought disorder, and comorbid phobias. The schizoaffective bipolar disorder group had higher values on all these variables than the bipolar disorder group. On the other hand, subjects in the schizoaffective bipolar disorder group had a higher frequency of manic episodes and longer average duration of mania than patients in the schizophrenia group.

5.1 Precipitating Factors

One of the defining characteristics of schizoaffective disorder, as initially conceptualized by Kasanin (1933), has been the presence of precipitants such as stressors or major life events. To some extent this notion has been validated empirically. Brockington et al. (1980b) reported that ten of 32 schizomanic patients had obvious recent stress such as childbirth, surgery, head injury, or the disruption of important personal relationships. M.T. Tsuang et al. (1986) found significantly more precipitants of any type in schizoaffective disorder (60%) compared with schizophrenia (11%), mania (27%), or depression (39%). Furthermore, schizoaffective patients had significantly more psychosocial, physical, and postpartum precipitants in most of the comparisons with these other diagnostic groups. In contrast, Marneros et al. (1990b) found equal percentages of schizoaffective and affective disorder patients with life events before onset (51%), compared to only 24% in schizophrenia. Tien and Eaton (1992) found that antecedent alcohol problems, but not daily marijuana abuse, increased the relative risk of DIS psychotic affective syndrome to 5.7.

5.2 Premorbid Factors

Premorbid or predisposing factors can give useful clues to the etiology and early course of the disorder,

but unfortunately little is known about such factors in schizoaffective disorder. Marneros et al. (1990b) reported a significantly higher educational level in schizoaffective patients compared with schizophrenic patients, but no difference between schizoaffective and affective disorder patients. The same pattern was obtained for employment/vocational training. Compared with schizoaffective patients, those patients with schizophrenia were more often in lower social classes; this was partly attributed to the parents' social class, and partly to the schizophrenic patients' downward mobility at the time of onset. In contrast, there was no significant difference between the schizoaffective and affective disorder group. Finally, all three diagnostic groups had similar percentages of patients from broken homes.

6 Genetic and Family Studies

Family studies of schizoaffective disorder have led to inconsistent results, which can be attributed in part to the inherent heterogeneity of this group of patients and to the lack of uniformity in diagnosis. It is of some interest, therefore, to find three studies that used different definitions of schizoaffective disorder yet obtained convergent results.

First, a review by Fowler (1978) summarized several studies showing schizophrenic patients with good prognosis to have a familial risk of affective disorder (20%) between that of unipolar depressive (16%) and manic patients (35%), and to have a familial risk of schizophrenia significantly greater (6%) than manic (<1%) or unipolar depressive patients (<1%). This was interpreted to be consistent with the conclusion that schizophrenia with a good prognosis was associated with elevated risks in relatives for both affective disorder and schizophrenia, and hence most consistent with an interpretation of heterogeneity. Gershon et al. (1988), in contrast, studied schizoaffective disorder as largely defined by RDC, where the emphasis is more on mixing affective and schizophrenic features rather than on a good outcome. The schizoaffective, chronic subtype in this study also revealed elevated risks (compared with controls) for nonaffective psychosis and affective disorder (pooling unipolar and bipolar cases). A third example of yet a different definition of schizoaffective disorder, namely, patients with "atypical psychosis" who for a variety of reasons fail to meet diagnostic criteria for schizophrenia or affective disorder, is found in a study by M.T. Tsuang (1991), where again high rates of schizophrenia and affective disorders were found in relatives of schizoaffective probands. Hence, whether good prognosis, mixing of affective and schizophrenic features, or atypicality is emphasized in the definition of schizoaffective disorder, family studies have found elevated rates of both schizophrenic and affective disorder in relatives of schizoaffective patients, consistent with genetic heterogeneity.

Another possibility is that schizoaffective disorder is a distinct entity. In general, however, family studies have not demonstrated an increased risk of schizoaffective disorder and no other disorders in relatives of schizoaffective patients, which would be the pattern most supportive of schizoaffective disorder as a distinct entity or "third psychosis" (Zerbin-Rudin 1986).

We have also tested the effect of gender on the familial risk for schizophrenia and affective disorders in probands with schizoaffective disorder (Goldstein et al. 1993). The sample consisted of 42 DSM-III schizoaffective probands and 149 first-degree relatives. Findings showed that relatives of females had significantly higher rates of schizophrenia and unipolar disorder than relatives of males. In addition, among relatives, males were at significantly higher risk for schizophrenia spectrum disorders than females. Results were similar when probands were subtyped into "schizoaffective depressed" or "schizoaffective manic" categories. Implications for the taxonomy of schizoaffective disorder suggest a stronger relationship with schizophrenia, although the relationship with affective disorder remains unclear.

Although there have been no molecular genetic studies of schizoaffective disorder, studies of schizophrenia and bipolar disorder have implicated genetic loci that may be involved in both disorders. If so, these may indicate that some susceptibility genes influence a broad range of psychoses, including schizoaffective disorder. For example, Maziade et al. (1997) failed to detect linkage at 6p24–22 in 18 large, multigenerational pedigrees from Eastern Quebec, using either broad or narrow definitions of schizophrenia. They did find suggestive evidence in one large pedigree, however, that the locus was associated with vulnerability to both schizophrenia and bipolar disorder when they utilized a broad phenotypic definition that included schizophrenia, schizoaffective disorder, schizophreniform disorder, bipolar disorder (I and II), and major depression (recurrent).

Moreover, other researchers have also suggested that at least one disorder in the schizophrenia spectrum – schizoaffective disorder – might belong to an affective disorder spectrum as well (Bertelsen and Gottesman 1995). Consistent with this possibility, evidence for linkage was obtained at this locus for bipolar disorder in Old Order Amish pedigrees (Ginns et al. 1996). Similarly, the chromosome 10p region was implicated

for both schizophrenia and bipolar disorder in the NIMH Genetics Initiative pedigrees (Rice et al. 1997; Faraone et al. 1998; Foroud et al. 1998).

Wildenauer et al. (1996) reported suggestive evidence of linkage to a region on chromosome 18p, using a sib-pair analysis. Their findings are interesting, in part because they obtained their highest logarithm of differences (lod) scores when they used a broad phenotypic definition that included relatives of schizophrenic patients with bipolar disorder and major depression, in addition to schizophrenia and schizoaffective disorder. This group recently reported a lod score of 3.1 using this approach and confirmed in principle findings reported by Maziade et al. (1997) at chromosome 6p24–22. Moreover, the chromosome region at 18p has also been implicated in bipolar disorder (Berrettini et al. 1994; Stine et al. 1995).

If schizoaffective disorder is genetically heterogeneous, the next logical question is whether it can be successfully subtyped. M.T. Tsuang (1991) has demonstrated one approach to such subtyping by segregating atypical psychotic patients into those with an increased probability for schizophrenia or affective disorder, and a residual undifferentiated group. Marneros et al. (1989b) have approached the problem longitudinally by showing that schizoaffective disorder can be divided in terms of long-term course into those with bipolar and unipolar types. Others, including Angst et al. (1979) and Gershon et al. (1988), have had difficulty subtyping schizoaffective disorder when using family studies as a validator.

7 Long-Term Course and Outcome

Reasons for examining the long-term course of schizoaffective disorder include the importance of understanding the prognosis as the basis for clinical management and for comparisons of treatment efficacy; the possibility of identifying prognostic factors; and the use of longitudinal information to validate diagnostic concepts and to investigate diagnostic heterogeneity (e.g. by identifying homogeneous subgroups).

As a basic description of the course of the illness, we provide the following illustrative summary adapted from Samson et al. (1988) and subject to the limitations noted elsewhere in this chapter regarding the wide variability in the definition of schizoaffective disorder. Reported rates of recovery from schizoaffective episodes have ranged from 83% reported in a short-term follow-up study (Clayton et al. 1968) to 29% who recovered at any time during a 6-month follow-up period (Coryell et al. 1984). Approximately 20%–30% of schizoaffective patients go on to show a deteriorating course, e.g. one typified by persistent psychosis (Holmboe and Astrup 1957; Brockington et al. 1980a,b; Gross et al. 1986; Coryell et al. 1990a,b; M.T. Tsuang 1990; Grossman et al. 1991). Approximately 10% of patients show diagnostic shifts over time, becoming either more affective or more psychotic in symptom manifestation (Angst 1986). Schizoaffective patients have been reported to spend on average about 20% of their lifetimes hospitalized or in an episode (Angst 1986). Angst (1986) has also reported that the median number of hospitalizations over a 25-year period was between six and seven. Although many definitions of schizoaffective disorder allow for the sequential manifestation of psychotic and affective symptomatology, most patients show concurrent expressions of psychotic and affective symptoms (Marneros et al. 1986).

To put the results of longitudinal studies of schizoaffective disorder in context, it is helpful to keep in mind that, in general, the long-term outcome of schizoaffective disorder is better than in schizophrenia, but worse in comparison to affective disorder (for extensive reviews of this topic, see Harrow and Grossman 1984; Angst 1986; Samson et al. 1988). There is also some evidence that long-term outcome for the manic subtype of schizoaffective disorder is similar to that for mania or bipolar disorder, whereas outcome comparisons of the depressive subtype and major depression reveal substantial differences (Brockington et al. 1980a,b; Clayton 1982). Differential outcomes of other subgroupings of schizoaffective disorder have also been investigated, with much interest focusing on the mainly affective versus mainly schizophrenic distinction in the RDC. Earlier results indicated worse outcomes for the mainly schizophrenic subtype (Levinson and Levitt 1987), but several recent reports have not confirmed this pattern (Coryell et al. 1990a,b; Grossman et al. 1991). For example, Coryell et al. (1990a,b) concluded that chronicity was more predictive of outcome in both depressive and manic subtypes of RDC schizoaffective disorder.

Another study (Tsuang and Coryell 1993) examined the 8-year follow-up of patients with DSM-III-R psychotic depression, schizoaffective disorder, and schizophrenia. The purpose of this study was to investigate the long-term outcome of patients with functional psychoses. The functional status of patients with mood-congruent and mood-incongruent psychotic depression, schizoaffective disorder, and schizophrenia was examined. Patients with psychotic depression had much better outcomes than patients with schizoaffective disorder or schizophrenia. Forty-four percent of patients with psychotic depression were free from psychosis at follow-up in marked contrast to those who had schizoaffective disorder or

schizophrenia, none of whom had recovered. In terms of long-term outcome, patients with schizoaffective disorder could not be distinguished from patients with schizophrenia.

In a German multicenter treatment study (Doering et al. 1998), 354 patients with schizophrenia and schizoaffective disorder were followed for 2 years for the purpose of determining predictors of relapse and rehospitalization. In a statistical analysis of the entire sample, the diagnosis of schizoaffective disorder predicted a worse outcome, in contrast to the well-established view that affective symptoms in schizophrenia are connected with a better outcome. In part, this result might reflect the emphasis on relapse and repeated hospitalizations in the outcome criteria as well as an episodic course with phases that are more frequent, but shorter and more clearly demarcated and with less chronicity and disability than in schizophrenia. In this way, because of their changing psychopathology, patients with the diagnosis of schizoaffective disorder are more likely to meet the criteria for relapse and to need repeated hospitalizations. Nevertheless, outcomes in areas such as social adjustment or employability would usually be better for schizoaffective patients than for patients with schizophrenia.

A major goal of longitudinal studies is to identify prognostic factors, particularly those variables that predict especially good or poor outcomes. The one variable that has emerged with some consistency is the persistence of psychotic symptoms in the absence of affective symptoms, which substantially increases the risk of poor outcomes such as persistent psychosis (Brockington et al. 1980a; Himmelhoch et al. 1981; Maj et al. 1987; Coryell et al. 1990a,b). Other risk factors for a negative outcome include poor premorbid personality (Coryell et al. 1990a,b; del Rio Vega and Ayuso-Gutierrez 1990), premorbid instrumental skills (McGlashan and Williams 1990), chronicity at index assessment (Maj et al. 1987; Coryell et al. 1990a,b), frequency of relapses (del Rio Vega and Ayuso-Gutierrez 1990), and the number of typically schizophrenic symptoms (McGlashan and Williams 1990). Marneros et al. (1993) investigated factors influencing the long-term outcome of schizoaffective disorders in 101 patients with a mean duration of illness of 25.5 years. The most important factors influencing the development of persisting psychological alterations proved to be the absence of pure melancholic episodes during the course, life events at onset, the presence of first-rank schizophrenic symptoms, schizomanic–depressive mixed episodes, and a higher annual frequency of episodes. The most relevant factors influencing the development of negative social consequences due to the illness were found to be an asthenic/low self-confidence premorbid personality and elevated numbers of episodes and cycles. There were only partial similarities with schizophrenia or affective disorder.

To assist clinicians in identifying patients with an increased likelihood of having a schizophrenia-like course and outcome, Coryell et al. (1990a,b) developed the following "poor-outcome prototype": a patient who has had a poor premorbid or adolescent social adjustment and inadequate social adjustment as an adult, a chronic course, and, at some point, persistent psychotic features that dominated the clinical picture. This prototype appeared to be valid in both depressive and manic types of RDC schizoaffective disorder (Coryell et al. 1990a,b). A focus for future research will be to validate such predictors in other patient populations and to refine the concept of a poor prognosis prototype in homogeneous subgroups that are identified as being nosologically important.

8 Treatment Strategies

Studies addressing psychopharmacologic treatment of schizoaffective disorder are made more difficult to generalize from because of the nonuniform way in which schizoaffective disorder has been defined in the literature. As it is our contention that schizoaffective disorder is genetically heterogeneous, subtyping is a natural next step. We have found it useful for psychopharmacologic treatment purposes to divide schizoaffective disorder by polarity (e.g. bipolar vs. unipolar schizoaffective disorder) and to pay especially close attention to interepisode psychotic symptomatology (i.e. to psychotic symptoms that persist in the absence of a full affective syndrome).

When viewed cross-sectionally, schizoaffective disorder, bipolar type (or "schizomania") probably represents primarily a mixture of those patients with bipolar affective disorder and those with schizophrenia in excited states (Clayton 1982). A high index of suspicion for organic/toxic states is also important. If a certain proportion of these patients actually suffer from a form of bipolar disorder, certainly the use of antimanic agents, including neuroleptics, lithium, and anticonvulsants (e.g. carbamazepine and valproate), makes sense. Such agents have been explored alone (Prien et al. 1972; Abrams and Taylor 1976; Brockington et al. 1978; Pope et al. 1980) and in combination (Biederman et al. 1979; Okuma et al. 1989a,b). Biederman et al. (1979), for example, found a modest benefit from the combination of lithium carbonate and haloperidol, which must then be balanced against the additional risk of greater toxicity. When intermorbid psychotic symptoms persist after mixed symptom

episodes subside, it has been our experience that chronic neuroleptic therapy more likely is necessary. Okuma et al. (1989b) reported that carbamazepine, in combination with neuroleptics, was modestly useful in the treatment of excited states in a mixed group of schizophrenic and schizoaffective patients. Potential adverse effects included increased hallucinatory behavior and worsened psychomotor activity, possibly related to the reported inducing by carbamazerpine of its own metabolism and that of concomitant neuroleptics thus lowering neuroleptic blood levels. Valporate, which does not have a tricyclic structure and does not induce the metabolism of hepatically cleared agents (McElroy et al. 1992), would be a possible alternative. Clozapine has recently also been proposed as an additional alternative (McElroy et al. 1991) for patients with schizoaffective disorder, bipolar or depressed type.

