The ICD-10 categories "psychoactive substance use psychotic disorders" (F1x.5) and "residual disorders and late onset psychotic disorder" (F1x.7) are dispersed among the syndrome sections in DSM-IV under the heading of "substance-induced [syndrome]" disorders. ICD-10 substance-induced psychotic disorders include disorders with predominantly depressive or manic symptoms. As they are defined, they have to be psychotic, i.e., include hallucinations or delusions. Substance-induced non-psychotic affective disorder has to be classified as residual affective disorder (F1x.72).

4.2 Schizophrenia and Related Psychotic Disorders

For schizophrenia, the ICD-10 and DSM-IV criteria sets are different as to duration, but appear more similar as to characteristic symptoms. For duration, ICD-10 requires 1 month of symptoms be present most of the time irrespective of treatment, whereas DSM-IV requires 6 months of symptoms including a 1 month active phase with characteristic symptoms or less than 1 month if successfully treated. Thus schizophrenia is of a chronic nature in DSM-IV, whereas in ICD-10 it may correspond to DSM-IV's schizophreniform disorder if it lasts for less than 6 months. The presentation of the characteristic symptoms also shows subtle but important differences. ICD-10 requires either at least one first-rank symptom (Schneider 1967) or "bizarre" delusions or, instead, a combination of at least two of the following: (a) hallucinations with non-affective delusions, (b) disorganized speech, (c) catatonic behaviour and/or (d) negative symptoms. The DSM-IV presentation appears more user-friendly, requiring two or more of the following: (a) delusions, (b) hallucinations, (c) disorganized speech, (d) grossly disorganized or catatonic behaviour and/or (e) negative symptoms. In a footnote, it is added that only one symptom is required if the delusions are bizarre or if the hallucinations consist of commenting or discussing voices. Thus the combination of hallucinations and delusions, whether affective or non-affective, is sufficient for the diagnosis, whereas the combination of hallucinations with non-affective delusions is only counted as one out of two necessary symptoms in ICD-10. As far as bizarre delusions are concerned, the quality of bizarreness is defined differently in the two systems. In ICD-10, they are not called bizarre, but are defined as "persistent delusions that are culturally inappropriate *and* completely impossible", whereas DSM-IV states that "delusions are deemed bizarre if they are clearly implausible and not understandable, and do not derive from ordinary life experiences" with the caution that "bizarreness" may be difficult to judge, especially across different cultures. It is obvious that delusions that are clearly implausible may all the same not be completely impossible. Furthermore, the bizarre delusions in DSM-IV are meant to cover the Schneiderian first-rank symptoms of experiences of subjective thought disorder and replacement of will, which, however, are combinations of subjective experiences and delusional explanations, albeit of a highly implausible character. In ICD-10, the Schneiderian first-rank auditory hallucinations are meant to be in the third person, which, however, is not clearly stated in either ICD-10 or DSM-IV. In ICD-10, audible thoughts and hallucinatory voices coming from some part of the body also qualify as a single symptom characteristic of schizophrenia. Furthermore, ICD-10 has no social criteria including occupation and interpersonal relationships, but as usual distress or interference with personal daily-life functioning is implicit in the definition of an ICD-10 disorder. For severe or chronic cases, these differences are of no practical significance, but for new cases with a recent onset and moderate or subtle symptoms, the differences are of substantial importance. As to the exclusion criteria, ICD-10 excludes primary or simultaneous presence of a manic or depressive syndrome, which will be classified under schizo-affective disorder, requiring for schizophrenia that the full schizophrenia syndrome must have been met before the mood disturbance developed. In DSM-IV, a concurrent mood syndrome is either ruled out or, if it occurs with the active-phase symptom, the duration must have been brief relative to the total duration of the active-phase and residual symptoms. The criteria to rule out substance use or a general medical condition are identical. Finally, DSM-IV requires prominent delusions or hallucinations for at least 1 month if the disorder appears in addition to autistic or other pervasive developmental disorders.

The schizophrenia subtypes are not fully equivalent and are defined in a slightly different way. Paranoid schizophrenia, however, has the same criteria in the two classifications. Hebephrenic schizophrenia in ICD-10 is referred to as schizophrenia, disorganized type, in DSM-IV and here requires prominent symptoms of disorganized speech, disorganized behaviour and flat and inappropriate affect, whereas the ICD-10 criteria only requires either disorganized behaviour or disorganized speech in addition to flat or inappropriate affect. The catatonic subtype in ICD-10 requires 2 weeks with at least one of a number of catatonic symptoms, whereas DSM-IV requires that the clinical

picture is dominated by at least two of similar catatonic symptoms. Undifferentiated schizophrenia in DSM-IV does not meet the criteria for any of the previous mentioned types, but in ICD-10, schizophrenic disorders with symptoms that meet the criteria for more than one of the previously mentioned types are also included under the heading "undifferentiated schizophrenia". For residual schizophrenia type, DSM-IV requires the presence of negative symptoms together with two or more characteristic symptoms in an attenuated form, whereas ICD-10 requires negative symptoms to have been present for 12 months in patients who have met the criteria for schizophrenia earlier, but not within the previous 12-month period. ICD-10 has a subtype of post-schizophrenic depression with a depressive syndrome of at least mild severity together with at least one schizophrenic symptom, which, however, must not be Schneiderian or bizarre delusions, so that it simultaneously fulfils the criteria for schizophrenia, which must have been met earlier within the previous 12 months. This subtype has no equivalent in DSM-IV, but has been included in appendix B under the heading of "postpsychotic depressive disorder of schizophrenia". Finally, ICD-10 includes simple schizophrenia as a subtype, defined by the progressive development over a period of 1 year of a significant and consistent change in the overall quality of personal behaviour, gradual appearance and deepening of negative symptoms and marked decline in social, scholastic or occupational performance (one of the exceptions to the principle of avoidance of social criteria in ICD-10). At the same time, the patient must never have had psychotic symptoms. This subtype does not have an equivalent in the DSM-IV classification either, but is included in the appendix B under the heading "simple deteriorative disorder".

The schizophreniform disorder of DSM-IV corresponds to ICD-10's schizophrenia F20.0, F20.1, F20.2, F20.3, F20.8 and F20.9 if the active-phase symptoms have lasted for at least 1 month irrespective of treatment. If the active phase has a duration of less than 1 month due to successful treatment, the criteria nevertheless require that the total duration is at least 1 month, also including prodromal or residual symptoms, and schizophreniform disorder therefore does not correspond to F23.2 (acute schizophrenia-like psychotic disorder) or F23.1 (acute polymorphic psychotic disorder with symptoms of schizophrenia).

The main difference between the schizophrenia concepts in the two systems is therefore that the ICD-10 definition of schizophrenia is purely descriptive and phenomenological, without taking into consideration course or social criteria. The duration of 1 month irrespective of treatment was primarily chosen to separate schizophrenia from acute, transient schizophrenia-like psychotic disorder and from substance-induced schizophreniform disorder, which usually remits within 1 month of abstinence from substance use. DSM-IV changed the active-phase duration from 1 week to 1 month for the same reason and in order to be consonant with ICD-10, but retained the chronic course criterion and added the social criterion. ICD-10's schizophrenia therefore seems to cover a broader area in spite of the more prominent stress on Schneiderian first-rank symptoms and the more narrow definition of bizarreness. The ICD-10 concept is further broadened by the extra subtypes, particularly by the specially defined "simple schizophrenia".

In ICD-10, schizotypal disorder (F21) is included among the schizophrenia-related disorders, whereas DSM-IV has it as a personality disorder. The diagnostic criteria sets essentially define the same condition.

For persistent delusional disorder (F22), ICD-10 requires a minimum duration of 3 months, whereas the similarly defined delusional disorder in DSM-IV only requires 1 months' duration and further allows tactile or olfactory hallucinations to be present if related to the delusional theme. ICD-10 has a subgroup of "other persistent delusional disorders" (F22.8), which include delusions accompanied by persistent hallucinatory voices or other schizophrenic symptoms that do not meet the criteria for schizophrenia. Durations shorter than 3 months are categorized under "acute and transient psychotic disorder" (F23).

The ICD-10 category of "acute and transient psychotic disorders" is defined by an acute onset of fully developed psychotic symptoms within 2 weeks, excluding delirious states, mood disorders and organic aetiology. They are subdivided into acute polymorphic psychotic disorder without or with symptoms of schizophrenia, acute schizophrenia-like psychotic disorder and other acute predominantly delusional psychotic disorder. Polymorphic disorders require at least two of the following: (a) emotional turmoil, (b) perplexity or misidentification and/or (c) markedly increased or decreased motility. In this way, they correspond to the cycloid psychosis of Kleist and Leonhard and to the *bouffée délirante* of the French traditional classification (Berner et al. 1992; Sartorius et al. 1990). A fifth character allows subtyping into disorders without and with associated acute stress, the latter corresponding to the concept of reactive psychosis. ICD-9's reactive confusion may now be classified as acute polymorphic psychotic disorder or among the other acute and transient psychotic disorders (F22.8) if the confusion is only transient and does not fulfil the symptomatic criteria for delirium. Some cases of reactive confusion, however, will more readily correspond to dissociative disorders such as dissociative fugue or trance and possession disorders. The

duration must not exceed 1 month for polymorphic psychotic disorder with symptoms of schizophrenia or acute schizophrenia-like psychotic disorder in order to distinguish the disorder from schizophrenia. The other acute and transient psychotic disorders have a duration limitation of 3 months to delineate them from delusional disorders. DSM-IV's brief psychotic disorder with psychotic symptoms of less than 1 months' duration may correspond to any ICD-10 acute and transient psychotic disorder of short duration (less than 1 month). DSM-IV also provides a subdivision relating to the presence of a marked stressor.

Schizoaffective disorders differ substantially in their definitions in the two systems. The ICD-10 definition requires the presence of a full affective syndrome of moderate or severe degree together with symptoms characteristic of schizophrenia for at least 2 weeks, including first-rank symptoms, bizarre delusions, disorganized speech or catatonic behaviour. Both the mood and the schizophrenic symptoms must be prominent and appear concurrently for at least a part of the episode. DSM-IV requires furthermore a period of at least 2 weeks with delusions or hallucinations in the absence of prominent mood symptoms. In DSM-IV, psychotic symptoms which occur only in the presence of a mood episode are diagnosed as a mood disorder with psychotic features, regardless of the characteristics of the psychotic symptoms. ICD-10's schizoaffective disorders are thus a much broader concept that includes many cases of DSM-IV mood disorders with psychotic features. The ICD-10 diagnostic guidelines mention that their relationship to typical mood disorders and schizophrenic disorders is uncertain, but that they are given a separate category because they are too common to be ignored. It further mentions that the cross-sectional diagnosis of schizoaffective disorder, appearing occasionally in a series of typical affective disorders, should not invalidate the diagnosis of bipolar disorder or recurrent depressive disorder.

4.3 Mood Disorders

The ICD-10 and DSM-IV systems both group together disorders with affective symptoms. They are primarily subdivided according to the nature of the symptoms into manic, depressive and mixed episodes. The episodes are further subdivided according to severity and the presence of psychotic symptoms. A manic episode requires in both systems the presence of expansive elevated or irritable mood for at least 1 week or less if severe enough to require hospital admission, accompanied by three manic symptoms, or four if the mood is irritable, out of a number of almost identical manic symptoms grouped slightly differently in the two systems. DSM-IV further requires severe interference with social functioning, whereas ICD-10 stresses interference with personal daily-life functioning. Hypomania is defined in DSM-IV by precisely the same symptoms, except that the required duration is only at least 4 days. The disorder should be distinct and observable by others, but should not cause severe interference with social functioning or necessitate hospitalization. ICD-10's hypomania requires elevated or irritable mood for at least 4 consecutive days accompanied by three symptoms among a number of hypomanic or manic symptoms, leaving out inflated self-esteem or grandiosity and flight of ideas and stressing that it should only lead to some interference with personal functioning in daily living. As to the presence of psychotic symptoms, ICD-10 includes delusions or hallucinations other than those listed as typically schizophrenic, i.e., first-rank symptoms and bizarre delusions, whereas DSM-IV allows any psychotic symptoms, regardless of their nature, as long as they are confined to the mood episode. This makes the DSM-IV concept much broader, covering a number of the schizoaffective disorders in ICD-10. Both systems have a further subdivision according to congruence of the psychotic symptoms with the mood state.

The depressive episode in ICD-10 and the major depressive episode in DSM-IV have different thresholds. ICD-10 mentions three nuclear depressive symptoms: (1) depressed mood, present for the most of the day, almost every day for at least 2 weeks, (2) loss of interest or pleasure and (3) decreased energy or increased fatigability. In addition to the nuclear symptoms, seven accessory or additional depressive symptoms are mentioned. To qualify as a depressive episode, four or more depressive symptoms are required, including at least two of the nuclear symptoms. DSM-IV has a different algorithm for major depressive episodes, requiring five or more depressive symptoms including either depressed mood or loss of interest or pleasure. Severity in ICD-10 is correlated with the number of depressive symptoms, whereas DSM-III relies on clinical judgement. Moderate or severe depression fulfils the criteria in both systems, but mild depressive episodes have a lower threshold in ICD-10. A linguistic problem with the use of the word "major" may contribute to the higher threshold in DSM-IV. In non-English-speaking countries, the word "major" might be understood as "severe", restricting the use of the diagnosis in clinical practice. Recommendations for anti-depressant treatment are furthermore often linked to "major depression" due to the extensive use of DSM diagnostics in psychopharmacological treatment literature, thus also including mild cases, recommendations which, on the other hand, make the pharmaceutical companies happy. As

to the presence of psychotic symptoms, the same differences apply as for the manic episodes with psychotic symptoms. Depressive episodes of mild or moderate severity in ICD-10 have a further subdivision according to the presence of a "somatic syndrome", corresponding to the melancholic features in DSM-IV.

A mixed affective episode in ICD-10 requires either a mixture or a rapid alternation of hypomanic–manic and depressive symptoms during an episode lasting for at least 2 weeks, whereas DSM-IV defines a mixed episode as one which meets the criteria for a manic episode and the symptomatic criteria for a major depressive episode nearly every day for at least a 1-week period, causing marked interference with social functioning or necessitating hospitalization.

The mood disorders in ICD-10 are further subdivided as to single hypomanic, manic, depressive or mixed affective episodes or recurrent episodes in the form of bipolar disorder or recurrent depressions. A bipolar disorder is defined by the presence of at least two episodes, of which one is hypomanic, manic or mixed. Episodes are limited from each other either by a shift of polarity or a period of at least 2 months' remission without prominent mood symptoms. DSM-IV includes single manic, hypomanic or mixed episodes in the bipolar disorders and thus has a more simplistic main division between bipolar and depressive disorders. DSM-IV has further subdivisions into bipolar I and bipolar II disorders, which are considered to be various combinations of affective syndromes in ICD-10's bipolar disorders. DSM-IV further subdivides by specifiers for catatonic or atypical features, post-partum onset, longitudinal course, seasonal pattern and rapid cycling, which are considered as variations in course and symptomatology in ICD-10. The presence of atypical or catatonic features, particularly if they reach a state of extreme catatonic excitement, previously described as acute delirium in psychotic disorders, may in ICD-10 lead to consider the use of the diagnostic category F3x.8 ("other").

In addition to the episodic disorders, both systems include persistent mood disorders, cyclothymia and dysthymia, which in DSM-IV are grouped together with bipolar and depressive disorders, respectively. Both systems require numerous episodes of hypomanic or mild depressive symptoms for cyclothymia or sub-threshold depressive symptoms alone for dysthymia with only short-lasting remissions, not exceeding 2 months, occurring within a total period of at least 2 years with no manic, mixed or depressive episodes, which in DSM-IV may occur later as superimposed on a persistent mood disorder. ICD-10 provides a list of hypomanic or mild depressive symptoms, of which patients should have at least three during some of the episodes as well as the elevated or depressed mood, but, as mentioned, not enough to fulfil the criteria for a manic or depressive episode. For dysthymic disorders, DSM-IV has a list of six depressive symptoms, of which only two or more should be present together with depressed mood.

Finally, ICD-10 includes recurrent brief depressive disorder in the category of "other mood disorders" (F38.1). DSM-IV has no equivalent, but includes the disorder in appendix B in the criteria sets and axes provided for further study. Both systems contain many subcategories, particularly DSM-IV with all its subspecifications (possibly too many, because extensive use of a very high number of subcategories may cause reliability problems, especially in research).

4.4 Anxiety Disorders

Anxiety in ICD-10 is always autonomic anxiety, i.e., requires the presence of at least one of the autonomic arousal symptoms (palpitations, sweating, trembling or dry mouth), in contrast to DSM-IV, which merely mentions anxiety, fear or discomfort without specific qualification. The difference may, however, be more theoretical than practical except in mild or very mild cases. ICD-10 subdivides the anxiety disorders into phobic disorders, including agoraphobia, social phobia and specific phobias, and other anxiety disorders, including panic disorder and generalized anxiety disorder.

Agoraphobia appears in situations or places in which it may be difficult to escape or get help, such as in crowds, public places, when travelling alone or away from home, and at least two of these situations should be implied. Social phobia appears in social situations with fear of being the focus of attention or of behaving embarrassing or humiliating. Specific phobias appear in the presence of specific objects or in certain situations other than the previously mentioned ones. The phobic disorders are manifested by fear or avoidance of the situations or objects, and they must have appeared at least once with a minimum of at least two anxiety symptoms, one being autonomic, out of a list of 14 anxiety symptoms, accompanied in social phobia by either blushing or shaking, fear of vomiting or of micturation or defecation. The individual must realize that the fear or avoidance is excessive or unreasonable. In addition to the presence of organic aetiology, exclusion criteria are those of psychotic disorders and mood disorders, i.e., the simultaneous presence of a depressive episode will give preference to the diagnosis of a depressive disorder. This is in contrast to the co-morbidity rule in DSM-IV.

Panic disorder is defined by the occurrence of at least four panic attacks in a 4-week period, each attack including at least four anxiety symptoms, of which one must be autonomic. The DSM-IV criteria for panic attacks also require four or more anxiety symptoms out of an almost identical list of symptoms, but they do not have to be autonomic, and for panic disorder, the attack only needs to be recurrent without a specified minimum number of attacks. In DSM-IV, the diagnosis of agoraphobia is linked together with panic disorder as the primary disorder which may appear together with or without agoraphobia. Agoraphobia can also appear alone (agoraphobia without history of panic disorder). ICD-10 deals with this the other way round, with a subdivision of agoraphobia according to the presence or absence of panic disorder. ICD-10's panic disorder has a subdivision into moderate and severe panic disorder, the severe form requiring four panic attacks per week over a 4-week period.

Generalized anxiety disorder in both systems requires a period of 6 months with prominent tension, worry and apprehension about everyday events and problems. In ICD-10, at least four anxiety and tension symptoms are required, one being autonomic, out of a list of 22 symptoms, including the previous 14 anxiety symptoms and an additional eight tension and nonspecific symptoms. This corresponds to six symptoms mentioned in DSM-IV, of which three are required to be present; however, only one symptom is required in children, for which ICD-10 has a specific category, "generalized anxiety disorder of childhood" (F93.80).

ICD-10 further includes a category for mixed anxiety and depressive disorder, which includes very mild subthreshold anxiety or depression with no specific criteria provided. This was prompted by a strong desire on the part of primary health care physicians. It has no equivalent in DSM-IV, but it is included in appendix B for further study.

4.5
Obsessive Compulsive Disorder

DSM-IV also includes obsessive–compulsive disorders among the anxiety disorders, whereas in ICD-10 they appear as an independent type of neurotic disorders (F42). ICD-10 requires obsessions or compulsions for at least 2 weeks and differentiates between predominantly obsessional, compulsive or mixed disorders. DSM-IV requires practically the same symptoms and characteristics, but stresses the relation to anxiety and distress, caused by the symptoms and by the individual's attempts to ignore, suppress or neutralize the obsessional thoughts or impulses by other thoughts or actions leading to compulsion. If these attempts are purely mental acts, the DSM-IV's "cognitive compulsions" are equivalent to ICD-10 "obsessions".

4.6
Reaction to Severe Stress and Adjustment Disorders

DSM-IV further includes acute stress reaction and post-traumatic stress disorder among the anxiety disorders, whereas ICD-10 places them in the subsection F43 (reaction to severe stress and adjustment disorders). The criteria for acute stress disorder differ markedly between the two systems. ICD-10 requires the presence of anxiety and tension symptoms, which may be sufficient for mild cases, whereas moderate and severe cases require at least two or four symptoms, respectively, of a list of seven symptoms: (1) withdrawal from social interaction, (2) narrowing of attention, (3) apparent disorientation, (4) anger or aggression, (5) despair or hopelessness, (6) inappropriate or purposeless overactivity and/or (6) uncontrollable and excessive grief. For severe cases, dissociative stupor may be present instead of the four symptoms. Symptoms must appear immediately after exposure to an exceptional mental or physical stressor (within 1 h) and should diminish after not more than 8 h, or not more than 48 h for continued stressors. DSM-IV does not require any time frames for onset or duration and requires three or more of five dissociative symptoms and repeated experiences of the traumatic event with avoidance of stimuli that arouse recollections of the trauma, in addition to symptoms of anxiety or increased arousal. For post-traumatic stress disorder, the criteria are quite similar, although they are presented in a different way, the main difference being that ICD-10 may substitute persistent symptoms of increased arousal by inability to recall important aspects of the traumatic exposure and that ICD-10 does not require a minimum duration of 1 month as DSM-IV does.

Adjustment disorder has a separate section in DSM-IV just before the personality disorders. ICD-10's adjustment disorder requires onset of symptoms within 1 month of exposure to an identifiable psychosocial stressor, not of an unusual or catastrophic type, in contrast to DSM-IV, which requires the onset of symptoms within 3 months of any stressor so long as the criteria for acute stress disorder or post-traumatic stress disorder are not met. Both systems mention depressive, anxiety and behavioural symptoms, which must not meet the criteria for any other disorders. ICD-10 has a duration limitation of 6 months, except for brief depressive reaction, which should not exceed 1 month, and prolonged depressive reaction with a

duration not exceeding 2 years. DSM-IV gives a subspecification into acute and chronic adjustment disorder according to whether the duration was less or more than 6 months.

4.7 Somatoform Disorders

Somatoform disorders in both systems include somatization disorder, undifferentiated somatoform disorder, hypochondriacal disorder and pain disorder. ICD-10's somatization disorder requires a history of at least 2 years of complaints of multiple and variable physical symptoms that cannot be explained by a detectable physical disorder, with preoccupation with the symptoms causing distress and leading to repeated consultation or investigations, with a persistent refusal to accept medical reassurance. A total number of at least six symptoms from two organ groups are required out of a total of 14 gastrointestinal, cardiovascular, genitourinary or skin and pain symptoms. The preoccupation should be with symptoms alone and not with a belief of any serious physical disease as in hypochondriacal disorder. DSM-IV requires a combination of four pain symptoms, two gastrointestinal symptoms, one sexual symptom and one pseudo-neurological symptom occurring over a period of several years beginning before the age of 30, resulting in consultations for treatment or impaired social functioning. As in ICD-10, the symptoms and their effects cannot be explained by a known general medical condition or as the effect of any substance or medication. DSM-IV further mentions that they must not be intentionally produced or feigned.

Undifferentiated somatoform disorder has almost identical criteria in the two systems, only requiring a duration of at least 6 months and a lower number of somatoform symptoms.

Hypochondriacal disorder in ICD-10 corresponds to DSM-IV's hypochondriasis and body dysmorphic disorder, and they have similar criteria.

Pain disorder, referred to in ICD-10 as persistent somatoform pain disorder, requires a period of at least 6 months' persistent, severe and distressing, unexplained pain, which has become the main focus of the patient's attention. DSM-IV is more circumscript in the pain disorder criteria, requiring that psychological factors are judged to play an important role and that the pain symptoms are not intentionally produced or feigned. DSM-IV provides a subspecification into pain disorder associated with psychological factors and pain disorder associated with both psychological factors and a general medical condition and makes a further subdivision into acute and chronic pain disorders with a duration of less or more than 6 months.

ICD-10 has a category of somatoform autonomic dysfunction for somatoform symptoms accompanied by autonomic arousal, attributed to a physical disorder in at least one out of five organ systems: the cardiovascular system, the upper and lower gastrointestinal system, the respiratory system and the genito-urinary system. DSM-IV has no specific equivalent, but includes the disorder under "undifferentiated somatoform disorder".

DSM-IV includes among the somatoform disorders conversion disorder, which in ICD-10 is included among the dissociative disorders. Conversion disorder corresponds to ICD-10's dissociative motor disorders, dissociative convulsions, dissociative anaesthesia and sensory loss, and mixed dissociative disorders, with almost the same diagnostic criteria except that for the main group of dissociative disorders ICD-10 requires a convincing temporal association between the onset of symptoms and stressful events, problems or needs. DSM-IV stresses a delimitation from intentionally produced or feigned symptoms.

Among the dissociative disorders, ICD-10 further includes dissociative amnesia, fugue, trance and possession disorders, and other dissociative disorders with Ganser's syndrome and multiple personality disorder. The requirement of association with a psychosocial stressor is general for all dissociative disorders, and the term "dissociative disorder" is defined as a partial or complete loss of the normal integration between memories of the past, awareness of identity and immediate sensations and control of bodily movements. Dissociative disorders in DSM-IV are defined as a dissociation of the integrated functions of consciousness, memory, identity and perception of the environment, but not including control of bodily movements. DSM-IV's dissociative disorders include dissociative amnesia, fugue, identity disorder (formerly multiple personality disorder) and depersonalization disorder, the equivalent of depersonalization–derealization syndrome (F48.1) in ICD-10. The criteria for the subtypes are quite similar in the two systems.

ICD-10 includes one further "neurotic" disorder diagnosed in various parts of the world, i.e., neurasthenia, for which DSM-IV has no specific equivalent but includes the disorder under undifferentiated somatoform disorder.

As far as the dissociative disorders are concerned, DSM-IV has a section on factitious disorders, which in ICD-10 are placed in a rest group of other disorders of adult personality and behaviour (F68), with the long title of "intentional production or feigning of symptoms or disabilities either physical or psychological (factitious disorder)" (F68.1). However, both systems use almost identical criteria sets.

4.8
Eating Disorders

ICD-10 includes eating disorders under the heading "behavioural syndromes associated with physiological disturbances and physical factors" (F5). Eating disorders are subdivided into anorexia nervosa, atypical anorexia nervosa, bulimia nervosa, atypical bulimia nervosa and overeating or vomiting associated with other psychological disturbances. DSM-IV differentiates between only three categories: anorexia nervosa, bulimia nervosa and eating disorder not otherwise specified. For anorexia nervosa, the main criteria are similar, but ICD-10 specifically requires that weight loss must be self-induced by avoidance of fattening foods and excludes bulimic episodes, in contrast to DSM-IV, which give anorexia nervosa precedence over bulimia nervosa, with a subspecification into the restricting type and the binge-eating/purging type. For bulimia nervosa, ICD-10 excludes anorexia nervosa, but otherwise has almost the same criteria. Combinations of anorexia and bulimia are included under atypical bulimia nervosa in ICD-10, whereas atypical anorexia nervosa corresponds to DSM-IV's eating disorder not otherwise specified The classification of eating disorders in ICD-10 is one of the subclassifications which has caused most dissatisfaction, and psychiatrists treating these disorders seem to prefer the DSM-IV classification.

4.9
Sleep Disorders

Sleep disorders are defined in essentially the same way in the two systems, except that DSM-IV includes narcolepsy and breathing-related sleep disorder in the classification, which in ICD-10 are classified in Chap. VI (diseases of the nervous system).

4.10
Sexual and Gender Identity Disorders

Sexual and gender identity disorders are grouped together in DSM-IV, whereas in ICD-10 they are divided into non-organic sexual dysfunction (F52), gender identity disorder (F64) and disorders of sexual preference (F65). Sexual dysfunction has the same subcategories and similar diagnostic criteria, except that ICD-10 requires a minimum duration of 6 months and provides separate criteria for males and females when appropriate. DSM-IV has subspecifications according to whether the disorder is lifelong or acquired, generalized or situational and whether psychological or combined factors are present. DSM-IV's sexual dysfunction due to a general medical disorder or to substance use is included in ICD-10 under other specified mental disorders due to brain damage and dysfunction and to physical disease (F06.8) or under other mental or behavioural disorders due to psychoactive substance use (F1x.8), both with associated codes for particular syndromes from Chap. XIV in ICD-10 (diseases of the genito-urinary system).

Gender identity disorder is subdivided in ICD-10 into transsexualism, dual-role transvestism and gender identity disorder of childhood, with differentiated diagnostic criteria contained in the criteria for the single DSM-IV category "gender identity disorder".

Disorders of sexual preference, referred to in DSM-IV as paraphilias, are defined and subcategorized in similar ways in the two systems. DSM-IV includes frotteurism and subdivides sadomasochism into sexual masochism and sexual sadism.

ICD-10's psychological and behavioural disorders associated with sexual development and orientation, including sexual maturation disorder, egodystonic sexual orientation and sexual relationship disorder (F66) have no specific equivalents in DSM-IV, which includes them under sexual disorder not otherwise specified.

4.11
Personality Disorders

The general diagnostic criteria for personality disorders are almost identical in the two systems, requiring an inflexible, pervasive, enduring pattern of deviating inner experience and behaviour affecting two or more of the areas of cognition, affectivity, impulse control and interpersonal functioning, leading to distress or impaired social functioning, in ICD-10 also including adverse impact on the social environment. They are lifelong with onset in late childhood or adolescence and are therefore difficult to diagnose before the age of 18, except for antisocial personality disorder, which often is a continuation of childhood conduct disorder. The criteria are restrictive and demanding, and the category is not easy to use in a clinical setting. They are subdivided into specific personality disorders, which in addition require a number of typical personality traits for each disorder. DSM-IV presents the specific disorders in three clusters: Cluster "A" includes paranoid, schizoid and schizotypal personality disorder, of which the latter is grouped with schizophrenia and related disorders in ICD-10. Cluster "B" with antisocial, borderline, histrionic and narcissistic personality disorder corresponding to ICD-10's dyssocial, histrionic and emotionally unstable personality disorder of borderline type. ICD-10 has no equivalent to narcissistic personality disorder, which, however, is included in an

annex with provisional (DSM-IV) criteria for selected disorders. DSM-IV cluster "C" includes avoidant, dependent and obsessive-compulsive personality disorder, corresponding to ICD-10's anxious, dependent and anankastic personality disorders. ICD-10 further includes emotionally unstable personality disorder of impulsive type, which has no equivalent in DSM-IV. The corresponding personality disorders have differently formulated criteria in the two systems, but nevertheless essentially define the same conditions. ICD-10 further includes subcategories for mixed personality disorder with a mixture of features not fulfilling the criteria for any specific personality disorders; troublesome personality changes regarded as secondary to co-existing affective or anxiety disorders; and enduring personality change after catastrophic experiences or after psychiatric illness due to the impact of the catastrophic events or the experience of psychiatric illness from which the patient has recovered completely without residual symptoms. DSM-IV has no equivalents, but includes these disorders under personality disorder not otherwise specified.

4.12 Other Disorders

Finally, DSM-IV has a section with impulse-control disorders not elsewhere classified, including intermittent explosive disorder, kleptomania, pyromania, pathological gambling and trichotillomania. The corresponding category in ICD-10 (F63, habit and impulse disorders) includes pathological gambling, fire-setting, stealing and trichotillomania. Pathological gambling is presented differently in ICD-10, requiring two or more episodes within a period of 1 year, with mental preoccupation with gambling and an intense urge to gamble which is difficult to control, accompanied with lack of profitable outcome, personal distress and interference with personal functioning. DSM-IV requires at least five out of a total number of ten characteristic features which roughly reflect the same condition as defined in ICD-10. The other impulse disorders have essentially the same criteria. Intermittent explosive disorder has no specific equivalent in ICD-10, but has to be included among other habit and impulse disorders. If lifelong, it may correspond to ICD-10's emotionally unstable personality disorder of impulsive type.

ICD-10 finally includes a few categories with no specific equivalents in DSM-IV: mental and behavioural disorders associated with the puerperium, not elsewhere classified (F53), psychological and behavioural factors associated with disorders or diseases classified elsewhere (F54) and elaboration of physical symptoms for psychological reasons (F68.0).

4.13 Disorders of Infancy, Childhood or Adolescence

The disorders of infancy, childhood or adolescence in both systems include mental retardation, development disorders and behavioural and emotional disorders. Developmental disorders (ICD-10 F8) include specific disorders affecting various areas of speech, language, motor or scholastic skills and pervasive developmental disorders such as autistic disorder, atypical autism, Rett's syndrome and other childhood disintegrative disorder, covering corresponding diagnostic categories in the two systems.

ICD-10's behavioural and emotional disorders with onset usually occurring in childhood and adolescence (F9) include hyperkinetic disorders, conduct disorders, emotional disorders, social functioning disorders and other disorders with onset specific to childhood or adolescence. In DSM-IV, attention deficit or hyperactivity disorder covers a broader area, including cases with attention deficit alone. DSM-IV conduct disorder has almost the same diagnostic criteria as ICD-10 conduct disorder, but a different subcategorization into childhood-onset or adolescence-onset type and subspecification according to severity, whereas ICD-10 subdivides the disorder into conduct disorder confined to the family context, unsocialized and socialized conduct disorder and further includes oppositional defiant disorder, which is separately categorized in DSM-IV.

Among the emotional disorders, ICD-10 provides criteria for separation anxiety disorder similar to the corresponding DSM-IV category. It further provides diagnostic criteria for the subcategories phobic social disorder, generalized anxiety disorder of childhood and sibling rivalry disorder.

The ICD-10 disorders of social functioning include elective mutism and reactive and disinhibited attachment disorder of childhood, which correspond to DSM-IV's selective mutism and reactive attachment disorder of infancy or early childhood.

Finally, both categories include a number of other childhood psychiatric disorders such as tic disorders, feeding or elimination disorders and speech disorders.

ICD-10 also has a nonspecific residual category (F99, mental disorder not otherwise specified) for disorders which do not fulfil any specific criteria and cannot even be placed in the main section's subcategories for unspecified disorders. DSM-IV has no equivalent, but may use unspecified mental disorder for non-psychotic disorders.

DSM-IV on the other hand has a section for other conditions that may be a focus of clinical attention, including psychological factors affecting medical con-

ditions, which corresponds to ICD-10's psychological and behavioural factors associated with disorders or diseases classified elsewhere (F54). DSM-IV further includes medication-induced movement disorders or adverse effects of medication corresponding to ICD-10 conditions from the neurological chapter on problems related to abuse or neglect, other relational problems, conditions or factors with corresponding specific T or Z categories in ICD-10. DSM-IV provides additional codes for deferred or provisional diagnoses indicating diagnostic uncertainty.

4.14 Multiaxial Presentation

DSM-IV has continued the multiaxial presentation introduced by DSM-III with five axes: axis I for clinical disorders, axis II for personality disorders and mental retardation, axis III for general medical conditions, axis IV for psychosocial and environmental problems and axis V for global assessment of functioning (American Psychiatric Association 1994). ICD-10 has introduced a corresponding multiaxial presentation for adult psychiatric disorders with three axes: axis I for clinical diagnoses of any type, including personality disorders, developmental disorders or mental retardation and general medical conditions, axis II for impairments, disabilities and handicaps due to mental disorders affecting various areas of social functioning and, finally, axis III containing a number of contextual factors influencing health status and contact with health services, derived from the ICD-10 Z categories and comprising problems related to social environment and circumstances, negative life events in childhood, problems related to upbringing or to primary support groups and problems related to lifestyle or difficulties in life management (World Health Organization 1997).

No criteria are provided for axis II or III. For axis II, the WHO revision of the *International Classification of Impairments Disabilities and Handicaps* is awaited.

For child psychiatry, a *Multiaxial Classification of Child and Adolescent Psychiatric Disorders* is provided with six axes: clinical psychiatric syndromes, developmental disorders, intellectual level, physical disorders, psychosocial factors and global assessment of psychosocial disability (World Health Organization 1996).

5 Diagnostic Instruments

In collaboration with the U.S. National Institutes of Health (NIH), WHO has provided instruments for the assessment of symptoms required for the diagnostic criteria in both the ICD-10 and the DSM systems. Schedules for Clinical Assessment in Neuropsychiatry (SCAN; World Health Organization 1992c) and the International Personality Disorder Examination (IPDE; Loranger et al. 1997; World Health Organization 1992d) cover the majority of adult psychiatric disorders and are designed for use in clinical research with computer-assisted diagnostic processing. In epidemiological research, the Composite International Diagnostic Interview (CIDI; World Health Organization 1990, 1993b) is a fully structured interview schedule to be used by lay interviewers for both ICD-10 and DSM diagnoses. The schedules have been updated to also cover DSM-IV diagnoses (World Health Organization 1994, 1995, 1997).

6 ICD-10 and DSM-IV General Status

The majority of mental and behavioural disorders are included in both classification systems, although for some disorders with different systematic distribution and under different headings. A few categories appear only in one of the classifications, and not in the other. Thus ICD-10 includes mild cognitive disorder, post-concussional syndrome, simple schizophrenia, post-schizophrenic depression, recurrent brief depressive disorder, somatoform autonomic dysfunction, neurasthenia, enduring personality change after catastrophic experience or psychiatric illness and generalized anxiety disorder of childhood. They have no equivalents in DSM-IV, which, however, has placed several of them in the appendix B in the criteria sets and axes provided for further study under slightly different headings. DSM-IV, on the other hand, includes a variety of subspecifications regarding course and special features in the mood disorders, narcolepsy, breathing-related sleep disorder, intermittent explosive disorder and narcissistic personality disorder and a special section for other conditions that may be a focus of clinical attention, including medication-induced movement disorders, relational problems, problems related to abuse or neglect and other additional problems such as non-compliance with treatment, malingering, borderline intellectual functioning, age-related cognitive decline, bereavement, acculturation problems, phase of life problems and religious or spiritual problems, which are not included in ICD-10's mental and behavioural disorder section, but may find equivalent codes in other ICD-10 chapters.

The diagnostic criteria for the majority of categories are almost identical or at least quite similar, defining essentially the same conditions. For some disorders,

however, they may differ substantially as to the threshold for inclusion in the diagnostic category in question. This applies to important main categories such as schizophrenia and major depressive episode. For moderate or severe disorders, however, the correspondence is almost complete, which is the case for the majority of patients in clinical psychiatry. For disorders of mild severity, just above the threshold for inclusion in the diagnostic categories, differences may be substantial and will primarily affect epidemiological research or primary health care. The DSM-IV use of social criteria may contribute to this differentiation.

ICD-10 and DSM-IV both rely on demonstrated satisfactory reliability for main categories and subcategories. Further validation is still needed to provide evidence for which criteria sets have the most valid delineations with the most valid thresholds for inclusion. The WHO ICD-10 Advisory Committee has called for a moratorium of at least 10 years before the next round of revisions begin in order to allow time for such validation studies. Classificatory areas in special need of validation would be schizoaffective disorders in comparison with schizophrenia and psychotic mood disorders, some of the special ICD-10 categories such as mild cognitive disorder, simple schizophrenia and neurasthenia, and the specific personality disorders. Candidates for validation studies in DSM-IV are found in appendix B (criteria sets and axes provided for further study), including some of the categories corresponding to the special ICD-10 categories. The major psychiatric journals should be encouraged to accept contributions using either of the two classification systems or both, in order to promote publication of validation studies essential for future revisions of both systems. WHO has not yet achieved its goal of one common language in international psychiatry. Future revisions will hopefully approximate the classifications further with the ultimate goal of having one common classification system to the benefit of psychiatric patients all over the world.

Conversion Tables for ICD-10 and DSM-IV

Table 1. Conversion table: ICD-10 to DSM-IV (ICD-9-CM)

ICD-10	DSM-IV (ICD-9-CM)
F00–F99 Organic, including symptomatic, mental disorders	
A fifth character may be added to specify dementia in F00–F03, as follows: 0 Without additional symptoms 1 Other symptoms, predominantly delusional 2 Other symptoms, predominantly hallucinatory 3 Other symptoms, predominantly depressive 4 Other mixed symptoms	
F00 Dementia in Alzheimer's disease	(For all subtypes also code 331.0 Alzheimer's disease on axis III)
F00.0 Dementia in Alzheimer's disease with early onset (also code G30.0 Alzheimer's disease with early onset)	290.xx Dementia of the Alzheimer's type, with early onset .10 Uncomplicated .12 With delusions .13 With depressed mood
F00.1 Dementia in Alzheimer's disease with late onset (also code G30.1 Alzheimer's disease with late onset)	290.xx Dementia of the Alzheimer's type, with late onset .0 Uncomplicated .20 With delusions .21 With depressed mood
F00.2 Dementia in Alzheimer's disease, atypical or mixed type	No equivalent
F00.9 Dementia in Alzheimer's disease, unspecified	No equivalent
F01 Vascular dementia	290.xx Vascular dementia .40 Uncomplicated .42 With delusions .43 With depressed mood (also code vascular condition on axis III; no specifiers for subtypes)
F01.0 Vascular dementia of acute onset	
F01.1 Multi-infarct dementia	
F01.2 Subcortical vascular dementia	
F01.3 Mixed cortical and subcortical vascular dementia	
F01.8 Other vascular dementia	
F01.9 Vascular dementia, unspecified	
F02 Dementia in other diseases classified elsewhere	
F02.0 Dementia in Pick's disease (also code G31.0 Pick's disease)	290.10 Dementia due to Pick's disease (also code 331.1 Pick's disease on axis III)
F02.1 Dementia in Creutzfeldt-Jakob disease (also code A81.0 Creutzfeldt-Jacob disease)	290.10 Dementia due to Creutzfeldt-Jakob disease (also code 046.1 Creutzfeldt-Jakob disease on axis III)
F02.2 Dementia in Huntington's disease (also code G10 Huntington's disease)	294.1 Dementia due to Huntington's disease (also code 333.4 Huntington's disease on axis III)
F02.3 Dementia in Parkinson's disease (also code G20 Parkinson's disease)	294.1 Dementia due to Parkinson's disease (also code 332.0 Parkinson's disease on axis III)
F02.4 Dementia in human immunodeficiency virus (HIV) disease (also code B22.0 HIV dementia)	294.9 Dementia due to HIV disease (also code 043.1 HIV infection affecting central nervous system on axis III)
F02.8 Dementia in other specified diseases classified elsewhere	294.1 Dementia due to other general medical conditions (also code aetiological code on axis III)
F03 Unspecified dementia	294.8 Dementia NOS
F04 Organic amnesic syndrome, not induced by alcohol and other psychoactive substances	294.0 Amnestic disorder due to a general medical condition
F05 Delirium, not induced by alcohol and other psychoactive substances	
F05.0 Delirium, not superimposed on dementia, so described	293.0 Delirium due to a general medical condition
F05.1 Delirium, superimposed on dementia	290.11 Dementia of the Alzheimer's type with early onset, with delirium 290.3 Dementia of the Alzheimer's type with late onset, with delirium 290.41 Vascular dementia with delirium
F05.8 Other delirium	–.– Delirium due to multiple aetiologies
F05.9 Delirium, unspecified	780.09 Delirium NOS

ICD-10	DSM-IV (ICD-9-CM)
F06 Other mental disorders due to brain damage and dysfunction and to physical disease	
F06.0 Organic hallucinosis	293.82 Psychotic disorder due to a general medical condition, with hallucinations
F06.1 Organic catatonic disorder	293.89 Catatonic disorder due to a general medical condition
F06.2 Organic delusional (schizophrenia-like) disorder	293.81 Psychotic disorder due to a general medical condition, with delusions
F06.3 Organic mood (affective) disorders	293.83 Mood disorder due to a general medical condition
.30 Organic manic disorder	- With manic features
.31 Organic bipolar disorder	- With depressive features
.32 Organic depressive disorder	- With major depressive-like episode
.33 Organic mixed affective disorder	- With mixed features
F06.4 Organic anxiety disorder	293.89 Anxiety disorder due to a general medical condition
F06.5 Organic dissociative disorder	*No equivalent, use*: 293.9 Mental disorder NOS due to a general medical condition
F06.6 Organic emotionally labile (asthenic) disorder	*No equivalent, use*: 293.9 Mental disorder NOS due to a general medical condition
F06.7 Mild cognitive disorder	294.9 Cognitive disorder NOS (*see also Appendix B*: Mild neurocognitive disorder)
	-.- Sexual dysfunction due to a general medical condition
F06.8 Other specified mental disorders due to brain damage and dysfunction and to physical disease	780.5x Sleep disorder due to a general medical condition
F06.9 Unspecified mental disorder due to brain damage and dysfunction and to physical disease	293.9 Mental disorder not otherwise specified due to a general medical condition
F07 Personality and behavioural disorders due to brain disease, damage and dysfunction	
F07.0 Organic personality disorder	310.1 Personality change due to a general medical condition
F07.1 Post-encephalitic syndrome	294.4 Cognitive disorder, NOS
F07.2 Post-concussional syndrome	294.4 Cognitive disorder, NOS (*see also Appendix B*: Post-concussional disorder)
F07.8 Other organic personality and behavioural disorders due to brain disease, damage and dysfunction	310.1 Personality change due to a general medical condition, other type
F07.9 Unspecified organic personality and behavioural disorder due to brain disease, damage and dysfunction	310.1 Personality change due to a general medical condition, unspecified
F09 Unspecified organic or symptomatic mental disorder	293.9 Mental disorder not otherwise specified due to a general medical condition
F10–F19 Mental and behavioural disorders due to psychoactive substance use	
F10.– Mental and behavioural disorders due to use of alcohol	Alcohol-related disorders
F11.– Mental and behavioural disorders due to use of opioids	Opioid-related disorders
F12.– Mental and behavioural disorders due to use of cannabinoids	Cannabis-related disorders
F13.– Mental and behavioural disorders due to use of sedatives or hypnotics	Sedative-, hypnotic- or anxiolytic-related disorders
F14.– Mental and behavioural disorders due to use of cocaine	Cocaine-related disorders
F15.– Mental and behavioural disorders due to use of other stimulants, including caffeine	Amphetamine (or amphetamine-like)- and caffeine-related disorders
F16.– Mental and behavioural disorders due to use of hallucinogens	Hallucinogen-related disorders
F17.– Mental and behavioural disorders due to use of tobacco	Nicotine-related disorders
F18.– Mental and behavioural disorders due to use of volatile solvents	Inhalant-related disorders
F19.– Mental and behavioural disorders due to multiple drug use and use of other psychoactive substances	Phencyclidine (or phencyclidine-like)-related disorders Polysubstance-related disorder Other (or unknown) substance-related disorders

ICD-10	DSM-IV (ICD-9-CM)
Four- and five-character categories may be used to specify the clinical conditions, as follows:	
.0 Acute intoxication	303.00 Alcohol intoxication 305.90 Caffeine intoxication 292.89 Amphetamine, cannabis, cocaine, hallucinogen, inhalant, opioid, phencyclidine, sedative, hypnotic, anxiolytic or other (or unknown) substance intoxication
.00 Uncomplicated	No equivalent
.01 With trauma or other bodily injury	No equivalent
.02 With other medical complications	No equivalent
.03 With delirium	291.0 Alcohol intoxication delirium 292.81 Amphetamine, cannabis, cocaine, hallucinogen, inhalant, opioid, phencyclidine, sedative, hypnotic, anxiolytic or other (or unknown) substance intoxication delirium
.04 With perceptual distortions	292.89 Amphetamine, cannabis, cocaine, opioid, phencyclidine or other (or unknown) substance intoxication with perceptual disturbances
.05 With coma	No equivalent
.06 With convulsions	No equivalent
.07 Pathological intoxication	No equivalent
.1 Harmful use	305.00 Alcohol abuse 305.70 Amphetamine abuse 305.20 Cannabis abuse 305.60 Cocaine abuse 305.30 Hallucinogen abuse 305.50 Opioid abuse 305.40 Sedative, hypnotic or anxiolytic abuse 305.90 Inhalant, phencyclidine and other (or unknown) substance abuse
.2 Dependence syndrome	303.90 Alcohol dependence
.20 Currently abstinent	305.10 Nicotine dependence
.21 Currently abstinent, but in a protected environment	304.40 Amphetamine dependence
.22 Currently on a clinically supervised maintenance or replacement regime (controlled dependence)	304.30 Cannabis dependence 304.20 Cocaine dependence
.23 Currently abstinent, but receiving treatment with aversive or blocking drugs	304.60 Inhalant dependence 304.20 Opioid dependence
.24 Currently using the substance (active dependence)	304.50 Hallucinogen dependence
.25 Continuous use	304.90 Phencyclidine dependence
.26 Episodic use (dipsomania)	304.10 Sedative, hypnotic or anxiolytic dependence 304.80 Polysubstance dependence 304.90 Other (or unknown) substance dependence *Specifiers*: – With physiological dependence – Without physiological dependence – Early full remission – Early partial remission – Sustained full remission – Sustained partial remission – On agonist therapy – In a controlled environment
.3 Withdrawal state	291.8 Alcohol withdrawal 292.0 Cocaine, amphetamine, nicotine, opioid, sedative, hypnotic, anxiolytic or other (or unknown) substance withdrawal
.30 Uncomplicated	No equivalent
.31 With convulsions	No equivalent
.4 Withdrawal state with delirium	291.0 Alcohol withdrawal delirium 292.81 Sedative, hypnotic or anxiolytic withdrawal delirium 292.81 Other (or unknown) substance-induced delirium

ICD-10	DSM-IV (ICD-9-CM)
.40 Without convulsions	No equivalent
.41 With convulsions	No equivalent
.5 Psychotic disorder	291.x Alcohol-induced psychotic disorder
.51 Predominantly delusional	.5 With delusions
.52 Predominantly hallucinatory	.3 With hallucinations
.50 Schizophrenia-like	292.xx Amphetamine-, cannabis-, cocaine-, hallucinogen-,
.53 Predominantly polymorphic	inhalant-, opioid-, phencyclidine-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced psychotic disorder
	.11 With delusions
	.12 With hallucinations
.54 Predominantly depressive symptoms	291.8 Alcohol-induced mood disorder or
.55 Predominantly manic symptoms	292.84 Amphetamine-, cannabis-, cocaine-, hallucinogen-,
.56 Mixed	inhalant-, opioid-, phencyclidine-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced mood disorder
	– With depressive features
	– With manic features
	– With mixed features
.6 Amnesic syndrome	291.1 Alcohol-induced persisting amnestic disorder
	292.82 Sedative-, hypnotic-, anxiolytic or other (or unknown) substance-induced persisting amnestic disorder
.7 Residual and late-onset psychotic disorder	
.70 Flashbacks	292.89 Hallucinogen persisting perception disorder
.71 Personality or behaviour disorder	No equivalent
.72 Residual affective disorder	292.84 Amphetamine-, cannabis-, cocaine-, hallucinogen-, inhalant-, opioid-, phencyclidine-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced mood disorder
	– With depressive features
	– With manic features
	– With mixed features
.73 Dementia	291.2 Alcohol-induced persisting dementia
	292.83 Sedative-, hypnotic-, or anxiolytic, Other (or unknown) substance-induced persisting dementia
.74 Other persisting cognitive impairment	No equivalent
.75 Late-onset psychotic disorder	No equivalent
.8 Other mental and behavioural disorders	291.8 Alcohol-induced anxiety, sleep disorder and sexual dysfunction
	292.89 Amphetamine-, caffeine-, cannabis-, cocaine-, hallucinogen-, inhalant-, phencyclidine-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced anxiety disorder
	292.89 Amphetamine-, cocaine-, opioid-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced sexual dysfunction
	292.89 Amphetamine-, caffeine-, cocaine-, opioid-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-induced sleep disorder
.9 Unspecified mental and behavioural disorder	291.9 Alcohol-related disorder NOS
	292.9 Amphetamine-, caffeine-, cannabis-, cocaine-, hallucinogen-, inhalant-, phencyclidine-, sedative-, hypnotic-, anxiolytic- or other (or unknown) substance-related disorder NOS
F20–F29 Schizophrenia, schizotypal and delusional disorders	
F20 Schizophrenia	295.xx Schizophrenia or 295.40 Schizophreniform disorder
A fifth character may be used to classify course:	(see note below F20)

ICD-10	DSM-IV (ICD-9-CM)
0 Continuous	– Continuous
1 Episodic with progressive deficit	– Episodic with inter-episode residual symptoms
2 Episodic with stable deficit	
3 Episodic remittent	– Episodic with no inter-episode residual symptoms
4 Incomplete remission	– Single episode in partial or full remission
5 Complete remission	
8 Other	– Other or unspecified pattern
9 Course uncertain, period of observation too short	
F20.0 Paranoid schizophrenia[a]	295.30 Schizophrenia, paranoid type
F20.1 Hebephrenic schizophrenia[a]	295.10 Schizophrenia, disorganized type
F20.2 Catatonic schizophrenia[a]	295.20 Schizophrenia, catatonic type
F20.3 Undifferentiated schizophrenia[a]	295.90 Schizophrenia, undifferentiated type
F20.4 Post-schizophrenic depression	*See Appendix B*: Post-psychotic depressive disorder of schizophrenia
F20.5 Residual schizophrenia	295.60 Schizophrenia, residual type
F20.6 Simple schizophrenia	*See Appendix B*: Simple deteriorative disorder
F20.8 Other schizophrenia[a]	No equivalent
F20.9 Schizophrenia, unspecified[a]	No equivalent
F21 Schizotypal disorder	301.22 Schizotypal personality disorder
F22 Persistent delusional disorders	*For all subtypes*:
F22.0 Delusional disorder	297.1 Delusional disorder
F22.8 Other persistent delusional disorders	
F22.9 Persistent delusional disorder, unspecified	
F23 Acute and transient psychotic disorders	*For all subtypes*:
A fifth character may be used to identify the presence or absence of associated acute stress:	298.8 Brief psychotic disorder (only if duration is less than 1 month; see note below F23)
0 Without associated acute stress	– Without marked stressor(s)
1 With associated acute stress	– With marked stressor(s)
F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia[b]	
F23.1 Acute polymorphic psychotic disorder with symptoms of schizophrenia	
F23.2 Acute schizophrenia-like psychotic disorder	
F23.3 Other acute predominantly delusional psychotic disorders	*If duration is more than 1 month, use*: 297.1 Delusional disorder
F23.8 Other acute and transient psychotic disorders[b]	
F23.9 Acute and transient psychotic disorders, unspecified[b]	
F24 Induced delusional disorder	297.3 Shared psychotic disorder
F25 Schizoaffective disorders	*For all subtypes*:
F25.0 Schizoaffective disorder, manic type	295.70 Schizoaffective disorder
F25.1 Schizoaffective disorder, depressive type	– Bipolar type
F25.2 Schizoaffective disorder, mixed type	– Depressive type
F25.8 Other schizoaffective disorders	– Bipolar type
F25.9 Schizoaffective disorder, unspecified	
F28 Other non-organic psychotic disorders	No equivalent
F29 Unspecified non-organic psychosis	298.9 Psychotic disorder NOS
F30–F39 Mood affective disorders	
F30 Manic episode	296.0x Bipolar I disorder, single manic episode
F30.0 Hypomania	No equivalent
F30.1 Mania without psychotic symptoms	.01 Mild, .02 moderate and .03, severe without psychotic features
F30.2 Mania with psychotic symptoms	.04 Severe with psychotic features
F30.8 Other manic episodes	– With catatonic features
F30.9 Manic episode, unspecified	296.80 Bipolar disorder NOS

[a]*Note: The conversion for F20.0–F20.3, F20.8 and F20.9 applies for a duration of 6 months or more. For duration less than 6 months, use*: 295.40 Schizophreniform disorder.

[b]*Note: The conversion for F23.0–F23.2, F23.8 and F23.9 applies for a duration of less than 1 month. For a duration of more than 1 month use*: 298.9 Psychotic disorder NOS.

ICD-10	DSM-IV (ICD-9-CM)
F31 Bipolar affective disorder	296.xx Bipolar I disorder or 296.89 Bipolar II disorder
F31.0 Bipolar affective disorder, current episode hypomanic	296.40 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode hypomanic
F31.1 Bipolar affective disorder, current episode manic without psychotic symptoms	296.4x Bipolar I disorder .41, .42, .43 Most recent episode manic, mild, moderate, or severe without psychotic features
F31.2 Bipolar affective disorder, current episode manic with psychotic symptoms	296.44 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode manic, severe with psychotic features
F31.3 Bipolar affective disorder, current episode mild or moderate depression	296.51 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode depressed, mild
.30 Without somatic syndrome	296.52 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode depressed, moderate
.31 With somatic syndrome	– With melancholic features
F31.4 Bipolar affective disorder, current episode severe depression without psychotic symptoms	296.53 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode depressed, severe without psychotic features
F31.5 Bipolar affective disorder, current episode severe depression with psychotic symptoms	296.54 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode depressed, severe with psychotic features
F31.6 Bipolar affective disorder, current episode mixed	296.6x Bipolar I disorder, most recent episode mixed .61 mild, .62 moderate, .63 severe without psychotic symptoms, .64 severe with psychotic symptoms
F31.7 Bipolar affective disorder, currently in remission	296.5 Bipolar I disorder or 296.89 Bipolar II disorder, in partial remission
	296.6 Bipolar I disorder or 296.89 Bipolar II disorder, in full remission
F31.8 Other bipolar affective disorders	296.xx Bipolar I disorder or 296.xx Bipolar II disorder
	– With catatonic features
	– With atypical features
F31.9 Bipolar affective disorder, unspecified	296.7 Bipolar I disorder or 296.89 Bipolar II disorder, most recent episode unspecified
	296.80 Bipolar disorder NOS
F32 Depressive episode	296.2x Major depressive disorder, single episode
F32.0 Mild depressive episode	.21 Mild
.00 Without somatic syndrome	
.01 With somatic syndrome	– With melancholic features
F32.1 Moderate depressive episode	.22 Moderate
.10 Without somatic syndrome	
.11 With somatic syndrome	– With melancholic features
F32.2 Severe depressive episode without psychotic symptoms	.23 Severe without psychotic features
F32.3 Severe depressive episode with psychotic symptoms	.24 Severe with psychotic features
F32.8 Other depressive episodes	– With catatonic/atypical features
F32.9 Depressive episode, unspecified	.20 Unspecified
F33 Recurrent depressive disorder	296.3x Major depressive disorder, recurrent
F33.0 Recurrent depressive disorder, current episode mild	.31 Mild
.00 Without somatic syndrome	
.01 With somatic syndrome	– With melancholic features
F33.1 Recurrent depressive disorder, current episode moderate	.32 Moderate
.10 Without somatic syndrome	
.11 With somatic syndrome	– With melancholic features
F33.2 Recurrent depressive disorder, current episode severe without psychotic symptoms	.33 Severe without psychotic features
F33.3 Recurrent depressive disorder, current episode severe with psychotic symptoms	.34 Severe with psychotic features
F33.4 Recurrent depressive disorder, currently in remission	.35 In partial remission or .36 In complete remission
F33.8 Other recurrent depressive disorders	– With catatonic/atypical features
F33.9 Recurrent depressive disorder, unspecified	.30 Unspecified
F34 Persistent mood (affective) disorders	
F34.0 Cyclothymia	301.13 Cyclothymic disorder
F34.1 Dysthymia	300.4 Dysthymic disorder