Cross-sectional diagnoses of schizoaffective disorder, unipolar type (or "schizodepression") probably primarily represent a mixture of patients with psychotic affective disorder (e.g. delusional depression) and schizophrenic patients with depressive syndromes (Brockington et al. 1980a), together with some patients with bipolar disorder and diverse other conditions (Clayton 1982). Again, combination treatment suggests itself. The use of antidepressants from all classes in combination with neuroleptics is plausible, with tricyclics and monoamine oxidase inhibitors (MAOI) so far being most closely examined (Siris et al. 1978, 1987). It has been suggested that one source of variance in whether these patients respond to the addition of an antidepressant is whether or not patients with current florid psychotic symptoms are excluded (Kramer et al. 1989). In light of additional weight gain seen as a potential side effect of combining phenothiazines and tricyclics (Prusoff et al. 1979), selective serotonin reuptake inhibitors (which do not cause weight gain) might be an attractive alternative, although to our knowledge this alternative has so far not been studied systematically. Augmentation with lithium, analogous to that used with treatment-resistant depressions (de Montigny et al. 1983), has also been suggested for the treatment of refractory psychotic depression, especially that associated with a bipolar course (Nelson and Mazure 1986). Additionally, it has been suggested by M.T. Tsuang et al. (1979) that electroconvulsive therapy may reduce mortality in schizoaffective patients.

In a recent review of controlled treatment studies, Keck et al. (1996) found that in the acute treatment of schizoaffective disorder, bipolar type, typical antipsychotics and lithium were comparable in efficacy except in agitated patients, for whom antipsychotics were superior. The combination of lithium and antipsychotics appeared to be superior to antipsychotics alone in this patient subgroup. Some preliminary data from open trials suggests that the mood stabilizers valproate and carbamazepine and the novel antipsychotics clozapine and resperidone may be promising treatments for schizoaffective disorder. Fenn et al. (1996) also found, in a 5-year naturalistic study of phamacotherapy in schizoaffective disorder, that valproate monotherapy had increased as a percentage of total pharmacotherapies, while lithium monotherapy had declined.

9 Conclusion

We have reviewed schizoaffective disorder, perhaps the most common atypical psychosis, from multiple perspectives. Our necessarily provisional view is that schizoaffective disorder is a genetically heterogeneous condition primarily composed of schizophrenia and affective disorders and perhaps a residual, currently undifferentiated condition. For research purposes, schizoaffective disorder can accordingly be subtyped into schizophrenic, affective, and undifferentiated categories. Other subtyping schemes (e.g. chronic vs. nonchronic, and manic vs. depressive) also have potential value and should not be prematurely excluded at this stage of the investigation. For psychopharmacological treatment purposes, subtyping into bipolar and unipolar categories has proved to be of clinical value. Future research will be needed to resolve the continuing uncertainty regarding diagnosis, treatment, and prognosis in this heterogeneous but important group of psychoses.

CHAPTER

30

J.E. Cooper, S.P. Singh

Acute and Transient Psychoses

1 Introduction: Disorders but Not Diseases

The traditional binary division of functional psychosis into schizophrenia and manic-depressive psychosis does not account satisfactorily for acute psychotic disorders which have an abrupt onset, short duration, no association with organic states and good outcome. Such disorders are now recognised in both the ICD-10 and the DSM-IV as being separate from the schizophrenic syndromes and the affective psychoses (see the Appendix). This indicates a widespread international agreement that these conditions have a reasonable degree of identity as descriptive clinical states, but in both the classifications this recognition is only as "disorders", i.e. as sets of symptoms and behaviour that are "clinically recognisable" (ICD-10) or "clinically significant" (DSM-IV). There is not yet sufficient knowledge about their aetiology, their genetics or the mechanisms and processes that underlie their symptoms to move them any significant distance along the sliding scale that leads from the modest status of clinical disorder to recognition as a disease entity.

The psychiatric literature is replete with terms for such short-lasting, non-affective and good-outcome psychosis. Floru (1974) collected one hundred such terms, the more common ones being "acute", "atypical", "psychogenic", "reactive", "hysterical" and "third" psychosis. Some of these terms, such as psychogenic psychosis, reactive psychosis and hysterical psychosis, presume an aetiological significance of stress or personality factors, while others, such as atypical psychosis and third psychosis, reflect only a presumption of their distinction from other functional psychosis. Some of the original terms have maintained their regional popularity, such as reactive psychosis in Scandinavia, *bouffée délirante* in France and hysterical psychosis in India. The overlap between concepts is well illustrated in Perris's monograph on cycloid psychoses; he lists 28 different terms proposed by psychiatrists in five different countries that, as he points out, "label quite similar psychotic syndromes" (Perris 1974).

The main justification for the present descriptive separation of the acute and transient psychoses from other functional psychoses does not depend only upon a very acute onset, since the association of an acute onset with a comparatively brief illness has been observed in almost all types of psychoses. For instance, the report on the International Pilot Study of Schizophrenia contains the conclusion that "acute cases have a propensity to recover regardless of the cultural setting" (Sartorius et al. 1978). It is the association of acute onset and favourable outcome with an unusually varied and changing clinical picture that possesses nevertheless a reasonable degree of clinical similarity on recurrence that tips the balance in favour of separation. Other studies provide additional justification (Guinness 1992; Ohaeri 1993; Susser et al. 1995a).

Some of the original authors of these concepts made overt assumptions that these symptoms were caused by underlying pathological processes or mechanisms that would soon be discovered; almost 100 years later, these mechanisms (if they exist at all) are still unknown. Manschreck and Petri (1978) pointed out the several methodological shortcomings of research in this area, especially the inadequacies of definitions, aetiological prejudices, the use of non-standardised assessment methods often under emergency conditions, poor pre-morbid and follow-up assessments and a limited understanding of the interactions between cultural influences and psychopathology. Their extensive review of this complicated topic made it clear that, up until then, the different findings could not be compared in any detail. Cultural issues concerning acute psychoses have been discussed extensively (German 1972; Leff 1981) and are still one of the priority areas for further fieldwork (see also Chap. 14, Vol. 2, Part 1).

An understanding of the present position (illustrated by the criteria to be found in the ICD-10 and DSM-IV; see the Appendix) is best approached by a brief commentary on the historical development of concepts. Further progress is unlikely to occur until large-scale epidemiologically based and prospective studies that use defined criteria and comparable methodology have been carried out. In addition, direct participation by medical and social anthropologists in both the fieldwork and the interpretation of data is necessary to clarify the cultural issues involved. This chapter follows the ICD-10 and DSM-IV in excluding from this group acute psychosis with predominantly depressive or manic symptoms, however abrupt their onset or brief their duration. Two types of psychoses that are usually acute and of brief duration are mentioned in this chapter for completeness, but are described elsewhere in more detail; these are schizo-affective psychoses (see Chap. 29, Vol. 3, Part 1) and puerperal psychoses (see Chap. 13, Vol. 2, Part 1).

2 Historical Development of Concepts

The historical development of concepts will be discussed in four parts: (1) three distinct national traditions (of France, Germany and the Nordic countries), (2) schizo-affective and schizophreniform psychoses, (3) acute psychoses associated with social

changes or with particular cultures and (4) puerperal psychoses.

2.1 Three National Traditions

The three national traditions discussed here overlap in both time and in clinical content. The approximate historical sequence is as follows: (a) the French concept of *bouffée délirante*, (b) the German school of Kleist and Leonhard, emphasising "cycloid psychoses", later developed by Perris, and (c) the Nordic concept of reactive (and psychogenic) psychoses.

2.1.1 Bouffée Délirante

Magnan (in 1886) and Legrain (in 1890) were the first to suggest that a special group of very acute and transient psychotic states could be identified as separate from other and more lasting mental illnesses (Pichot 1982). Their description of *bouffée délirante* has stood the test of time as a clinical state that can be recognised if sought after, but there is very little information about its frequency outside France. Even there, the fairly infrequent use of this diagnosis (around 10% or less in the study of one mental hospital) may be diminishing in favour of more conventional categories such as acute schizophrenia (Johnson-Sabine et al. 1983).

The first descriptions emphasised that 75%–80% of cases had no obvious precipitating cause. In an attempt to convey the abrupt and spectacular nature of the disturbance, the original authors used phrases such as "the delusions may erupt with astonishing speed", "delusions are many and various", "hallucinations are frequent and florid" and "the patient undergoes marked changes of mood, violent oscillations, and 'waves' of delusions" (Ey 1960). Remission of the first episode is described as usually complete within anything from a few days to a few weeks, but recurrence is expected in at least 40%–50% of patients. In addition, several studies of long-term outcome agree that as many as 20% of patients eventually develop obvious chronic schizophrenia.

2.1.2 German School of Kleist and Leonhard and the Concept of Cycloid Psychosis

Kleist (1928) and his pupil Leonhard (1961, 1972) studies over many years some special varieties of acute psychoses and gave them names such as "anxiety-elation psychosis", "confusion psychosis" and "motility psychosis", collectively referred to as "cycloid psychoses" (Chap. 28, Vol. 3, Part 1). Their main features are a sudden onset, a varied and fluctuating clinical picture and rapid resolution; they therefore have many similarities with *bouffée délirante*. Kleist himself made it clear that he regarded these states as nosological entities separate from schizophrenia, since he assumed that "there must be different centres in the brain stem in which these psychoses originate". Most other authorities have not accepted this presumption of a distinct anatomical or physiological basis and have preferred to regard these states as special varieties of either schizophrenia or of manic-depressive psychosis.

The concept of a cycloid psychosis was developed further by Perris in Sweden (Perris 1974), who follows Kleist and Leonhard in regarding it as separate from both the schizophrenic syndrome and the affective psychoses, but on the grounds of familial occurrence and clinical features, rather than a presumption of disturbed brain physiology or structure. More recent attempts to study this concept in the UK (retrospectively re-diagnosed using case notes of patients originally studied for other reasons) have produced only qualified support for the usefulness of this concept as a separate clinical category (Cutting et al. 1978; Brockington et al. 1982a).

2.1.3 Nordic Concept of Reactive (or Psychogenic) Psychosis

Psychogenic psychosis has been a common diagnosis in Scandinavian countries since the turn of the century, used for patients who develop an acute psychosis, usually of short duration with complete recovery, immediately following a severe emotional trauma. Wimmer of Copenhagen started this tradition in 1916, and Faergeman (1963) and others later developed the psychoanalytic and dynamic aspects of the concept. But again, the problems associated with these concepts were evident in Faergeman's follow-up study, in that about half of the 70 patients followed up had clearly developed a schizophrenic or affective illness after 16–19 years. In contrast, Anderson and Laerum (1980) found more recently that only 10% of their cohort of psychogenic psychosis developed schizophrenia over a 10- to 14-year follow-up period. Half the patients who had a recurrence were again diagnosed as having psychogenic psychosis in recurrent episodes. McCabe (1975) applied Jasper's criteria for psychogenic reactions to all patients newly admitted to a Danish hospital. Jasper's criteria include a temporal correlation between onset of illness and a precipitating stress, adequacy of the precipitating stress in psychogenesis and a symbolic meaning such

as defence, wish fulfilment etc. between the contents of the reaction and the stress. Patients thus identified as having a reactive psychosis had an acute onset precipitated by stress, affective symptoms, good premorbid adjustment, preservation of affect, brief duration of illness and absence of family history of schizophrenia. Unfortunately, the application of this logical set of criteria to real patients resulted in many being rejected. McCabe started with 388 patients with a hospital diagnosis of reactive psychosis, of which 250 appeared to fulfil these criteria at the documentary level. Just over 100 of these were examined in the study, only 40 of which fulfilled the criteria above. In other words, his study confirms the puzzling fact that the majority of patients with acute and brief psychoses have illnesses which do not have any understandable relationships with their personality or with their life experiences. Nevertheless, psychogenic and reactive psychoses are still popular concepts in the Scandinavian countries and may be gaining acceptance elsewhere. Stromgren (1989) has argued that reactive psychoses are nosologically distinct and "invariably have a good prognosis". In a recent multicentric study of Nordic psychiatrists, Hansen et al. (1992) found that inter-rater reliability for "reactive psychosis" was as high as for schizophrenia and affective psychosis (but their study was based only upon case summaries, and not upon joint live assessments). A 6-month prospective study of "reactive psychosis" in Chandigarh, North India, found that the diagnosis was stable over time and most patients showed clinical and social recovery over 6 months (Chavan and Kulhara 1988). As compared to Scandinavian patients, Indian patients had more delusions, hallucinations and emotional syndromes.

Other retrospective case studies have emphasised the stability of this diagnosis over time, its relation to stress and its better outcome as compared to schizophrenia. It is likely that the authors of many of these reports also assume that schizophrenia is by definition a comparatively long-standing illness with an unfavourable outcome (Kapur and Pandurangi 1979; Andersen and Laerum 1980; Stephens et al. 1982; Beighley et al. 1992). Reactive psychosis is reported to be similar to hysterical psychosis except for the presence of premorbid histrionic traits in the latter (Modestin and Bachmann 1992) and also similar to the French diagnostic category of *bouffée délirante* (Pichot 1986).

2.2 Schizo-affective and Schizophreniform Psychoses

Schizo-affective disorders are dealt with in Chap. 29 (Vol. 3, Part 1), but deserve a brief mention here because some of the patients to whom this term has been applied in the past are also covered by the other acute psychotic states described in this chapter. The term "schizo-affective" was first used by Kasanin (1933) in the USA to describe patients whose psychosis was characterised by "a very sudden onset in a setting of marked emotional turmoil with a distortion of the outside world ... the psychosis lasts a few weeks to a few months and is followed by a recovery." He also emphasised that these psychoses were usually associated with a severe mental stress. It seems clear that Kasanin regarded these patients as having unusual forms of schizophrenia rather than a different illness, but the resemblance to the clinical states described above is obvious. Schizo-affective has more recently been used with a quite different meaning in both the ICD-10 and DSM-IV to describe illnesses with a mixture of marked schizophrenic and affective symptoms present at the same time, in more or less equal proportions and with no necessary implication of abrupt onset, psychological causation or short duration (although these may well be present).