ICD-10	DSM-IV (ICD-9-CM)
F34.8 Other persistent mood (affective) disorders	300.4 Dysthymic disorder with atypical features
F34.9 Persistent mood (affective) disorder, unspecified	No equivalent
F38 Other mood (affective) disorders	
F38.0 Other single mood (affective) disorders	296.0x Bipolar I disorder, single mixed episode
.00 Mixed affective episode	.01 Mild, .02 moderate, .03 severe without psychotic symptoms, .04 severe with psychotic symptoms
F38.1 Other recurrent mood (affective) disorders	
.10 Recurrent brief depressive disorder	*See Appendix B*: Recurrent brief depressive disorder
F38.8 Other specified mood (affective) disorders	No equivalent
F39 Unspecified mood (affective) disorder	296.90 Mood disorder NOS
F40–F48 Neurotic, stressrelated and somatoform disorders	
F40 Phobic anxiety disorders	
F40.0 Agoraphobia	
.00 Without panic disorder	300.22 Agoraphobia without history of panic disorder
.01 With panic disorder	300.21 Panic disorder with agoraphobia
F40.1 Social phobias	300.23 Social phobia
F40.2 Specific (isolated) phobias	300.29 Specific phobia
F40.8 Other phobic anxiety disorders	No equivalent
F40.9 Phobic anxiety disorder, unspecified	300.00 Anxiety disorder NOS
F41 Other anxiety disorders	
F41.0 Panic disorder (episodic paroxysmal anxiety)	300.01 Panic disorder without agoraphobia
F41.1 Generalized anxiety disorder	300.02 Generalized anxiety disorder
F41.2 Mixed anxiety and depressive disorder	*See Appendix B*: Mixed anxiety–depressive disorder
F41.3 Other mixed anxiety disorders	No equivalent
F41.8 Other specified anxiety disorders	No equivalent
F41.9 Anxiety disorder, unspecified	300.00 Anxiety disorder NOS
F42 Obsessive–compulsive disorder	*For all subtypes*:
F42.0 Predominantly obsessional thoughts or ruminations	300.3 Obsessive–compulsive disorder
F42.1 Predominantly compulsive acts (obsessional rituals)	
F42.2 Mixed obsessional thoughts and acts	
F42.8 Other obsessive–compulsive disorders	
F42.9 Obsessive–compulsive disorder, unspecified	
F43 Reaction to severe stress and adjustment disorders	
F43.0 Acute stress reaction	308.3 Acute stress disorder
F43.1 Post-traumatic stress disorder	309.81 Post-traumatic stress disorder
F43.2 Adjustment disorders	309.xx Adjustment disorder
.20 Brief depressive reaction	.0 With depressed mood (excludes bereavement)
.21 Prolonged depressive reaction	
.22 Mixed anxiety and depressive reaction	.28 With mixed anxiety and depressed mood
.23 With predominant disturbance of other emotions	.24 With anxiety
.24 With predominant disturbance of conduct	.3 With disturbance of conduct
.25 With mixed disturbance of emotions and conduct	.4 With mixed disturbance of emotions and conduct
.28 With other specified predominant symptoms	No equivalent
F43.8 Other reactions to severe stress	No equivalent
F43.9 Reaction to severe stress, unspecified	No equivalent
F44 Dissociative (conversion) disorder	
F44.0 Dissociative amnesias	300.12 Dissociative amnesia
F44.1 Dissociative fugue	300.13 Dissociative fugue
F44.2 Dissociative stupor	300.15 Dissociative disorder NOS
F44.3 Trance and possession disorders	300.15 Dissociative disorder NOS (*see also Appendix B*: Dissociative trance disorder)
	300.11 Conversion disorder
F44.4 Dissociative motor disorders	– With motor symptom or deficit
F44.5 Dissociative convulsions	– With seizures or convulsions
F44.6 Dissociative anaesthesia and sensory loss	– With sensory symptom or deficit

ICD-10	DSM-IV (ICD-9-CM)
F44.7 Mixed dissociative (conversion) disorders	– With mixed presentation
F44.8 Other dissociative (conversion) disorders	300.15 Dissociative disorder NOS
.80 Ganser's syndrome	
.81 Multiple personality disorder	300.14 Dissociative identity disorder
.82 Transient dissociative (conversion) disorders occurring in childhood and adolescence	300.15 Dissociative disorder NOS
.88 Other specified dissociative (conversion) disorders	
F44.9 Dissociative (conversion) disorder, unspecified	300.15 Dissociative disorder NOS
F45 Somatoform disorders	
F45.0 Somatization disorder	300.81 Somatization disorder
F45.1 Undifferentiated somatoform disorder	300.81 Undifferentiated somatoform disorder
F45.2 Hypochondriacal disorder	300.7 Hypochondriasis or 300.7 Body dysmorphic disorder
F45.3 Somatoform autonomic dysfunction	*No equivalent, use*: 300.81 Undifferentiated somatoform disorder
.30 Heart and cardiovascular system	
.31 Upper gastrointestinal tract	
.32 Lower gastrointestinal tract	
.33 Respiratory system	
.34 Genitourinary system	
.38 Other organ or system	
F45.4 Persistent somatoform pain disorder	307.80 Pain disorder, associated with psychological factors
F45.8 Other somatoform disorders	300.81 Somatoform disorder NOS
F45.9 Somatoform disorder, unspecified	300.81 Somatoform disorder NOS
F48 Other neurotic disorders	
F48.0 Neurasthenia	*No equivalent, use*: 300.81 Undifferentiated somatoform disorder
F48.1 Depersonalization–derealization syndrome	300.6 Depersonalization disorder
F48.8 Other specified neurotic disorders	No equivalent
F48.9 Neurotic disorder, unspecified	300.9 Unspecified mental disorder (non-psychotic)
F50–F59 Behavioural syndromes associated with physiological disturbances and physical factors	
F50 Eating disorders	
F50.0 Anorexia nervosa	307.1 Anorexia nervosa
F50.1 Atypical anorexia nervosa	307.50 Eating disorder NOS
F50.2 Bulimia nervosa	307.51 Bulimia nervosa
F50.3 Atypical bulimia nervosa	307.1 Anorexia nervosa, binge-eating type
F50.4 Overeating associated with other psychological disturbances	No equivalent
F50.5 Vomiting associated with other psychological disturbances	No equivalent
F50.8 Other eating disorders	No equivalent
F50.9 Eating disorder, unspecified	307.50 Eating disorder NOS
F51 Non-organic sleep disorders	
F51.0 Non-organic insomnia	307.42 Primary insomnia
F51.1 Non-organic hypersomnia	307.44 Primary hypersomnia
F51.2 Non-organic disorder of the sleep–wake schedule	307.45 Circadian rhythm sleep disorder
F51.3 Sleepwalking (somnambulism)	307.46 Sleepwalking disorder
F51.4 Sleep terrors (night terrors)	307.46 Sleep terror disorder
F51.5 Nightmares	307.47 Nightmare disorder
F51.8 Other non-organic sleep disorders	307.47 Dyssomnia NOS or 307.47 Parasomnia NOS
F51.9 Non-organic sleep disorder, unspecified	307.47 Dyssomnia NOS or 307.47 Parasomnia NOS
F52 Sexual dysfunction, not caused by organic disorder or disease	
F52.0 Lack or loss of sexual desire	302.71 Hypoactive sexual desire disorder
F52.1 Sexual aversion and lack of sexual enjoyment	
.10 Sexual aversion	302.79 Sexual aversion disorder
.11 Lack of sexual enjoyment	*No equivalent, use*: 302.70 Sexual dysfunction NOS

ICD-10	DSM-IV (ICD-9-CM)
F52.2 Failure of genital response	302.72 Female sexual arousal disorder or 302.72 Male erectile disorder
F52.3 Orgasmic dysfunction	302.73 Female orgasmic disorder or 307.74 Male orgasmic disorder
F52.4 Premature ejaculation	302.75 Premature ejaculation
F52.5 Non-organic vaginismus	306.51 Vaginismus (not due to a general medical condition)
F52.6 Non-organic dyspareunia	302.76 Dyspareunia (not due to a general medical condition)
F52.7 Excessive sexual drive	*No equivalent, use*: 302.70 Sexual dysfunction NOS
F52.8 Other sexual dysfunction, not caused by organic disorders or disease	302.70 Sexual dysfunction NOS
F52.9 Unspecified sexual dysfunction, not caused by organic disorder or disease	302.70 Sexual dysfunction NOS
F53 Mental and behavioural disorders associated with the puerperium, not elsewhere classified	No equivalents
F53.0 Mild mental and behavioural disorders associated with the puerperium, not elsewhere classified	
F53.1 Severe mental and behavioural disorders associated with the puerperium, not elsewhere classified	
F53.8 Other mental and behavioural disorders associated with the puerperium, not elsewhere classified	
F53.9 Puerperal mental disorder, unspecified.	
F54 Psychological and behavioural factors associated with disorders or diseases classified elsewhere	316 Psychological factors affecting medical condition
F55 Abuse of non-dependence-producing substances	*For all subtypes*:
F55.0 Antidepressants	305.90 Other substance abuse
F55.1 Laxatives	
F55.2 Analgesics	
F55.3 Antacids	
F55.4 Vitamins	
F55.5 Steroids or hormones	
F55.6 Specific herbal or folk remedies	
F55.8 Other substances that do not produce dependence	
F55.9 Unspecified	
F59 Unspecified behavioural syndromes associated with physiological disturbances and physical factors	316 Other or unspecified psychological factors affecting medical condition
F60–F69 Disorders of adult personality and behaviour	
F60 Specific personality disorders	
F60.0 Paranoid personality disorder	301.0 Paranoid personality disorder
F60.1 Schizoid personality disorder	301.20 Schizoid personality disorder
F60.2 Dyssocial personality disorder	301.7 Antisocial personality disorder
F60.3 Emotionally unstable personality disorder	No equivalent
.30 Impulsive type	
.31 Borderline type	301.83 Borderline personality disorder
F60.4 Histrionic personality disorder	301.50 Histrionic personality disorder
F60.5 Anankastic personality disorder	301.4 Obsessive–compulsive personality disorder
F60.6 Anxious (avoidant) personality disorder	301.82 Avoidant personality disorder
F60.7 Dependent personality disorder	301.6 Dependent personality disorder
F60.8 Other specific personality disorders	301.81 Narcissistic personality disorder or 301.9 Personality disorder NOS (*see also Appendix B*: Passive–aggressive personality disorder)
F60.9 Personality disorder, unspecified	301.9 Personality disorder NOS
F61 Mixed and other personality disorders	301.9 Personality disorder NOS
F61.0 Mixed personality disorders	
F61.1 Troublesome personality changes	
F62 Enduring personality changes, not attributable to brain damage and disease	*No equivalents, use*: 301.9 Personality disorder NOS
F62.0 Enduring personality change after catastrophic experience	

ICD-10	DSM-IV (ICD-9-CM)
F62.1 Enduring personality change after psychiatric illness	
F62.8 Other enduring personality changes	
F62.9 Enduring personality change, unspecified	
F63 Habit and impulse disorders	
F63.0 Pathological gambling	312.31 Pathological gambling
F63.1 Pathological fire-setting (pyromania)	312.33 Pyromania
F63.2 Pathological stealing (kleptomania)	312.32 Kleptomania
F63.3 Trichotillomania	312.39 Trichotillomania
F63.8 Other habit and impulse disorders	312.30 Impulse-control disorder NOS
F63.9 Habit and impulse disorder, unspecified	312.30 Impulse-control disorder NOS
F64 Gender identity	
F64.0 Transsexualism	302.85 Gender identity disorder in adolescents or adults
F64.1 Dual-role transvestism	302.85 Gender identity disorder in adolescents or adults
F64.2 Gender identity disorder of childhood	302.6 Gender identity disorder in children
F64.8 Other gender identity disorders	302.6 Gender identity disorder NOS
F64.9 Gender identity disorder, unspecified	302.6 Gender identity disorder NOS
F65 Disorders of sexual preference	
F65.0 Fetishism	302.81 Fetishism
F65.1 Fetishistic transvestism	302.3 Transvestic fetishism
F65.2 Exhibitionism	302.4 Exhibitionism
F65.3 Voyeurism	302.82 Voyeurism
F65.4 Paedophilia	302.2 Paedophilia
F65.5 Sadomasochism	302.83 Sexual masochism or 302.84 Sexual sadism
F65.6 Multiple disorders of sexual preference	302.9 Paraphilia NOS
F65.8 Other disorders of sexual preference	302.9 Paraphilia NOS
F65.9 Disorder of sexual preference, unspecified	302.9 Paraphilia NOS
F66 Psychological and behavioural disorders associated with sexual development and orientation	*For all subtypes*: 302.9 Sexual disorder NOS
F66.0 Sexual maturation disorder	
F66.1 Egodystonic sexual orientation	
F66.2 Sexual relationship disorder	
F66.8 Other psychosexual development disorders	
F66.9 Psychosexual development disorder, unspecified	
A fifth character may be used to indicate association with: .0 Heterosexuality .1 Homosexuality .2 Bisexuality .8 Other, including prepubertal	
F68 Other disorders of adult personality and behaviour	
F68.0 Elaboration of physical symptoms for psychological reasons	*No equivalent, use*: 300.81 Undifferentiated somatoform disorder
F68.1 Intentional production or feigning of symptoms or disabilities, either physical or psychological (factitious disorder)	300.1 Factitious disorder .16 With psychological signs and symptoms .19 With physical signs and symptoms .19 With combined psychological and physical signs and symptoms .19 NOS
F68.8 Other specified disorders of adult personality and behaviour	301.9 Personality disorder NOS
F69 Unspecified disorder of adult personality and behaviour	301.9 Personality disorder NOS
F70–F79 Mental retardation	
F70 Mild mental retardation	317 Mild mental retardation
F71 Moderate mental retardation	318.0 Moderate mental retardation
F72 Severe mental retardation	318.1 Severe mental retardation
F73 Profound mental retardation	318.2 Profound mental retardation

ICD-10	DSM-IV (ICD-9-CM)
F78 Other mental retardation	319 Mental retardation, severity unspecified
F79 Unspecified mental retardation	319 Mental retardation, severity unspecified
A fourth character may be used to specify the extent of associated behavioural impairment: F7x.0 No, or minimal, impairment of behaviour F7x.1 Significant impairment of behaviour requiring attention or treatment F7x.8 Other impairments of behaviour F7x.9 Without mention of impairment of behaviour	(No specifiers for associated behavioural impairments)
F80–F89 Disorders of psychological development	
F80 Specific developmental disorders of speech and language	
F80.0 Specific speech articulation disorder	315.39 Phonological disorder
F80.1 Expressive language disorder	315.31 Expressive language disorder
F80.2 Receptive language disorder	315.31 Mixed receptive–expressive language disorder
F80.3 Acquired aphasia with epilepsy (Landau–Kleffner syndrome)	307.9 Communication disorder NOS
F80.8 Other developmental disorders of speech and language	307.9 Communication disorder NOS
F80.9 Developmental disorder of speech and language, unspecified	307.9 Communication disorder NOS
F81 Specific developmental disorders of scholastic skills	
F81.0 Specific reading disorder	315.00 Reading disorder
F81.1 Specific spelling disorder	*No equivalent, use*: 315.9 Learning disorder NOS
F81.2 Specific disorder of arithmetical skills	315.1 Mathematics disorder
F81.3 Mixed disorder of scholastic skills	315.9 Learning disorder NOS
F81.8 Other developmental disorders of scholastic skills	315.9 Learning disorder NOS
F81.9 Developmental disorder of scholastic skills, unspecified	315.9 Learning disorder NOS
F82 Specific developmental disorder of motor function	315.4 Developmental coordination disorder
F83 Mixed specific developmental disorders	No equivalent
F84 Pervasive developmental disorders	
F84.0 Childhood autism	299.00 Autistic disorder
F84.1 Atypical autism	299.80 Pervasive developmental disorder NOS (includes atypical autism)
F84.2 Rett's syndrome	299.80 Rett's disorder
F84.3 Other childhood disintegrative disorder	299.10 Childhood disintegrative disorder
F84.4 Overactive disorder associated with mental retardation and stereotyped movements	*No equivalent, use*: 299.80 Pervasive developmental disorder NOS
F84.5 Asperger's syndrome	299.80 Asperger's syndrome
F84.8 Other pervasive developmental disorders	299.80 Pervasive developmental disorder NOS
F84.9 Pervasive developmental disorder, unspecified	299.80 Pervasive developmental disorder NOS
F88 Other disorders of psychological development	313.9 Disorder of infancy, childhood or adolescence NOS
F89 Unspecified disorder of psychological development	313.9 Disorder of infancy, childhood or adolescence NOS
F90–F98 Behavioural and emotional disorders with onset usually occurring in childhood and adolescence	
F90 Hyperkinetic disorders	
F90.0 Disturbance of activity and attention	314.0 Attention-deficit/hyperactivity disorder
F90.1 Hyperkinetic conduct disorder	*No equivalent, use both* 314.0 and 312.8 Conduct disorder
F90.8 Other hyperkinetic disorders	314.9 Attention-deficit/hyperactivity disorder NOS
F90.9 Hyperkinetic disorder, unspecified	314.9 Attention-deficit/hyperactivity disorder NOS
F91 Conduct disorders	
F91.0 Conduct disorder confined to the family context	312.8 Conduct disorder

ICD-10	DSM-IV (ICD-9-CM)
F91.1 Unsocialized conduct disorder	312.8 Conduct disorder
F91.2 Socialized conduct disorder	312.8 Conduct disorder
F91.3 Oppositional defiant disorder	313.81 Oppositional defiant disorder
F91.8 Other conduct disorders	312.9 Disruptive behaviour disorder NOS
F91.9 Conduct disorder, unspecified	312.9 Disruptive behaviour disorder NOS
F92 Mixed disorders of conduct and emotions	*No equivalents, use*: 312.8 Conduct disorder plus another appropriate category
F92.0 Depressive conduct disorder	
F92.8 Other mixed disorders of conduct and emotions	
F92.9 Mixed disorder of conduct and emotions, unspecified	
F93 Emotional disorders with onset specific to childhood	
F93.0 Separation anxiety disorder of childhood	309.21 Separation anxiety disorder
F93.1 Phobic anxiety disorder of childhood	300.29 Specific phobia or 300.22 Agoraphobia
F93.2 Social anxiety disorder of childhood	300.23 Social phobia
F93.3 Sibling rivalry disorder	V61.8 Sibling relational problem
F93.8 Other childhood emotional disorders	313.9 Disorder of infancy, childhood or adolescence NOS
F93.9 Childhood emotional disorder, unspecified	313.9 Disorder of infancy, childhood or adolescence NOS
F94 Disorders of social functioning with onset specific to childhood and adolescence	
F94.0 Elective mutism	313.23 Selective mutism
F94.1 Reactive attachment disorder of childhood	313.89 Reactive attachment disorder of infancy or early childhood – Inhibited type
F94.2 Disinhibited attachment disorder of childhood	313.89 Reactive attachment disorder of infancy or early childhood – Disinhibited type
F94.8 Other childhood disorders of social functioning	313.9 Disorder of infancy, childhood or adolescence NOS
F94.9 Childhood disorders of social functioning, unspecified	313.9 Disorder of infancy, childhood or adolescence NOS
F95 Tic disorders	
F95.0 Transient tic disorder	307.21 Transient tic disorder
F95.1 Chronic motor or vocal tic disorder	307.22 Chronic motor or vocal tic disorder
F95.2 Combined vocal and multiple motor tic disorder (Gilles de la Tourette's syndrome)	307.23 Tourette's disorder
F95.8 Other tic disorders	307.20 Tic disorder NOS
F95.9 Tic disorder, unspecified	307.20 Tic disorder NOS
F98 Other behavioural and emotional disorders with onset usually occurring in childhood and adolescence	
F98.0 Non-organic enuresis	307.6 Enuresis (not due to a general medical condition)
F98.1 Non-organic encopresis	787.6 Encopresis with constipation and overflow or 307.7 Encopresis without constipation and overflow
F98.2 Feeding disorder of infancy and childhood	307.59 Feeding disorder of infancy or early childhood
F98.3 Pica of infancy and childhood	307.52 Pica
F98.4 Stereotyped movement disorders	307.3 Stereotypic movement disorder
F98.5 Stuttering (stammering)	307.0 Stuttering
F98.6 Cluttering	307.9 Communication disorder NOS
F98.8 Other specified behavioural and emotional disorders with onset usually occurring in childhood and adolescence	313.9 Disorder of infancy, childhood or adolescence NOS
F98.9 Unspecified behavioural and emotional disorders with onset usually occurring in childhood and adolescence	313.9 Disorder of infancy, childhood or adolescence NOS
F99 Unspecified mental disorder	*No equivalent, use*: 300.9 Unspecified mental disorder (non-psychotic)

NOS, not otherwise specified.

Table 2. Conversion table: DSM-IV (ICD-9-CM) to ICD-10

DSM-IV (ICD-9-CM)	ICD-10
If criteria are currently met, one of the following severity specifiers may be noted after the diagnosis: mild, moderate or severe. If criteria are no longer met, one of the following specifiers may be noted: in partial remission, in full remission or prior history.	
Disorders usually first diagnosed in infancy, childhood or adolescence	
Mental retardation	
Note: These are coded on axis II.	*Note: The fourth character .9 (without mention of impairment of behaviour) is used, because* DSM-IV *has no specifier for associated impairment of behaviour.*
317 Mild mental retardation	F70.9 Mild mental retardation
318.0 Moderate mental retardation	F71.9 Moderate mental retardation
318.1 Severe mental retardation	F72.9 Severe mental retardation
318.2 Profound mental retardation	F73.9 Profound mental retardation
319 Mental retardation, severity unspecified	F79.9 Unspecified mental retardation
Learning disorders	
315.00 Reading disorder	F81.0 Specific reading disorder
315.1 Mathematics disorder	F81.2 Specific disorder of arithmetical skills
315.2 Disorder of written expression	F81.8 Other developmental disorders of scholastic skills
315.9 Learning disorder NOS	F81.9 Developmental disorder of scholastic skills, unspecified
Motor skills disorder	
315.4 Developmental coordination disorder	F82 Specific developmental disorder of motor function
Communication disorders	
315.31 Expressive language disorder	F80.1 Expressive language disorder
315.31 Mixed receptive–expressive language disorder	F80.2 Receptive language disorder
315.39 Phonological disorder	F80.0 Specific speech articulation disorder
307.0 Stuttering	F98.5 Stuttering (stammering)
307.9 Communication disorder NOS	F80.9 Developmental disorder of speech and language, unspecified
Pervasive developmental disorders	
299.00 Autistic disorder	F84.0 Childhood autism
299.80 Rett's disorder	F84.2 Rett's syndrome
299.10 Childhood disintegrative disorder	F84.3 Other childhood disintegrative disorder
299.80 Asperger's disorder	F84.5 Asperger's syndrome
299.80 Pervasive developmental disorder NOS (includes a typical autism)	F84.9 Pervasive developmental disorder, unspecified, or F84.1 Atypical autism
Attention-deficit and disruptive behaviour disorder	
314.xx Attention-deficit/hyperactivity disorder	
.01 Combined type	F90.0 Disturbance of activity and attention
.00 Predominantly inattentive type	F98.8 Attention deficit disorder without hyperactivity
.01 Predominantly hyperactive–impulsive type	F90.0 Disturbance of activity and attention
314.9 Attention-deficit/hyperactivity disorder NOS	F90.9 Hyperkinetic disorder, unspecified
312.8 Conduct disorder	F91.8 Other conduct disorders
Specify type: childhood-onset type/adolescent-onset type	
313.81 Oppositional defiant disorder	F91.3 Oppositional defiant disorder
312.9 Disruptive behaviour disorder NOS	F91.9 Conduct disorder, unspecified
Feeding and eating disorders of infancy or early childhood	
307.52 Pica	F98.3 Pica of infancy and childhood
307.53 Rumination disorder	F98.2 Feeding disorder of infancy and childhood
307.59 Feeding disorder of infancy or early childhood	F98.2 Feeding disorder of infancy and childhood
Tic disorders	
307.23 Tourette's disorder	F95.2 Combined vocal and multiple motor tic disorder (Gilles de la Tourette's syndrome)
307.22 Chronic motor or vocal tic disorder	F95.1 Chronic motor or vocal tic disorder
307.21 Transient tic disorder	F95.0 Transient tic disorder
Specify if: single episode/recurrent	
307.20 Tic disorder NOS	F95.9 Tic disorder, unspecified

DSM-IV (ICD-9-CM)		ICD-10	
Elimination disorders			
–.–	Encopresis	F98.1	Non-organic encopresis
787.6	With constipation and overflow incontinence		.12 Soiling that is associated with excessively fluid faeces such as with retention with overflow
307.7	Without constipation and overflow incontinence	F98.1	Non-organic encopresis .11 Adequate bowel control with normal faeces deposited in inappropriate places .10 Failure to acquire physiological bowel control
307.6	Enuresis (not due to a general medical condition) *Specify type*: Nocturnal only Diurnal only Nocturnal and diurnal	F98.0	Non-organic enuresis .00 Nocturnal enuresis only .01 Diurnal enuresis only .02 Nocturnal and diurnal enuresis
Other disorders of infancy, childhood or adolescence			
309.21	Separation anxiety disorder *Specify if*: early onset	F93.0	Separation anxiety disorder of childhood
313.23	Selective mutism	F94.0	Elective mutism
313.89	Reactive attachment disorder of infancy or early childhood *Specify type*: Inhibited type Disinhibited type	F94.1 F94.2	Reactive attachment disorder of childhood Disinhibited attachment disorder of childhood
307.3	Stereotypic movement disorder *Specify if*: with self-injurious behaviour	F98.4	Stereotyped movement disorders .41 Self-injurious
313.9	Disorder of infancy, childhood or adolescence NOS	F98.9	Unspecified behavioural and emotional disorders with onset usually occurring in childhood and adolescence
Delirium, Dementia, Amnestic and other Cognitive Disorders			
Delirium			
293.0	Delirium due to ... (indicate the general medical condition) – If superimposed on dementia	F05.0 F05.1	Delirium, not superimposed on dementia, so described Delirium superimposed on dementia
---.–	Substance intoxication delirium (refer to substance-related disorders for substance-specific codes)	F1x.03	Acute intoxication with delirium due to psychoactive substances
---.–	Substance withdrawal delirium (refer to substance-related disorders for substance-specific codes)	F1x.4	Withdrawal state with delirium
---.–	Delirium due to multiple aetiologies (code each of the specific aetiologies)	F05.8	Other delirium
780.09	Delirium NOS	F05.9	Delirium, unspecified
Dementia			
290.xx	Dementia of the Alzheimer's type, with early onset (also code 331.0 Alzheimer's disease on axis III) .10 Uncomplicated .11 With delirium .12 With delusions .13 With depressed mood *Specify if*: with behavioural disturbance	F00.0	Dementia in Alzheimer's disease with early onset (also code G30.0 Alzheimer's disease with early onset) .00 Without additional symptoms Code F00.0 plus F05.1 Delirium superimposed on dementia .01 Other symptoms, predominantly delusional .03 Other symptoms, predominantly depressive .04 Other mixed symptoms
290.xx	Dementia of the Alzheimer's type, with late onset (also code 331.0 Alzheimer's disease on axis III) .0 Uncomplicated .3 With delirium .20 With delusions .21 With depressed mood *Specify if*: with behavioural disturbance	F00.1	Dementia in Alzheimer's disease with late onset (also code G30.1 Alzheimer's disease with late onset) .10 Without additional symptoms Code F00.1 plus F05.1 Delirium superimposed on dementia .11 Other symptoms, predominantly delusional .13 Other symptoms, predominantly depressive .14 Other mixed symptoms
290.xx	Vascular dementia .40 Uncomplicated .41 With delirium	F01.9	Vascular dementia, unspecified .90 Without additional symptoms Code F01.9 plus F05.1 Delirium superimposed on dementia

DSM-IV (ICD-9-CM)	ICD-10
.42 With delusions .43 With depressed mood *Specify if*: with behavioural disturbance	.91 Other symptoms, predominantly delusional .93 Other symptoms, predominantly depressive .94 Other mixed symptoms
294.9 Dementia due to HIV disease (also code 043.1 HIV infection affecting central nervous system on axis III)	F02.4 Dementia in human immunodeficiency virus (HIV) disease (also code B22.0 HIV dementia)
294.1 Dementia due to head trauma (also code 854.00 head injury on axis III)	F02.8 Dementia in other specified diseases classified elsewhere (also code S06.9 Intracranial injury unspecified)
294.1 Dementia due to Parkinson's disease (also code 332.0 Parkinson's disease on axis III)	F02.3 Dementia in Parkinson's disease (also code G20 Parkinson's disease)
294.1 Dementia due to Huntington's disease (also code 333.4 Huntington's disease on axis III)	F02.2 Dementia in Huntington's disease (also code G10 Huntington's disease)
290.10 Dementia due to Pick's disease (also code 331.1 Pick's disease on axis III)	F02.0 Dementia in Pick's disease (also code G31.0 Pick's disease)
290.10 Dementia due to Creutzfeldt-Jakob disease (also code 046.1 Creutzfeldt-Jakob disease on axis III)	F02.1 Dementia in Creutzfeldt-Jakob disease (also code A81.0 Creutzfeldt-Jacob disease)
294.1 Dementia due to ... (indicate the general medical condition not listed above; also code the general medical condition on axis III)	F02.8 Dementia in other specified diseases classified elsewhere
---.- Substance-induced persisting dementia (refer to substance-related disorders for substance-specific codes)	F1x.73 Dementia due to psychoactive substance abuse
---.- Dementia due to multiple aetiologies (code each of the specific aetiologies)	F02.8 Dementia in other specified diseases classified elsewhere
- Mixed Alzheimer and vascular dementia	F00.2 Dementia in Alzheimer's disease, atypical or mixed
294.8 Dementia NOS	F03 Unspecified dementia
Amnestic disorders	
294.0 Amnestic disorder due to ... (indicate the general medical condition) *Specify if*: transient/chronic	F04 Organic amnesic syndrome, not induced by alcohol and other psychoactive substance
---.- Substance-induced persisting amnestic disorder (refer to substance-related disorders for substance-specific codes)	F1x.6 Amnesic syndrome due to psychoactive substance use
294.8 Amnestic disorder NOS	No equivalent
Other cognitive disorders	
294.9 Cognitive disorder NOS	F06.7 Mild cognitive disorder
Mental disorders due to a general medical condition not elsewhere classified	
293.89 Catatonic disorder due to ... (indicate the general medical condition)	F06.1 Organic catatonic disorder
310.1 Personality change due to ... (indicate the general medical condition) *Specify type*: labile type/disinhibited type/aggressive type/apathetic type/paranoid type/other type/combined type/unspecified type	F07.0 Organic personality disorder
293.9 Mental disorder NOS due to ... (indicate the general medical condition)	F09 Unspecified organic or symptomatic mental disorder
Substance-related disorders	
[a]The following specifiers may be applied to substance dependence:	Currently using the substance
- With physiological dependence	F1x.241 With physical symptoms
- Without physiological dependence	F1x.240 Without physical symptoms
Code course of dependence in fifth character:	F1x.2 Dependence syndrome
- Early full remission/early partial remission/sustained full remission/sustained partial remission	.20 Currently abstinent
- In a controlled environment	.21 Currently abstinent, but in a protected environment
- On agonist therapy	.22 Currently on a clinically supervised maintenance or replacement regime (controlled dependence)