The term "schizophreniform" has also been subject to a change of meaning over the years. It was originally used by Langfeldt (1939) to describe patients with atypical forms of schizophrenia that had a clear psychogenic cause, an acute onset, a rapid response to treatment and a favourable outcome; Langfeldt was interested in differentiating these illnesses from more typical or "process" types with an insidious onset and poor outcome. The DSM-III (American Psychiatric Association 1980) used it to cover quite different patients who had typical symptoms of schizophrenia but with a duration less than the 6 months required for that diagnosis. There has been a change in the DSM-IV, which brings it back closer to the original meaning of Langfeldt, but it remains separate from the DSM-IV category of "brief psychotic disorder". The term "schizophreniform" has never been used in the ICD system.

2.3 Acute Psychoses Associated with Social Changes or with Particular Cultures

The occurrence of atypical and acute psychiatric disorders, including psychoses, has often been reported in association with potentially stressful social changes such as immigration (Lambo 1965; Leff 1981; Collins et al. 1996). There are also many reports suggesting that people living in non-European cultures are more likely to develop atypical psychoses than Europeans living in Europe (German 1972). This, of course, is using "atypical" as viewed from a European perspective, and it is not surprising that medical anthropologists, and some psychiatrists from non-

European cultures, have objected to the implicit assumption that what European psychiatrists regard as atypical is accepted as such in other parts of the world. This is one of the main issues that show the need for a contribution from social anthropologists to future studies of acute psychoses.

Psychiatric disorders of abrupt onset and often spectacular symptoms that are alleged to occur only in specific cultural settings have been described for many decades and are now featured in the Research Diagnostic Criteria of the ICD-10 (and also in the DSM-IV). Often previously described as the "culture-bound psychoses", there is now increasing agreement that these are not psychoses, however that term is defined. The more they are observed at first hand and in detail, the more apparent it becomes that they are best regarded as culturally influenced (and in a sense socially acceptable) states of anxiety, acute depression, distress, aggression and attention-seeking behaviour (Yap 1974; Leff 1981; see also Chap. 14, Vol. 2, Part 1).

2.4 Other Concepts

The term "hysterical psychoses" was revived briefly in the USA (Hollander and Hirsch 1964; Hirsch and Hollander 1969) in an attempt to emphasise the often individual and reactive clinical picture found in these disorders. The concept is of a disorder with a sudden and dramatic onset, temporally related to a psychosocial stressor in an individual with a "hysterical character". The clinical symptoms included hallucinations, delusions, depersonalisation, transient and circumscribed thought disorder, lack of affective flattening and grossly disruptive behaviour. The disorder lasts between 1 and 3 weeks with full recovery and no residual symptoms. Hysterical psychosis has also been described in India (Kuruvilla and Sitalakshmi 1964) and Switzerland (Modestin and Bachmann 1992).

2.5 Puerperal Psychosis

There has been a long-standing debate about whether puerperal psychosis should be regarded as a separate clinical entity. Because of the association with childbirth, puerperal psychoses have been given much more attention in recent years than other varieties of acute psychoses, and most of the information available is of good quality. The large majority of experts now accept that puerperal psychoses are best regarded as unusually acute variants of either affective psychoses (about 80%–90% of cases) or schizo-affective and schizophrenic psychoses (Brockington et al. 1982b). They are important because they are the most common of the very acute and transient psychoses, occurring after about two births in every 1000. Around 75% of these illnesses become manifest within 16 days of delivery. The most frequent pattern is that the mother becomes perplexed, restless and confused (although not disoriented in the organic sense) a few days after giving birth; over the next week or so, a more obvious affective state develops with manic symptoms being quite common. The optimal treatment and management of women with puerperal psychosis requires skilled assessment by experienced staff working together as a specialised team; it should be possible to combine admission facilities for a small number of mothers and babies with an extensive community and home-visiting service (Oates 1989).

3 Current Nosological Status

The increasingly widespread use of standardised interviewing and rating methods, e.g. in the World Health Organisation studies on schizophrenia and related disorders (Sartorius et al. 1978; Jablensky et al. 1992), has led to an improvement of the quality of research information on some important aspects of psychotic disorders. Only a limited part of this information was relevant to acute and atypical psychoses. There was nevertheless sufficient information to encourage a new and more systematic approach to this subject in the preparation of ICD-10 Chap. V (F). The structure of the final version of F23 – "Acute and Transient Psychoses" – allows the recording of the main clinical syndromes that have typified the national traditions already discussed but without making assumptions about relationships between the syndromes and the presence or absence of either acute stress or typical schizophrenic symptoms (see the Appendix). This point needs emphasis, because of the common (but false) clinical assumptions that a psychological stress can always be identified as the cause of an acute psychosis and that typical schizophrenic symptoms are never present. The 3-month duration criteria in the ICD-10 are supported by the finding of a recent study that 80% of patients with acute psychosis have a mean episode duration of 2 months (Susser et al. 1995b).

The diagnostic criteria for brief psychotic disorder in the DSM-IV (see the Appendix; American Psychiatric Association 1994) are broadly similar to those of F23 in the ICD-10, but the category has fewer subdivisions; it is probably compatible with a condensed form of F23.

4 Epidemiology

There are very few epidemiological studies of acute and brief psychoses in which standardised and reliable methods for the assessment of symptoms and diagnoses have been used. Using the data from some large-scale WHO International Collaborative Studies of psychotic disorders (Jablensky et al. 1992; Varma et al. 1992; Cooper et al. 1990), and also from a separate study in the USA, Susser and colleagues have found evidence to support the separation of acute brief psychoses from both schizophrenia and the affective psychoses. The field work of these studies preceded the publication of both the ICD-10 and DSM-IV, but the criteria put together for "acute non-affective remitting psychoses" are broadly similar to those of the ICD10 and DSM-IV. (Susser and Wanderling 1994; Susser et al. 1995a,b). These studies suggest that there may be large differences in the incidence of acute brief psychosis between different centres, but without the differences in incidence between the sexes that has been found for both schizophrenia and affective psychoses. However, until studies are done which use methods designed especially for the study of acute psychoses, these conclusions must be regarded as provisional.

5 Clinical Features

The clinical features of acute psychotic states have already been described in Sect. 2. The dramatic and often unexpected nature of the onset is the main feature that sets them apart from other psychoses, together with the liability for there to be rapid changes within a few hours from one predominant type of symptom to another. A good pre-morbid adjustment and the frequent absence of a family history of psychiatric disorder can make the development of such a clearly abnormal state very surprising for family and friends. The perplexity and "confusion" that are often prominent in the earliest stages need to be distinguished from the more persistent and stable disorientation of organic states, but with careful observation this distinction is usually not difficult to make. The content of the psychotic symptoms is sometimes understandable in the light of the patient's cultural background and experience of recent stress, but there are no clear links in a large proportion of patients. It is not uncommon to find that a person presenting with acute psychosis also has a mild non-specific pyrexia (Collins et al. 1996) or a history of having taken non-toxic amounts of alcohol, other drugs or local herbal remedies (i.e. amounts or substances that are not in themselves unusual for that person or that social setting). The significance of this is unknown, and in most cases it is likely that the substances were taken in the hope of counteracting the unpleasant early symptoms of psychosis that were already being experienced.

A large proportion of patients with acute psychoses make a full recovery within a few months, and three quarters may be in full remission at 1 year (Varma et al. 1996); others with persistent symptoms will require a change of diagnosis to schizophrenia, affective psychosis or persistent delusional disorder.

6 Management and Treatment

The main aims of the early management are to facilitate a rapid resolution of symptoms and to minimise the disruptive influence of the illness on the patient's personal and family relationships and activities.

6.1 Initial Assessment

Individuals with acute psychoses usually present initially to the medical services before being seen by an experienced psychiatrist, often at inconvenient times in inconvenient places. It is often many hours, if not several days, before detailed and skilled psychiatric assessment is carried out, by which time the most acute (and clinically important) phase has probably passed or has been modified by medication. The initial assessment should include the usual detailed personal history and full evaluation of the mental state. Interviews with close relatives or friends will be needed, since it is likely that the patient will be able to give only information that is heavily influenced by the symptoms, or at best only a partial account. Focus should be on the onset and early course of symptoms, with special attention paid to possible relationships with life events. Enquiry into pre-morbid coping skills, past vulnerability to stress, alcohol and drug history, family history of psychiatric illness and current social situation including family support will allow the development of an individual treatment plan, assuming that laboratory investigations have also been done to ensure that no physical illnesses are present. Careful assessment of cognitive functions is of particular importance, since perplexity in an acute psychosis can mimic the acute confusional state due to organic causes. However, patients in these "functional" acute

psychoses do not display the marked and persistent disorientation of an organic delirium.

In the differential diagnosis, a variety of medical disorders need to be considered, the most important being drug-induced delirium, head injury, epilepsy and drug-induced psychosis. It is likely that a number of laboratory investigations will be required, including a toxicology screen.

6.2 Initial Treatment

Patients will usually need to be admitted to hospital. This allows close observation of the mental state (often rapidly changing) and provides a safe environment in which overactivity and emotional turmoil can be contained. Hospitalisation also makes it possible for the patient to be observed for a drug-free period of several days; this is important, since some acute psychotic states may remit within days without medication. If drug therapy is started at the earliest possible time in every case, spontaneous remission cannot be differentiated from response to medication. Medication should only be started immediately if the symptoms are particularly severe or distressing. If the symptoms persist for more than 3–4 days, medication should be started.

Anti-psychotics are the mainstay of drug treatment of acute psychosis. A high-potency anti-psychotic such as haloperidol may be used, although others such as chlorpromazine have the advantage of sedation. Oral administration is usually sufficient, but in some patients liquid preparations to ensure intake or intramuscular use for more immediate action may be necessary. The anti-psychotics should be given initially in a low dose, with the increases adjusted according to the size and behaviour of the individual. There is some evidence that treatment response may be quicker in acute psychosis than in schizophrenia.

Anti-parkinsonian agents should not be given routinely, since only a comparatively short period of medication may be required. It is best to reserve their use for when comparatively large doses of anti-psychotics are needed and when extrapyramidal signs have appeared. In these circumstances, their use may also improve later compliance with drug therapy.

The short-term use of benzodiazapines in acute psychotic states is well established. They allow a rapid control of agitation, excitement and other behavioural disturbances, and their use may permit a lower dose of anti-psychotics. If excitement, overactivity and euphoria are very prominent (suggesting that the illness might be better viewed as a manic episode), then it is worth remembering that lithium can have a short-term anti-manic therapeutic effect, separate from its use as a long-term prophylactic.

A review of pharmacotherapy of acute psychoses is given in Remington et al. (1998).

6.3 Intermediate Treatment and Management

The early stage of the illness does not provide clues which allow the confident prediction of which patients will have a rapid resolution of symptoms with no further relapse (about one in four) and which patients will have enduring symptoms (again about one in four). Similarly, it is impossible to predict which patients will relapse after recovery from an episode. It is therefore best to adopt a cautious approach to decisions about how long to continue anti-psychotic medication. All patients with an acute psychotic illness of any type, however brief, should continue anti-psychotic medication for at least 6 months. For the last 3 months of this period, a comparatively low dose is justified so long as no symptoms re-appear. If schizophrenic symptoms were present at any time, the anti-psychotic medication should be continued for at least 1 year. The withdrawal of anti-psychotic medication should never be abrupt. The dose should be diminished gradually by stages over 2–3 months with the full knowledge of the patient and family, so that all concerned can watch out for early signs of relapse. A long-term maintenance regime of anti-psychotics (as used for other persistent psychotic disorders such as delusional disorder and the schizophrenic syndrome) is justified for patients who have two or more episodes of acute psychosis within a period of 2 years.

Patients whose symptoms persist beyond the time limits suggested in the diagnostic classifications will require a change in diagnosis; at this stage, they should be subject to a complete clinical review, with the adoption of a new and longer-term programme of management and treatment. The reader may also wish to refer to Chap. 11 (Vol. 3, Part 1) for the treatment of acute schizophrenia, Chap. 23 (Vol. 3, Part 1) for the treatment of acute mania and depression and Chaps. 13–17 (Vol. 2, Part 2) for the treatment of acute psychiatric states accompanying somatic illness.

6.4 Psychosocial Measures

As with all patients admitted to hospital with severe psychiatric disorders, the maintenance of contact between the patient, family and friends should be given a high priority by all members of the therapeutic team. The unexpected and often spectacular behaviour frequently proves to be unusually distressing for all concerned, and both the patient and those most directly

affected will benefit from positive contacts and support from the professional staff. Hospital visiting should be encouraged, even during the acute stage.

In all cases, individual "supportive" psychotherapy with a key worker should be started in the acute phase, and as the acute psychotic symptoms diminish, various psychosocial interventions should be considered. The therapeutic aims are to restore the patient's self-esteem and reduce any feelings of self-blame and inadequacy and fears of further violence or loss of control. It is important to assess the patient's vulnerability to stress and life events which may have triggered the psychosis; this should include a review of the coping mechanisms of the patient and family. It may be possible to improve problem-solving skills and to suggest strategies that may help in the avoidance of future personal crises. A return to normal functioning may be helped by a period in a structured environment such as a day-hospital, and long-term social support or psychotherapy should be considered for those patients with enduring personality or family problems.

In all these measures, the support and co-operation of the family are vital in ensuring the best possible compliance with treatment and to pick up early signs of relapse. Educative discussions by various members of the therapeutic team with both patient and family about the symptoms, the nature of the illness, problems and purposes of medication and likely prognosis and outcome should therefore be a prominent part of the management package.

6.5 Early Intervention and Cognitive Therapy

The early detection of patients developing any type of psychosis has come into prominence recently (Birchwood et al. 1997; Yung et al. 1996), with the aim of facilitating the earliest possible intervention in the psychotic clinical state. The addition of new forms of cognitive therapy for both acute and longer-lasting psychotic symptoms to the general principles of treatment and management described above is often a part of this new approach (Drury et al. 1996a,b; Kuipers et al. 1997). This work is attracting considerable interest and seems likely to develop rapidly in the near future.

Appendix. ICD-10 Criteria for Acute and Transient Psychotic Disorders and DSM-IV Criteria for Brief Psychotic Disorder

ICD-10 Chapter V (F)

(For reasons of space, only the brief description taken from the short glossary is given here. More detailed descriptions are contained in the *Clinical Descriptions and Diagnostic Guidelines* (WHO 1992) and the *Diagnostic Criteria for Research* (WHO 1993) of the ICD-10).

F23 Acute and Transient Psychotic Disorders

A heterogeneous group of disorders characterised by the acute onset of psychotic symptoms such as delusions, hallucinations and perceptual disturbances and by the severe disruption of ordinary behaviour. Acute onset is defined as a crescendo development of a clearly abnormal clinical picture in about 2 weeks or less. For these disorders there is no evidence of organic causation. Perplexity and puzzlement are often present, but disorientation for time, place and person is not persistent enough to justify a diagnosis of organically caused delirium. Complete recovery usually occurs within a few months, often within a few weeks or even days. If the disorder persists, a change in diagnosis will be necessary. The disorder may or may not be associated with acute stress, defined as usually stressful events preceding the onset by 1–2 weeks.