DSM-IV (ICD-9-CM)	ICD-10
– Mild/moderate/severe	.24 Currently using the substance (active dependence) or .25 continuous use
The following specifiers apply to substance-induced disorders as noted: – [I]With onset during intoxication – [W]With onset during withdrawal	
Alcohol-related disorders	F10.– Mental and behavioural disorders due to use of alcohol
Alcohol use disorders	
303.90 Alcohol dependence[a]	.2 Dependence
305.00 Alcohol abuse	.1 Harmful use
Alcohol-induced disorders	
303.00 Alcohol intoxication	.0 Acute intoxication
291.8 Alcohol withdrawal	.3 Withdrawal state
Specify if: with perceptual disturbances	
291.0 Alcohol intoxication delirium	.03 Acute intoxication with delirium
291.0 Alcohol withdrawal delirium	.4 Withdrawal state with delirium
291.2 Alcohol-induced persisting dementia	.73 Dementia
291.1 Alcohol-induced persisting amnesic disorder	.6 Amnesic disorder
291.x Alcohol-induced psychotic disorder	.5 Psychotic disorder
.5 With delusions[I,W]	.51 Predominantly delusional
.3 With hallucinations[I,W]	.52 Predominantly hallucinatory
291.8 Alcohol-induced mood disorder[I,W]	.5 Psychotic disorder .54 Predominantly depressive psychotic symptoms .55 Predominantly manic psychotic symptoms .56 Mixed .72 Residual affective disorder
291.8 Alcohol-induced anxiety disorder[I,W]	.8 Other mental and behavioural disorders
291.8 Alcohol-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
291.8 Alcohol-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
291.9 Alcohol-related disorder NOS	.9 Unspecified mental and behavioural disorder
Amphetamine (or amphetamine-like)-related disorders	F15.– Mental and behavioural disorders due to use of other stimulants, including caffeine
Amphetamine use disorders	
304.40 Amphetamine dependence[a]	.2 Dependence
305.70 Amphetamine abuse	.1 Harmful use
Amphetamine-induced disorders	
292.89 Amphetamine intoxication	.0 Acute intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.0 Amphetamine withdrawal	.3 Withdrawal state
292.81 Amphetamine intoxication delirium	.03 Acute intoxication with delirium
292.xx Amphetamine-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Amphetamine-induced mood disorder[I,W]	.5 Psychotic disorder .54 Predominantly depressive psychotic symptoms .55 Predominantly manic psychotic symptoms .56 Mixed .72 Residual affective disorder
292.89 Amphetamine-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.89 Amphetamine-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
292.89 Amphetamine-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
292.9 Amphetamine-related disorder NOS	.9 Unspecified mental and behavioural disorder
Caffeine-related disorders	F15.– Mental and behavioural disorders due to use of other stimulants, including caffeine
Caffeine-induced disorders	
305.90 Caffeine intoxication	.0 Acute intoxication
292.89 Caffeine-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.89 Caffeine-induced sleep disorder[I]	.8 Other mental and behavioural disorders
292.9 Caffeine-related disorder NOS	.9 Unspecified mental and behavioural disorder

DSM-IV (ICD-9-CM)	ICD-10
Cannabis-related disorders	F12.– Mental and behavioural disorders due to use of cannabinoids
Cannabis use disorders	
304.30 Cannabis dependence[a]	.2 Dependence
305.20 Cannabis abuse	.1 Harmful use
Cannabis-induced disorders	
292.89 Cannabis intoxication	.0 Acute intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.81 Cannabis intoxication delirium	.03 With delirium
292.xx Cannabis-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.89 Cannabis-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.9 Cannabis-related disorder NOS	.9 Unspecified mental and behavioural disorders
Cocaine-related disorders	F14.– Mental and behavioural disorders due to use of cocaine
Cocaine use disorders	
304.20 Cocaine dependence[a]	.2 Dependence
305.60 Cocaine abuse	.1 Harmful use
Cocaine-induced disorders	
292.89 Cocaine intoxication	.0 Acute intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.0 Cocaine withdrawal	.3 Withdrawal
292.81 Cocaine intoxication delirium	.03 Acute intoxication with delirium
292.xx Cocaine-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Cocaine-induced mood disorder[I,W]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Cocaine-induced anxiety disorder[I,W]	.8 Other mental and behavioural disorders
292.89 Cocaine-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
292.89 Cocaine-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
292.9 Cocaine-related disorder NOS	.9 Unspecified mental and behavioural disorder
Hallucinogen-related disorders	F16.– Mental and behavioural disorders due to use of hallucinogens
Hallucinogen use disorders	
304.50 Hallucinogen dependence[a]	.2 Dependence
305.30 Hallucinogen abuse	.1 Harmful use
Hallucinogen-induced disorders	
292.89 Hallucinogen intoxication	.0 Acute intoxication
292.89 Hallucinogen persisting perception disorder (flashbacks)	.70 Flashbacks
292.81 Hallucinogen intoxication delirium	.03 Acute intoxication with delirium
292.xx Hallucinogen-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Hallucinogen-induced mood disorder[I]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Hallucinogen-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.9 Hallucinogen-related disorder NOS	.9 Unspecified mental and behavioural disorder
Inhalant-related disorders	F18.– Mental and behavioural disorders due to use of volatile solvents
Inhalant use disorders	

DSM-IV (ICD-9-CM)	ICD-10
304.60 Inhalant dependence[a]	.2 Dependence
305.90 Inhalant abuse	.1 Harmful use
Inhalant-induced disorders	
292.89 Inhalant intoxication	.0 Acute intoxication
292.81 Inhalant intoxication delirium	.03 Acute intoxication with delirium
292.82 Inhalant-induced persisting dementia	.73 Dementia
292.xx Inhalant-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Inhalant-induced mood disorder[I]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Inhalant-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.9 Inhalant-related disorder NOS	.9 Unspecified mental and behavioural disorders
Nicotine-related disorders	F17.– Mental and behavioural disorders due to use of tobacco
Nicotine use disorder	
305.10 Nicotine dependence[a]	.2 Dependence
Nicotine-induced disorder	
292.0 Nicotine withdrawal	.3 Withdrawal
292.9 Nicotine-related disorder NOS	.9 Unspecified mental and behavioural disorder
Opioid-related disorders	F11.- Mental and behavioural disorders due to use of opioids
Opioid use disorders	
304.0 Opioid dependence	.2 Dependence
305.50 Opioid abuse	.1 Harmful use
Opioid-induced disorders	
292.89 Opioid intoxication	.0 Acute intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.0 Opioid withdrawal	.3 Withdrawal
292.81 Opioid intoxication delirium	.03 Acute intoxication with delirium
292.xx Opioid-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Opioid-induced mood disorder[I]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Opioid-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
292.89 Opioid-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
292.9 Opioid-related disorder NOS	.9 Unspecified mental and behavioural disorder
Phencyclidine (or phencyclidine-like)-related disorders	F19.– Mental and behavioural disorders due to multiple drug use and use of other psychoactive substances
Phencyclidine use disorders	
304.90 Phencyclidine dependence	.2 Dependence
305.90 Phencyclidine abuse	.1 Harmful use
Phencyclidine-induced disorders	
292.89 Phencyclidine intoxication	.0 Acute intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.81 Phencyclidine intoxication delirium	.03 With delirium
292.xx Phencyclidine-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Phencyclidine-induced mood disorder[I]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed

DSM-IV (ICD-9-CM)	ICD-10
	.72 Residual affective disorder
292.89 Phencyclidine-induced anxiety disorder[I]	.8 Other mental and behavioural disorders
292.9 Phencyclidine-related disorder NOS	.9 Unspecified mental and behavioural disorder
Sedative-, hypnotic- or anxiolytic-related disorders	F13.– Mental and behavioural disorders due to use of sedatives or hypnotics
Sedative, hypnotic or anxiolytic use disorders	
304.10 Sedative, hypnotic or anxiolytic dependence[a]	.2 Dependence
305.40 Sedative, hypnotic or anxiolytic abuse	.1 Harmful use
Sedative-, hypnotic- or anxiolytic-induced disorders	
292.89 Sedative, hypnotic or anxiolytic intoxication	.0 Intoxication
292.0 Sedative, hypnotic or anxiolytic withdrawal	.3 Withdrawal
Specify if: with perceptual disturbances	
292.81 Sedative, hypnotic or anxiolytic intoxication delirium	.03 Acute intoxication with delirium
292.81 Sedative, hypnotic or anxiolytic withdrawal delirium	.4 Withdrawal state with delirium
292.82 Sedative-, hypnotic- or anxiolytic-induced persisting dementia	.73 Dementia
292.83 Sedative-, hypnotic- or anxiolytic-induced persisting amnestic disorder	.6 Amnesic disorder
292.xx Sedative-, hypnotic- or anxiolytic-induced psychotic disorder	.5 Psychotic disorder
.11 With delusions[I]	.51 Predominantly delusional
.12 With hallucinations[I]	.52 Predominantly hallucinatory
292.84 Sedative-, hypnotic- or anxiolytic-induced mood disorder[I,W]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Sedative-, hypnotic- or anxiolytic-induced anxiety disorder[W]	.8 Other mental and behavioural disorders
292.89 Sedative-, hypnotic- or anxiolytic-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
292.89 Sedative-, hypnotic- or anxiolytic-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
292.9 Sedative-, hypnotic- or anxiolytic-related disorder NOS	.9 Unspecified mental and behavioural disorder
Polysubstance-related disorder	F19.– Mental and behavioural disorders due to multiple drug use and use of other psychoactive substances
304.80 Polysubstance dependence[a]	.2 Dependence
Other (or unknown) substance-related disorders	F19.– Mental and behavioural disorders due to multiple drug use and use of other psychoactive substances
Other (or unknown) substance use disorders	
304.90 Other (or unknown) substance dependence[a]	.2 Dependence
305.90 Other (or unknown) substance abuse	.1 Harmful use
Other (or unknown) substance-induced disorders	
292.89 Other (or unknown) substance intoxication	.0 Intoxication
Specify if: with perceptual disturbances	.04 With perceptual disturbances
292.0 Other (or unknown) substance withdrawal	.3 Withdrawal
Specify if: with perceptual disturbances	
292.81 Other (or unknown) substance-induced delirium	.03 Acute intoxication with delirium or .4 Withdrawal state with delirium
292.82 Other (or unknown) substance-induced persisting dementia	.73 Dementia
292.83 Other (or unknown) substance-induced persisting amnestic disorder	.6 Amnesic disorder
292.xx Other (or unknown) substance-induced psychotic disorder	.5 Psychotic disorder

DSM-IV (ICD-9-CM)	ICD-10
.11 With delusions[I,W]	.51 Predominantly delusional
.12 With hallucinations[I,W]	.52 Predominantly hallucinatory
292.84 Other (or unknown) substance-induced mood disorder[I,W]	.5 Psychotic disorder
	.54 Predominantly depressive psychotic symptoms
	.55 Predominantly manic psychotic symptoms
	.56 Mixed
	.72 Residual affective disorder
292.89 Other (or unknown) substance-induced anxiety disorder[I,W]	.8 Other mental and behavioural disorders
292.89 Other (or unknown) substance-induced sexual dysfunction[I]	.8 Other mental and behavioural disorders
292.89 Other (or unknown) substance-induced sleep disorder[I,W]	.8 Other mental and behavioural disorders
292.9 Other (or unknown) substance-related disorder NOS	.9 Unspecified mental and behavioural disorder or F55 Abuse of non-dependence-producing substances
Schizophrenia and other psychotic disorders	
295.xx Schizophrenia	F20 Schizophrenia
The following classification of longitudinal course applies to all subtypes of schizophrenia:	A fifth character may be used to classify course:
– Episodic with inter-episode residual symptoms (*specify if*: with prominent negative symptoms)	.x1 Episodic with progressive deficit
– Episodic with no inter-episode residual symptoms	.x2 Episodic with stable deficit
– Continuous (specify if: with prominent negative symptoms)	.x3 Episodic remittent
	.x0 Continuous
– Single episode in partial remission (*specify if*: with prominent negative symptoms/single episode in full remission)	.x4 Incomplete remission
	.x5 Complete remission
– Other or unspecified pattern	.x8 Other
	.x9 Course uncertain, period of observation too short
.30 Paranoid type	F20.0 Paranoid schizophrenia
.10 Disorganized type	F20.1 Hebephrenic schizophrenia
.20 Catatonic type	F20.2 Catatonic schizophrenia
.90 Undifferentiated type	F20.3 Undifferentiated schizophrenia
.60 Residual type	F20.5 Residual schizophrenia
295.40 Schizophreniform disorder *Specify if*: without good prognostic features/with good prognostic features	F20.x Schizophrenia, with duration less than 6 months
295.70 Schizoaffective disorder	F25 Schizoaffective disorders
Specify type:	
Bipolar type	.0 Manic type
Depressive type	.1 Depressive type
297.1 Delusional disorder *Specify type*: erotomanic type/grandiose type/jealous type/persecutory type/somatic type/mixed type/unspecified type	F22.0 Delusional disorder
298.8 Brief psychotic disorder	F23.1 Acute polymorphic psychotic disorder with symptoms of schizophrenia or F23.0, F23.2, F23.3, F23.8 and F23.9 with a duration of less than 6 months
Specify if:	
With marked stressor(s)	.x1 With associated acute stress
Without marked stressor(s)	.x0 Without associated acute stress
With postpartum onset	plus O99.3 Mental disorders and diseases of the nervous system complicating pregnancy, childbirth and the puerperium
297.3 Shared psychotic disorder	F24 Induced delusional disorder
293.xx Psychotic disorder due to ... (indicate the general medical condition)	
.81 With delusions	F06.2 Organic delusional disorder
.82 With hallucinations	F06.0 Organic hallucinosis

DSM-IV (ICD-9-CM)	ICD-10
---.- Substance-induced psychotic disorder (refer to substance-related disorders for substance-specific codes) *Specify if*: with onset during intoxication/with onset during withdrawal	F1x.5 Psychotic disorders due to psychoactive substance use
298.9 Psychotic disorder NOS	F29 Unspecified non-organic psychosis
Mood disorders *Code current state of major depressive disorder or bipolar I disorder in fifth digit*: 1=Mild 2=Moderate 3=Severe without psychotic features 4=Severe with psychotic features *Specify if*: mood-congruent psychotic features/mood-incongruent psychotic features 5=In partial remission 6=In full remission 0=Unspecified *The following specifiers apply (for current or most recent episode) to mood disorders as noted*: [a]Severity/psychotic/remission specifiers/[b]chronic/[c]with catatonic features/[d]with melancholic features/[e]with atypical features/[f]with postpartum onset *The following specifiers apply to mood disorders as noted*: [g]With or without full inter-episode recovery/[h]with seasonal pattern/[i]with rapid cycling	
Depressive disorders	
296.xx Major depressive disorder	
.2x Single episode[a–f]	F32.x Depressive episode .0 Mild .1 Moderate .2 Severe without psychotic symptoms .3 Severe with psychotic symptoms .4 In remission .8 Other (catatonic or atypical features) .9 Unspecified
.3x Recurrent[a–h]	F33.x Recurrent depressive disorder .0 Mild .1 Moderate .2 Severe without psychotic symptoms .3 Severe with psychotic symptoms .4 In remission .8 Other (catatonic or atypical features) .9 Unspecified
300.4 Dysthymic disorder *Specify if*: early onset/late onset *Specify if*: with atypical features	F34.1 Dysthymia
311 Depressive disorder NOS	F32.9 Depressive episode, unspecified
Bipolar disorders	
296.xx Bipolar I disorder	
.x Single manic episode[a,c,f]	F30.x Manic episode .1 Without psychotic symptoms .2 With psychotic symptoms
Specify if: mixed	F38.00 Mixed affective episode
	F31.x Bipolar affective disorder, current episode
.40 Most recent episode hypomanic[g–i]	.0 Hypomanic
.4x Most recent episode manic[a,c,f,g–i]	.1 Manic without psychotic symptoms or .2 Manic with psychotic symptoms
.6x Most recent episode mixed[a,c,f,g–i]	.6 Mixed

DSM-IV (ICD-9-CM)	ICD-10
.5x Most recent episode depressed[a–i]	.3 Mild or moderate depression or .4 Severe depression without psychotic symptoms or .5 Severe depression with psychotic symptoms
.7 Most recent episode unspecified[g–i]	.7 In remission or F31.9 Bipolar affective disorder, unspecified
296.89 Bipolar II disorder[a–i]	F31.x Bipolar affective disorder
Specify if: (current or most recent episode): hypomanic/depressed	.0 Current episode hypomanic
	.3 Current episode mild or moderate depression
	.4 Current episode severe depression without psychotic symptoms
	.5 Current episode severe depression with psychotic symptoms
– Catatonic or atypical features	F31.8 Other bipolar affective disorder (catatonic or atypical features)
301.13 Cyclothymic disorder	F34.0 Cyclothymia
296.80 Bipolar disorder NOS	F31.9 Bipolar affective disorder, unspecified
Other mood disorders	
293.83 Mood disorder due to ... (indicate the general medical condition)	F06.3 Organic mood (affective) disorder
Specify type	
With depressive features/with major depressive-like episode	.32 Organic depressive disorder
With manic features	.30 Organic manic disorder
With mixed features	.33 Organic mixed affective disorder
---.– Substance-induced mood disorder (refer to substance-related disorders for substance-specific codes)	F1x.5x Psychotic disorder due to psychoactive substance use
Specify type: with depressive features/with manic features/with mixed features	.54 Predominantly depressive symptoms
	.55 Predominantly manic symptoms
	.56 Predominantly mixed symptoms
	F1x.72 Residual affective disorder
Specify if: with onset during intoxication/with onset during withdrawal	
296.90 Mood disorder NOS	F39 Unspecified mood (affective) disorder
Anxiety disorders	
300.01 Panic disorder without agoraphobia	F41.0 Panic disorder
300.21 Panic disorder with agoraphobia	F40.01 Agoraphobia with panic disorder
300.22 Agoraphobia without history of panic disorder	F40.00 Agoraphobia without panic disorder
300.29 Specific phobia	F40.2 Specific (isolated) phobias
Specify type: animal type/natural environment type/blood-injection-injury type/situational type/other type	
300.23 Social phobia	F40.1 Social phobias
Specify if: generalized	
300.3 Obsessive–compulsive disorder	F42.x Obsessive–compulsive disorder
Specify if: with poor insight	.0 Predominantly obsessional thoughts or ruminations
	.1 Predominantly compulsive acts
	.2 Mixed obsessional thoughts and acts
	.8 Other obsessive–compulsive disorders
	.9 Obsessive–compulsive disorder, unspecified
309.81 Post-traumatic stress disorder	F43.1 Post-traumatic stress disorder
Specify if: acute/chronic	
Specify if: with delayed onset	
308.3 Acute stress disorder	F43.0 Acute stress disorder
300.02 Generalized anxiety disorder	F41.1 Generalized anxiety disorder
293.89 Anxiety disorder due to ... (indicate the general medical condition)	F06.4 Organic anxiety disorder
Specify if: with generalized anxiety/with panic attacks/with obsessive–compulsive symptoms	
---.– Substance-induced anxiety disorder (refer to substance-related disorders for substance-specific codes)	F1x.8 Other mental and behavioural disorders due to use of psychoactive substances

DSM-IV (ICD-9-CM)	ICD-10
Specify type: with generalized anxiety/with panic attacks/with obsessive-compulsive symptoms/with phobic symptoms *Specify if*: with onset during intoxication/with onset during withdrawal	
300.00 Anxiety disorder NOS	F41.9 Anxiety disorder, unspecified
Somatoform disorders	
300.81 Somatization disorder	F45.0 Somatization disorder
300.81 Undifferentiated somatoform disorder	F45.1 Undifferentiated somatoform disorder
300.11 Conversion disorder	F44.x Dissociative (conversion) disorders
Specify type:	
With motor symptom or deficit	.4 Dissociative motor disorders

Codes that precede the DSM-IV category are ICD-9-CM codes (*International Classification of Diseases*, 9th revision, clinical modification, 2nd edn, 1980. U.S. Government Printing Office. Washington DC, 20402). There are several differences between ICD-9 and ICD-9-CM, mainly on the level of the fourth digit. A conversion table between ICD-9 and ICD-9-CM is available on the Internet at www.who.ch: WHO Headquarters, Major Programmes; Division of Mental Health and Prevention of Substance Abuse; ICD-10 Conversion Tables.

NOS, not otherwise specified.

CHAPTER

5

A. Sims, S. Curran

Examination of the Psychiatric Patient

1 Underlying Principles

1.1 Purpose

Psychiatric treatment, using any recognised intervention, is based upon information concerning the present state and past history of the individual patient, described as the psychiatric examination. This has two essential components which are described in this chapter: history-taking and examination of mental state. Any medical examination is potentially experienced by the patient as unpleasant, and psychiatric examination is no exception. It is also time-consuming, and each item should therefore be carried out for a specific purpose. It is also important to ask the patient's permission and explain the procedure and its purpose beforehand. Repeated examinations of the same patient by different members of the clinical team should be discouraged, as this is unpleasant for the patient and will tend to undermine the value of the procedure.

1.2 Relationship Between Patient and Doctor

An important consequence of carrying out a psychiatric examination, although not its primary justification, is the forging of a therapeutic relationship between patient and doctor. This is both explicit and implicit in the contract that is established between them during history-taking and mental state examination. Explicit is the enquiry by the doctor for detailed information; implicit is that the doctor knows what questions need to be asked and is compassionate in demonstrating concern for the patient's distress.

These attributes of the doctor (competence, knowledge of the patient's problems and concern) help establish a therapeutic relationship and are equally important whatever the nature of treatment. Patients are sensitive to what they construe as the doctor being judgmental, and this is especially true at the initial interview.

1.3 Diagnosis

The diagnosis consists not of a single word or phrase encompassing everything about the patient, but rather a diagnostic formulation (see Vol. 1, Part 2, Chap. 2). The formulation states the problem and outlines the differential diagnosis, aetiology, further investigations, plan of treatment and prognosis.

To make a competent psychiatric diagnosis, the interviewer needs theoretical knowledge of psychiatry and an ability to elicit psychopathological phenomena with precision. A checklist of diagnostic criteria is never enough on its own; "the proper use of these criteria requires specialised clinical training that provides both a body of knowledge and clinical skills" (American Psychiatric Association 1994).

1.4 Formulating Management

Medical diagnosis is the process of ascertaining the nature of the problem presented and categorising it in such a way that those problems may be solved from a menu of options. This will usually involve pharmacological, psychological and social intervention rather than a single method of treatment.

1.5 Specific Purposes

Obtaining information may be distressing for patients and is time-consuming for the doctor. The interviewer should therefore be able to give a reason for each question asked. As well as diagnosis, forging relationships and formulating treatment, the interview may be used for other purposes:

- *Monitoring change.* The doctor will wish to assess regularly the condition of those under treatment by enquiring about their current state.
- *Medico-legal report.* Although the general principles remain similar, there are specific considerations which are discussed later.
- *Research.* Data collection must be comprehensive and consistent in its collection so that comparisons may be made between subjects.

1.6 Structuring the Interview

The purpose of a particular interview and the information that is required should have been decided and discussed with the patient beforehand. A framework for history-taking and examination is used so that significant areas of information are not omitted and patients are not irritated by repeated questions.

While proceeding through the predetermined schedule, the clinician gives emphasis to those parts of the history and examination that are particularly signifi-

cant in the particular case. Clinicians should develop interviewing structures that suit their particular practice and style, and any published framework is a guideline, and not a directive.

1.6.1 Interviewing and Communication

Putting the patient at ease from the start necessitates attention to the setting, careful planning of the interview and confidence in carrying out the examination. The patient is usually anxious, and this should be recognised by the doctor. The patient will be more comfortable if it is explained how long the interview will take and what areas will be covered.

A meaningful psychiatric history requires skilful use of *open-ended* questions, *direct* questions in significant areas and clarification of clinically important topics while watching carefully for verbal and visual clues revealing the patient's emotional state. The interviewer should have prepared strategies for dealing with frequent situations, e.g., a garrulous patient or a patient who becomes upset during interview.

Examination of the mental state requires the interviewer to find out as precisely as possible what is the subjective experience of the patient. The interviewer's own capacity for subjective experience is enlisted in understanding the patient's description and recounting this back to the patient: the method of empathy (Sims 1995a).

Psychiatrists must be able to communicate with their patients, and this implies knowledge of the stages through which an interview goes and the attitudes and expectations of the patient at different stages (apprehensive withholding at the beginning, garrulous irrelevancy in the middle and significant disclosure at the end). Clinicians should be aware that their own attitudes, prejudices and expectations can modify information given by the patient.

1.6.2 Training for Interviewing

On commencing psychiatric practice, trainees need to talk with patients and to learn interviewing skills, including how to structure the interview, with examples of good practice to emulate from more experienced clinicians. For example, a senior psychiatrist may elicit delusional perception or a skilful social worker may demonstrate a comprehensive family history. Trainees should rehearse interview technique and have feedback on their performance under non-threatening conditions, preferably with colleagues using video techniques to record and monitor progress. Attention should be paid to the wording of questions, strategies for alleviating anxiety and timing, both for the whole interview and its constituent parts. A hospital involved in the training of psychiatrists should have a designated senior clinician, knowledgeable in educational methods and interview techniques, acting as supervisor for this training.

1.6.3 Potential Pitfalls

Some skills used in ordinary conversation have a perverse effect when used in psychiatric interviewing. Although an odd response received in normal conversation would usually be ignored and the questioner would pass on to another topic, in the psychiatric interview this could result in missing significant psychopathology. In addition, distress should not be played down, as this will prevent further disclosure. Reassuring the patient before they have fully explained their predicament and falsely reassuring when the prognosis is poor are both harmful approaches. Furthermore, changing from a topic of discussion before patients have fully explained themselves discourages them from proceeding further with their account. All these gambits may be used by an inexperienced interviewer to keep the consultation at a "safe" level which may make the interviewer feel more comfortable, but does not help the patient.

1.7 Facilitating the Interview

Some apparently minor considerations can make the process of carrying out an interview comfortable and relatively stress free for both patient and doctor, but if neglected can result in the examination failing to meet its objectives.

1.7.1 Setting

It is important to consider the comfort of the patient and the needs of the interview. The room should be clean, comfortable, well appointed and without unnecessary distractions, such as extraneous noise. The interview should start promptly, and the patient should be seated comfortably at about the same level as the interviewer and on one side, not across a desk or table.

1.7.2 Mental State of the Interviewer

The posture adopted by the doctor conveys a message to the patient. Slouching back in a chair may be interpreted as disrespectful, while craning forward on

one's elbows may communicate tension or aggression. The interviewer must concentrate totally and ideally should be tranquil, free of immediate emotional distraction and unhurried.

1.7.3 Duration

The interview should start on time, progress steadily, cover the required ground and end at the specified time with a satisfying conclusion. If the process is likely to be prolonged, e.g., with a new in-patient, it is better to use separate periods of about 1 h rather than have a lengthy session which becomes arduous for the patient.

1.7.4 Order of Questions

The order of questions can influence the answers given to them. It is best to order the interview according to a recognised structure and to persist with this, thus making serial interviews with different patients comparable.

1.7.5 Direct Questions

Early in the interview or when starting on any new topic, it is best to use open-ended questions. These should then be followed by direct questions, which should not be "leading questions", i.e., directing an answer expected by the questioner. The skill of asking questions is to combine open enquiry that will allow unexpected comment with obtaining specific information required by the interviewer.

2 Method of Examination

The following section describes in detail the separate steps in history-taking and examination of psychiatric patients; a framework suitable as a basis for clinical practice is given in Table 1.

2.1 Source and Reasons for Referral

The referral may come from the patient (self-referral), family or hospital doctor, social worker, solicitor, probation officer, employer or another person, and this influences what the patient says and expects from the interview. The reason for referral (e.g., family doctor

Illusions and hallucinations
Orientation
Attention and concentration
Memory
Insight
Reaction to the patient

requesting recommendation for treatment) should be made explicit.

It is generally helpful to have an account from another person, especially when the patient is too disturbed to give a history or the facts are uncertain because of the mental state. Details concerning the informant should be recorded and comment made of both the patient's and the informant's reliability as historians.

2.2 Psychiatric History

A good psychiatric history must compromise between obtaining all pertinent information and common sense. For more detailed questioning, the interviewer should select those areas that are likely to be important. Verbatim quotation from the patient is usually better than psychiatric terminology.

2.2.1 Present Illness

The history of the presenting complaint is the key to understanding what is wrong with the patient and subsequently formulating treatment. It also helps forge the relationship between patient and doctor.

Nature
Complaints should be listed in the order of significance and described with precision, preferably in the patient's own words, as verbatim statements are both more graphic and more likely to convince clinicians who consult the case notes at a later date. Comment should be made upon severity and the degree of distress and social disability each symptom causes.

Timing
Important issues are the time of onset of each symptom, how long each episode lasts, whether symptoms are continuous or intermittent and what provokes these symptoms. The order of occurrence does not necessarily imply cause, but time relationships may help to confirm the diagnosis.

Development
Symptoms may change over time in their severity, prominence, the meaning they hold for the patient and their significance for the clinical picture. Sometimes change may be of diagnostic importance.

Precipitating or Relieving Factors
Most symptoms are influenced to some extent by outside circumstances; perhaps by distraction from other perceptions, by the time of day or by an appreciative audience. Violent behaviour becomes more likely with anxiety, uncertainty or constraint. Sometimes the attribution for change demonstrates abnormality of mental state, e.g., patients who believe that their thinking is disordered by an electronic machine.

Help Received So Far
Previous treatment, both pharmacological and psychosocial, should be recorded with its duration, dosage, any adverse reactions and relative effectiveness.

Impact of the Complaint
The impact of the complaint concerns the effects of symptoms upon work, social functioning and relationships and their association with physical functions.

Availability of Support
The availability of support should be assessed both from the practical aspect, i.e., whether people are available to help in a crisis, and the emotional one, i.e., whether supportive relationships are reassuring and encourage involvement in normal activity or whether they are restrictive and tend to collude with ideas of incapacity.

Patient's Attitudes Towards the Complaint
The patient's attitudes towards symptoms vary from neglect and denial to exaggerated anxiety and will be expressed differently to a psychiatrist than they will to relatives and friends. The meaning of symptoms for the patient should be explored, such as guilty ideas of incurability or heredity. Exploring such misconceptions is necessary in order to rectify them.

2.2.2 History of Similar Psychiatric Problems

A history of similar psychiatric problems gives valuable information about the natural history and therefore diagnosis of the illness.

Some conditions are episodic and occur in "attacks" against a background of normality; others are cyclical and may represent a pathological response to biological events such as menstruation, the puerperium and the time of day or season of the year. Psychiatric disorders may also be reactive to external social circumstances and the way they are perceived by the patient.