F23.0 Acute Polymorphic Psychotic Disorder Without Symptoms of Schizophrenia

An acute psychotic disorder in which hallucinations, delusions or perceptual disturbances are obvious but markedly variable, changing from day to day or even from hour to hour. Emotional turmoil, with intense transient feelings of happiness or ecstasy, or anxiety and irritability, is also frequently present. The polymorphism and instability are characteristic for the overall clinical picture and the psychotic features do not justify a diagnosis of schizophrenia (F20.-). These disorders often have an abrupt onset, developing rapidly within a few days, and they frequently show a rapid resolution of symptoms with no recurrence. If the symptoms persist the diagnosis should be changed to persistent delusional disorder (F22.-).

Includes:

- *Bouffée délirante* without symptoms of schizophrenia, or unspecified
- Cycloid psychosis without symptoms of schizophrenia, or unspecified

F23.1 Acute Polymorphic Disorder with Symptoms of Schizophrenia

An acute psychotic disorder in which the polymorphic and unstable clinical picture is present, as described in F23.0; despite this instability, however, some symptoms typical of schizophrenia are also in evidence for the majority of the time. If the schizophrenic symptoms persist the diagnosis should be changed to schizophrenia (F20.-).

Includes:

- *Bouffée délirante* with symptoms of schizophrenia
- Cycloid psychosis with symptoms of schizophrenia

F23.2 Acute Schizophrenia-Like Psychotic Disorder

An acute psychotic disorder in which the psychotic symptoms are comparatively stable and justify a diagnosis of schizophrenia but have lasted for less than about one month; the polymorphic unstable features, as described in F23.0, are absent. If the schizophrenic symptoms persist, the diagnosis should be changed to schizophrenia (F20.-).

Includes:

- Acute (undifferentiated) schizophrenia
- Brief schizophreniform disorder/psychosis
- Oneirophrenia
- Schizophrenic reaction

F23.3 Other Acute Predominantly Delusional Psychotic Disorders

Acute psychotic disorders in which comparatively stable delusions or hallucinations are the main clinical features, but do not justify a diagnosis of schizophrenia (F20.-). If the delusions persist, the diagnosis should be changed to persistent delusional disorder (F22.-).

Includes:

- Paranoid reaction
- Psychogenic paranoid psychosis

F23.4 Other Acute and Transient Psychotic Disorders

Any other specified acute psychotic disorders for which there is no evidence of organic causation and which do not justify classification to F23.0–F23.3.

Note: Any other acute psychotic disorders that are not classifiable under any other category in F23 (such as acute psychotic states in which definite delusions or hallucinations occur but persist for only small proportions of the time) should be coded here. States of undifferentiated excitement should also be coded here if more detailed information about the patient's mental state is not available, provided that there is no evidence of an organic cause.

Diagnostic Criteria for Brief Psychotic Disorder of DSM-IV

A. Presence of one (or more) of:
   1. Delusions
   2. Hallucinations
   3. Disorganised speech (e.g. frequent derailment or incoherence)
   4. Grossly disorganised or catatonic behaviour

Note: Do not include a symptom if it is a culturally sanctioned response pattern.

B. Duration of an episode of the disturbance is at least 1 day but less than one month, with eventual full return to level of premorbid level of functioning.

C. The disturbance is not better accounted for by a Mood Disorder With Psychotic Features, Schizoaffective Disorder, or Schizophrenia and is not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition.

Specify if:

- With marked stressor(s) (brief reactive psychosis): if symptoms occur shortly after and apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture
- Without marked stressor(s): if psychotic symptoms do *not* occur shortly after, or are not apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture
- With postpartum onset: if onset within 4 weeks postpartum

Electroconvulsive Therapy

1 Introduction

Despite its long history of use as an effective treatment for severe psychiatric illness, electroconvulsive therapy (ECT) is often misunderstood, even by mental health professionals. This is partly due to negative portrayals in the media, which often have distorted crucial facts about patient selection (e.g. ECT being used as punishment for antisocial behavior) or treatment technique (e.g. ECT being administered without anesthesia). However, the lack of knowledge about ECT may also have resulted from the relative lack of controlled research, especially in comparison to the large body of psychopharmacological research that emerged in the 1960s and 1970s. These disparate phenomena, and the efficacy of psychopharmacological agents, contributed to the reduced utilization of ECT from the 1960s to the early 1980s. This trend has reversed, and the past 15 years has seen renewed interest in ECT, reflected both in stabilization of its utilization and increased research, especially in the areas of treatment technique. In addition to highlighting new findings, this chapter will also review central clinical issues in ECT as well as research into mechanisms of action.

The use of ECT also has an impact on health care economics. Recent research has shown that the length of hospitalization and associated financial costs are reduced in depressed inpatients who receive ECT early during hospitalization compared to inpatients who do not receive ECT. This effect is particularly marked in psychotic depression (Olfson et al. 1998).

2 Patient Selection: Indications and Contraindications

2.1 Diagnostic Considerations

One of the most interesting aspects of ECT is that it is an effective treatment for a variety of severe psychiatric and neuropsychiatric syndromes. However, the broad spectrum of action of ECT should never obviate the necessity of careful diagnostic assessment prior to a treatment recommendation.

While introduced as a treatment for severe psychosis, early on it became evident that ECT had profound antidepressant effects. This clinical observation withstood rigorous scientific scrutiny, as both direct comparisons of ECT with antidepressant medications and a series of sham-controlled studies (i.e. general anesthesia without the passage of current) in the United Kingdom demonstrated the efficacy of ECT in major depressive disorder (Sackeim et al. 1995). Indeed, no other somatic treatment has ever been demonstrated to be superior in efficacy to ECT in the treatment of major depression, and ECT soon became the "gold standard" against which new antidepressant medications were compared. Response rates for major depression in contemporary research studies, which often employ stringent criteria, are on the order of 65%–80%. A conservative estimate of the efficacy rates in clinical samples would be even greater, perhaps in the range of 80%–90%.

Though less well studied, both clinical reports and controlled research have demonstrated a marked antimanic effect of ECT (Mukherjee et al. 1994). Indeed, ECT appears to be effective in manic patients who have failed treatment with neuroleptics or lithium. The clinical significance of the role of ECT in mania cannot be overemphasized. In fact, ECT may be a life-saving procedure in cases of manic delirium.

The role of ECT in the treatment of schizophrenia is perhaps both the least understood and the most debated. As mentioned, the first use of ECT was in chronically psychotic, institutionalized patients with essentially no other options for treatment. Partly due to sociocultural forces and partly due to the introduction of neuroleptic medications in the 1950s, the use of ECT for the treatment of schizophrenia receded. Since very little research had been conducted, the guidelines for using ECT in patients with schizophrenia that have evolved over the years are conservative and rather vague. For example, ECT is considered appropriate in patients with schizophrenia where "affective symptomatology is prominent" (American Psychiatric Association 1990, p. 8). At least two lines of research call such conservatism into question (Krueger and Sackeim 1995). First, a reevaluation of the few published studies in this area indicate that the efficacy of ECT in schizophrenia rivaled that of neuroleptics and suggested the particular usefulness of ECT early in the course of illness. Second, there is now a modest body of literature demonstrating that the combination of ECT and neuroleptics may be useful in cases of medication-resistance and is more effective than either ECT or antipsychotic medications alone.

In addition to these major psychiatric syndromes, ECT is useful in the treatment of several syndromes that bridge the gap between psychiatry and neurology (American Psychiatric Association 1990). One such illness is catatonia, which is uniquely responsive to ECT. Perhaps related on a pathophysiological level to catatonia is the neuroleptic malignant syndrome, where ECT has been reported to be of substantial benefit. Among neurological illnesses, Parkinson's disease (PD) has received attention as an indication

for ECT (Kellner et al. 1994). Many patients with PD are prone to develop severe depression. In addition, some patients become increasingly refractory to antiparkinsonian medications, leading to psychomotor stupor, while others develop psychosis secondary to pharmacological treatment. ECT is often dramatically effective in these clinical situations. Independent of its antidepressant and antipsychotic mechanisms in PD, ECT also appears to ameliorate motor symptoms, presumably via dopaminergic pathways. Unfortunately, such benefit can be short-lived.

In sum, while the majority of clinical outcome studies in the modern era involve patients with major depression, ECT should also be considered as a valuable tool in the treatment of mania (especially medication-resistant mania), catatonia, medication-resistant psychosis, severe parkinsonism, and certain rare organic mental states.

2.2 Medical Risk–Benefit Ratio

In addition to the appropriate diagnostic indication, the decision to employ ECT is also based on the overall medical health of the patient. In fact, ECT is often considered because a patient cannot tolerate the side effects of psychotropic medication. While ECT is generally a safe procedure, any potential adverse medical effects (see Sect. 4) must be weighed against the potential benefit of the reduction of severe psychopathology, such as extreme suicidality. All patients referred for ECT must undergo a basic medical evaluation, including physical examination, electrocardiogram, and blood and urine testing. A chest radiograph is also generally recommended. Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) is definitely indicated when there is clinical suspicion of intracranial pathology, but the cost-effectiveness of routine screening with these techniques is questionable.

While there are no *absolute* contraindications for the use of ECT, there are situations that pose increased medical risk (American Psychiatric Association 1990; Abrams 1992). The two most commonly encountered areas are cardiac disease (e.g. ischemic heart disease, severe congestive heart failure, or serious arrhythmia) and central nervous system disease (space-occupying lesions resulting in increased intracranial pressure). Other relative contraindications include unstable vascular malformations, pheochromocytoma, and retinal detachment. If any of these situations are known to exist (or are discovered during the pre-ECT medical evaluation), the next step should be to consult the appropriate medical or surgical specialist and obtain any additional diagnostic tests (e.g. cardiac stress test). Once the evaluation is complete, the patient, his or her family, and the physician must then reassess the potential benefits from ECT (e.g. rapid amelioration of suicidal intent) versus the potential medical risks (e.g. cardiac ischemia). Also central in this decision-making process are the possibilities of adding extra safeguards to ECT, such as modification of the cardiovascular response with intravenous beta blockers. Ultimately, if the decision is made to proceed with ECT, then the medical record and the informed consent process should be clear in indicating all aspects of this discussion.

2.3 Predicting Response

As with other treatment interventions, the ability to predict a likely responder (or nonresponder) to ECT would be of considerable clinical utility. In fact, over the past four decades there has been a significant effort to identify clinical or biological predictors of outcome with ECT (Nobler and Sackeim 1996). The vast majority of this research has involved patients with major depression. Ironically, from a statistical point of view, the uniformly high overall response rates to ECT make it difficult to discern possible outcome predictors. Indeed, some have contended that if the clinical diagnosis of major depression is accurate, then the issue of predicting response to ECT is moot. On the other hand, since ECT is increasingly provided as a treatment of "last resort," failure to respond often leaves patients and their families quite demoralized. Obviously, being able to provide patients with more realistic estimates of likelihood of response would still be valuable.

With these caveats in mind, some general conclusions can be drawn from the literature. In terms of subtypes of depression, despite the common clinical belief that patients with melancholic major depression are especially responsive to ECT, the available evidence suggests that patients without melancholic features are just as likely to have good outcome. In contrast, patients suffering from delusional depression do appear to be particularly responsive to ECT, which is in keeping with clinical experience. Independent of the clinical subtype of melancholic or delusional depression, severity of depression itself does not appear to be predictive of ECT response. While patient age may be statistically associated with response (with older patients doing better), this relation is probably too weak to be of clinical significance. As it turns out, the strongest clinical predictor of ECT response is episode duration, with a briefer length of the index episode of depression being associated with a better ECT outcome (Nobler and Sackeim 1996).

A more recent line of inquiry has focused on the role of proven medication resistance in terms of predicting

ECT response (Prudic et al. 1990, 1996). This approach is in keeping with the shift in referral trends, with ECT being considered after several unsuccessful medication trials. In fact, proven resistance to adequate pharmacotherapy predicts poorer ECT outcome. This finding may, in turn, help explain why both a longer duration of depressive episode and nondelusional (versus delusional) subtype are associated with lower ECT response rates. In the first situation, the longer an episode lasts, the more likely a patient will have received (and failed) at least one adequate medication trial. In the latter, the opposite may be true, as patients with delusional depression are unlikely to have received adequate pharmacotherapy (in this case, combination treatment of antidepressant plus neuroleptic medication). In fact, recent research indicates that very few patients with delusional depression referred for ECT ever receive or tolerate an adequate medication trial (Prudic et al. 1996).

In addition to the search for clinical predictors of ECT response, there has been much effort to identify biological predictors, including measures of endocrine, biochemical, and neurophysiological function (Nobler and Sackeim 1996). Historically, the greatest attention has been given to the dexamethasone suppression test (DST). Unfortunately, the DST has not emerged as a reliable predictor of ECT response. Similarly, the thyrotropin-releasing hormone stimulation test has been of doubtful value. Two promising areas for research include neurophysins and biopterins, but these preliminary findings require independent replication. Recently, much attention has been given to using the electroencephalographic (EEG) manifestations of individual ECT treatments as potential response predictors. For example, the degree of postictal bioelectric EEG suppression immediately following an ECT treatment appears to be related to positive ECT outcome (Nobler et al. 1993; Krystal et al. 1995). While this observation is statistically significant, the magnitude of the association may not be robust enough for direct clinical application. Another promising area for research focuses on correlating changes in cerebral blood flow (CBF) and cerebral metabolic rate (CMR) with clinical outcome (Nobler and Sackeim 1998). Again, preliminary observations await replication.

3 Treatment Technique

3.1 Questioning Basic Premises

From a historical perspective, it must be stressed that ECT was not the first form of convulsive therapy (Fink 1979). In fact, therapeutic seizures were first elicited chemically. For a variety of reasons, the production of seizures by means of passing an electric current soon became the predominant mode of treatment. However, the link between all the forms of convulsive therapy was the elicitation of a generalized seizure. Thus, over the ensuing decades, the elicitation of the seizure at ECT was viewed as both necessary and sufficient for therapeutic action. In other words, the belief was that as long as a seizure of at least adequate duration was produced, the treatment was considered as optimally effective. This was initially supported by studies which indicated that ECT was less effective if subconvulsive electrical stimuli were administered (i.e. stimuli which did not elicit a generalized seizure). Later, a series of classic research studies in the 1960s reinforced this notion, demonstrating that seizures modified by lidocaine (which has anticonvulsant properties and interfered with seizure expression) had diminished therapeutic efficacy, while seizures elicited with very high electrical stimuli led to greater cognitive side effects (Ottosson 1960). The role of electrical stimulus intensity was otherwise overlooked in this epoch, and the belief arose that, while cognitive side effects were due to the passage of current, this was an unavoidable step in the elicitation of the all-important seizure.

The net result of the early research was that practitioners became focused only on ensuring that seizures were elicited at ECT, and not on any particular aspects of the electrical stimulus required to cause the seizure, nor on aspects of the seizures themselves, apart from their duration. Indeed, an influential paper from the 1970s emphasized that longer seizure duration was associated with superior ECT outcome (Maletsky 1978). However, these concepts came under question due to two lines of converging research in the mid-1980s: (1) The discovery that generalized seizures of adequate duration could be elicited by a form of right unilateral (RUL) ECT that lacked therapeutic efficacy (Sackeim et al. 1987) and (2) the finding that speed of response to bilateral (BL) ECT could be influenced by the intensity of electrical stimulation (Robin and de Tissera 1982). These data led to a critical reevaluation of fundamental notions about the primacy of the seizure and its duration and the role of the electrical stimulus.

3.2 Stimulus Dosing and Electrode Placement

Apart from the waveform (sine wave versus brief pulse), overall intensity, and specific parameters (frequency of pulses, pulse width, current, and train duration) of the electrical stimulus, the other main technical feature of ECT is the positioning of the two

electrodes. Over the decades, a wide variety of electrode placements have been employed, with the major distinction being whether both sides (BL) or just one side of the head (unilateral) are stimulated. In practice, BL ECT has become standardized as bifrontotemporal placement of the electrodes, while widely spaced positioning in unilateral ECT (frontotemporal and vertex) on the nondominant hemisphere is the most common form of RUL ECT.

From very early on in the history of ECT, it was recognized that RUL electrode placement resulted in fewer adverse cognitive effects than BL placement, often dramatically so. At the same time, however, there was considerable disagreement as to whether RUL ECT matched BL ECT in antidepressant efficacy. This led to the controversy in ECT, which exists to this day, of whether BL or RUL ECT should be the treatment of choice. Several significant findings in the past decade are now helping to end this controversy. As mentioned, it was demonstrated that a form of RUL ECT could elicit adequate seizures at ECT that lacked therapeutic efficacy in comparison with BL ECT. Specifically, this was RUL ECT delivered at a stimulus intensity that was just above the minimum intensity that was required to elicit a generalized seizure (also known as the seizure threshold). This seizure threshold was empirically determined or "titrated" at the patient's first ECT treatment by first stimulating at very low levels of charge and then restimulating with successively greater amounts of charge until a seizure was produced. A subsequent study found that if the stimulus intensity relative to the initial seizure threshold were increased to two and a half times this threshold, then the efficacy rate of RUL began to approach that of BL ECT (Sackeim et al. 1993). (The duration of the seizures in each of these treatment conditions were not significantly different, indicating that seizure duration lacked any prognostic significance.) New research now indicates that markedly suprathreshold RUL ECT is as effective as BL ECT while retaining advantages with respect to cognitive side effects (McCall et al. 2000; Sackeim et al. 2000). This, and other research (Abrams et al. 1991), essentially demonstrates that there is a dose-response function for RUL ECT by which this form of ECT may be optimized.

In sum, increasing the stimulus intensity of RUL ECT enhances the efficacy of this modality, while increasing the intensity of either BL or RUL ECT appears to quicken the speed of response to both of these modalities. It must be emphasized that what may be critical is not the absolute level of the electrical stimulus, but rather the degree to which it exceeds seizure threshold. Seizure threshold ranges as much as 50-fold among patients, and the only current method of determining this variable with a modicum of precision is by empirical titration (Lisanby et al. 1996). Thus, especially with RUL ECT, inadequate response can occur in patients with high seizure thresholds even when the absolute stimulus intensity is high.

3.3 Frequency and Number of Treatments

Although remission of major depression is occasionally achieved after only two or three treatments, the typical ECT course consists of six to 12 treatments. Of course, the exact number of ECT treatments required for a given patient cannot be predetermined. Rather, ECT is administered until there is remission of target symptoms. If a patient is receiving RUL ECT and has not shown significant improvement after at least eight treatments, switching to BL ECT may be advisable. If a patient has received ten to 15 BL treatments and not responded, the appropriateness of further ECT needs to be seriously reconsidered.

Treatments are typically given two or three times per week, on nonconsecutive days. While ECT three times per week leads to a quicker response, the same level of symptomatic remission can be reached with twice weekly ECT (Lerer et al. 1995). Moreover, less closely spaced treatments generally result in fewer adverse cognitive effects.

4 Adverse Effects

4.1 Medical Considerations

For the vast majority of patients, ECT is an extremely safe procedure. Patients arrive for treatment having had nothing to eat or drink for at least 6 h. An intravenous catheter is placed, and monitors for electrocardiogram, blood pressure, pulse, oxygen saturation, and EEG are routinely set up. Pretreatment with an anticholinergic agent such as atropine is given to protect against bradycardic events. This is followed by general anesthesia with a brief-acting agent such as methohexital.

While most practitioners prefer methohexital, alternatives include thiopental, propofol, etomidate, and ketamine. Once the patient is unconscious, succinylcholine is given to achieve muscle paralysis. The patient is oxygenated by mask with 100% oxygen during this time until spontaneous respiration resumes. The electrical stimulus is applied, and a seizure is elicited, usually lasting for less than 1 min. This entire process lasts for about 5–7 min. Once patients have regained consciousness, are breathing without assistance, and

vital signs have returned to baseline, they are moved to a recovery area. Patients are generally observed in the recovery area for about 30 min or until they are reoriented and can ambulate without assistance.

In the preanesthetic era, there was a high complication rate with ECT, largely due to the effects of unmodified convulsions, with consequent bone fractures and hypoxia. In contemporary practice, the major area of concern is the potential cardiovascular effects of ECT (Zielinski et al. 1993). Generalized seizures are associated with dramatic increase in heart rate and systolic and diastolic blood pressure. Individuals without ischemic heart disease can tolerate such sustained elevation for the brief ictal period. However, the same hemodynamic state may precipitate coronary artery ischemia in vulnerable patients. As mentioned earlier, a careful pre-ECT medical evaluation should identify such high-risk patients, and, in addition to optimizing medication regimens, intravenous agents (such as beta blockers) can be given during ECT to modify the cardiovascular response. Tachyarrhythmias may also occur in the immediate postictal period. Most are transient and benign, but more malignant rhythms can be rapidly treated with lidocaine. Analogous to ischemic cardiac disease, patients with preexisting arrhythmias are much more likely to develop arrhythmias as a consequence of ECT. Independent of cardiovascular risk, the pre-ECT evaluation should be tailored to the medical status of the patient. For example, while spine films are no longer routine, they may be of value in patients with severe osteoporosis or a history of fracture. In each of these instances, a thorough medical evaluation and modifications of anesthetic technique can minimize adverse consequences of ECT.

4.2 Cognitive Effects

Of more practical concern are the cognitive effects of ECT, which constitute the major factor limiting its use (Sackeim 1992). The most common and stereotypical of these are transient postictal disorientation and retrograde and anterograde amnesia. Less common but more worrisome are severe organic mental syndromes. In general, there is rapid recovery of cognitive function just after the ECT course, with return to baseline by several weeks following treatment. There may be, however, permanent spottiness in memory for events prior to, during, and immediately following the ECT course. In very rare instances, a patient may complain of severe, persistent, and pervasive memory loss. Such patients have been difficult to study in a systematic fashion.

Technical aspects of ECT treatment greatly impact on adverse cognitive effects. BL electrode placement is much more likely than RUL placement to result in prolonged postictal disorientation, amnesia, and organic mental syndromes. The type of electrical waveform delivered by the ECT device also affects cognitive outcome. Less efficient stimulus waveforms, such as sine wave, are much more toxic than brief or ultrabrief pulse stimuli. Finally, increasing the electrical stimulus dose relative to seizure threshold appears to worsen short-term cognitive side effects, and, with BL ECT, may increase the risk of severe organicity (Sackeim 1992).

5 Long-Term Outcomes

5.1 Relapse

While ECT is perhaps the most effective somatic antidepressant treatment, it has long been recognized that relapse rates following a successful course of ECT are disappointingly high. Despite the obvious public health burden of this phenomenon, there has been very little research into possible predictors of relapse after ECT. In terms of clinical variables, one study found that medication resistance prior to successful ECT was associated with higher relapse rates following treatment among patients receiving continuation pharmacotherapy (Sackeim et al. 1990). We also lack biological predictors of relapse. The DST has received the most study, but the findings are not at all consistent and lack clinical usefulness (Nobler and Sackeim 1996).

5.2 Continuation Pharmacotherapy

High rates of relapse after ECT with placebo treatment were observed during a series of trials in the 1960s which demonstrated the superiority of continuation pharmacotherapy with tricyclic antidepressants (TCA) or monamine oxidase inhibitors (MAOI). Due to the influence of these studies, the standard recommendation became to place patients on these medications following ECT. However, many of the patients in these trials had received ECT as a first-line treatment, and it is unknown how many would have been resistant to antidepressants. Given that clinical practice and referral patterns have moved ECT back in the line of treatment options (with many patients having failed antidepressant trials prior to ECT) and that proven medication resistance predicts post-ECT relapse, the wisdom of reflexively placing patients on these medications after ECT has been questioned (Sackeim et al. 1990). New attempts at improving continuation phar-

macotherapy following ECT are in progress. Preliminary findings from a recent multicenter trial indicate that the combination of TCA with lithium is superior to TCA alone and to placebo in reducing 6-month relapse rates.

5.3 Continuation Electroconvulsive Therapy

In the field of psychopharmacology, once a patient responds to an acute trial of medication, the compound is usually continued for some minimum period of time (e.g. 6–9 months), depending on the particular illness and the severity of symptoms. Thus, from a logical point of view, it may seem odd that once a patient responds to ECT, we typically discontinue it. Of course, indefinitely continuing ECT two or three times a week would pose the risk of worsening cognition, not to mention the medical risk of multiple repeated general anesthesia. However, ECT practitioners have known for years that many patients are able to well tolerate a transition from an acute ECT course to a course of continuation ECT (C-ECT). In fact, C-ECT may be the only viable treatment option for patients who cannot tolerate (or repeatedly fail) continuation pharmacotherapy and are at high risk for relapse. There is a large body of literature of an uncontrolled nature demonstrating the utility of C-ECT (Sackeim 1994a). For various practical reasons, it has been difficult to conduct prospective, randomized, and controlled studies in this area, although a large multicenter trial is underway in the United States. C-ECT usually begins as once per week treatment, with a gradual lengthening of the space between treatments to roughly once per month, as needed. In addition, continuation treatments are well suited for outpatients and can be minimally intrusive in patients' lives.

6 Mechanisms of Action

Ironically, while ECT may be the most effective somatic treatment in psychiatry, its definitive mechanism of action remains unknown. Instead, we possess a vast body of animal and clinical data as to its effects on neurophysiology, biochemistry, and endocrine physiology, which reflects the myriad of changes that take place in the brain and in the body following a generalized seizure. This has led, in turn, to a variety of theories regarding mechanisms of action. In understanding these various theories, it is important to realize that they may not be mutually exclusive, but rather may explain interrelated phenomena at different hierarchical levels. As this is an extensive topic, the following is intended as a synopsis, and the reader is also referred to recent comprehensive reviews (Fochtmann 1994; Sackeim 1994b).

6.1 Methodological Considerations

When relying on preclinical data, certain caveats must be kept in mind. First, the overwhelming majority of animal data derives from studies in rodents. Despite the problem of interspecies differences, the ability to generalize findings to humans is also hampered by the lack of good animal models for the major psychiatric syndromes. Second, the time course of biological changes relative to electrical stimulation needs to be considered. For instance, neither the effects of a single electroconvulsive shock (ECS) nor the application of multiple ECS in a single day may be relevant to the clinical situation. Third, the majority of preclinical studies compare ECS to standard antidepressant medications. However, while both ECT and antidepressant medications have some degree of overlap in terms of therapeutic applications, ECT clearly has a broader spectrum of action. Thus studies that limit the comparison of ECS to TCA or MAOI may thereby be skewing the interpretations of the findings towards a common mechanism of action.

While clinical studies are immediately relevant, they are constrained at the practical level by the fact that assays of the central nervous system are often indirect, as when peripheral measures of a neurotransmitter metabolite are used as an estimate of central activity. On the theoretical level, the fact that ECT is so highly effective has constricted our ability to tease apart critical factors related to its therapeutic mechanisms. In other words, to demonstrate putative mechanisms of action, the biological effects of an active treatment intervention should be compared among responders and nonresponders to the treatment. Alternatively, the effects of the active treatment could be compared with either an inactive treatment or an attenuated form of active treatment. Since sham ECT studies are generally no longer conducted, the ability to compare the effects of "active" ECT (BL and high-dose RUL ECT) with "weak" ECT (low-dose RUL ECT) has offered some opportunities to test theories regarding mechanisms of action.

6.2 Biochemical Mechanisms

Several decades of research, mostly preclinical, has examined the effects of ECS and ECT on the classical

neurotransmitter systems (Kety 1974; Fochtmann 1994). Much of this work has been derived from animal studies comparing ECS with TCA or MAOI. One of the most consistent findings is that, similar to antidepressant medications, ECS leads to a downregulation of β-adrenergic receptors. This fact has led many to the conclusion that the antidepressant effect of both standard medications and ECT is mediated through noradrenergic pathways. However, human studies have yielded inconsistent results as to changes in noradrenergic function. Furthermore, if such a theory is postulated, it is difficult to explain why ECT would be effective in patients resistant to TCA or MAOI. In contrast to the downregulation of the 5-hydroxytryptamine receptor (5-HT_2) typically seen with antidepressants, ECS leads to an increased density of 5-HT_2 receptors. While human studies have demonstrated an increase of 5-HT metabolites in the cerebrospinal fluid following a course of ECT, other probes of 5-HT function have yielded inconsistent results. Animal studies have consistently demonstrated profound increases in dopaminergic function following acute and chronic ECS. Clinical studies have been less consistent, but also point in the direction of enhanced dopaminergic functioning with ECT. Indeed, this may underlie the antiparkinsonian effect of ECT. Other preclinical work has focused on transmitters such as γ-aminobutyric acid (GABA), adenosine, and the endogenous opioids. These systems may be particularly important in understanding the biochemical basis of the anticonvulsant effects of ECT.