2.2.3 Family History

Enquiry about the family not only informs the clinician about the patient's inheritance and the possibility of genetic illness, but also about the environment and atmosphere in which he or she developed and now lives. This involves enquiry about family history of disease and evaluation of relationships. Illnesses, and deaths, with causes are recorded for close relatives. It is important to ascertain whether family membership is

biological or adoptive. Family history of psychiatric disorder, personality problems, epilepsy and other neurological disease is directly relevant. Relationships and separations between parents and siblings should be noted, and the clinician should assess whether family relationships are close and emotional support is forthcoming.

2.2.4 Previous Medical History

Significant illnesses and operations and the patient's reaction to these should be recorded.

2.2.5 Previous Psychiatric History

Other psychiatric disorders from which the patient has suffered may indicate the nature and course of the present condition. Full details of previous treatment should be noted, including the setting and the doctor who provided treatment.

2.2.6 Personal History

As the personal history provides the background from which the patient came and the context in which he or she now lives, it is clearly crucial in understanding the patient's state and response to illness.

Early Life and Development
Any significant features concerning the mother's pregnancy, the patient's birth, habit training and achieving milestones should be noted.

Childhood Problems
Social, physical and behavioural variations from normal during childhood, including parental separations, events concerning other siblings, emotional and behavioural problems and any notable illnesses of the patient are recorded.

Schooling
The interviewer should enquire about achievement, intellectual ability and capacity for relationships with peers and authority figures during the patient's schooling.

Occupation
The patient's occupations with dates at each place of work, reasons for changing, present financial situation and satisfaction with work are listed. The duration and geographical location of military service, highest rank achieved and any problems should be recorded.

Marital and Personal Relationships
When enquiring about marital and personal relationships, the age of patient and his or her spouse at marriage, relevant matters of courtship, previous relationships and the quality of the relationship should be noted.

Menstrual History
The patient's menstrual history includes the age of menarche, regularity of periods, any significant menstrual symptoms and attitudes of the patient towards menstruation.

Sexual History
Sexual history includes attitudes to sex, heterosexual and homosexual experience, use of contraception and any past experience of sexual abuse.

Children
Names, ages, gender, development, temperament and behaviour of a patient's children should be recorded with a note on the quality of relationships of the patient with each child and between siblings. Evidence of recent change in the relationship between the patient and the children is relevant.

2.2.7 Present Social Situation

The patient's present social situation concerns his or her financial, residential and legal situation and has a bearing on assessment of diagnosis and treatment plan. The interviewer must decide how much should be asked about each of the topics within the psychiatric history at the initial interview and what should be left until later when the doctor–patient relationship has become more securely established. The pursuit of useful information should be tempered by the importance of maintaining a relationship.

2.3 Premorbid Personality

Assessment of personality is a valuable part of the psychiatric examination, because, if carried out accurately, it can be predictive of future behaviour, including the response to mental illness. The interviewer should use an accepted classification of abnormal personality and its disorder, such as the International Classification of Diseases, 10th edition (World Health Organisation 1992). Personality assessment requires skilled observation of the patient during the interview and enquiry of another informant; it is predictive of future behaviour and responses patients might make to their illness. The interviewer looks for distinctive traits that indicate personality type and style of functioning in everyday life, assessing whether these traits have developed to an extent which would fall within a broad range of normal or whether they are

excessive. Abnormal personality, which does not of itself denote disorder, is present when a personality trait considered to be clinically significant is developed to an extent that does not conform with the majority. Personality disorder is present when this abnormality of personality causes either the patient or other people to suffer.

2.3.1 Relationships

The capacity for establishing and maintaining relationships, both intimate and companionable, is assessed. This includes the capacity for relationship with the same and the other sex and the ability to relate to superiors, equals and subordinates.

2.3.2 Use of Leisure

Leisure activities are examined, i.e., whether they are solitary or social, sedentary or physically active, creative, studious or aesthetic. Note is taken of hobbies, preferred activities and membership of societies, clubs and political or religious organisations.

2.3.3 Predominant Mood

The following points need to be considered: What are the characteristics of this individual's prevailing mood? Are they present long-term or do they fluctuate? If there are alterations in mood, how rapidly do they change and in response to what provocation? How is the patient's prevailing mood perceived by the patient and what effect does it have upon other people? Are there problems resulting from the predominant mood?

2.3.4 Character

Character is the consistent aspect of personality which determines usual behaviour, i.e., whether people can form and maintain close relationships, whether they can express feelings of love, anger, frustration and sadness and whether they lose their temper or lose control of their feelings.

2.3.5 Attitudes and Standards

Moral, religious and health attitudes are significant. Moral standards are concerned not only with judgements about right and wrong, but also the latitude one will allow oneself, the guilt associated with wrongdoing, and whether standards for one's own behaviour are different from the way one judges others. Religious values not only include religious affiliation but also beliefs and the effect these have upon emotions and external behaviour (Sims 1994). Patients' attitudes towards their own health, minor symptoms and sensations and their body should be assessed.

2.3.6 Habits

Habits concerning ingestion of food, alcohol, tobacco and other drugs should be assessed. More detailed enquiry should be undertaken if relevant.

2.4 Examination of the Mental State

Mental state examination not only explores the subjective experience of the patient, but also investigates the contents of the mind as signs for the diagnosis of psychiatric entities.

In examining the mental state, the interviewer learns a comprehensive scheme and then modifies it appropriately for each patient. Although at times history-taking and examination of mental state overlap (e.g., when delusional material intrudes into the history), conceptually and in the record they should be kept *separate*. The examination of mental state should also include observations of nursing staff for an in-patient or relatives for a patient at home. Not every phenomenon will be revealed at the first interview, and sometimes significant material only becomes apparent after several interviews. Examples of psychopathology should be recorded using verbatim statements of the patient. Evaluating the mental state involves comparing observed speech of the patient with what might be expected in that situation; this requires both accurate observation and a knowledge of normality.

2.4.1 Appearance and Behaviour

When assessing appearance and behaviour, the interviewer should concentrate on general appearance, the face, posture, movement and social behaviour. General appearance includes both the way patients present themselves in terms of clothing, personal hygiene, tidiness and any idiosyncrasies and also physical characteristics such as body build, evidence of recent weight gain or loss and generally looking well or ill. Facial appearance usually reveals current mood state such as irritability, perplexity. Posture and movement may also reveal mood or the presence of neuropsychiatric disturbances. Social behaviour assesses the

patient and his or her context, e.g., jocularity during a psychiatric interview is inappropriate. A patient with dementia may demonstrate loss of contact with reality through inappropriate behaviour.

2.4.2 Speech

Speech is the only reliable way of obtaining access to thought processes of the patient. Analysis of speech, of the words used and their inaccuracies and innuendoes, is particularly valuable in exploring psychopathology (see Vol. 1, Part 1, Chap. 1; Sims 1995b). Articulation and the stream of speech should be noted. The form of thought is evaluated by assessing the relevance, precision and appropriateness of answers given. Abnormal speech should be recorded.

2.4.3 Mood

The interviewer makes a sophisticated assessment of mood by observing the affective state and describing whether mood is appropriate or not appropriate, profound or superficial, sustained or labile, etc. The patient is also asked about subjective mood, consistent feelings, and changes with time and in response to outside circumstances. Incongruity between the patient's description of mood and the interviewer's observation is noted. For rapport, the interviewer assesses the patient's ability to communicate his or her own internal state to the interviewer, measuring the patient's capacity against a notional standard of normality.

2.4.4 Depersonalisation and Derealisation

Depersonalisation describes a peculiar change in the awareness of self in which the individual feels as if he or she is unreal (Sedman 1970). Depersonalisation is common, difficult for the patient to describe and frequently accompanied by the symptom of derealisation, which denotes a similar change in the awareness of the external world. These symptoms are experienced as extremely unpleasant by patients.

2.4.5 Obsessional Phenomena

According to Lewis (1936), obsessional thoughts have three essential elements: (1) feeling of subjective compulsion, (2) resistance to it and (3) the preservation of insight. It has become conventional to make a distinction between obsessional thoughts, ideas, images or ruminations and compulsive acts.

2.4.6 Delusion

A delusion is an unshakeable false idea or belief out of keeping with the patient's educational, cultural or social background and held with extraordinary conviction and subjective certainty. Psychopathological enquiry should explore for delusion, but it cannot be enquired about directly, as the patient does not distinguish between delusion and normal ideas. The cultural context of the belief and the patient's evidence for holding that belief is assessed.

2.4.7 Illusion and Hallucinations

Three types of false perception are encountered in examining the mental state: illusion, hallucination and pseudo-hallucination; it is important both to search for them and to distinguish between them, because identifying hallucination usually indicates the diagnosis and therefore has implications for management (see Vol. 1, Part 1, Chap. 1).

2.4.8 Orientation

In assessing orientation, the patient is asked about awareness of time, place and person. Temporal disorientation may occur with milder degrees of organic disorder, while orientation of person is only lost at a late stage. Standard questions about orientation in time and place are used and the patient is also observed, e.g., finding his or her way about the hospital ward. Examining for orientation of person starts with questions about other people and their role; if this shows disturbance, enquiry is made concerning the patient's own identity.

2.4.9 Attention and Concentration

Attention is the active or passive focusing of consciousness upon an experience. Concentration is the maintaining of that focusing of consciousness on the task in hand. For formal testing, the "serial sevens" test is most often used. As always in the mental state examination, the observed result for this test is compared with what would be expected from this person in normal health.

2.4.10 Memory

In the course of history-taking, the interviewer will already have obtained information about the patient's

memory. During examination, tests are given for immediate, recent and remote memory. When abnormality is suggested, more precise cognitive testing is needed. *Immediate memory* is usually tested using digit span, forwards and backwards, which must be administered rigorously. Concentration is also involved in this test, especially in the reversed digits test. *Short-term memory* is often assessed by repeating a name and address immediately after the interviewer and then testing for its retention 5 min later; most of the name and address should be remembered correctly. Other testing for recent events will involve asking the patient about recent news, both nationally and in his or her own life. *Long-term memory* is tested by asking about events that happened further back in time; dates and names are particularly useful. The patient's social and cultural context must be taken into account. Possible abnormality in memory testing should be an indication for further standardised and structured memory testing (see Vol. 1, Part 1, Chap. 13).

2.4.11 Insight

David (1990) considered that insight "is not an 'all' or 'nothing' phenomenon but is composed of three distinct, overlapping dimensions, namely, the recognition that one has of mental illness, compliance with treatment, and the ability to re-label unusual mental events (delusions and hallucinations) as pathological." The doctor will have obtained an indication about the patient's capacity for insight during the history-taking and earlier part of the examination. Any illness of moderate to severe degree will alter patients' perspectives about themselves and their world. Insight is the understanding the individual has about his or her own state of health, capacity and worth; it also relates this assessment of personal state to other people and the world outside.

2.4.12 Reaction to the Patient

It is helpful for the interviewer to record the impression the patient makes. This can be used subsequently in evaluating prognosis and expected response to treatment; it is also useful in evaluating the credibility of the history and findings on mental state examination.

2.5 Physical Examination

The physical examination provides information about other concurrent conditions and also constitutional features. Poor physical health and psychiatric morbidity frequently co-exist, with over 50% of acute psychiatric patients having at least one physical disorder (Porter 1996). Physical examination should be conducted after the history and mental state examination, and the patient should be told what this will involve and consent should be obtained. The environment should have adequate lighting and privacy, an examination couch and appropriate, reliable instruments for the examination. In addition, there should be a chaperone for examination by a male doctor of a female patient.

2.6 Collecting Information from Other Informants

Obtaining further information from another person can sometimes be essential (see Sect. 3) and is almost always helpful in providing a different perspective. After the history has been taken, it usually becomes clear who the significant informants are in terms of providing both factual information and observational comment. However, caution is necessary when obtaining information from relatives and friends; issues of confidentiality are important, and sometimes the patient specifically forbids contact with others. The informant, most often a relative, should have known the patient over an extended period of time. A separate interview is organised, preferably face to face, with the purpose of gathering additional information, determining how disabling the condition is and how it affects the patient and other people and discussing treatment plans. The doctor should emphasise that confidential information given by the patient will not be passed on to relatives, and the patient should consent to this interview. In addition, any confidential information divulged by relatives should not be disclosed to the patient. This process also allows the reliability of statements made by both patients and informant to be verified. It also permits an assessment of the interaction between patient and informant to be assessed, which may have diagnostic significance.

2.7 Physical Investigations

2.7.1 Routine Laboratory Investigations

Routine laboratory investigations include blood and urine tests. Patients should undergo a thorough assessment as described above, and subsequent simple investigations should be chosen depending upon symptoms, signs and the differential diagnosis. No single set of routine investigations is relevant for every case, and only those investigations should be

undertaken for which there is a clinical indication. Before undertaking any investigation, patients should be told what the procedures involve and what will be undertaken, and they should be told the results. Investigations include full blood count (haemoglobin, white cell count and platelets), plasma viscosity, urea and electrolytes, thyroid function tests, liver function tests, random blood sugar and syphilis screen. Urine testing, using commercially available kits, is carried out to detect protein, ketones and sugar.

2.7.2 Neuroimaging and Electroencephalography

Neuroimaging and electroencephalographic techniques include anatomical measures, such as skull X-ray, computed tomography (CT) and magnetic resonance imaging (MRI), and functional measures, such as positron emission tomography (PET), single photon emission computed tomography (SPECT) (see Vol. 1, Part 1, Chap. 11), electroencephalography (EEG) and evoked potentials (EPS). It is important to realise that, although special investigations are useful, in 90% of cases the diagnosis can be made on the basis of the history (Gawel 1992), rising to over 95% if the physical examination is included. The EEG measured on the surface of the cerebral cortex is the spatial average of the underlying dendritic fields of the cells in the superficial layer of the cortex (Fenwick 1992), and since its introduction in the 1920s, the EEG has become an important investigation in psychiatry. EPS were first reported in the 1940s and have proved to be useful for the evaluation of certain clinical conditions. A flash of light or an auditory click produces an electrical response in the corresponding cortex, and these responses can be recorded (*evoked potentials*), showing changes in the wave form, e.g., in schizophrenia and Alzheimer's disease (Fenwick 1992; see Vol. 1, Part 1, Chap. 12).

The skull X-ray is useful for identifying skull fractures, areas of thickening and sclerosis and other abnormalities such as copper beating, vascular markings, calcification of tumours and erosion of the sella. CT scan is the primary investigation for cerebral and spinal pathology, but the posterior fossa is poorly visualised and some lesions may be isodense and thus missed. MRI provides outstanding anatomical quality. However, patients must be free of all metal, and many patients, especially children and the elderly, find the procedure very frightening. PET provides information about the central nervous system (CNS) and allows both cerebral blood flow and regional metabolism to be assessed. SPECT provides similar information to PET scans, but with lower resolution. Cerebral angiography was a relatively common procedure in the past, but has serious complications and, with the advent of superior modern neuroimaging techniques, it is now less commonly used.

2.8 Psychological Assessment

2.8.1 Simple Assessment

The patient will have undergone "informal" psychological assessment both in the assessment of personality and mental state examination. Additional simple psychological assessments that can be undertaken include observing the patient's behaviour in a variety of settings (alone, interactions with members of staff, other patients and members of the public), ability to perform activities of daily living (dressing, personal hygiene, shopping), compliance with medication, the effects of psychoactive drugs, and sleep and eating behaviour. These simple observations provide valuable information about the patient with regard to diagnosis and management, but are not standardised.

2.8.2 Special Assessment

Rating scales are extremely numerous (Royal College of Psychiatrists 1994) and include both observer- and self-rating scales. They can be used to assess behaviour, mood, speech and language, thought processes and cognitive function. Any scales used should have a high validity and a high test–retest and inter-rater reliability. Neuropsychological tests will usually be undertaken by a clinical psychologist. These instruments assist in localising regional brain damage and measure psychomotor performance, visual and auditory memory, short- and long-term memory and verbal fluency (Lezak 1983). Personality inventories may be useful in clinical research, but they have not proved to be as useful in clinical practice (see Vol. 1, Part 2, Chap. 6).

2.9 Social Assessment

Man is a social animal and usually lives in a family, neighbourhood and/or working group. Exploring the social context provides useful information on aetiology and for treatment. Social assessment reviews the patient's occupation, home environment, social class, ethnicity and religion.

2.9.1 Occupation

Occupational history gives an indication of premorbid intelligence and functioning, and any change in

employment status will help reveal the impact of the psychiatric disorder on the individual's life. Certain occupations are more likely to be associated with a particular disorder, e.g., individuals involved with the sale of alcohol, who have an increased risk of alcohol dependence. Assessment of the patient for occupation may help patients to return to work as quickly as possible. The best occupational assessment is one which takes place in the environment where the patient works, since this will be directly relevant to the individual. Many hospitals also have workshops where individuals can be assessed prior to returning to work; this is especially important if working involves using dangerous equipment or driving heavy goods vehicles (Department of Health 1995).

2.9.2 Home Environment

Although every psychiatric patient might benefit from home assessment, it is particularly important in old age psychiatry. It may give useful insight into the patient's mental state (e.g., windows covered to repel "X-rays") and clues to aetiology (e.g., empty bottles of spirits). Factors likely to exacerbate poor mental health such as inadequate heating and diet and the general layout of the house may be identified. The patient's safety at home can be assessed, e.g., presence of gas appliances or psychotropic drugs that may contribute to the mental disorder. The safety of other family members, such as children, can also be assessed from the perspective of either neglect or physical abuse. It may be more efficient for another member of the multidisciplinary team to carry out the home assessment.

2.9.3 Legal Aspects

A criminal record is relevant, especially when preparing a psychiatric report on an individual who has committed a serious offence. It may sometimes be necessary to obtain official records about previous convictions from other agencies. A history of violence is one of the best predictors of future violence (Scott 1977), and a gradual escalation in the seriousness of offences also provides invaluable information.

2.9.4 Ethnicity

Knowledge of the patient's ethnic background may be helpful in understanding the patient's psychopathology. It may also help in establishing a rapport with the patient and in maintaining the therapeutic relationship. Some conditions are commoner in certain ethnic groups, and relevant information may help with diagnosis, management and prognosis (Cox and Jorsh 1992).

2.9.5 Religious Affiliation and Belief

Assessment of a patient's religious group and beliefs is often linked to their cultural and ethnic background and can thus be important when trying to interpret and understand a particular patient's symptoms. The individual's religious beliefs may profoundly affect presentation, prognosis and response to treatment.

3 Specific Issues

Many of the particular difficulties in psychiatric examination discussed in this section are caused by barriers to communication – verbal, non-verbal and emotional. Problems occur when the patient is acutely disturbed, has limited comprehension, as in patients from other cultures, the blind and the deaf or those with a learning disability, or is incapacitated for expression, as in some neurological disorders, especially motor dysphasia.

3.1 Child and Adolescent Psychiatry

Assessment of children and adolescents differs from examination of adults in several respects. The consultation is seldom initiated by the child, and the problem is usually present as either abnormal development or behaviour. As disturbance in other family members is usual, psychiatric examination involves assessment of the whole family. Although a full psychiatric history should be taken, the focus is very much on the developmental and family history, and normal milestones for development must be known. A child has less language; other methods of assessment should therefore be utilised, such as observing play and social interactions with other children. Many different individuals contribute to the assessment of children and adolescents, including parents, the family doctor, teachers, paediatricians, social workers and educational psychologists, hence forging a working relationship is essential in the assessment. In assessing adolescents, one needs to bear in mind that this is a period of rapid physical, psychosexual, social and emotional change (Graham 1986; Steinberg 1982).

In children and adolescents with a learning disability, there may be a complicated mixture of medical, psychological, social and developmental problems in

addition to intellectual impairment and, frequently, sensory deficits, which make assessment more complicated. Assessment should be unrushed and thorough and should include input from other health care professionals and agencies to give a broad picture of the clinical problem. The assessment is aimed at targeting resources more specifically to enable the patient to reach his or her full potential, and it is necessary to involve the family, who may be under considerable stress (Clarke et al. 1985).

3.2 Acute Psychiatric Disorders

Acute psychiatric disorders may occur unexpectedly, often with seriously disruptive behaviour, and often it is impossible to undertake detailed history. In addition, assessments are frequently made in unsatisfactory situations, such as police cells or casualty departments. One should obtain as full a history as possible from the patient, family, old case notes and information from others, such as the general practitioner or police, including presenting symptoms (onset, course and severity), past psychiatric history and medical history (Macpherson et al. 1996). Mental state examination is always undertaken, however uncooperative the patient, and should include attention to hostility, aggression and withdrawal when possible physical examination is conducted. Once this has been acheived, a management plan can then be implemented (McGrath and Bowker 1987).

3.2.1 Assessing Violence

Violent incidents in hospitals are common and appear to be increasing (Haller and Deluty 1988). Assessment of such incidents is usually undertaken as an emergency and should have preceded administration of psychoactive drugs. Information should be collected from observers, and a mental state examination performed. Other staff should be available to deal with violent incidents (but out of sight), and the interview should be conducted in a calm, non-confrontational and reassuring manner, preferably by someone the patient trusts. The environment is also important. Where possible, heavy objects should be removed that could be easily thrown by the patient, and the psychiatrist should be close to the exit and have access to a personal alarm.

It is important in the assessment of potentially violent, personality disordered patients to pay attention to engagement (Norton 1996). Mutual respect and trust is vital for carrying out the clinical task professionally.

3.2.2 Assessing Suicide Risk

Direct questions about suicide do not increase the probability that an individual will commit suicide (Hawton 1987). On the contrary, such questions are an essential part of the assessment. Risk factors should be noted; these include male gender, old age, loneliness, chronic painful conditions and direct statements of intent and hopelessness (Beck et al. 1985). It is also important to evaluate factors which may reduce the risk of suicide, such as concern for one's children and religious convictions.

3.2.3 Assessing Victims of Acute Psychological Distress

Acute reactions to stress (World Health Organisation 1992) are transient disorders, usually lasting several hours to a few days in response to exceptionally stressful events, such as natural catastrophes or following a crisis in a relationship. It may not be possible to obtain a full account from the individual, but registering personal details and a subsequent offer of help, given in a calm, reassuring manner, may be all that is required.

3.3 Psychiatry of Neurology

Neuropsychiatry provides a bridge between neurology and psychiatry (Reynolds and Trimble 1989). It has been suggested that as many as 49% of neuropsychiatric referrals have a clear organic aetiology (Lishman 1992), and psychiatrists frequently assess patients with neurological problems. An integrated approach to assessment is needed, and this may be best undertaken in a combined clinic, which enables joint assessment and treatment to be undertaken. The range of psychiatric and neurological disorders seen in a neuropsychiatric setting is large (Scheepers et al. 1995), requiring knowledge of neurology and psychiatry for adequate assessment and treatment.

3.4 Old Age Psychiatry

Assessment of the elderly patient differs in some important respects from general psychiatry. Cognitive and psychomotor decline, failing physical health, decreased psychosexual function, loss of children, bereavements, retirement, loss of income and loss of role may have occurred. It is important to distinguish between change due to normal ageing and that due to

pathology. This can be difficult, especially with memory impairment, but is usually indicated by quantitative differences and rate of decline over time. Home assessment is often helpful as this gives invaluable information. Varying degrees of sensory impairment may result in the assessment taking longer. It is vital to involve relevant family members and other health care professionals (Jacoby and Oppenheimer 1995).

3.5 Forensic Examination

Forensic assessment requires both psychiatric skills and knowledge of relevant law (Faulk 1988). Two important aspects are the assessment of dangerousness and preparation of medico-legal reports. Although patient confidentiality should be respected wherever possible, it will be necessary to prepare reports, e.g., court reports, which might be discussed in public. Under such circumstances, the patient should always be informed about this *before* the interview begins.

The best predictor of future violence is previous violence. Although dangerousness is difficult to predict, Gelder et al. (1996) have suggested factors that may be associated with dangerousness (Table 2).

Table 2. Factors associated with dangerousness

Type	Factor
History	One or more previous episodes of violence
	Repeated impulsive behaviour
	Evidence of difficulty in coping with stress
	Previous unwillingness to delay gratification
	Sadistic or paranoid traits
Offence	Bizarre violence
	Lack of provocation
	Lack of regret
	Continuing major denial
Mental state	Morbid jealousy
	Paranoid beliefs plus a wish to harm others
	Deceptiveness
	Lack of self-control
	Threats to repeat violence
	Attitude to treatment
Circumstances	Provocation or precipitant likely to recur
	Alcohol or drug abuse
	Social difficulties and lack of support

3.6 Substance Misuse

To assess patients referred with drug-related problems, full psychiatric history, mental state and physical examination looking for specific signs will be required. A further discussion can be found elsewhere (see Vol. 2, Part 2, Chap. 11; Vol. 3, Part 2, Chaps. 15, 18, 20).

3.6.1 Smoking History and Examination

All patients should be asked about their smoking habits, but under-reporting of the amount is common. It is important to record the type of tobacco consumed (e.g., cigarettes), quantity per day, whether inhaled and any recent changes; physical signs such as stained fingers should be observed.

3.6.2 Alcohol History and Examination

Alcohol history includes detailed social history, development of the habit, craving, loss of control and dependence, adverse consequences, both physical and psychosocial, and an assessment of the quantity consumed in units. Both psychiatric and physical examination will be required. A detailed social assessment is also essential, since families frequently suffer emotionally, physically and financially (Edwards 1982).

3.6.3 Drug History and Examination

In terms of their drug history, patients may mislead; corroboration should therefore be sought from informants and from physical examination. The development of an illicit drug habit, drugs consumed, their quality and evidence for craving and loss of control should be recorded. In addition, landmarks (both social and psychological ones) should be noted. Enquiry and examination concerning drugs should always be included in the assessment. Urine and hair analysis may prove useful.

3.7 History and Examination Prior to Psychotherapy

Before undergoing psychotherapy, patients should be carefully assessed in terms of personal relationships, personality disorder, motivation for treatment, capacity for psychological understanding and intelligence. They require sufficient ego strength to deal with the stressful aspects of therapy and must be free from major psychiatric disorders. These preconditions for psychotherapy, especially with regard to psychiatric disorders, are primarily valid for classic psychoanalytic therapy. They are less valid for other forms, including supportive and behavioural psychotherapy. The psychiatric assessment should include a full psychiatric

history and focus principally on the issues described above (Brown and Pedder 1979; Bloch 1986).

3.8
Transcultural Issues

Cultural background is always significant, including information about customs, religion and language. Using an interpreter will take much longer than a standard interview, and the interpreter is unlikely to be familiar with psychiatric terminology. When a family member acts as interpreter, there may be issues of confidentiality and the patient may be reluctant to discuss personal details through a family member (Cochrane 1977; Littlewood and Lipsedge 1985).

3.9
Community-Based Psychiatry

Community-based assessments have the advantage of convenience for the patient. However, the patient should have some choice concerning where the interview will take place, provided circumstances are satisfactory. Confidentiality may be a consideration, since relatives or neighbours are sometimes intrusive. Safety issues for the doctor require attention, especially when assessments are undertaken in large cities: someone should be informed where the doctor is going; he or she should not carry valuables; a mobile phone is a sensible precaution; and a system needs to be arranged pending failure to return by an expected time (Parkman and Bixby 1996).

3.10
Liaison Psychiatry: Interviewing in Hospital Settings

Particular matters concerning interviews on medical or surgical wards are that patients may not have been informed about the nature of their referral (merely told that a "specialist" is coming to see them); there may be issues of confidentiality in an open ward, and conditions for interview are often difficult. It may therefore be difficult to gain the patient's trust. Many patients will have anxieties about seeing a psychiatrist, and these will need to be discussed. The notes should be consulted, laboratory investigations reviewed and discussion carried out with medical and nursing staff. As only one assessment is usual, this must be as thorough as possible (Lipowski 1985; see Vol. 1, Part 2, Chap. 13).

3.11
Examination of Professional Colleagues

Although the assessment is essentially no different to any other psychiatric examination, there are particular problems associated with interviewing medical colleagues. Having a written letter of referral from the doctor's general practitioner helps to maintain both people in a doctor–patient relationship. Psychiatrists should avoid treating relatives, friends and close colleagues, as these relationships impede the necessary psychiatric objectivity. It is essential that confidentiality is ensured, but at the same time there is a duty to assess fitness to practice and the interests of patients should be paramount. All these considerations strongly indicate that this type of assessment is preferably carried out by an experienced practitioner.

4
Utilising the Examination

Once a full psychiatric history has been taken, a mental state and physical examination performed and additional information collected, a formulation of the case should be produced. This information needs to be accurately recorded and any decisions communicated to the patient, relatives and other health care professionals.

4.1
Formulation

The formulation is a concise review of the case and includes a brief summary, the working diagnosis and differential diagnoses with arguments for and against each of these. This is followed by a review of the aetiological factors, a discussion of the treatment options and the prognosis is outlined. A good formulation is a balanced appraisal of the psychiatric assessment, but should be very firmly based on the facts of the case rather than on speculation. It also encapsulates the main issues in the case, which then facilitates communication with other health care professionals (Tantam and Greenberg 1987).

4.2
Recording Data

Recording information about the consultation is important for several reasons: it is difficult to remember

details about every patient one sees; notes recorded by one individual can be accessed by another; the record enables the patient's condition to be viewed longitudinally. In addition, notes are a legal document which the psychiatrist, by virtue of the treatment contract he or she has entered into, is obliged to preserve and, if necessary, produce; in particular, they may be demanded by a court of law.

4.2.1 Case Notes

Case notes allow information from different sources to be brought together (e.g., medical, nursing, psychology, social work) and thus form a comprehensive document about the patient. Notes should be carefully ordered, with a clear system, to make access to information both logical and simple. Entries should clearly indicate the location of assessment, e.g., in casualty, case summaries, appropriate formulations and life charts. Increasingly, patients are given access to their own notes and their content may be influenced by this (Kosky and Burns 1995).

4.2.2 Confidentiality

For a trusting therapeutic relationship, confidentiality of the psychiatric assessment is essential. Within health care teams, it is necessary to discuss patients, and patients should be informed about such discussions. Discussions should only be made with other individuals, including relatives, with the *explicit* consent of the patient, except where failure to disclose information would place the patient or someone else at risk of death or serious harm. Where information about the patient might be disclosed (perhaps in a court), the patient should be advised at the start of the assessment so that the patient may choose not to disclose this information (O'Brien 1995; General Medical Council 1995).