6.3 Endocrine Mechanisms

A wide variety of endocrine changes occur following ECT, and it has been challenging to separate out potential therapeutic mechanisms from what may simply be epiphenomena of seizure activity. For instance, prolactin is released acutely following ECT, and elevations in plasma levels are consistently easy to detect. However, while BL and higher-dosage ECT lead to a greater relative prolactin surge, a recent study found that, when treatment technique is controlled for, prolactin values are not independently associated with clinical outcome (Lisanby et al. 1998). Other endocrine theories have focused on alterations in the hypothalamic–pituitary–adrenal or the thyroid axis. As mentioned, the DST has yielded inconsistent results with respect to clinical outcome. While investigations of the hypothalamic–thyroid axis have also proved inconsistent, the report that thyroid hormone may augment the efficacy of ECT indicates the need for further study in this area (Stern et al. 1991).

6.4 Neurophysiological Mechanisms

At the neurophysiological level, generalized seizures – the repetitive hypersynchronous depolarization of neurons – are accompanied by dramatic changes in blood–brain barrier permeability and marked increases in cerebral blood flow and metabolic rate (Nobler and Sackeim 1998). The postictal period is characterized by decreases in CBF and CMR as well as stereotypical changes in the EEG. Just following a course of ECT, CBF and CMR may remain decreased, while slow-wave activity becomes prominent in the EEG. The degree, anatomic location, and, to some extent, persistence of these effects appear to be related to positive ECT response (Nobler et al. 1994; Sackeim et al. 1996).

Brain imaging studies of major depression have generally indicated that there are baseline reductions in CBF and CMR, both regionally and globally. Thus, at first glance, it seems paradoxical that further reductions in CBF would be involved in therapeutic mechanisms. Studies are underway to help clarify this issue.

6.5 Anticonvulsant Mechanisms

One particular neurophysiological theory regarding the mechanism of action of ECT centers on its anticonvulsant properties (Sackeim 2000). In animals, ECS raises the threshold for subsequent seizures. The seizure threshold also progressively increases in patients during a course of ECT, while seizure duration decreases. Both an increase in seizure threshold and a decrease in seizure duration are the hallmarks of an anticonvulsant effect. Additional theoretical support for an anticonvulsant mechanism is lent by the fact that both anticonvulsant medications and ECT are powerful treatments for mania.

The anticonvulsant theory posits that the therapeutic mechanisms for ECT are tied to the endogenous processes which terminate seizures, and not to the seizures themselves. These processes include the release of endogenous inhibitory or anticonvulsant compounds such as GABA and adenosine. Further, the magnitude of this active inhibition is most likely indexed by acute reductions in CBF and CMR and by

the degree of immediate postictal bioelectric suppression on the EEG.

Psychosurgery

1 Definition

The term "psychosurgery" describes neurosurgical operations performed in order to improve the psychic condition of patients. In other words, brain surgery for psychiatric indications is described as "psychosurgical intervention." The American Psychiatric Association (APA) defines psychosurgery as a "neurosurgical intervention to sever fibers connecting one part of the brain with another or to remove or destroy brain tissue with the intent to modifying or altering severe disturbances of behavior, thought content or mood" (Stone 1989).

The term is not meant to denote "direct surgical intervention into the human psyche," which might suggest a direct correlation between psyche and the connecting fibers of the brain, which is not intended. Therefore, the term psychosurgery might be misleading. In spite of terminological questions, no alternative terms such as "psychiatric surgery," "behavioral surgery," or "psychiatrically indicated neurosurgery" have prevailed thus far. In our opinion, the adoption of the term "psychiatrically indicated stereotactic neurosurgical intervention" would be more adequate to the subject in question.

2 History

The first psychosurgical intervention was performed in 1935 by Egaz Moniz, Professor of Neurology, with the help of the neurosurgeon Almeida Lima. They initially performed a prefrontal leukotomy by injecting pure alcohol into the frontal lobe. After seven operations they changed their technique. They severed the white substance of the frontal lobes with a small needle ("leukotome") (Moniz 1936, 1937). At that time, there were hardly any therapeutic possibilities available to help mentally ill patients. Thus, when Moniz announced that 14 out of 20 severely ill patients (seven schizophrenic patients, 13 patients with affective disorders or phobias) showed significant improvement after the operation (Moniz 1936), considerable enthusiasm was elicited from the medical community. In 1937, the neuropsychiatrist Walter Freemann and the neurosurgeon James Watts applied a modified technique in which they severed all connections to the prefrontal cortex by bilaterally entering the brain through the orbit (Freeman and Watts 1937, 1950). This method was soon commonly adopted, and the following two decades saw a sharp increase in neurosurgical operations on mentally ill patients. Different groups developed new methods with the intent to reduce side effects by limiting the seize of the lesion. In 1949, Professor Moniz received the Nobel Prize for his outstanding work in the field of psychosurgery. It is estimated that, in 1950 alone, approximately 5000 psychiatrically indicated neurosurgical operations were conducted. In 1952 and 1953, approximately 300 reports on neurosurgical interventions were published per year.

In spite of the new techniques, the indication for psychosurgery, and thus the number of operations performed, was significantly reduced by the late 1950s (Cosyns et al. 1994). This was due to an often uncritical application of the new methods with corresponding unsatisfactory results and the development of effective pharmacological treatments (chlorpromazine in 1952, benzodiazepine in 1957, haloperidol in 1958, and tricyclic antidepressants in 1958). From the mid-1960s to the end of the 1970s, stereotactic operations for sexual deviations were a means of intervention in Germany (Adler and Saupe 1979). Up to 80 such operations were performed by three different teams, mainly on criminals with often doubtful indications and eventually dubious results (Schorch and Schmidt 1979). This led to vehement public discussions (Fülgraff and Barbey 1978) and to an increasingly critical attitude towards psychosurgery. The number of psychosurgical operations decreased sharply in subsequent years. Another reason was the increasing use of psychotherapy for the treatment of mental disorders such as depression. Although psychoanalysis was only rarely effective for severely ill patients, the introduction of behavioral therapy in the early 1960s justly gave rise to the hope that many patients could be helped who suffered from depression, obsessive-compulsive disorder (OCD), or phobias.

With these developments, psychosurgery as a treatment for mentally ill patients has been greatly reduced. In some countries such as Japan, the United States, and Germany, psychosurgery is performed only in rare cases. However, in certain European countries (e.g. Sweden, the United Kingdom, Spain, Belgium, and the Netherlands), psychosurgery is still performed on a regular basis, in specialized centers, conducted by experienced teams. This is in part due to the new stereotactic methods, which allow a very precise positioning of small lesions, and by the recognition by psychiatrists that, in spite of all the new pharmacological and psychotherapeutic treatments, a group of patients remain who cannot be helped adequately by these conservative means.

3 Ethical Aspects

Psychosurgery is looked upon with some reservation in all countries by both the general public and the medical community. This is especially true in Germany because of its historical background. This concern is understandable considering that psychosurgery has two serious differences compared to other treatments:

1. Operations on anatomically intact brain involve a certain incalculable risk for the patient with regard to possible behavioral consequences in view of the still limited knowledge about the function of individual brain structures. Most significant is the fact that the targeted brain areas are damaged irreversibly.
2. Since psychosurgery is intended to influence the mental and emotional functioning of the patient, it necessarily invades the sphere of what a patient regards as the essence of his or her selfhood. This affects the moral and/or religious beliefs held by some people. It is clear that some patients will have severe difficulties overcoming their ethical reservations to such a procedure.

The ethical problems psychosurgery raises for the physician and the patient include moral philosophy as well as questions regarding acceptable practical means to alleviate human suffering.

In 1988, A.J. Bouckoms from the Harvard Medical School in Boston formulated the following recommendations (Bouckoms 1988):

1. No consideration of ethics in psychosurgery is complete without consideration of both the scientific data and moral conflicts.
2. The liberal advocation of autonomy without responsibility is an amoral, not a liberating, point of view.
3. Politics should be denounced as the most serious ethical problem in medical decision-making. Political intrusion into scientific matters and the doctor–patient relationship has created ethical problems with psychosurgery and continues to do so today.

The probability of the success of scientific research should be weighted against philosophical norms and rules regarding ethic and moral conflicts relating to altruism, autonomy, and human suffering.

Generally, the following principles have to be considered in the context of psychosurgical interventions:

1. All conservative, i.e. reversible, treatments (pharmacological and psychotherapeutic treatment, electroconvulsive therapy, if applicable) must have been applied adequately without yielding satisfactory results. Psychosurgery should be the last resort.
2. Psychosurgical interventions are thus never an emergency treatment; they require intensive preparation and planning with sufficient time for the patient to realize the possible risks and consequences of the operation and to make an appropriate decision. It is desirable that the relatives are involved and support the patient's decision.
3. Fundamentally, psychosurgical interventions must have a therapeutic goal and must not be considered as an experimental trial. This means that, based on previous experience, there must be a realistic chance of alleviating the suffering of a patient with regard to his or her mental illness by psychosurgery.
4. The indication and performance of psychosurgery should only be conducted by experienced psychiatrists and neurosurgeons. The neurosurgeon should be competent and versed in the planning and execution of the appropriate stereotactic intervention. The psychiatrist must be able and willing to provide adequate and intensive pre- and postoperative care.

For this reason some countries such as the Netherlands and Belgium have formed advisory boards comprising independent psychiatrists, neurosurgeons, neurologists, and sometimes ethics specialists and lawyers. The United States, too, have established a board to investigate psychosurgical interventions and to develop new concepts.

4 Indication and Selection of Patients

Considering the controversial nature of the issue, which was outlined above, it is important to point out the psychiatric symptoms for which a neurosurgical intervention may be indicated with some chance of success. While the range of indications was rather diffuse in the euphoric beginnings of psychosurgery, clearly defined criteria have emerged over the past 10–15 years.

Psychosurgical interventions may be indicated in patients with affective disorders (major depressions and bipolar disorders), OCD, and anxiety disorders (generalized anxiety disorders, agoraphobia with panic attacks). In addition, psychosurgery might possibly be indicated in patients showing extremely aggressive behavior combined with mental retardation, although this remains a contentious issue.

Schizophrenia and substance abuse, although

discussed, are not considered an indication by most authors (Balasubramaniam 1997; Meyerson 1996). Cluster A and B personality disorders according to DSM-III-R are generally perceived as a relative contraindication to surgery, but not those of cluster C. Severe axis III symptomatology according to DSM-III-R, e.g. brain tumors or leukodystrophy, are contraindications for psychosurgery.

In contrast to many other areas in the field of psychiatry, there seems to be a wide and interdisciplinary consensus regarding the criteria for the selection of patients. Before psychosurgery should be considered for a patient, the following criteria must be met:

1. The diagnosis of the mental illness should be confirmed by standardized instruments, such as ICD-10 or DSM-III-R.
2. The disorder must be chronic, i.e. the patient must suffer from the illness for a period of at least 3 years (some authors even call for 5 years); during that time, the patient must be severely impaired in his or her private and professional life.
3. The patient must be suffering severely because of his or her mental illness.
4. The mental illness must have led to a significant functional impairment in the prior year, reflected in a global assessment of function score of between 30 and 50 (axis V according to DSM-III-R).
5. The disorder must be refractory to conventional therapies. All pharmacological treatment options must have not resulted in satisfactory improvement in spite of adequate dosage and duration of treatment or must have had to be aborted due to severe side effects. Extensive psychiatric treatment, particularly cognitive psychotherapy and behavioral therapy, must have resulted in no satisfactory change.

Major depression, in particular, is considered refractory when the following therapies have failed:

a) Treatment with various tricyclic antidepressants at dosages of approximately 300–400 mg per day for at least 2 months, as well as equivalent combined treatments. In addition, adequate treatments with monoamine oxidase inhibitors and serotonin reuptake inhibitors should have been tried.
b) At least one therapy with lithium and with lithium in combination with an antidepressant should have been tried.
c) Two cycles of electroconvulsive treatment, with several months between them, should have been tried.

OCD, in particular, are considered refractory when the following therapies have failed:

a) At least three pharmacological treatment cycles with medications that are known to be effective against OCD. Each cycle should last for least 10 weeks, and one of them should have been conducted with clomipramine. Compliance should be checked by testing medication levels in patients' blood samples.
b) Three additional therapy cycles should have been carried out with combined medications, one including clonazepine.
c) Intensive behavioral therapy should have been conducted at the same time as medical treatment, including exposure and response prevention over a period of at least 30 h.
d) Finally, intensive inpatient treatment must have been tried.

6. The prognosis of the mental illness must be considered bad without psychosurgical intervention.
7. The patient should be completely and carefully informed, preferably by a interdisciplinary team of experts, and these discussions should preferably include a relative. The patient should have sufficient time to understand the meaning and the possible consequences of the operation and to form his or her own opinion about it. The patient should not only agree to the operation, but should actively be in favor before it is carried out.
8. Intensive psychiatric pre- and postoperative care, including rehabilitation measures, must be provided.
9. A careful examination and documentation of the pre- and postoperative status is mandatory, using approved psychological tests, e.g., Hamilton depression scale (HAMD) and Yale-Brown obsession-compulsion scale (YBOCS). A similarly precise survey of the postoperative status is desirable in order to critically evaluate the outcome.
10. Exclusion criteria for a psychosurgical intervention are as follows:

    a) Age under 20 or over 65 years.
    b) Patients who are under custody in psychiatric institutions, e.g. prisoners, patients in forensic psychiatry, and involuntarily committed patients.
    c) Incompetent patients who are under legally appointed guardianship.

In the past, there were often controversies over points b) and c), especially with regard to psychosurgical interventions for sexual deviations. On the one hand, the ability of such patients to freely express agreement or disagreement with a psychosurgical intervention possibly entailing nontherapeutic goals such as premature release appears to be restricted. On the other hand, with these patients, a psychosurgical operation may be the only effective therapeutic means. Nowa-

days, it is generally felt that patients in prison and those under custody or guardianship are dependent individuals whose seemingly free decisions are determined by very different factors that cannot be accepted from a medical point of view (Adler and Saupe 1979).

5 Techniques and Target Areas

5.1 General Neurosurgical Technique

In contrast to the beginnings of psychosurgery, almost all neurosurgical interventions in psychiatric disorders are now carried out using stereotactic techniques. This method allows a precise placement of the lesion as well as minimization of the lesion. A stereotactic intervention does not require general anesthesia; most patients are under mild sedation with local anesthesia. Thus the patient can talk and report on the effects of stimulation during the procedure. This way, the targeted location of the lesion can be stimulated intraoperatively in order to evoke symptoms associated with the disorder and, through feedback with the patient, to check and – if necessary – correct the placement of the probe.

The operation involves the fixation of the stereotactic frame with the fiducial plates on the patient's skull followed by stereotactic imaging – formerly ventriculography, now computed tomography (CT) and more frequently magnetic resonance imaging (MRI). The next step is the definition of the target point for the lesion and calculation of the stereotactic coordinates using the images. The settings on the stereotactic frame and the aiming bow are made in accordance with these coordinates, and the frame is fixed to the ring on the patient's head in a predefined position, with the aiming bow serving as instrument guide. Bilateral burr holes are made in front of the coronal suture, 1 inch lateral to the midline, through skin incisions of little more than 1 inch. After incision of the dura mater and coagulation of the cortex, the probe is advanced with the electrode holder on the aiming bow. The accuracy of this procedure is around 1 mm. The lesion itself is produced by heating the electrode and thermocoagulating the tissue within the desired area.