4.2.3 Computerised Information

Computers are increasingly used to store information about patients, and they have a number of advantages: such records are easier to read; large quantities of information can be stored in a relatively small space; information can usually be retrieved rapidly; access to patient records can be facilitated from different sites. Computers also have disadvantages: information may be lost; the clinical service could be disrupted by computer crime; issues of confidentiality are more problematic with the use of computers for information storage.

4.3 Planning Management

The most important use of the information gained from psychiatric examination is to plan management: *short term* (first few days), *medium term* (duration of hospitalisation) and *long term* (after discharge). Assessment allows decisions to be made concerning physical treatments, psychological therapies and social interventions.

Following the psychiatric assessment and formulation, it must be decided to whom relevant findings will be communicated and how this will be done: verbally or by letter, briefly or in detail, but with the *explicit* consent of the patient.

The multidisciplinary team (MDT) requires information from different sources to be brought together and ideas exchanged to produce a single, unified management plan.

Patients frequently complain that they are poorly informed about their illness. They should be given as much information as possible concerning diagnosis, management plan and prognosis. Involving patients in their own assessment and management empowers them to reduce anxiety and enhances the doctor–patient relationship, leading to improved compliance.

It is vital that the patient's family practitioner (and any other doctors involved with care) are fully informed about all aspects of the patient's problem. Written information should be communicated as concisely and as quickly as possible.

Relatives should usually be informed about the patient's progress, as they are likely to be anxious and their involvement after discharge will be important for long-term care. However, if the patient requests that relatives should not be informed, this *must* be respected.

Standardised Measurement Instruments in Psychiatry

Translator: S. Johnson

1 Aims and Methods

Standardised methods of examination are used in psychiatry to assess objectively, and, in some cases, quantify psychopathological phenomena and other clinically relevant domains, making it easier to communicate these, to verify their status and to analyse them statistically (Stieglitz and Baumann 1994; Möller et al. 1996). They are essential to develop models of psychopathology.

Major areas in which standardised procedures are applied in psychiatry include the following:

- Cross-sectional quantitative description of psychopathological abnormalities
- Assignment by a standardised method of individual cases to diagnostic categories
- Quantitative assessment of change over time in psychopathological abnormalities (with or without therapeutic interventions)

Those who favour intuitive phenomenological methods have expressed the concern that applying standardised methods cannot take sufficient account of each patient's individuality (Huber 1976). However, this criticism seems largely unfounded. There are individual characteristics which such standardised methods will not fully capture; this is necessarily the case, as standardised measurement instruments tend to be constructed on the principle that a symptom only qualifies for inclusion if it is present in at least a specified minimum proportion of the populations for which the instrument is intended. However, when required, this deficit can be remedied by using additional methods of investigation aimed at capturing distinctive characteristics of individuals. Indeed, reports of positive experiences with measurement methods aimed specifically at the investigation of individual cases may be advanced as a counter-argument (Frey et al. 1979). Such methods have a long history (see Shapiro 1966) and continue to be applied, e.g. to delusional beliefs (e.g. Brett-Jones et al. 1987).

Standardised measurement procedures can be categorised on the basis of their methodologies into standardised assessment instruments, systematic behavioural analysis and objective tests in the narrower sense of the word (based on von Zerssen and Möller 1980). The terms standardised assessment instrument or rating scale are applied to structured methods of assessing current and/or past behaviour and/or experience, based on lists of characteristics and, in some cases, descriptions of these characteristics. The extent of standardisation varies from a simple list of symptoms filled in on the basis of a freely structured exploratory interview to semi- or fully structured interview schedules. These standardised assessment procedures are especially suitable to examine the full spectrum of psychiatric symptomatology; in addition, as they are less restrictive than other procedures, they are particularly practicable. A variety of interview schedules are available and in general use.

Systematic behavioural analysis involves using a fixed set of categories to classify the quantity and type of various forms of behaviour (including speech and actions) occurring during a fixed observation frame (methods involving sampling fixed periods of time or particular events). This usually focuses on manifest behaviour, and systems of categorisation are often developed specifically to fit the particular question being asked. This method has found particular favour in the areas of behaviour therapy and research about individual communication and interactions.

Objective tests measure reactions to standardised and fixed "stimulus material". They allow analysis of specific particular psychological functions such as perception, concentration, attention and intelligence, usually from the point of view of performance. This category includes tests of attention and concentration, intelligence tests and a variety of psychophysiological indices. These tests are said to be objective as they cannot really be falsified by the examiner or the subject and there are fixed assessment criteria with corresponding methods of data analysis and fixed norms.

Because they are very practicable, rating scales are often preferred to the other methods we have discussed if the results of patient examinations are to be documented in the context of routine professional care (see Vol. 1, Part 2, Chap. 5). They are also frequently applied in clinical psychiatric research, such as clinical trials of drugs, studies of longitudinal course, in routine clinical documentation or in epidemiological studies (Cronholm and Daly 1982; Möller et al. 1983; see Vol. 1, Part 1, Chap. 2), even though, in terms of their level of precision, standardised assessment measures are methodologically inferior to objective tests and systematic behavioural analysis. Despite the methodological superiority of these latter methods, they tend to be included in clinical psychiatric research only as supplementary measures for the sake of completeness. An exception to this can be found in the investigation of specific aspects of cognitive functioning, e.g. the debate over the potential of clozapine to reduce schizophrenics' cognitive impairment (e.g. Lee et al. 1999) and of certain questions of differential diagnosis. This limited use results not only from the amount of time and effort involved in applying these tests, but also, particularly in the case of objective tests, from the fact that the constructs which they measure are rather more remote from the psychiatric approach than the more complex phenom-

ena issues which can be described using rating scales. However, some would argue that they are closer to the "core" of the disturbance.

Investigations of the relationship between the three domains of assessment form the basis of much research in psychopathology. Because standardised assessment methods are so widely applied in psychiatric practice and research, they will be the focus of the following discussion.

2 Scale Construction, Scoring Methods and Quality Criteria

Standardised methods of assessment, or rating scales, allow description in terms of numerical values of psychological abnormalities of various characteristic forms. Different measurement scales allow the degree of abnormality to be quantified to varying extents. In the simplest instances, such as symptom checklists, scales simply allow for a rating of 0 or 1 to be made for each symptom or complex of symptoms, indicating whether or not it is present. More precise assessment becomes possible if the construction of the scale allows the severity of phenomena to be described using a scale consisting of a series of levels. As there is a danger that different assessors will base their evaluations on different standards, it is important to establish a framework for the assessment by providing anchor points, e.g. by giving examples of situations which would be characteristic for each point on the scale. Overly detailed assessment using an excessively broad scale is not meaningful, as differences at the extreme end of the scale cease to reflect real and significant variations in the phenomena being examined, so that the differentiations being made are not real ones.

In some assessment instruments, the values at which points on the scale are fixed may be varied as required, so that a scale may be constructed which is as finely differentiated as required; examples include visual analogue methods of assessing subjective well-being (Luria 1975). As the measurement of psychological phenomena is essentially imprecise, a relatively coarse scale is usually adequate, especially for comparisons between individuals. A fine scale may have advantages for intra-individual comparisons. However, any improvement in measurement precision will generally be achieved not by refining the construction of the scale, but rather by improving methods of measurement (von Zerssen 1977).

The values for characteristics which belong together (e.g. individual symptoms within a syndrome) can be added together to produce a summary score. The extent to which characteristics belong together to make up a syndrome is determined during the process of test construction (see below) by applying multivariate statistical procedures such as factor and cluster analysis. In some cases, before adding together the figures for each characteristic to produce a summary score, these figures will be weighted to indicate the relative importance of each characteristic within the syndrome. However, if the characteristics have been shown to be relatively independent, theoretical or practical justification is required for any such summation (see Garety and Hemsley 1987).

Measures of psychopathology obtained from standard rating scales generally have the level of measurement of ordinal scales, i.e. they give only a rank order and do not possess the measurement level of an interval scale, in which there are equal intervals between points on the scale. A fundamental problem in measurement is that measurement instruments with more detailed scales and higher levels of precision tend to bring with them greater restrictions regarding the phenomena which can be measured. This normally means that increasing quality of measurement is accompanied by increasing abstraction from the theoretical or conventional understanding of the characteristic which is the starting point (the reliability/validity dilemma).

Standardised assessment instruments should meet the following quality criteria derived from test theory as far as possible (Lienert 1969; Fischer 1974; Sarris and Rey 1981):

1. *Objectivity*: The results should not depend on who carries out the assessment and analyses the results. Procedure, analysis and interpretation should be standardised so that, as far as possible, the same results are obtained regardless of who administers the instrument, analyses it or interprets it.
2. *Reliability*: This refers to the reliability with which a standardised assessment instrument records a characteristic. When the measurement is repeated, the same result should be obtained.
3. *Validity*: This is the extent to which the instrument records what it is intended to record. The connection between the results of measurement and any external criteria available for assessing what is to be measured should be as close as possible.
4. *Establishment of norms*: Reference values for different clinical groups and varying groups of normal probands and, where applicable, a representative sample of the general population should be available.
5. *Practicability*: The amount of resources required for administering standardised assessment instruments in terms of time, staff and material should be as low as possible.

For a particular test, these criteria will not necessarily be highly correlated with one another. For example, a test of concentration may give a reliable, but not a valid measurement of individual differences in performance when a test designed for intellectually normal individuals is applied to people with learning difficulties; in this group, it no longer functions as a measure of concentration, but rather of intelligence (Sarris and Lienert 1974). There is a partial incompatibility inherent in the relationship between reliability and validity (the reliability/validity dilemma): improvement in reliability is often accompanied by a reduction in validity and vice versa.

While for psychometric tests in the narrower sense the availability of norms is largely taken for granted, this has been approached with a great deal less rigour for clinical rating scales. Thus, for example, the Inpatient Multidimensional Psychiatric Scale (IMPS; Lorr 1974) is almost the only observer-rated scale measuring psychopathology for which norms for a representative sample of the general population are available (Hiller et al. 1986). For a number of rating scales, reference values are available for particular diagnostic groups. Referring to such norms or, more precisely, reference values has a substantial impact on the interpretation of results. For example, moderately high scores for the domain of paranoid syndromes have quite a different significance from moderately high scores for depressive symptoms, in that depressive symptoms are common in the general population, whereas paranoid symptoms are not.

In producing norms for a standardised assessment instrument, the usual starting point is the normal distribution of values. There has to be a relation to the normal distribution in order for it to be possible to derive confidence intervals (see below) and to apply particular statistical tests, such as Pearson's product–moment correlation. Two values need to be known to characterise a particular normal distribution: (1) the mean of all scores obtained for the test and (2) a measure of the extent of dispersion of these values, generally expressed in the form of standard deviation. Once these values are known, the standard properties of the Gaussian (normal) distribution allow the proportion of subjects who will have a particular test score to be calculated. Thus, for example, 68% of patients will have a test value which falls within one standard deviation either side of the mean, and around 95% a value which is no more than two standard deviations from the mean. On the basis of the norm values, it will therefore be possible to calculate where a proband's score lies in relation to a reference population (Fig. 1).

Norm values for a particular test can be straightforwardly expressed by giving the mean and standard deviation. Once this information is available, a statement may be made about the position of the proband in relation to the reference population. However, a disadvantage of referring to the numerical value of the standard deviation for a particular test is that it is difficult to compare the results obtained by a particular proband for several different tests. To allow comparisons of this sort to be made, a z-value can be calculated; this is the result obtained in a particular test expressed in terms of units of the standard deviation for that test. Results obtained by a particular proband in different tests may also be compared using percent-

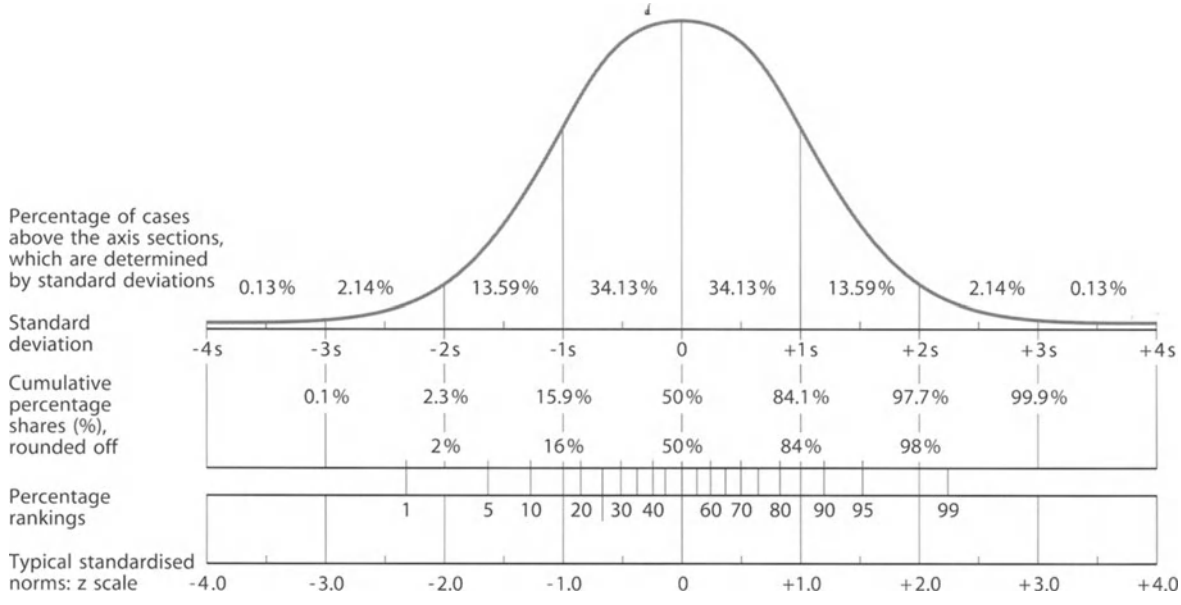

Fig. 1. Relationship between some frequently used standardised scales and the normal distribution curve

age rankings, by specifying for each test what proportion of a reference population has higher or lower scores for the test.

Various empirical methods may be used to test whether the test quality criteria specified above have been met. Appropriate ways of examining the reliability of a test include test–retest reliability, inter-rater reliability, the split-half correlation coefficient and internal consistency. To determine test–retest reliability, the same test is given to the same group of people at two different time points. The time between the two applications of the test depends on the interval to which the test is intended to apply. For tests in which the aim is to record enduring personality traits, an interval between applications of the test of between 14 days and 1 year is recommended. For tests where the aim is to record rapidly fluctuating characteristics (such as mood or subjective well-being), a time span between several minutes and a few hours is appropriate. Ideally, identical results should be obtained for each measurement, but of course this is not the case in practice, as measurement errors necessarily occur (related to strong influences caused by the test situation, practice effects, etc.). The correlation between the two values gives the test–retest reliability coefficient. Deciding whether the reliability of a test is sufficiently high depends very much on the purpose of administering the test (Hofstätter 1957; Meili 1961; Lienert 1969). As a rule, a reliability coefficient in excess of 0.8 is required. Methods for which the test–retest reliability is below 0.5 are not generally useful. The measurement accuracy of a test may be different for different diagnostic groups (differential reliability).

Several different procedures also exist for determining the validity of a test, e.g. examination of consensual validity, predictive validity, construct validity and content validity. Consensual validity is determined by correlating the results of applying the tests to a sample of probands with comparable data obtained by methods other than the application of the test (external criteria). For example, results for the test may be correlated with corresponding scores obtained for the same subjects for another test examining the same psychological characteristics. Whereas with consensual validity, test values and external criteria are measured at the same time, predictive validity is determined by investigating whether events predicted on the basis of the test results have actually happened. A classic example is the correlation of test results from an intelligence test with assessment at a later date of actual success at school.

A requirement which needs to be emphasised is that following translation of a scale from one language into another, new validity tests must be carried out with the translated version. This is also true if the scale is modified in any way.

3 Standardised Instruments for the Description of Psychopathology

Standardised assessment instruments relate to past or current behaviour and experience. The extent of psychological abnormalities is rated using fixed scales. These rating scales may focus on a single aspect, e.g. anxiety (unidimensional scales) or on several aspects (multidimensional scales) of psychopathology. For each aspect of psychopathology, assessment may be based on a global rating or on different elements within the aspect being assessed, e.g. on individual symptoms of the depressive syndrome. In this latter case, the overall score on the instrument is obtained by adding together values for these different elements.

The level of standardisation of standardised assessment scales, also known as rating scales, falls between that of unstructured clinical assessment and that of objective tests. In some of these instruments, standardisation is limited to providing guidelines describing items and the categories used for assessing them and to specifying a method of analysis (generally one or more summary scores are calculated). In other scales, a time frame is also stipulated for the assessment, and in some the framework in which observation takes place is also fixed. In the latter case, the instrument is referred to as a fully structured or standardised interview. The more extensive the standardisation procedures undertaken, the greater the reliability of an assessment instrument generally becomes. However, a highly standardised instrument tends to become less practicable. For this reason, both in everyday clinical use and in research, where resources are constrained, simpler scales such as the Present State Examination (PSE; Wing et al. 1978) tend to be preferred to fully structured instruments. The latter require a fully structured interview, whereas the simpler rating scales can be completed following a routine psychiatric interview. Particularly for the simpler rating scales, inter-rater reliability for observer-rated instruments can be improved by systematic joint training of the raters (Heimann et al. 1977). In principle, fully structured interview methods with extensive individual interviewing ought to produce high inter-rater reliability, and they therefore have particular advantages in multicentre, multinational studies in which great discrepancies need to be taken into account not only in terms of how mental states are assessed, but also in the psychiatric interview techniques used.

Standardised assessment instruments may be classified on the basis of who carries out the assessment into self-rated and observer-rated instruments. In observer-rated instruments, psychopathological abnormalities

are identified by trained assessors (e.g. doctors, psychologists, care staff, lay people trained to administer the instrument) or by significant others (e.g. partner, relatives, friends). The assessment concerns the behaviour and/or experience of the patient and is based on the assessor's own observations and/or information given by the patient. Observer-rated scales need to be constructed so that they are appropriate to the level of training of the particular types of interviewer to be involved in their administration. Thus there are scales for doctors trained in psychiatry, e.g. the AMDP (*Arbeitsgemeinschaft für Methodik und Dokumentation in der Psychiatrie*; Study-Group for Methodology and Documentation in Psychiatry) system (Baumann and Stieglitz 1983), for clinical psychologists, e.g. the Structured Clinical Interview (SCI; Burdock and Hardesty 1969), for care staff trained in psychiatry, e.g. the Nurses' Observation Scale for Inpatient Evaluation (NOSIE; Honigfeld and Klett 1965) and also for patients' relatives, e.g. the Symptoms and Social Behaviour Rating Scale for Relatives (Katz and Lyerly 1963).

Observer-rated scales mainly focus on psychopathological state, either with the global epidemiological question of classifying each individual overall as a "case" or "non-case", e.g. the interview developed by Goldberg and colleagues (Goldberg 1972), with the recording of specific aspects of mental state such as depression or anxiety, e.g. the Hamilton Depression Scale or the Hamilton Anxiety Scale (Hamilton 1959, 1967) or with assessment of the whole spectrum of psychopathology, e.g. the AMDP questionnaire (AMDP 1995). In scales which record the whole range of psychopathology, there is usually an emphasis on the detection of symptoms of functional psychoses, while only limited account is generally taken of organic or neurotic symptomatology. For specific measurement of the latter types of symptomatology, the use of scales which focus specifically on them is recommended (Table 1).

In addition to mental state, domains such as social adjustment (Weissman et al. 1981) or quality of life may also be measured by observer-rated scales. Examples include the Social Interview Schedule (SIS;

Table 1. Overview of clinical observer-rated schedules (examples)

Domain	Procedure	Reference	Abbreviation	Distinguishing mark
Global psychopathology	Brief Psychiatric Rating Scale	Overall and Gorham (1976)	BPRS	18 symptom complexes, overall score and 5 sub-scales
	Comprehensive Psychiatric Rating Scale	Asberg et al. (1978), Kuny et al. (1982)	CPRS	65 items, 4 sub-scales, 2 overall scores
	Befundbogen des AMDP-Systems (Rating schedule for the AMDP System)	AMDP (1995)	AMDP	140 items, 9 sub-scales, 3 overall scores
	Inpatient Multidimensional Psychiatric Scale	Hiller et al. (1986)	IMPS	90 items, overall score, 12 sub-scores
Depressive symptoms	Hamilton Depression Scale	Hamilton (1976a)	HAMD	17–21 items, 2–6 sub-scales
	Montgomery–Asberg Depression Scale	Montgomery and Asberg (1979)	MADRS	10 items, overall score
Mania	Bech–Rafaelson Mania Scale	Bech et al. (1978, 1991)	BRMAS	11 items, summary score
Schizophrenia	Positive and Negative Symptom Scale	Kay et al. (1988)	PANSS	30 items, summary scores, 3 sub-scales
Anxiety disorders	Anxiety Status Inventory	Zung (1976a)	ASI	20 items, summary score
	Hamilton Anxiety Scale	Hamilton (1976b)	HAMA	14 items, summary score
Obsessive–compulsive disorders	Yale-Brown Obsessive Compulsive Scale	Goodman et al. (1989a,b)		
Dementia	Arbeitsgemeinschaft für Gerontopsychiatrie	Gutzmann et al. (1989)	AGP-System	176 items, 6 sub-scales
	Alzheimer's Dementia Assessment Scale	Ihl and Weyer (1993)	ADAS	21 items, 1 summary score, 2 sub-scores

Faltermaier et al. 1987) and the Disability Assessment Schedule (Jablensky et al. 1980). Personality characteristics (Möller and von Zerssen 1987) and personality disorders can also be described using observer-rated instruments, as in the new methods of assessment of personality developed for the rating of axis II (personality disorders) of DSM-III (Pfohl et al. 1983; Saß 1986; Stangl et al. 1985). Standardised assessment instruments may also be used to document the side-effects of treatment with psychotropic drugs, as in the scales developed by Simpson and Angus (1970) for the documentation of extrapyramidal motor side-effects, or the UKU Side Effect Rating Scale, which includes a full spectrum of psychotropic drug side-effects (Lingjaerde et al. 1987).

On the basis of multivariate statistical analysis (factor and cluster analysis), the data obtained from administering rating scales may be used to derive factors. These factors identify groups of individual symptoms which tend to occur together. If we consider that the term "clinical syndrome" generally refers to a group of symptoms which frequently occur in combination, it then becomes apparent that the factors extracted from rating scales relating to mental state are conceptually identical to clinical syndromes. Multivariate analysis of the data obtained from different multidimensional psychiatric rating scales applied to different samples of patients has tended to repeatedly generate the same factors or symptom clusters (Cairns et al. 1983a,b; Gebhardt et al. 1981; Lorr et al. 1962; Mombour 1974a,b): paranoid-hallucinatory syndrome, manic syndrome, depressive syndrome, apathetic syndrome, hypochondriacal syndrome, phobic-obsessional syndrome, amnesiac syndrome. For some well-developed observer-rated scales, it has been shown that the factor structure also remains relatively stable across different studies, and for many of the factors this is true even with repeated measurements in the course of treatment (Baumann and Stieglitz 1983; Möller and Hacker 1988; Steinmeyer and Möller 1992). This invariability of the structure of factors across different samples and time points is an important aspect of the validity of a scale (factorial validity). Different psychiatric diagnostic groups are reflected in different characteristic syndrome profiles when rating scales are applied (Möller and von Zerssen 1980).

It is important to bear in mind that identically named syndromes from different scales may vary greatly in terms of the items included, and the correlation between analogous syndrome scores is not always very great. The more syndromes that are represented in a scale, the wider the range of its potential applications will be. However, in order to address specific questions, these broadly applicable rating scales should be combined with one or more specific observer-rating scales, e.g. when studying people with schizophrenia, specific scales for precise measurement of the negative syndrome should be included (Andreasen 1982). In the interests of economy, when research questions are narrow in scope (e.g. if they concern depression), it makes sense to administer specific scales which include only a few factors. As scales which measure the same domain (e.g. depressive symptoms) sometimes focus on different aspects of this domain (Mombour 1976), certain questions may be best addressed by using a combination of them. In terms of developing models of psychopathology, there is continuing debate on the relative merits of single-symptom versus syndrome research strategies (see Bentall 1992; Lenzenweger 1999). At present, the approaches are best viewed as complementary.

When observer-rated instruments are administered by professionally trained observers, it is usually assumed that, in making the rating, the observer decides how much weight to put on the information the patient gives, e.g. an observable improvement in general behaviour and demeanour is taken into account in the rating even if the patient gives no clear report of this improvement. An advantage of this expert assessment is that it reduces the scope for inaccurate assessments resulting from the distortions in patients' perception of themselves, but on the other hand it introduces the danger of distortions which are related to the assessment (rater bias). Systematic distortion in the assessor's observations (Hasemann 1971) can result from the following factors in particular:

1. *Rosenthal effect*: The assessor's expectations influence the result of the assessment.
2. Tendency on the rater's part to systematically *over- or under-rate* the degree of disturbance.
3. *Halo effect*: The result of assessment of one characteristic is influenced by the rater's knowledge of the subject's other characteristics or by the overall impression made by the subject.
4. *Logical errors*: The result of the assessment is influenced by the assessors reporting only those detailed observations which make sense to them in the context of their theoretical and logical preconceptions.

These errors may be partially compensated for by combining observer-rated scales with self-rated scales (von Zerssen 1979, 1982; von Zerssen and Möller 1980). In self-rated instruments, patients can themselves classify past or current behaviour and experience on the basis of fixed rating scales. Self-rated scales have the further advantage that their use is very economical for the assessor and eliminates observer bias. However, their use also introduces the disadvantage that conscious or unconscious tendencies to falsify responses (e.g. tendencies to exaggerate or conceal symptoms, the positive response bias, social

desirability effects) will have a greater impact on patients and are only partially detectable through use of control scales (so-called lie detector scales). Self-assessment procedures tend to be applied especially in order to identify enduring personality dispositions (see below) or current psychiatric disturbance, e.g. the *Klinische Selbstbeurteilungs-Skalen* (Clinical Self-Rating Scales, KSbS; von Zerssen 1976a–d, 1986) or the Self-Report Symptom Inventory (SCL-90; C.R. Derogatis 1977). Self-rated scales in the form of visual analogue scales (so-called barometer scales on which particular dimensions or current experience are graphically represented) are especially useful for intra-individual studies of course over time (Luria 1975). A problem with most personality scales in clinical use, e.g. the Minnesota Multiphasic Personality Inventory (MMPI; Dahlström et al. 1975; Hathaway and McKinley 1963), is that, contrary to their goals, they do not distinguish precisely between habitual personality dispositions and current disturbances in behaviour.

As with observer-rated scales, self-rated scales can also record domains other than psychopathological abnormalities, e.g. social adjustment (Weissman and Bothwell 1976), quality of life (Möller et al. 1996) or the side-effects of psychotropic drugs (National Institute of Mental Health 1976).

Apart from a few scales measuring current mental state which, as with the Self-Report Symptom Inventory (SCL-90), record a very broad spectrum of psychopathological symptoms, most self-rated scales focus on specific aspects of disturbance of subjective experience (Table 2). Examples are inventories of physical and systemic complaints (Fahrenberg 1975; von Zerssen 1976d), depressive symptom scales (Beck et al. 1961; Zung 1965; von Zerssen 1976b) or measures of general subjective well-being (Janke and Debus 1977; von Zerssen 1976c). One of the advantages of this approach is that the quantity of items is limited, a particular strength where severely disturbed psychiatric patients are concerned. In order to obtain a sufficiently clear view of the current psychological state from a subjective point of view, it is always better not only to present a checklist of adjectives describing complaints, but also to add other symptom-oriented scales such as the paranoid-depressiveness scale (von Zerssen 1976b).

However, very precise differentiation between different aspects of "subjective state" is probably not generally meaningful (von Zerssen 1979), in contrast to the detailed measurement of psychological disturbances which may be made by observer assessment. In fact, where results from clinical self-rated scales are compared with observer-rated scales administered by specialists, it seems that the various dimensions of the subjective state which self-rated instruments describe are more similar to one another than the different aspects of psychopathology delineated by clinical observer-rated assessments. This is indicated by joint factor analysis of data from observer ratings and self-ratings of mental state, for example (von Zerssen and Cording 1978). This finding was reported from a study in which the Inpatient Multidimensional Psychiatric Scale (IMPS; Lorr 1974) was applied as an observer-rated measure, while the KSbS (von Zerssen 1976a–d) were used as a self-assessed measure. The self-assessed data were mainly represented in a single factor, the first to emerge, while the observer-rated data were

Table 2. Clinical self-rated procedures (examples)

Domains	Procedure	Abbreviation	Author(s)
Global psychopathology	Self-Report Symptom Inventory	SCL-90	L.R. Derogatis et al. (1976)
		SCL-90R	CIPS (1996)
Depression	*Depressivitäts-Skala* (Depressive Symptom Scale)	DS	von Zerssen (1976b)
	Befindlichkeits-Skala (Mental State Scale)	Bf-S	von Zerssen (1976c)
	Beck Depression Inventory	BDI	Beck et al. (1986)
Anxiety disorders	Self-Rating Anxiety Scale	SAS	Zung (1976b), see also CIPS (1996)
	State-Trait Angst-Inventar (State-Trait Anxiety Inventory)	STAI	Laux et al. (1981)
Obsessive–compulsive symptoms	Hamburger Zwangsinventar (Hamburg Compulsive Inventory)	HZI	Zaworka et al. (1983), Klepsch (1989)
Alcoholism	Münchner Alkoholismustest (Munich Alcoholism Test)	MALT	Feuerlein et al. (1979)

distributed across five further factors. However, it cannot be concluded from this secondary factor analysis (in which the primary factors derived from initial analysis of each scale were also entered as variables) that self-assessment simply produces a factor reflecting a global tendency to complain rather than a differentiated picture of subjective impairment. Primary factor analysis based on single items from the KSbS and also on other self-rated instruments indicates that it certainly can be differentiated at a subjective level between different dimensions of disturbance, such as depressiveness, paranoid tendencies and somatic complaints. However, the depressiveness factor is closely associated with each of the various other types of subjective disturbance.

The level of agreement between self-assessment and observer assessment is variable and depends among other things on the type of disturbance and on symptom severity (Heimann and Schmoker 1974; Prusoff et al. 1972a,b; White et al. 1984). Thus, for example, where depressive symptomatology is severe, as at the time of inpatient admission, agreement is substantially more limited than after partial remission of symptoms at the time of discharge. This is probably connected with greater limitation of the capacity for self-observation among the severely depressed, and probably also with the fact that observers tend to recognise very severe depressive symptoms on the basis of non-verbal evidence to a greater extent than with less severe depressive symptoms, where the patient's verbal reports are more important. Compared with patients with endogenous depressions, those with neurotic depressions show a greater tendency to overstate their symptoms. Degree of agreement between self-rating and observer rating is substantially greater for the amount of change, as measured in longitudinal studies, e.g. in the context of treatment studies, than when psychopathological phenomena are recorded at a single cross-sectional time point (von Zerssen 1986; Möller and von Zerssen 1995).

Multi-methodological diagnostic procedures in which a combination of self-rated and observer-rated scales is applied (Möller et al. 1983; Seidenstücker and Baumann 1978) offer the best guarantee of satisfactory description of both subjective and objective psychopathological state. So far, this has rarely been taken account of in quality of life research, which has mainly been based on self-rating scales (see Vol. 1, Part 2, Chap. 7). In some rating instruments, a combination such as this is a specific requirement, e.g. the *Münchner Alkoholismus-Test* (Munich Alcoholism Test, MALT; Feuerlein et al. 1979). The *Nürnberger Altersinventar* (Nuremberg Old-Age Inventory) similarly requires a combination of self-ratings and observer ratings, further supplemented by tests of performance (Oswald 1979).

Measures of subjective well-being are of particular interest in the area of treatment assessment, particularly barometer scales which measure current disturbances of psychological well-being and lend themselves especially well to repeated measurement. These methods allow a very good description at the self-assessment level of response to a therapeutic intervention. Modern methods of statistical analysis, such as some of the procedures developed for time series analysis, allow satisfactory analysis of such data (Möller et al. 1987, 1989). A full discussion of such approaches is presented by Morley (1994).

Most survey instruments allow the description of current state and, with repeated application, can also be used to examine change over time.

Generally, any multidimensional instrument for examining psychopathology allows us to try to make a diagnostic classification by applying specific algorithms, e.g. to detect characteristic symptom profiles. As would be expected, the results of nosological classification based solely on psychopathological rating scales are not very satisfactory (Möller and von Zerssen 1980), as diagnosis is generally also based on information about clinical history and on hypotheses about the cause of the illness. The Catego system of Wing et al. (1974) is based on the PSE, together with a supplementary scale describing history. This combination allows very satisfactory results to be obtained in the sphere of functional psychoses, and it has now been applied in a variety of large national and international research projects (Wing et al. 1974).

In some simpler scales, a judgement about differential diagnosis may be made simply through calculations on the basis of fixed cut-off scores. Examples are the Newcastle Scale (Carney et al. 1965), designed to differentiate between endogenous and neurotic depression, and the Hachinski Scale, designed to distinguish between multi-infarct dementia and Alzheimer-type dementia (Hachinski et al. 1975).

In connection with the development of operationalised diagnosis systems such as the Research Diagnostic Criteria (RDC) and the Diagnostic and Statistical Manual III-R and IV (DSM-IIIR, DSM-IV), standardised survey instruments have been produced to allow examination of the aspects of clinical history and psychopathology on which the operationalised diagnostic criteria are based. As the RDC encompasses only endogenous psychoses, the corresponding survey instruments can of course be briefer than for the more extensive DSM-III system, which covers all diagnoses. The Schedule of Affective Disorders and Schizophrenia (SADS) was developed specifically for the RDC (Spitzer et al. 1975). For DSM-III, which covers all diagnostic categories, the Diagnostic Interview Schedule (DIS; Robins et al. 1982) was initially developed. A particular goal in the development of the DIS was that it should

be possible for it to be applied in epidemiological field studies by non-psychiatrists (e.g. social workers), but this concept did not lead to fully satisfactory results (Wittchen et al. 1985). A series of fully structured interview schedules and diagnostic instruments developed in the last decade allow both ICD-10 and DSM-III diagnoses to be generated: the Composite Diagnostic Interview (CIDI; Wittchen and Semler 1991), the Structured Clinical Interview for DSM-III (SCID; Wittchen et al. 1991) and the PSE-based Schedules for Clinical Assessment in Neuropsychiatry (SCAN; WHO 1991). An overview of the instruments developed in cooperation with the WHO is provided by Sartorius and Janca (1996). The SCID and the SCAN are currently being partly adapted to DSM-IV. These latter instruments were conceived from the beginning as coherent interview procedures with fully formulated questions (see Vol. 1, Part 1, Chap. 2), whereas the Polydiagnostische Interview (Polydiagnostic Interview, PODI; Philipp and Maier 1986), developed in Mainz, and the Polydiagnostisches System (Polydiagnostic System; Katschnig et al. 1987), developed in Vienna, simply set out and place in context the criteria for individual diagnoses in the diagnostic systems included – not only the RDC and DSM, but also a variety of others. Overall, all these instruments seem likely to lead to a considerable increase in inter-rater reliability in mental state assessment and diagnostic classification.

4 Standardised Procedures for Personality Assessment

Most standardised assessment procedures in personality diagnosis are self-assessment instruments. One of the oldest instruments, the MMPI (Hathaway and McKinley 1943), is still one of the most frequently applied world-wide. In its long form, the MMPI contains 566 items, which through the standard method of analysis provide summary scores on ten clinical and three validity scales. In addition, there are quite a number of short forms, including a German one by Gehring and Blaser (1993). A revised and newly standardised American edition has been available since 1989 (MMPI-2; Hathaway and McKinley 1989). The content of the MMPI items ranges from general statements ("I like reading technical journals") which describe interests and character traits to statements about overt psychiatric symptoms ("Sometimes I hear voices when other people do not hear them"). This and its empirical scale construction (selection of items which distinguish between a particular clinical target group such as depressed patients and a reference group, in this example non-depressed psychiatric patients), is the basis of the MMPI's leading position in psychiatric personality diagnosis. A further reason is the diverse range of validity information, which claims to make it possible to separate deliberately falsified test responses or chance responses from those indicating true psychological cases.

In the 50 years of its existence, thousands of publications about and using the MMPI have appeared (for a comparative review, see Butcher and Rouse 1996), and there is therefore much more information available to the user than its short handbook can convey. Much of the fundamental methodological work about personality questionnaires has been carried out on the basis of the MMPI (for reviews, see Meehl 1973; Wiggins 1973; see also Angleitner and Wiggins 1986). In fact, the MMPI has also been described as a "methodological nightmare" (Rodgers 1972), particularly because individual items may be counted several times over and contribute to up to six summary scales and because of the high correlations between individual scales which result from this and also from the overlap in content between different items.

Not least because of these criticisms, personality questionnaires have increasingly been developed in the United States which, unlike the MMPI, are not based on clinical experience and concepts, but on factor analysis methodology. This is based on the assumption that a more economical and stable description of personality is possible using such orthogonal scales. However, the superiority predicted in theory has not been demonstrated in practice. There are good empirical data which indicate that the various methodological starting points lead to qualitatively similar results (Burisch 1984). Examples of questionnaires constructed by factor analysis are the 16PF by Cattell (Institute for Personality and Ability Testing, Champaign, IL), the various questionnaires by Eysenck (most recently the EPS; Eysenck 1983) and in recent years above all the Big Five Questionnaires (see below) by Costa and McCrae (1992), which have had an important impact on personality psychology in the last few years. The sphere of application of these procedures is not so much in clinical practice as in occupational psychology or research. Only very recently have new developments appeared which have gone through an extensive process of development based on contemporary techniques and explicitly take into account the area of psychological disturbances. These are the Basic Personality Inventory (BPI) by Jackson (1989), a 240-item interview with 12 clinical scales, and the Personality Assessment Inventory (PAI) of Morey (1991), in which responses to 344 statements lead to ratings on a 4-point scale for 22 non-overlapping scales, of which four are validity scales, 11 clinical scales, five treatment scales and two interpersonal scales.

In German-speaking countries, the *Freiburger Persönlichkeitsinventar* (Freiburg Personality Interview, FPI) has come to be the most widely used personality test (Schorr 1995), both in its old edition of 1970 (Fahrenberg et al. 1970) and also in the revised edition FPI-R of 1984 (Fahrenberg et al. 1994). In addition to character traits in the narrower sense (e.g. inhibitedness, excitability, aggression, openness), the scope of the FPI-R also includes psychosomatic concepts such as somatic complaints, satisfaction with life and concerns about health. It thus extends beyond the relatively narrow realm of validity of "normal" personality inventories such as the 16PF (Schneewind et al. 1994), the Big Five Questionnaires NEO-PI and NEO-FFI (Costa and McCrae 1992) or the MPT, developed primarily on the basis of clinical psychiatric personality concepts (von Zerssen et al. 1988), to mention but a few, but it does not measure the full range of psychological disturbances. The Giessen-Test (GT; Beckmann et al. 1990) covers a similar domain of application, but places social psychological concepts at the fore (scales include dominance, susceptibility to influence, social power, social responsiveness, control and prevailing mood). The test is constructed on the basis of psychoanalytic theories.

In connection with the introduction of operationalised definitions of personality disorders in DSM-III (and its successors) and ICD-10, discussions took place about the extent to which self-assessment questionnaires or specific personality questionnaires could complement assessment or even stand alone as an economical screening method in the diagnosis of personality disorders. When this was tried both using existing instruments (e.g. MMPI; Morey et al. 1985; Colligan et al. 1994) and new questionnaires constructed specifically for this purpose (MCMI; Millon et al. 1994), it emerged that too much and probably the wrong thing was being expected of personality questionnaires if categorical agreement diagnoses rather than dimensional agreement with syndromes was required (Engel 1981; Dittman and Stieglitz 1994).

In order to avoid this conflict of purpose, specific instruments for the detection of personality disorder have been developed, based on the concepts of DSM-III, DSM-III-R, DSM-IV and ICD-10. These have essentially involved inclusion of additional observer ratings (Bronisch et al. 1995; Hyler et al. 1988; Loranger et al. 1994; Pfohl et al. 1989).

The International Personality Disorder Examination (IPDE; Loranger 1996) is a procedure which has already become widespread internationally and consists of a combination of a short screening questionnaire followed by a detailed interview with an experienced rater.

An important theme in psychopathological research, which has as yet been taken up relatively little internationally, is the description of premorbid personality in psychiatric patients and its possible influence on vulnerability and course. In this area, von Zerssen (for summaries, see von Zerssen 1993, 1994) has been a particularly significant contributor of concepts and instruments (MPI; von Zerssen et al. 1988).

5 Systematic Observation of Behaviour

In comparison with standardised assessment procedures, a higher level of objectivity is achieved in systematic behavioural analysis, in which only directly observable behaviour is recorded, e.g. counting up of particular details of behaviour or complexes of behaviour during defined periods of observation (von Cranach and Frenz 1969; Fassnacht 1979; Goldfried 1976). Audiovisual recording of behaviour opens up additional possibilities for these methods (Helmchen and Renfordt 1978). Because resource expenditure is great, systematic behavioural analysis has not taken on any great significance in everyday clinical practice apart from behaviour therapy, but has been preserved almost exclusively for research purposes. Even in research, it has generally been used in projects which are especially well staffed, e.g. in research on psychotherapeutic questions.

Systematic behavioural analysis appears to be particularly useful with complex social phenomena, e.g. analysis of the doctor–patient relationship or the interactions between partners (Scholz 1982), which could not be depicted in a sufficiently detailed way through simple rating scales. Interactional analysis involves not only the recording of simpler (e.g. eye contact; Wagner et al. 1983) and more complex modes of behaviour (e.g. content of speech; Winkler and Ellgring 1981), but also analysis of their sequences and of the recurring patterns which appear in these sequences (Hahlweg et al. 1984; Hirschbrunner et al. 1981).

For the study of non-verbal aspects of behaviour (Ellgring 1981), systematic behavioural observation is the most appropriate research method. The potential field of application is wide here. For clinicians, the methods promise to be especially interesting for diagnostic and treatment studies, e.g. of patients with depression (Ellgring and Clarke 1978). These methods not only allow examination of particular aspects of gesture and expression (Ekman and Friesen 1978; Ellgring 1986; Ellgrin and Nagel 1986; Polzer et al. 1992), but can have as a goal the study of the overall functioning of the psychomotor system (Frey et al. 1979, 1981). They are particularly useful where verbal communication is not possible, such as with the severely demented (see Gaebler and Hemsley 1991).

Not only non-verbal but also verbal communication may of course be examined by systematic behavioural observation (Matarazzo and Wiens 1977; Weintraub and Aronson 1967; Winkler and Ellgring 1981). Study of speech may focus on the form of speech (volume, pitch and rate), on the length of utterances or on content. Well-known methodologies include content analysis based on the Gottschalk-Gleser procedure (Gottschalk and Gleser 1969) and the Ulm methods for computerised analysis of the form and content of psychotherapeutic communication (Kächele 1976; Mergenthaler 1985).

6 Objective Tests

The data obtained from objective tests in the narrower sense of the word are derived not from the subject's statements, but from his or her reactions to fixed "stimulus material". Such tests allow analysis of particular psychological or psychologically related functions such as perception, concentration, attention and motor functioning, generally focusing on the performance aspect of these (Jäger and Petermann 1992; Brickenkamp 1996). One of the central aims of the measurement of memory and of "higher" cognitive functions (such as word comprehension or the visual motor system) is the objective demonstration of disturbances of function resulting from organic brain disorders (Lezak 1983; von Cramon et al. 1993). Other useful functions are the measurement of the effects of drugs or psychotherapy, e.g. showing improvement in concentration after anxiety reduction through psychological treatment. Such measures are also increasingly seen as being useful as predictors of real life functioning in schizophrenia (see Wykes et al. 1992). A problem for most psychological performance tests is that no standards are available for the older age-groups with whom old-age psychiatry is concerned. In this respect, the performance tests included in the Nuremberg Old-Age Inventory (Oswald and Fleischmann 1995) represent an important advance.

According to a survey carried out by Schorr (1995) of a representative sample of members of the German Association of Psychologists, of the test procedures carried out in German psychiatric treatment settings, around 24% are intelligence tests, 6% tests of general performance, 59% personality tests and 9% tests of personality development or projective test procedures. Of the intelligence tests, the Wechsler-based procedures – all versions of the *Hamburg-Wechsler Intelligenztest für Erwachsene* (HAWIE), the German version of the Wechsler Adult Intelligence Test Scale (WAIS), and the *Hamburg-Wechsler Intelligenztest für Kinder* (HAWIK), the German version of the Wechsler Intelligence Scale for Children (WISC) – were by far the most common (40% of respondents used the test frequently), and of the personality tests it was the *Freiburger Persönlichkeitsinventar* (by a long way, 37% of respondents), followed by the Giessen-Test and the MMPI. Of the projective procedures, the Thematic Apperception Test (TAT), the Sceno-Test and the Rorschach-Test continue to be used by 13%, 13% and 9% of respondents, respectively. These figures indicate a conservative tendency to adhere to old established test procedures, even though new tests are appearing on the market almost daily.

In the clinical sphere, the best-known and most internationally widespread are the intelligence tests of Wechsler, whose current form is the Wechsler Adult Intelligence Scale-Revised (WAIS-R; Wechsler 1981). In contrast to modern intelligence tests based on factor analysis and despite a number of revisions, the WAIS has psychometric weaknesses, including relatively high correlations between some sub-tests, lack of an objective method for analysis of the open items in the test and limited standardisation of the conditions in which it is carried out (e.g. Weise 1975). However, in clinical use, this disadvantage is more than compensated for by other factors, such as high attractiveness of the test materials, variety and clinical relevance of the test tasks (Klingler and Saunders 1975) and constant contact with the tester; indeed, the limited standardisation of the test situation as a result of the use of open questions, the heterogeneous test material and the interactive way in which the test is carried out are responsible both for some of its weaknesses and for its strengths.

Particularly in the clinical sphere and for people with low intelligence, the IQ scores obtained from the HAWIE-R lie on average up to 10 points below those delivered by the old version of HAWIE (Satzger et al. 1996a). Still greater IQ shifts in the standardisation studies were found in the earlier revision of the HAWIE-R (Schallberger 1987) and clearly show the problems arising from the use of older test norms. Changing from one test to another may lead to substantial errors on repeated measurement if appropriate corrections are not made.

Similar problems with the comparability of different norms can arise when short procedures to estimate general intelligence such as the *Reduzierte Wechsler Intelligenztest für Psychiatrisch Kranke* (Short Wechsler Intelligence Test for the Mentally Ill, WIP; Dahl 1968) or vocabulary tests such as the *Wortschatztest* (WST; Vocabulary Test) (Schmidt and Metzler 1992) or the *Mehrfachwahl-Wortschatz-Intelligenztest* (MWT-B; Multiple Choice Vocabulary Intelligence Test; Lehrl 1989) are used for reasons of economy. When a single sample was examined with both the

WIP and the HAWIE, discrepancies of the order of 9 IQ points were found (Orgass and Hartje 1974), indicating that the WIP values cannot be seen as numerically almost identical to the HAWIE values. The relationships with the HAWIE of norms for the more frequently used vocabulary tests vary: the MWB-R in particular provides considerably higher estimates of IQ than the HAWIE-R, while systematic deviations in norms from the HAWIE-R were not found for the WST (Satzger et al. 1996b).

In the clinical psychiatric sphere, there have been attempts not only to apply the Hamburg-Wechsler Test as a measure of global intelligence, but also to use it to describe strengths in performance and to assess differential diagnostic questions. Profile interpretations and the calculation of various indices, e.g. a quotient of discrepancies or the relationship between verbal and performance IQ, have been used to try to describe characteristic differences in the structure of intelligence between neurotic people, schizophrenics and patients with organic brain damage and even to differentiate between different forms of organic brain disease (e.g. Hobi and Klär 1972; Köhler 1974; Scheller 1973; Scheller and Sittauer 1974; Wechsler 1956). However, other studies indicate that this endeavour should be treated with considerable scepticism (Bäumler 1969; Dahl 1968; Hahlweg 1980; Hunger and Kleim 1976; Mayer et al. 1969; Seydel 1972; Sturm et al. 1975). Most of these indices are derived from theoretical considerations or have been devised or discovered more or less ad hoc on the basis of rather small samples. On a more empirical basis, Baxa and Pakesch (1972) used standards from the HAWIE to develop their Organicity Index, which compares the age-susceptible sub-tests Number Symbol Test and Mosaic Test with the relatively stable tests of "general knowledge" and "general understanding". This index rises sharply with age and thus often allows a clinically meaningful statement to be made about "premature cognitive ageing" (Engel and Satzger 1988; see also Giambra et al. 1995; Rebok et al. 1990). In an empirical investigation of the validity of different indices in distinguishing patients with diffuse organic brain disorders from a group with a variety of neurotic disturbances, this index did hold its own (Baud and Rauchfleisch 1982), although Lindsay and Powell (1994) argue that any such indices should be interpreted cautiously.

A criticism of the Wechsler test which is frequently put forward relates to its high level of dependence on speech, which it has been suggested makes the test results very susceptible to social and educational influences. At the opposite pole, there are a variety of speech-free intelligence tests such as Raven's Matrices (Standard Progressive Matrices, Advanced Progressive Matrices, most recently published in German in Raven 1996a,b) or the Culture Fair Intelligence Tests of Cattell (Institute for Personality and Ability Testing, Champaign, IL). These tests are often very valuable in the clinic, even if they cannot always fulfil their promise of great fairness with respect to sociocultural influences.

In making diagnoses in clinical psychiatric practice, tests of general performance are also frequently applied, e.g. the Pauli Test, the *Konzentrationsleistungstest* (Concentration Performance Test, KLT) and the *d2 Aufmerksamkeits-Belastungs-Test* (d2 Attention Performance Test). In people with mental illnesses, values falling below the expected norms are generally found (Brickenkamp 1994). They allow measurement of performance ability in simple visual-motor or routine cognitive tasks. The validity of these concentration tests in differential diagnosis between organic and non-organic psychological disturbances is not established (Arnold 1975; Eich 1978; Hahlweg 1979), and as the cognitive capacities required vary from test to test, their interpretation can be very difficult even with organically impaired patients.

Differential diagnosis of organic brain disturbances has always been of particular importance in routine clinical practice. In the past, it was usual to apply single tests such as the Benton-Test (Benton 1972) or the *Diagnosticum für Cerebralschädigung* (Diagnostic Test for Brain Damage, DCS; Hillers 1993), generally in combination with a general intelligence battery such as the WAIS. This approach focused excessively on relatively global psychological functions, which are known to often be substantially influenced by non-organic psychological disturbances, as in depressive pseudodementia or the cognitive disturbances characteristically found in patients with schizophrenia (Chapman 1979; Fieguth and Gonzalves 1977). More recently, prevailing test practice has been strongly influenced by neuropsychology, one of whose undoubted effects has been to sharpen awareness of whether the right question is being asked. In psychiatric clinics, detailed neuropsychological results are increasingly collected, in which individual domains of cognitive functioning are examined with specific procedures (Keefe 1995; Reischies 1987; Hartje 1981). Unfortunately, no consensus has yet been reached in this process regarding the precise procedures which should be used. This is in part because assessments vary in their aims, and these need to be clearly specified.

Comprehensive batteries of neuropsychological tests, of which expectations were high in the 1970s and early 1980s, e.g. the *Tübinger Luria-Christensen Neuropsychologische Untersuchungsreihe* (TULUC) by Hamster et al. (1980) or the *Luria Nebraska Neuropsychologische Testbatterie* (LNNB) by Golden et al. (1980) have only rarely been used, in one case (TULUC) because of excessive complexity of administration, validation and interpretation, in another (the

LNNB) because of heavy criticism (e.g. Adams 1980) of a tendency to over-simplify, coarsen and abbreviate. Moreover, while the idea of a unitary "cognitive measurement technology", embodied in a comprehensive measurement methodology, is appealing and has many adherents, especially in the United States (e.g. Russell 1994), this approach tends to break down when attempts are made to apply comprehensive batteries in practice.

A more promising approach is a flexible one in which the individual areas of functioning to be measured are selected more precisely on the basis of the particular question being asked (Bauer 1994; Benton 1994). To a large extent, this is a return to Luria's syndrome analytic approach to description of higher cortical functions (Luria 1970), which starts from a comprehensive and systematic reduction to their components of complex modes of behaviour. The analysis of the cognitive effects of brain damage is ideally suited to single-case methodology, as discussed by Canavan (1994).

Precise measurement of cognitive deficits is especially important in people with dementia (Carlesimo and Oscar-Berman 1992; Butters et al. 1995) and people with schizophrenia (Elliott and Sahakian 1995; Frith 1992). Here, two domains of functioning have particular importance: attention and memory performance in the case of dementia and "executive functions" (planning and judgement ability, mental flexibility, decisiveness) in schizophrenia. Speed of cognitive performance (as discussed by Schuri et al. 1994) is measured using reaction time measurements in paper and pencil tests such as the *Zahlen-Verbindungs-Test* (Number-Joining Test) or the Trail Making Test (new norms in Spreen and Strauss 1991), and selective attention using the aforementioned d2 Attention Performance Test. The usefulness of the Continuous Performance Task (CPT; Cornblatt and Keilp 1994; Kathmann et al. 1996) in measuring sustained attention, particularly in schizophrenia research, has been established, but the various forms of the test may reflect different psychological processes (see Nuechterlein et al. 1994).

Memory tests which are quite commonly used include a wide range of forms of word lists, e.g. Rey's auditory verbal learning test (description and norms, e.g. in Lezak 1983 and Spreen and Strauss 1991) or the corresponding sub-tests in the Alzheimer's Disease Assessment Scale (ADAS; Rosen et al. 1984) and the *Demenztest* (Dementia Test; Kessler et al. 1988), memory batteries containing a wide variety of tasks such as the revised version of the Wechsler Memory Scale (WMS-R; Wechsler 1987) and more recent computerised test procedures which make somewhat easier the work of the tester, which may be all too monotonous (Satzger and Engel 1996). The classical Benton Test should also be mentioned here (Benton 1996); in addition to memory, this test also requires awareness, visuospatial awareness and motor abilities. These abilities are often diffusely disturbed in patients with organic brain deficits, which explains the relative sensitivity of the Benton Test as an "omnibus test" for organic brain disorders (Larrabee et al. 1985; von Kerekjarto 1961; Strunk and Faust 1967). However, it has not been clearly established whether the Benton Test is valid in making a differential diagnosis when applied to other samples of psychiatric patients (Hasse-Sander et al. 1996; Hahlweg 1979; Hegenscheit and Cohen 1972; Velkoborsky 1964). For example, memory impairment in schizophrenia is particularly well documented (e.g. Saykin et al. 1991).

To measure planning ability (executive functions), the Wisconsin Card Sorting Test (WCST; see Nelson 1976) and the book version of Halstead's Category Tests (HCT; DeFillipis and McCampbell 1976) are often used. Together with the CPT, these latter instruments are also popular as stimulation tests in functional brain examinations with electrophysiological or radiological methods, in which localised brain functions are being described (e.g. Seidman et al. 1994; Catafau et al. 1994; see also Malloy and Richardson 1994).

Measurement instruments have a particular role in the area of dementia. While psychological tests generally measure circumscribed areas of performance across a wide range of subjects, in dementia instruments focus on measurement of a wide range of cognitive abilities which cannot very clearly be separated from one another, targeting a limited specific group of subjects. Typically, they are not standardised in the usual sense, but instead reference values are provided for particular groups and particular grades of severity.

A very frequently used instrument is the Mini-Mental State Examination (MMSE) by Folstein et al. (1975). The MMSE is a simple screening instrument to measure severe cognitive disturbances in older people. In the space of 5 min, questions and tasks are administered in the areas of orientation, attention, calculation, memory, speech and performance of simple tasks, and a global score is calculated. The MMSE is probably the most frequently used instrument to describe the level of severity in samples of demented patients.

While the MMSE can be administered without difficulty by someone with quite a basic level of training (and in this respect resembles most psychological tests), this is no longer the case for other procedures. The *Strukturiertes Interview für die Diagnose vom Alzheimer-Typ, der Multiinfarktdemenz und Demenzen anderer Ätiologie nach DSM-III-R und ICD-10* (Structured Interview for the Diagnosis of Alzheimer-

Type Dementia, Multi-infarct Dementia and Dementias of other types according to DSM-III-R and ICD 10 (SIDAM) by Zaudig et al. (1990) begins by setting similarly simple cognitive tasks, but the scope of the instrument then goes beyond that of the MMSE (the MMSE rating can be calculated on the basis of the SIDAM) with the inclusion of clinical ratings, allowing greater specificity about the diagnosis of dementia. Two further commonly used instruments in the area of dementia also consist of a similar combination of tests and rating procedures.

The Alzheimer's Disease Assessment Scale (ADAS; Rosen et al. 1984) is an extended form of the MMSE; it gives more weight to deficits in memory and is primarily applied in clinical trials of anti-dementia drugs. The Cambridge Mental Disorders of the Elderly Examination (CAMDEX; Roth et al. 1988) is a more extensive procedure; in addition to 60 standardised presented cognitive items, it also calls for interviews with the patient and with an informal carer. The advantages and disadvantages of a variety of cognitive measures for use with the elderly are presented by Woods (1994).

Assessing the Quality of Life in Mental Illness

Translator: K. Schlag

1 Health-Related Quality of Life as a Subject of Psychiatry

Whenever in the past few years goals and standards for the assessment of medical management have been debated, health-related quality of life has increasingly been an issue (Najman and Levine 1981; Spilker 1996). This development originated in the question of whether the classical medical treatment outcome criteria (symptoms, survival time) provide a sufficient basis for treatment. With the definition of health as suggested by the World Health Organization (WHO) in 1947 (i.e. physical, mental and social well-being) in mind and based on a humanistic view of patients as individuals, the concept of health-related quality of life reflects our modern-day philosophy (Schölmerich and Thews 1992).

Health-related quality of life is defined by international agreement as well-being and functioning – physically, psychologically (i.e. emotionally and mentally) and socially – as reported by the patient (Bullinger 1991). The WHO working group on quality of life defined this term as an individual's subjective perception of his or her own role in life in relationship to the culture and value systems he or she lives in and taking into account the goals, expectations, standards and concerns of a person. This is a working concept that is influenced in a complex manner by physical health, the psychological state, the extent of independence, social relationships and marked characteristics of a person's surroundings (WHOQOL Group 1994). It comprises many areas – physical, psychological, functional, social, moral and spiritual – as well as minor aspects of these.

The concept of quality of life is not new in that it sets the standard for a physician's decisions, but in that it is an attempt to assess the subjective well-being and functioning of a patient, which could thus become accessible for scientific research. Consideration needs to be given to the fact that health-related quality of life cannot be measured directly and is a theoretical psychological concept that can only be assessed if the relevant aspects and components are operationalised, keeping in mind the multi-dimensionality and subjective quality of the concept (Bullinger 1996).

The assessment of quality of life can be considered as established in medicine, pioneers having been those working in the field of oncology, surgery and cardiovascular medicine (see Spilker 1996), whereas the subject of quality of life only sporadically began to be discussed in psychiatry in the 1980s and only more extensively in the past few years (Lehmann et al. 1982; Katschnig and König 1994; Möller et al. 1996).

The reasons for this relative inactivity in psychiatry in comparison with other medical disciplines are manifold (Hogan and Awad 1992; Helmchen 1990; Lehmann 1996).

The main reason seems to lie in the belief that psychiatry has always essentially and primarily been concerned with the well-being and functioning of the patient, as these areas represent symptoms of psychiatric illness. This can be countered by arguing that an assessment of the symptoms of a psychiatric disorder cannot be compared with quality of life as experienced by the patient.

A second reason can be found in the assumption that the patients' self-report will be distorted – precisely because of their psychiatric illness – and therefore will not be reliable. This applies especially for psychotic episodes in the course of schizophrenic diseases, but also for affective disorders such as depression. In these cases, symptoms and quality of life are almost identical. It remains questionable whether patients are always able to describe and assess their well-being and functioning adequately and whether a psychiatric patient's judgement of his or her own personal experience and behaviour differs in principal from that of patients with other disorders.

A third reason has to do with the sceptical attitude many have towards the validity of such a complex concept as the quality of life. Not only has the lack of a theoretical backing for quality of life of patients in general and psychiatric patients in particular been criticised, but doubts have also been expressed concerning the question of whether an interpersonal, not individually centered assessment of quality of life with standardised instruments is even possible, meaningful or desirable. This brings up the issue of the theoretical foundation and measuring models that the quality of life assessment instruments are based on, especially with respect to their applicability to psychiatric patients.