5.2 General Anatomical Considerations

The morphological substrate of psychiatric illnesses and therefore the exact action of lesional therapy are not totally understood. There are indications from neuroimaging investigations – positron emission tomography (PET), single photon emission computed tomography (SPECT), or functional MRI – that for some psychiatric conditions the prefrontal cortex, the cingulate gyrus, and the basal ganglia might play a major role. The target areas for lesioning are closely correlated, and for effective therapy connections with the limbic system and the circuit of Papez are postulated. It is remarkable that lesions at different sites for the same disorder and lesions at identical sites for different disorders seem to be effective. This supports the theory that a dysregulation of control circuits may be involved in the development of psychiatric illness (Meyerson 1996; Cosgrove and Rauch 1995; Cosgrove and Ballantine 1996).

Different target regions will be discussed below; the reader should bear in mind that the lesions are always placed symmetrically and bilaterally.

5.3 Target Regions

5.3.1 Cingulotomy

Anterior cingulotomy, first suggested by Fulton (1951), is the most common psychosurgical intervention, at least in the United States. Initially used as a therapy for chronic pain (Foltz and White 1962), it was later reported to be a safe and successful treatment for a large number of psychiatric patients (Ballantine et al. 1987). This operation is the one that is most noted in current literature (Baer et al. 1995; Jenike et al. 1991; Cosgrove and Ballantine 1996). It involves bilateral lesions in the cingulate gyrus disrupting the limbic pathways of the circuit of Papez contained therein. Target coordinates are calculated for a point within the cingulum 2 cm posterior to the tip of the frontal horns and 7 mm lateral to the midline. The lesions are made by thermocoagulation (Ballantine et al. 1995) and are equivalent to a cylinder of 2 cm in length with a diameter of 1 cm. The adverse effects that can sometimes occur include reversible bladder dysfunction or an elevated temperature. Lasting cognitive or behavioral deficits have not been observed, but some authors report lasting improvements in the performance of memory and intelligence tests, which is attributed to improved concentration (Cosgrove and Ballantine 1996; Ballantine et al. 1995; Tippin and Henn 1982). Thus cingulotomy seems to be the safest of the neurosurgical procedures in psychiatric illness. Psychiatric indications are severe affective disorders, anxiety disorders, and OCD.

5.3.2 Anterior Capsulotomy

First reported by Talairach et al. (1949), anterior capsulotomy was used for a variety of psychiatric conditions on a larger scale mainly by Lars Leksell (Bingley et al. 1977). This procedure seems to be the most frequently used in Europe (Cosgrove and Ballantine 1996). The target area is the anterior limb of the internal capsule, where frontothalamic pathways are located, connecting the limbic system to the frontal lobes. The lesions are produced by thermocoagulation or radiosurgical methods (gamma knife) (Mindus and Meyerson 1995; Leksell and Backlund 1979). Reversible disorientation between postoperative day 2 and 5 has been reported as a complication in 90% of the patients (Mindus and Nyman 1991). Long-lasting adverse effects consisted in weight gain, fatigue, and memory deficits (Mindus and Nyman 1991), whereas no evidence for cognitive dysfunction was found (Bingley et al. 1977; Burzaco 1981; Herner 1961). A tendency for recurrence with time has not been observed (Meyerson 1977), but in 17 of 85 patients a second procedure was necessary due to suboptimal lesion size or positioning, this second procedure being effective in 52% of the patients (Burzaco 1981). Major indications are chronic anxiety disorders, OCD, and major depression.

5.3.3 Subcaudate Tractotomy

Subcaudate tractotomy was introduced by Knight in 1964 (Knight 1964), mainly to reduce the size of the surgical lesions and therefore to reduce the side effects seen with standard prefrontal lobotomies. The lesion can be produced by thermocoagulation or stereotactic placement of radioactive seeds (Cosyns et al. 1994). The target region is the white matter directly below the head of the caudate nuclei with the fiber tracts of the orbital cortex. Complications reported include epileptic seizures in 2.2% and inadvertent personality changes in 6.7%; in addition, transient disinhibition was frequently observed. Main indications are depression, OCD, and anxiety disorders. Patients with personality disorders, schizophrenia, and drug or alcohol abuse had poor outcomes (Goktepe et al. 1975; Balasubramaniam 1997).

5.3.4 Limbic Leukotomy

Limbic leukotomy is a combination of anterior cingulotomy and subcaudate tractotomy and was introduced in 1973 by Kelley (Kelley et al. 1973) in order to improve results in OCD patients. Adverse effects included bladder dysfunction, fatigue, and disorientation during the immediate postoperative period (Cosgrove and Rauch 1995). A total of 12% of the patients complained of a lasting lethargy, while epileptic seizures were not observed and the patients' intelligence quotient (IQ) showed a slight increase. Indications are concurrent with the single procedures and include OCD, affective disorders, and anxiety disorders.

5.3.5 Intralaminar and Dorsomedial Thalamotomy

Introduced by Hassler and Dieckmann (1973), the intralaminar and dorsomedial thalmotomy procedure consists of a lesion within the dorsomedial nucleus of the thalamus encompassing the adjacent medial lamella. Because of its difficult anatomical location close to the important mamillothalamic tract, the target remains controversial. If used at all, it should be employed in disorders with aggressive behavior in combination with mental retardation (Gybels and Cosyns 1995), because there are hardly any alternatives for such patients. Complications include reversible somnolence, development of hydrocephalus, and mild hemiparesis in one patient (Cosyns et al. 1994). Experience with this procedure is only very limited compared to other methods.

5.3.6 Amygdalotomy

According to Narabayashi and Shima (1973), amygdalotomy is based on a lesion of the corticomedial nucleus of the amygdala and, like dorsomedial thalamotomy, it is employed in patients with aggressive disorders with mental retardation. Again, experience is very limited (Cosyns et al. 1994). It should be emphasized that psychosurgery for aggressive behavior is controversial and generally not recommended.

5.3.7 Ventromedial Hypothalamotomy

On the basis of different and controversially assessed results from animal experiments (Orthner 1982; Schorsch and Schmidt 1979), ventromedial hypothalamotomy was applied as therapy for sexual deviations (Müller et al. 1974). The lesion was meant to influence sexual behavior in such a way as to reduce "hypersexuality" and "perversion" as observed in patients

with lesions of both medial temporal lobes, for example (Klüver and Bucy 1939). Experience with this method was gathered practically only in Germany, and it was only carried out to a small extent and was insufficiently documented (Schorsch and Schmidt 1979).

In general, in any kind of neurosurgical intervention in psychiatric illness, there is the risk of complications regardless of the area of lesioning, as with every neurosurgical operation. With varying frequency, general complications such as intracerebral hemorrhage (0%–2%), infections (0%–1%), and development of postoperative epileptic seizures (1%) are reported.

6 Results and Perspectives

An evaluation and comparison of the results of neurosurgical intervention for the treatment of psychiatric symptoms poses some difficulties. One of these difficulties arises from the fact that different techniques, diagnostic criteria, and standards for postoperative examinations/surveys are being used in different centers.

In addition, most of the published papers are based on retrospective surveys, and there are only a few prospective studies, each with only a small number of patients (Baer et al. 1995; Kartsounis et al. 1991). Because of the limited, severely ill population of patients, prospective randomized studies are not possible, and because the treatment involves surgery, double-blind studies are neither feasible nor ethically justifiable. However, with the advent of radiosurgical methods, this may be considered, and consequently a double-blind study is currently being carried out on capsulotomy for the treatment of OCD patients, possibly providing the desired evidence to improve the basis of decision-making for the application of psychosurgery (Mindus et al. 1994).

A total of 18 OCD patients were observed in a prospective study on cingulotomy using strict criteria for therapeutic success, and 30% were felt to be responders (Baer et al. 1995). Applying less strict criteria, Ballantine et al. (1987) reported an improvement of symptoms in 64% of patients with affective disorders, 56% of patients with OCD, and 79% of patients with anxiety disorders in an investigation of 196 patients who underwent cingulotomy for their disorder.

A success rate of between 64% and 70% has been reported for capsulotomy in OCD patients (Mindus and Meyerson 1995; Bingley et al. 1977; Meyerson 1977, 1996), and in patients with anxiety disorders the percentage of markedly improved patients was 71% (Rylander 1979).

Table 1. Probability of a positive outcome in patients with obsessive-compulsive disorder (OCD) and affective disorder using various psychosurgical techniques

	Anterior cingulotomy (%)	Anterior capsulotomy (%)	Subcaudate tractotomy (%)	Limbic leucotomy (%)
OCD	56	67	50	61
Affective disorder	65	55	68	78

Good results have been reported for *subcaudate leukotomy* in 68% of depressive patients, 62.5% of patients with anxiety disorders, and 50% of patients suffering from OCD (Goktepe et al. 1975).

Mitchell-Heggs et al. (1977) reported on an improvement in 89% of OCD patients, 68% of patients suffering from a chronic anxiety disorder, and 78% of depressives after *limbic leukotomy*.

There seems to be a greater likelihood of therapeutic improvement after surgery if significant vegetative symptoms and/or anxiety are concomitant in a patient with an underlying diagnosis of depression or OCD.

A comparison of results across centers is problematic, since imprecise criteria for diagnosis, nonstandardized presurgical evaluation tools, and different outcome assessment scales have been used. However, in nearly all of the published reports, some modification of the Pippard Postoperative Rating Scale (Pippard 1955) may be ascertained; this scale rates outcome in the following five categories: (1) symptom free, (2) much improved, some symptoms remaining but no additional treatment necessary, (3) slightly improved, (4) unchanged, and (5) worse. The probability of a positive outcome in the different combinations of disorders and stereotactic target areas is given in Table 1, with categories 1 and 2 regarded as successful (Cosgrove and Rauch 1995).

In general, applying restrictive criteria and selective indications, an improvement can be expected in more than 50% of patients. However, the published results do not allow a statistically significant evaluation of the effectiveness of the different techniques. Concurrently, it appears that patients with depressive disorders and OCD do not show an improvement until after up to 6 months, which involves intensive postoperative therapy, whereas patients with anxiety disorders often show an immediate improvement.

Obsessive–Compulsive Disorder

1 Introduction

Up to the early 1980s, obsessive-compulsive disorder (OCD) was considered a treatment-refractory, chronic condition of psychological origins. The management of OCD consisted of dynamic psychotherapy, which was of little benefit, and several pharmacological treatments which had been tried without much success (Salzman and Thaler 1981). However, two findings have substantially changed this field: several researchers have reported that OCD might be a prevalent disorder (Robins et al. 1984; Weissman et al. 1994), and numerous studies have reported the efficacy of various specific therapies for this disorder. Today, OCD is believed to be biologically driven and to be highly treatable by serotonin reuptake inhibitors (SRI).

The observation that clomipramine (CMI), a tricyclic antidepressant with a serotonergic profile, is effective in treating symptoms of OCD (Renynghe de Voxrie 1968; Fernandez-Cordoba and Lopez-Ibor 1967) has resulted in intense interest in the relationship between serotonin and this disorder. Substantial evidence now suggests that OCD is almost unique among psychiatric disorders, as only serotonergic medications appear to be effective in this disorder (Dolberg et al. 1996). Researchers agree that non-serotonergic drugs, such as desipramine (DMI), a potent antidepressant and antipanic agent, are ineffective in OCD (Zohar and Insel 1987; Goodman et al. 1990; Leonard et al. 1991). The specific response to serotonergic drugs has paved the way to further research on the pathogenesis of OCD and OCD-related disorders and has improved the prognoses of these patients.

2 Epidemiology

The lifetime prevalence of OCD in the general population is 2%–3% (Karno et al. 1988; Robins et al. 1984), more than 40 times more than previous estimations. OCD is the fourth most common psychiatric disorder after phobias, substance-related disorders, and major depressive disorder(MDD) (Karno et al. 1988), with even higher rates for subclinical OCD (Valleni-Basile et al. 1996). Despite initial estimations that OCD exists mainly in Western cultures, the high prevalence of OCD has been confirmed across cultures (Weissman et al. 1994). The prevalence of OCD among children and adolescents has been reported by several researchers to be as high as among adults (Flament et al. 1988), but most specialists agree that OCD is more frequent in middle-aged adults than in people of other age groups.

Recently, the above-mentioned numbers have been challenged, as Nelson and Rice (1997) and Stein et al. (1997) have suggested that diagnosis of OCD by the Diagnostic Interview Schedule (DIS) and by laymen leads to overdiagnosis. Thus, lower prevalence rates of 1%–2% were suggested.

Men and women are equally likely to be affected, although some reports have suggested a slight female predominance (Weissman et al. 1994). However, during adolescence, boys are more commonly affected than girls. The mean age of onset is about 20 years of age, although OCD can commence earlier. Single people are more commonly affected, representing their difficulty to maintain a relationship.

Patients with OCD are commonly affected by other mental disorders. The lifetime prevalence for MDD in OCD patients is approximately 67% (Weissman et al. 1994; Rasmussen and Eisen 1992). Other common comorbid psychiatric diagnoses include alcohol use disorders, social phobia, specific phobia, panic disorder, and eating disorders. The comorbidity with schizophrenia and with tic disorders raises interesting pathophysiological and therapeutic implications. In juvenile OCD, the rate of tic disorders can be as high as 40% of patients (Geller et al. 1996). Only 15%–35% of OCD patients have had premorbid obsessional traits.

3 Clinical Features and Diagnosis

The growing interest in OCD has drawn attention to the need for accurate diagnostic tools for OCD and the diagnostic criteria of DSM were reevaluated. The DSM-IV diagnosis of OCD is based on the presence of either obsessions or compulsions, which cause marked distress, are time-consuming (more than 1 h per day), or significantly interfere with the person's normal routine and academic and social activities. It is required that at some point during the course of the disorder the person has recognized that the obsessions or compulsions are excessive or unreasonable.

Specific questions to identify OCD include the following:

1. Do you wash or clean a lot?
2. Do you check things a lot?
3. Is there any thought that keeps bothering you that you would like to get rid of but can't?
4. Do your daily activities take a lot of time to finish?
5. Are you concerned about orderliness or symmetry?

If another axis I disorder is present, it is mandatory that the content of the obsessions or compulsions is not restricted to it (e.g. preoccupation with food or weight in eating disorders or guilt ruminations in the

presence of MDD). The disturbance should not be due to the direct effects of a substance (e.g. a drug of abuse or a medication) or a general medical condition.

A subtype of OCD with poor insight is described, if for most of the time during the current episode, the person does not recognize that the obsessions and compulsions are excessive or unreasonable. This subtype should be distinguished from other psychotic disorders (see "Differential Diagnosis").

The obsessions are recurrent, intrusive, and distressing thoughts, images, or impulses, whereas the compulsions are repetitive, seemingly purposeful behaviors or thoughts that a person feels driven to perform (compulsions). Obsessions are usually unpleasant and increase a person's anxiety, whereas carrying out compulsions reduces a person's anxiety. Resisting carrying out a compulsion, however, results in increased anxiety. The patient usually realizes that the obsessions are irrational and experiences both the obsession and the compulsion as ego-dystonic. The patient has a strong desire to resist the obsessions or compulsions. However, about half of the patients hardly resist the compulsion. About 80% of all patients believe that the compulsion is irrational, but sometimes obsessions and compulsions become overvalued to the patients. Some may insist that compulsive cleanliness is morally correct, even though they have lost their job because of the cleaning compulsion.

Patients with both obsessions and compulsions constitute at least 75% of the affected patients. Most patients present with multiple obsessions and compulsions. The symptoms may shift and a patient who had washing rituals during childhood may present with checking rituals as an adult.

Four major symptom patterns exist. The most common pattern is an obsession of contamination by dirt or germs, followed by washing or accompanied by compulsive avoidance of the presumably contaminated object (not touching doorknobs, electrical switches, newspapers, people's hands, phones). The feared object is hard to avoid (e.g. feces, urine, dust, or germs). Patients wash their hands excessively and sometimes avoid leaving home because of fear of germs. Patients feel anxiety, avoid exposure to the feared object, and avoid every contact they believe that may spread the germs.

The second most common pattern is an obsession of doubt, followed by a compulsion of checking. The person checks whether he closed the door of the house or whether he closed the stove (indirect danger of violence), and the checking may involve multiple trips back home to check the stove, for example. Instead of resolving uncertainty, the checking often contributes to even greater doubt, which leads to further checking. The patients exhibit obsessional self-doubt, as they always feel guilty for having forgotten or committed something (i.e. fear of hurting someone while driving, leading to repetitive driving back over the same spot again and again).

The third most common pattern is one with merely intrusive obsessional thoughts without compulsions. Such obsessions are usually repetitious thoughts of some sexual or aggressive act that is reprehensible to the patient. The fourth most common pattern is the need for symmetry or precision, which leads to a compulsion of slowness in an attempt to do things "just right": patients can take hours to eat a meal or shave. Unlike other OCD patients, these patients do not resist the symptoms. Other patterns include hoarding and religious obsessions.

The gap between the knowledge that the symptoms are irrational and the overwhelming urge to perform them (even after resisting and failing) adds more tragic color to the immense suffering associated with this disorder.

About 15% of chronic schizophrenia patients may also suffer from OCD, six times more than in the general population. Although many patients report symptoms that resemble OCD superficially, DSM-IV requires that the obsessive-compulsive symptoms should not be related to the delusions content in order to allow both diagnoses. Despite present attempts to treat various psychopathologies according to symptom clusters, the difference between the "obsessive syndrome" seen in the framework of other mental disorders and OCD as an independent disorder comorbid with other mental disorders (e.g. schizophrenia) should still be borne in mind.

Many schizophrenic patients can distinguish the ego-dystonic obsessive-compulsive symptoms, perceived as coming from within, from the ego-syntonic delusions, perceived as introduced from the outside. Long-term follow-up studies demonstrate diagnostic stability over the years and suggest that the presence of OCD in schizophrenia predicts a poor prognosis. Several studies among schizophrenic patients with OCD reported an improvement in OCD symptomatology after the addition of a specific antiobsessive medication (Zohar et al. 1993). Preliminary data also show some role for the new atypical neuroleptics, such as olanzapine, in treating this subset of patients.

The poor prognosis of schizo-obsessive patients, preliminary data regarding their response to the unique combination of antipsychotic and antiobsessive medications, and the high prevalence of this presentation suggest that a schizo-obsessive category may be of value.

4 Differential Diagnosis

Personal distress and functional impairment, which are required for the diagnosis, differentiate OCD from

ordinary or mildly excessive worries, thoughts, and habits. The medical differential diagnosis includes tic disorders (especially Tourette's syndrome, in which two-thirds of patients meet the diagnostic criteria for OCD), temporal lobe epilepsy, head trauma, and postencephalitic complications.

Psychiatric diagnoses that should be ruled out include schizophrenia, obsessive-compulsive personality disorder (OCPD), phobias, and depressive disorders. OCD can usually be differentiated from schizophrenia by the absence of other schizophrenic symptoms, by the less bizarre nature of symptoms, and by the patients' insight into their disorder. OCPD and the ICD-10, parallel anankastic personality disorder, do not have the degree of functional impairment characteristic of OCD and are ego-syntonic.

Phobias are distinguished by the absence of a relation between the obsessive thoughts and the compulsions. MDD can sometimes be associated with obsessive ideas, but patients with OCD usually fail to meet all the criteria of MDD. Other psychiatric diagnoses that are closely related to OCD are hypochondriasis, body dysmorphic disorder, and trichotillomania. Several researchers have investigated these disorders, their relations to OCD, and the response to various drugs (Hollander 1997).

5 Course and Prognosis

More than half the patients with OCD have a sudden onset of symptoms, usually after a stressful event, such as pregnancy, a loss, or a sexual problem. Due to the secretive nature of the disorder, there is often a 5- to 10-year delay before patients come to psychiatric attention, although the delay might shorten due to the increased public awareness of the disorder through articles, books, and films on the subject. The course is usually long, but variable; some patients experience a fluctuating course, while others experience a chronic course.

About 20%–30% of the patients have significant improvement in their symptoms, and 40%–50% have moderate improvement. The remaining 20%–40% become chronic or have a worsening of their symptoms.

Patients are prone to depression and sometimes even to suicide. A poor prognosis is indicated by yielding to (rather than resisting) compulsions, childhood onset, bizarre compulsions, the need for hospitalization, a coexisting MDD, delusional beliefs, the presence of overvalued ideas (i.e. some acceptance of the obsessions and compulsions), and the presence of personality disorder (especially schizotypal personality disorder). A good prognosis is indicated by a good social and occupational adjustment, the presence of a precipitating event, and an episodic nature of the symptoms. The obsessional content does not seem to be related to the prognosis.

6 Etiology

6.1 Neurotransmitters

The many clinical trials that have been conducted with various serotonergic drugs support the hypothesis that a dysregulation of serotonin is involved in the response to these treatments. However, this does not necessarily reflect on pathogenesis. Abnormality of the serotonergic system and particularly hypersensitivity of postsynaptic 5-HT (hydroxytryptamine) receptors remains the leading hypothesis for the underlying pathophysiology of OCD (Zohar and Insel 1987).

Clinical studies have assayed cerebrospinal fluid (CSF) levels of serotonin metabolites, e.g. 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of 5-HT serving as an index of 5-HT turnover) (Thoren et al. 1980; Insel et al. 1985), and affinities of platelet-binding sites of tritiated imipramine (which binds to serotonin reuptake sites) (Weizman et al. 1986; Marazziti et al. 1992; Vitiello et al. 1991; Kim et al. 1991) and have reported variable findings of those measures in OCD patients. A recent study supporting the relationship between decreased function of the serotonergic system and positive response to selective SRI (SSRI) is that of Marazziti et al. (1997), who showed normalization of the number of platelet 5-HT transporters following treatment with different SSRI.

In a study by Thoren et al. (1980), patients who responded to CMI had higher pretreatment levels of 5-HIAA than the nonresponders, and clinical improvement was positively correlated with the decrease in CSF concentration of 5-HIAA. Flament et al. (1987) examined peripheral measures of serotonergic and noradrenergic function in adolescents with OCD participating in a double-blind, placebo-controlled study with CMI. Clinical improvement during drug therapy closely correlated with pretreatment platelet serotonin concentration and monoamine oxidase (MAO) activity, as well as with the decrease in both measures during CMI administration. Moreover, only the plasma levels of CMI, a potent 5-HT reuptake inhibitor, but not the plasma levels of its primary metabolite, desmethyl CMI, which has noradrenergic properties, correlated significantly with improvement in obsessive-compulsive symptoms. These findings suggested

that the effects of CMI on serotonin function are pertinent to the antiobsessional action observed.

Additional evidence for the derangement in the serotonergic system in OCD was provided by challenge studies which differ from biological markers which examine systems in equilibrium. Challenges with L-tryptophan (Charney et al. 1988), m-chlorophenylpiperazine (mCPP; Zohar and Insel 1987; Hollander et al. 1992), sumatriptan (5-HT1D agonist; Zohar 1996), ipsapirone (a 5-HT1A receptor ligand; Lesch et al. 1991), and MK-212 (affecting 5HT1A and 5HT2C; Bastani et al. 1990), among others, were used to evaluate whether they worsen obsessive-compulsive symptoms or whether they have thermal or neuroendocrine effects. Some of these studies have shown behavioral hypersensitivity and neuroendocrine hyposensitivity to be characteristic of the OCD challenge response. These studies might have the potential to pinpoint the receptor subtype involved in OCD, raising the possibility that 5HT1D and 5HT2C receptors, but not 5HT1A, may be involved in OCD (Sasson and Zohar 1996).

Additional support for the importance of serotonin in the therapeutic response to SRI in OCD was given by Benkelfat et al. (1989). This group of investigators administered the serotonin receptor antagonist metergoline and placebo to ten patients with OCD in a double-blind crossover study. Patients receiving CMI on a long-term basis responded with greater anxiety to a 4-day administration of metergoline when compared with the placebo phase. Obsessive-compulsive symptoms also peaked during the metergoline phase. Metergoline lowered plasma prolactin concentrations, providing further evidence of physiologically significant 5-HT antagonism. In another study, metergoline abolished the above-mentioned increase in obsessive-compulsive symptoms caused by mCPP.

6.2 Dopamine and Serotonin

The most compelling evidence for dopaminergic involvement in OCD comes from the abundance of obsesssive-compulsive symptoms in basal ganglia disorders, such as Tourette's syndrome and postencephalitic Parkinson's disease. The therapeutic benefit obtained with coadministration of dopamine blockers and SRI (McDougle et al. 1990) has suggested a role for dopamine dysfunction. Marazitti et al. (1992) evaluated not only peripheral markers of serotonin, but also levels of platelet sulphotransferase, an enzyme involved in the catabolism of catecholamines, which provides a marker of presynaptic dopamine function. OCD patients had a decreased level of platelet H3-imipramine binding and a parallel increase in the level of sulphotransferase activity compared with controls, a finding consistent with the hypothesis of reduced 5-HT activity and increased dopamine transmission in OCD.

6.3 Immune Factors

The study of autoimmune factors has been prompted by the association between OCD and the autoimmune disease of the basal ganglia, Sydenham's chorea, a complication of rheumatic fever that is accompanied by obsessive-compulsive symptoms in over 70% of patients (Swedo et al. 1994). This group reported that ten out of 11 children had antibodies directed against the caudate. These children had a history of obsessive-compulsive symptoms which started prior to the onset of the chorea, reached a peak in line with the motor symptoms, and declined with their resolution. This led to the postulation that Sydenham's chorea might constitute a medical model of OCD, consistent with the hypothesis of basal ganglia dysfunction in OCD. Antibodies against two peptides of the basal ganglia have also been found (Roy et al. 1994). A strong connection was reported between OCD/Tourette's syndrome and the B cell antibody D8/17, another anti-brain antibody (Swedo et al. 1997). Successful immunomodulatory treatments of Sydenham's chorea with plasmapheresis and I.V. immunoglobulin have provided more evidence for the autoimmune theory of OCD (Allen et al. 1995). Cell-mediated immune function alterations were reported in OCD, but replication studies are needed.

6.4 Brain Imaging Studies

Positron emission tomography (PET) has displayed increased activity (i.e. metabolism and blood flow) in the frontal lobes, the basal ganglia (especially the caudate nucleus), and the cingulum of OCD patients (Rauch 1998). Pharmacological and behavioral treatments reportedly reverse those abnormalities (Baxter et al. 1992). The data from functional imaging studies are consistent with the data from structural brain imaging studies. Both computed tomography and magnetic resonance imaging studies have found decreased sizes of caudates bilaterally. Both functional and structural imaging procedures are also consistent with the observation that neurological procedures involving the cingulum are sometimes effective in the treatment of OCD patients.

Overall, the brain imaging research provides evidence that the underlying dysfunction is likely to be in

the prefrontal cortex–basal ganglia thalamic circuitry rather than in any one single brain region. Dysfunction of these circuits can be explored by neuropsychological testing and evoked potentials. A recent study of OCD patients showed that they are slower in performing tasks involving frontocortical systems, suggesting alterations at this level (Galderisi et al. 1995). An evoked potential study in 17 patients by Towey et al. (1994) showed enhanced processing negativity in the frontal cortex consistent with prefrontal hyperactivity shown in brain imaging studies.

There may be an abnormality of the orbitofrontal cortex in OCD. Patients perform poorly on orbitofrontal cognitive tests (such as the Object Alternation Test), showing a different neuropsychological profile to other disorders such as schizophrenia, where patients classically exhibit deficits on such tests as the Wisconsin Card Sorting Test (Abbruzzese et al. 1995). The data suggest an anatomically specific frontal lobe dysfunction in OCD.

6.5 Genetics

The inheritance of OCD has a significant genetic component, but research is still needed in this area. A significantly higher concordance rate was found for monozygotic twins than for dizygotic twins (Rasmussen and Tsuang 1986). A total of 35% of the first-degree relatives of OCD patients are also afflicted with the disorder (Lenane et al. 1990). Thus, a genetic component of OCD is supported by family and twin studies. Nevertheless, genetic research has yet to find abnormalities at the 5-HT transporter gene level. A recent study exploring the polymorphism of the promoter region of the gene for the 5-HT transporter failed to identify any differences between OCD patients and controls (Billet et al. 1997). A trend towards homozygosity among the OCD group was demonstrated, but there was no correlation with the clinical response to SRI.

6.6 Other Biological Data

Sleep EEG and neuroendocrine studies have found abnormalities similar to those seen in depression, such as decreased rapid eye movement (REM) latency, nonsuppression on the dexamethasone–suppression test (DST), and decreased growth hormone secretion with clonidine infusions (Sasson and Zohar 1996).

6.7 Behavioral Factors

Based on postulations from the learning theory, obsessions are conditioned stimuli. When a relatively neutral stimulus is coupled with an anxiety-provoking one, through conditioning it will produce anxiety even when presented alone. Compulsions are acquired through their anxiety-reducing effect, causing the patient to repeat them in order to avoid anxiety. Avoidance strategies are learned and become fixed.

6.8 Psychosocial Factors