A fourth reason is to be found in ethical objections to quality of life research. The concept of health-related quality of life implies certain values and is connected with implicit standards that refer to experience and behaviour. If the term "quality of life" is used in order to postulate an ideal standard and to assess patients according to their achievement of this standard, a discussion of "worthwhile living" – including the dark German history in this matter – becomes inevitable. In this context, the issue arises of the extent to which the concept of "health-related quality of life" brings us a step forward (towards more say and an optimisation of treatment for patients) or a step backward (towards establishing outlived role concepts and classifications of psychiatric patients).

2 Concepts of Quality of Life

The concept of quality of life has played a role in sociological literature ever since the 1940s and 1950s. In the 1960s, in particular, large and even intercultural studies were conducted to explore the quality of life in different countries, "quality of life" being defined primarily in the context of socio-economic resources and people's health standard in a country and assessed by various means, e.g. in terms of the gross national product and the rate of newborn mortality. Campbell (1981) took a more individual approach to quality of life research in America in his study on the *Quality of American Life*, in which questions were answered concerning the individuals' satisfaction with life. Likewise, Glatzer and Zapf (1984) examined the quality of life in the Federal Republic of Germany. An important contribution to the discussion on quality of life has also been made in psychology, using the term "well-being" (Abele and Becker 1991).

The concept of quality of life was introduced fairly late in medicine. According to several authors, it was introduced by an early article in 1967, while others believe it entered the field of medicine when more began to be written on the subject (Spilker 1996). It did not take very long for "health-related quality of life" to become a recognised expression, in contrast to the term "quality of life", as defined in sociology, because in medicine aspects of human experience and behaviour need to be regarded with particular reference to health (Patrick and Erikson 1992). North America especially, but also England, plays a leading role in research in the area of quality of life, referred to in these countries as "health outcome research" (Stewart and Ware 1992).

In Germany, the concept of quality of life was welcomed somewhat reluctantly, and systematic and broader attempts at research in this field have been noted since the end of the 1980s.

In contrast to the literature on happiness, well-being and satisfaction, which is at least partially empirically based, it is very surprising how little theoretical work has been done on the concept of quality of life so far in medicine (and, for that matter, in sociology). An early compilation of the aspects of quality of life (Calman 1987) includes different approaches, none of which can be called theories in a scientific sense, because they tend to represent basic definitions and simple models.

Basically, three types of quality of life models can be differentiated. The first focuses on the individual and postulates that quality of life can never be assessed independently of the person in question, as it differs by definition from one person to another in its dimensions. The advocates of this approach presuppose that quality of life can only be described intra-individually.

A second category of definitions is based on the assumption that quality of life can be assessed for a limited number of aspects that are relevant to different individuals. Various authors agree that these aspects seem to be the health aspects defined by WHO, namely physical, mental and social well-being. The corresponding approaches to measurement attempt to make this dimensionality accessible to assessment and to characterise individuals according to their fulfillment of a certain aspect or patterns of different aspects.

A third group of definitions postulates that quality of life cannot be measured as a relevant aspect either intra-individually or inter-individually, but that quality of life is an implicit concept. In this case, it is presupposed that quality of life cannot be ascertained by direct questioning but can only be implicitly assessed depending on the priorities of the patient. This is the so-called health-economic or cost-utility approach to measuring quality of life; the individuals concerned assess their health outcome with the help of certain state of health scenarios or approaches taken from game theory.

Each of these roughly outlined conceptual approaches has led to the emergence of a specific methodology that has manifested itself in the development of measuring tools. As far as the basic question of the definability of quality of life is concerned, there is agreement that a nominal definition would not make sense, that an operational definition exists and that a truly scientific theoretical basis is not feasible at the present time (Bullinger 1991). The operational definition is preferred by researchers who postulate inter-individual universality of quality of life, referring mainly to the above-mentioned aspects of physical, mental, social and functional health from the perspective of the individuals concerned. The assumption is that, on a high level of abstraction, people differ less than expected in their appreciation of quality of life.

There are approaches in the literature on social psychology concerning the theoretical discussion of a general quality of life concept that show that quality of life assessments depend on complex "social comparisons" (Glatzer and Zapf 1984), on the individual relationship between expectation and achievement ("goal attainment"; Brunstein 1993) and on processes of adjustment to external circumstances (adjustment level theory).

Angermeyer (1994) employs somewhat different models in psychiatric research for the quality of life assessment of mentally ill individuals. The basis of these is the assumption that the concept of quality of life far exceeds disease-related aspects such as symptoms, impairments and disabilities and comprises the

patient's very subjective experience of his or her objective life situation. The models include the satisfaction model, the necessities model and the role function model. The *satisfaction model* postulates that a patient's quality of life results from his or her objective circumstances in different areas of life and his or her satisfaction with these circumstances (Lehmann 1983). The component "significance" needs to be included in the satisfaction model because people differ in their individual values and preferences when confronted with different objective circumstances of life (Becker et al. 1993).

In contrast to the satisfaction and significance models, the *necessities model* is explicitly based on the hierarchy of human motives as described by Maslow (1970). Bigelow et al. (1982) also express the opinion that happiness and satisfaction are based on social and environmental conditions that form a basis for the fulfillment of needs. Katschnig (1994) critically points out, however, that a multi-dimensional rather than hierarchical view of human needs has an important function and that the quality of life of psychiatric patients can be seen as a reduction of disabling factors. This approach is similar to the role function models that stress the fulfillment of socially expected roles, as is also true for the applications of the quality of life model, e.g. of rehabilitation research.

Bech (1996) postulates that patients' health-related quality of life can be compared with the subjective assessment of their own health profile, which he describes as subjective well-being. He suggests an approach which differentiates between varying levels of assessment and, in the assessment of quality of life, between an incidence-related (i.e. objective) and an assessment-related (i.e. subjective) approach. In so doing, he differentiates aspects of quality of life according to physical (P), cognitive (C), affective (A), social (S), economic (E) and ego strength-related (E) aspects. The resulting PCASEE model is both a theoretical model and a way to assess quality of life, with incidence relating to the severity of the symptom and assessment relating to the evaluation of a symptom's effect on the patient's well-being.

The question of whether quality of life depends more on objective circumstances of life or more on subjective perceptions of well-being and functioning has been much more controversial in psychiatry than in other medical disciplines. Objective circumstances of life include living situation, work and recreational possibilities, the availability of which is seen as an indicator of a high quality of life. With this approach, however, several problems come up: It is not clear (a) whether the objective circumstances are an inherent part or external determinants of quality of life, (b) whether how favourable the objective circumstances are, as assessed by the external observer, coincides with the subjective experience of the patient and (c) whether quality of life assessment should not rather focus on the subjective extent of well-being and functioning after all.

In a survey of the approaches used to date towards an assessment of quality of life in psychiatric patients, Kilian (1995) notes that there is little to no correlation between objective circumstances of life and subjective satisfaction and that treatment has only a short-lived effect on a person's subjective satisfaction with life, which returns to its original level in the course of treatment.

3 Methods for Assessing Quality of Life

The focus on quality of life in medicine has not only led to a considerably higher number of relevant publications, but also to the development of a multitude of measuring tools for quality of life assessment. In currently more than 20,000 publications, 800 instruments for the assessment of quality of life are to be found. These are usually questionnaires, but also include interviews, mainly ascertaining self-reporting by the patient, but also ratings by other people (e.g. family, nursing staff). The measuring tools available to date (see Table 1) can be roughly divided into those that assess the non-disease-specific quality of life of the respondents, i.e. that can be applied to healthy or sick individuals independently of their current health condition, and those that assess quality of life specifically for a certain illness, so-called disease-specific measuring tools. In this respect, a difference can again be made in psychiatry between methods that are applicable to chronically mentally ill patients in general and those that were developed specifically for certain disease entities (e.g. schizophrenia, depression, anxiety disorder).

3.1 Generic Methods

The generic methods are particularly well established in the American-speaking countries and were developed in the course of epidemiological, public health and health systems research (McDowell and Newell 1987; Spilker 1996). Among these are instruments such as the Nottingham Health Profile (NHP; Hunt et al. 1981), the Sickness Impact Profile (SIP; Bergner et al. 1981), the SF-36 Health Survey (Ware and Sherbourne 1992) and the General Health Rating Index (GHQ; Goldberg and Hillier 1979). The SCL-90 is also increasingly being used as an assessment instrument

Table 1. Scales for the assessment of quality of life of psychiatric patients

for quality of life (Derogatis et al. 1973). These methods are also available in German and can be employed independently of the patient's current health condition and refer to a self-report of mental, social and physical well-being as well as of behaviour in everyday life. Moreover, methods have recently been developed in German-speaking countries that explore satisfaction with and significance of certain areas of life (e.g. Huber et al. 1988), such as the Munich life quality dimension list (MLDL; Heinisch et al. 1991; Franz et al. 1996), or that assess the instrumental component of quality of life (Questionnaire on Everyday Life; Bullinger et al. 1993).

Newly developed and currently being tested in psychiatry is the quality of life questionnaire brought out by WHO (WHOQOL Group 1994). This research is particularly interesting as, in the course of developing the questionnaire, representatives of different cultures were asked to identify the essential aspects of quality of life (Sartorius 1995). The resulting discussion brought forth a matrix of relevant quality of life aspects that – by relating back to the corresponding individual culture – could then be filled with content on location by means of focus groups, i.e. the individual cultures were asked to formulate different items for the assessment of these aspects. Fifteen nations participated in the study, and the resulting item pool of over 3000 questions was translated into English and tested by an expert group for redundancy. At the same time, the aspects of quality of life were weighted independently of the different countries. The resulting matrix of over 300 questions, which referred to both subjective perception and the current condition concerning certain aspects of quality of life, was tested psychometrically in a further study on 300 people in 15 countries (on a total of 4500 individuals). The results of the psychometric testing, inter alia using structural analysis techniques, lead to the conclusion that culture-independent essential aspects exist in psychological, physical, social, spiritual, functional and economic areas, although minor differences were found in the significance of these aspects for the individual cultures.

3.2 Disease-Specific Methods

In the past few years, especially in Anglo-American countries, a series of methods have been developed that assess the disease-specific quality of life of the mentally ill.

Among these is the Standardized Social Schedule (SSS; Clare and Cairns 1978). It is performed as an interview, includes 48 questions and takes approximately 45 min. It has been tested psychometrically and is also available in German; it covers six life domains: living situation, occupation, social role, economic situation, leisure and social activities and family.

A semi-structured interview is found in the Community Adjustment Form (CAF; Stein and Test 1980). This interview assesses quality of life using 140 questions referring to 12 aspects with regard to leisure, circumstances, occupational background, etc. The Quality of Life Checklist (QLC; Malm et al. 1981) is a rating scale covering 93 items on 13 areas of life that can be performed in the context of a semi-structured interview. The Satisfaction with Life Domain Scale (SLDS; Baker and Intagliata 1982) is a self-report assessed by questionnaire exploring 15 items on satisfaction with different life domains. The Oregon Quality of Life Questionnaire (OQLQ; Bigelow et al. 1982, 1990) exists as a structured interview that assesses the patient's self-report (263 items) and as a semi-structured interview that is assessed by the interviewer (146 items). The OQLQ results in 14 scale scores and takes approximately 45 min. The psychometric characteristics of the OQLQ have been evaluated for varying patient populations. This is also true for the Quality of Life Interview (QOLI; Lehmann 1988; Lehmann et al. 1986, 1993), which consists of a structured interview version for the patient's self-report. It has 143 items and takes 45 min to perform, comprising eight aspects of life (life situation, daily activities and functions, family relationships, social relations and finances, work and school, legal and security aspects and health). An objective description of circumstances of life and a subjective assessment of satisfaction with a specific life domain are made. The Quality of Life Scale (QLS; Heinrichs et al. 1984) is a semi-structured interview that has not yet been tested psychometrically; it is filled out by a trained clinician. It includes 21 items that reflect the interviewer's assessment of the functioning of the patient in each of the 21 domains and takes 45 min to perform. The 21 items can be reduced to four scales, namely basic intrapsychic elements, interpersonal relationships, instrumental role functions and a total value. The Client Quality of Life Interview (CQLI; Mulkern et al. 1986) is a structured interview of a person's self-report and is carried out by a trained interviewer. It consists of 46 questions that assess the patients and 19 interviewer ratings with ordinal scales. For each life domain (e.g. basic necessities of life, professional training, daily activities, privacy), both the activities and the subjective feelings of the patient are explored. The California Well-Being Project Client Interview (CWBPCI; Campbell et al. 1989) was developed for patients (151 questions), for family members (76 questions) and for doctors and nurses (77 items). The questions are asked in the form of an interview, although completion and submission by post by the patient or group administration by questionnaire is

also possible. The Lancaster Quality of Life Profile (LQOLP; Oliver 1992), based on the QOLI by Lehmann, is a structured interview of the patients' self-report carried out by trained nursing staff and takes 60 min. The 100 items assess both objective and subjective aspects of the quality of life in several domains, including work, education, leisure, participation in social activities, religion, finances, life situation, legal and security aspects, family relationships, social relations and health. Among the psychometric characteristics are reliability quotients of $\alpha = 0.49–0.78$. The Wisconsin Quality of Life Index for Mental Health (QLI-MI; Becker et al. 1992) assesses nine aspects with 103 items that are evaluated according to their significance in a patient self-report; parts of the report can also be filled out by the doctor or family. Tests that have been done so far on this method (which is still under development) on 40 chronically mentally ill patients show a good test–retest reliability.

The semi-structured Quality of Life Schedule (QOLIS; Holcomb et al. 1993) consists of 87 items that explore eight aspects of quality of life in the form of an interview by expert assessment. So far, the method has been used on 201 chronically mentally ill patients and been successfully tested psychometrically.

A new tool is the Quality of Life Enjoyment and Satisfaction Questionnaire (Q-LES-Q; Endicott et al. 1993), consisting of 93 items that are transformed into eight sum scales, including physical health, subjective feelings, recreational activities, social relationships and general activities.

3.3 Comparison of Different Procedures

The older literature is characterised by lengthy procedures that are carried out in the form of an interview and often with an assessment by the interviewer. However, newer publications tend to concentrate on shorter scales that can also be obtained as self-reports from the patients in the form of questionnaires. Some procedures aim at contrasting objective circumstances of life and subjective assessments, whereas others focus more on direct self-reports by the patients concerning their experience and behaviour. An attempt to streamline procedures and a growing reliance on self-reporting by patients are evident in this development.

Some publications compare the characteristics of several different tools, e.g. the Quality of Life Interview by Lehmann et al. (1993) and the Quality of Life Scale by Heinrichs et al. (1984). For 59 patients who were assessed using both measuring tools with a 2-month interval together with SCL-90 and the BPRS (Brief Psychiatric Rating Scale), this comparison showed that the correlations between the two measuring tools in corresponding contexts were significant and the test–retest correlations of both instruments were good.

In other publications, the correlation between assessment by the patient and assessment by caregivers was investigated with reference to the quality of life of these patients. A total of 31 chronic psychiatric patients were evaluated by a measuring tool constructed ad hoc that measures nine aspects of quality of life and that can be assessed by patients and nursing staff alike. It became evident that patients can assess their quality of life consistently and that they assessed it significantly higher than the people caring for them (Thapa and Rowland 1989). A more recent publication compared assessments made by 37 schizophrenic patients and their doctors, e.g. with the help of the Wisconsin Quality of Life Index for Mental Health (Sainfort et al. 1996).

The results in this case were that the assessments made by the patients and by those that took care of them tended to correlate positively, and much more so for clinical aspects such as symptoms and functional impairments than for social or professional aspects. Accordingly, the percentage of correspondences was lowest for social support (44%) and highest for functioning (66%).

In contrast to the use of specific tools for the assessment of patients' quality of life, the application of well-standardised procedures from generic quality of life research has become established. Different subscales from existing instruments are often employed together. One example of this kind of approach is a study by Revicki et al. (1992), who employed clinical instruments and subscales from the SF-36 Health Survey and the SIP on 40 patients with clinical depression. It took the patients 10 min to fill out the whole questionnaire, and reproducibility was very good, with an intra-class coefficient of $r = .77$. The correlation between measuring tools for quality of life and the clinical symptom scales (Montgomery/Asberg scale) was substantial ($r = 0.3–0.62$); symptom changes were associated with changes in the quality of life scales. Reliability and validity of the newly created instrument were also acceptable.

In addition to the variety of scales available for the assessment of psychiatric patients' quality of life, there are other areas that should be mentioned briefly in this context. One area refers to quality of life assessment of caregivers, both family members and medical personnel (Schene et al. 1996), while another refers to the assessment of patients' satisfaction with treatment (Kelstrup et al. 1993; Leimkühler and Müller 1996).

In contrast to the internationally (methodically) well-researched generic measuring tools (such as SF-36

and NHP), only few of the disease-specific measuring tools that are available in English have been tested in their original language for psychometric characteristics such as reliability, validity and sensitivity. Exceptions are the WHO Quality of Life Scale and the Berlin Life Quality Inventory. Moreover, for the tools that were originally in English, neither an adequate translation nor any psychometric testing according to current internationally accepted criteria and procedures are available (Sartorius and Kuyken 1994).

4
Application of Quality of Life Scales in Psychiatry

In publications, life quality scales have been used to describe the quality of life of patient populations, i.e. the determinants by which to judge quality of life and to evaluate the effect of medical care strategies in the out-patient and rehabilitation sectors. There are a small number of studies in this respect that test the effects of certain kinds of care (supervised living situations, hospitalisation) on the patients' quality of life. In contrast to this, the employment of quality of life scales in clinical psychiatric studies can be described as rudimentary. Barely any regard has been given to the question of the extent to which quality of life indicators can be helpful in analyses of health economics. At the present time, only theoretical considerations about the instruments applied in this respect have been addressed in survey articles (Gudex 1996).

4.1
Characteristics and Determinants of the Quality of Life of Psychiatric Patients

In cross-sectional studies, tools have been employed for quality of life assessment in order to characterise patient groups in terms of quality of life compared to different reference populations. For psychiatric patients compared with physically ill patients and healthy controls, quality of life indicators pointed to a marked impairment not only in mood but also in role function. Correspondingly, by means of a precursor of the SF-36 Health Survey, significantly lower scale values were found for psychiatric patients than for age- and sex-matched normal populations not only in the subscales of mental well-being, but also for vitality, emotional and physical role functioning and social functioning (Spitzer et al. 1995). Satisfaction with life assessments gave similar results (Franz et al. 1996; Huber et al. 1988; Lehmann 1996).

The socio-demographic findings on quality of life are heterogeneous. In one literature survey on sex-related differences in the quality of life of schizophrenic patients, it was found that schizophrenic women report higher satisfaction ratings than men (Röder-Wanner 1995; Priebe et al. 1996). In another study, the effects of sex and age on the assessment of quality of life were investigated (Lehmann et al. 1992). The result of this was that psychiatric symptoms correlated with objective quality of life indicators markedly less than with subjective satisfaction with life indicators. In mid-life, however, chronically mentally ill men differ from women in that men are significantly more satisfied with their life than women, especially with regard to leisure. Furthermore, in 110 patients with severe psychiatric disorders, significant differences were found, with working patients having a higher quality of life (Fabian 1992).

The influence of clinical symptoms on quality of life was investigated in a more recent study on 49 chronic psychiatric patients (Corrigan and Buican 1995). The patients were examined with the Quality of Life Interview developed by Lehmann and also filled out questionnaires on social functions and support; in addition, observer-rated psychopathology was assessed by means of the BPRS. It was found that a higher quality of life index correlated positively with more social competence and intelligence and negatively with the depression score in the BPRS. In a multiple regression, it was found that depression, social network, intelligence and interpersonal contact were predictors for quality of life with a declared variance of 55%, which points to the contribution of these factors to the concept of quality of life.

The role of social support was also pointed out in a study on 729 severely ill psychiatric patients who had a significantly positive correlation between quality of life – as measured with the Satisfaction with Life Domain Scale – and social support (Baker et al. 1992).

Furthermore, in a population of 101 psychiatric patients, it was found that a high degree of self-reported quality of life was connected with fewer depressive symptoms, fewer side effects of medication and better family interaction (Sullivan et al. 1992).

In a study of 500 chronically ill patients, Mechanic et al. (1992) observed that disease attribution had a major effect on quality of life. Patients who attribute their symptoms to a physical, biological or medical cause – as opposed to those who describe themselves as insane "for no reason" – report more positive social relations and a higher quality of life. The negative effect of symptoms being attributed to "insanity" on quality of life was explained by the authors to be due to the perceived stigma, low self-esteem and a higher degree of depressive symptoms.

4.2 Schizophrenia

Quality of life publications on schizophrenic patients primarily focus on how neuroleptic treatment is perceived by patients. The Instrument for Assessment of Subjective Well-Being Under Neuroleptic Treatment (SWN; Naber 1995) measures five aspects of schizophrenic patients' well-being by means of 38 questions regarding the subjective effect of neuroleptics (15–20 min duration for completion) and has been successfully tested for its psychometric characteristics on 280 patients. In another study on 216 schizophrenic patients in remission, patients who later showed compliance had already differed from non-compliant patients at the time of discharge from hospital. This points to the fact that subjective well-being during neuroleptic treatment should be an important criterion in assessing the outcome of neuroleptic treatment (Naber et al. 1994). Moreover, it was shown that subjective well-being during treatment with neuroleptics (as measured with the SWN) correlated quite highly ($r = 0.6$) with quality of life in general (as measured with the MLDL), whereas both aspects correlated only poorly ($r = 0.3$–0.4) with objective psychopathology (as measured with PANSS).

In using the Q-Sort Procedure, in which patients rank their agreement with different statements in a certain order, a more recent study was able to distinguish four groups of patients according to how they had answered the questions on their medication; these groups were characterised as (a) "barely questioning", (b) "autonomously sceptical", (c) "balanced agreement" or (d) "autonomously positive". The groups differed in how they judged the effect of neuroleptic treatment on their quality of life, the first group reporting lower values for quality of life (Day et al. 1996).

In a group of 53 chronic schizophrenic patients undergoing treatment with depot neuroleptics, Larsen and Gerlach (1996) found that 60% of patients generally regarded their medication as positive, but that – despite the overall positive assessment – the majority felt bothered by the side effects. Abnormal movements were perceived by the patients to be the least and by the doctors to be the most bothersome, and the patients felt most impaired by the psychological side effects, which were found to be least impairing by the physicians. No correlation was found between the clinical severity of the illness and the severity as judged by the patients themselves.

Awad (1992) also points out that, in order to understand the effects of medication on the quality of life of schizophrenic patients, not only knowledge of the side effects but also of the subjective perception of the effects of neuroleptics is needed. So far, quality of life scales have not been widely employed in clinical studies (Selai and Trimble 1994).

4.3 Depression

In contrast to the state of affairs in the research of schizophrenia, patient self-reports have been included for a while now as a criterion in the assessment of treatment results in depression research. The instruments used include the Hospital Depression and Anxiety Scale, the Hopkins Symptom Checklist and the Psychological General Well-Being Index. The SF-36 Health Survey has been tested and validated in depressed patients (Wells et al. 1989; Bech 1995). The Smith-Klein and Beecham Quality-of-Life Scale (SBQOL; Stocker et al. 1992) is particularly suited to the assessment of depression; using 23 items in three domains, it measures the relative discrepancy between current and self-ideal assessments in different areas of life. The method was employed in a population of 129 depressive patients, and validity and test–retest reliability were found to be adequate. A further test developed for depressive patients is the Quality of Life in Depression Scale (QLDS; Hunt et al. 1981), which comprises 29 items measuring only one domain (albeit reliably); this test was found to correlate with the Hospital Depression Scale in a study with 196 patients (Grégoire et al. 1994).

So far, there have been studies on the effect of serotonin re-uptake inhibitors and monoamine oxidase inhibitors with regards to quality of life. In one study, the (non-disease-specific) testing of fluoxetine versus moclobemide in 209 depressive patients by means of a precursor of the SF-36 Health Survey and a dimensional measurement to assess quality of life showed a positive effect of both forms of treatment on quality of life, although there was no significant difference between the two treatment strategies (Lonnqvist et al. 1994). Using the SF-36 Health Survey and the General Health Questionnaire for assessment purposes, 651 depressive patients showed a significant improvement in quality of life during as opposed to prior to treatment with moclobemide (Walker et al. 1995).

A one-dimensional "thermometer scale" on quality of life compared 100 monopolarly and bipolarly depressed patients with two control groups comprising 50 healthy patients and 50 patients with personality disorders: in the patients with affective disorders, no significant differences were found between those treated with lithium and a

control group in respect to quality of life (Lepkifer et al. 1988).

4.4 Anxiety Disorders

Quality of life of patients with panic disorders was assessed in a large-scale epidemiological study using an earlier version of the SF-36 Health Survey from the Medical Outcome Study. A total of 18,000 adults were interviewed in the course of 18 years, 5034 of which were chosen from a specific area and 250 of which had panic disorders. It was shown that panic disorders coincide with clearly evident social and physical impairments, comparable to those of clinical depressions. These include subjective feelings of poor physical and mental health, but also alcohol and drug abuse, a higher probability of suicide attempts, limited social and personal functioning, lack of financial independence and a more frequent use of psychoactive medication or consultation of physicians because of emotional problems (Markowitz et al. 1989).

Significantly reduced quality of life, especially in the areas of role function, social function and partnerships, was also found by Massion et al. (1993), who examined 357 individuals with a current episode of panic disorder and/or generalised anxiety disorder by means of the SF-36 Health Survey. The only study that has been performed to date on treatment effects on patients' quality of life was carried out by Telch et al. (1995), who divided 156 patients with panic disorder and agoraphobia randomly into a cognitive/behavioural therapy treatment group and a waiting control group. The Social Adjustment Scale (SAS) and a scale that measures functioning disorders (SDS) were both used as self-reports. At the beginning of treatment, the patients showed strongly impaired quality of life; these impairments diminished significantly during treatment in comparison to the control group and remained lower in follow-up. Fear and phobic avoidance were significantly correlated with a lower quality of life, but the frequency of panic attacks was not.

4.5 Quality of Life in Patients After Hospitalisation

A Canadian study investigated the quality of life of 43 patients up to 3 years after discharge from psychiatric rehabilitation programmes. A total of 86% of the patients appreciated the greater independence and privacy of their life outside the programme, and 77% perceived their quality of life to be higher than during hospitalisation, which was also apparent in higher values for the quality of life domains social functioning, recreational activities and circumstances of life (Gerber et al. 1994).

An Italian observational study on 40 patients in the course of 1 year after discharge from hospital showed that those who had taken part in a vocational rehabilitation programme reported a higher quality of life (Pirfo et al. 1994).

In a British study on 62 patients, no differences in quality of life were found between flat-sharing, supervised living groups and private living (Oliver and Mohamed 1992).

A larger group of 1527 patients was questioned concerning their (generally highly assessed) quality of life; an important predictor of quality of life proved to be income and the feeling of having control over one's own life (Rosenfeld 1992). Twenty-nine patients living in the community were questioned with the help of the Quality of Life Inventory developed by Lehmann; the result was a significant improvement in circumstances, social contact and recreational activities 1 year after discharge from hospital (Barry and Crosby 1996). By means of one analytical method, Mercier (1994) found for 152 patients that more autonomy leads to a higher quality of life and that this in turn leads to integration in the community.

In a study on 61 out-patients, the standard of living after discharge proved to play a major role in the quality of life, although satisfaction with one's self played less of a role (Skantze et al. 1992).

In a comparison between American and British out-patients, comparable quality of life was found despite a greater extent of psychopathological disorders in the American group, which, according to the authors, points out how much more adequate medical care is in the United States (Warner and Huxley 1993). Dencker and Dencker (1995) also stress the necessity of quality control in medical care in order to provide a basis for a positive development of patients' quality of life.

In an American study, 53 patients were questioned on their quality of life 11 years after discharge (Okin and Pearsall 1993). The result was that socially integrated patients assessed their quality of life highest. These results not only point out the role of circumstances, but also that relevant learning and training programmes can promote patients' social competence and quality of life (Mercier 1994; Englert et al. 1994). Atkinson et al. (1996) reported on a randomised study in which a group trained in this respect benefitted significantly from what they had learned in social functioning in comparison to a waiting control group. In general, research on psychiatric care – immediate care, rehabilitation and community care – focuses strongly on the subjective experience of the patient, which is seen as an important outcome criterion

(Sartorius 1995; Perschak et al. 1994; Simmons 1994; Corten et al. 1994).

5 Prospects

Since it first began, research on quality of life has had three main issues to deal with; these were brought up by other sources, especially from the realm of medicine. The first issue has to do with a basic scepticism towards any possibility of defining quality of life and making it operationally conceivable (Kilian 1995). The second issue refers to the construction and quality of the methods intended to assess quality of life, with these methods all too often being suspected of being "too subjective", susceptible to bias and therefore worthless (Guyatt et al. 1993). The third aspect concerns the usefulness of quality of life assessment, i.e. of the extent to which the results of this research are relevant for health policies or for medical treatment on an individual basis. This is where the goals of quality of life research need to be discussed.

In quality of life research, questions remain open concerning the individual representation of a quality of life concept or rather the problem of representing individual aspects of quality of life by means of standardised instruments; in addition, there is the question of the congruence between self-reports and observer reports; the conceptual accordance between well-being, depression and quality of life; and the weighting of quality of life indicators, the clinical relevance of quality of life assessments in practice and the question of what is most important for patients: their objective circumstances or their subjective quality of life.

Although there is consensus on the fact that the quality of life concept is at least three-dimensional and should also be assessed multi-dimensionally as well as based on patients' statements, there has been much doubt as to whether this is the right solution for the application of such a complex concept. As far as the problem of measurability is concerned, the generic and disease-specific approaches existing so far present a limited, though methodically acceptable approach to quality of life research. The question of how valid a report is and to what extent the substantial criteria of the individual patient's quality of life concept are represented by it still remains to be answered.

A critical analysis of the value of quality of life as a criterion in medicine suggests that the application of research results should also be regarded with scepticism. Clinical studies may have provided information on positive treatment effects on quality of life. However, considering in particular the large differences between clinical results and results of quality of life research, the consequences that changes in quality of life have in modern-day, individually focused treatment concepts and/or will be able to have within the borders that health policies define remain questionable. If the improvement of patients' quality of life is really to become a primary criterion in medical decisions, this will become expensive, as it cannot be realised with classical measures alone and thus will be a subject of intense social discussion.

The inclusion of the concept of quality of life in international psychiatric research has progressed slowly in comparison to other medical disciplines (Lehmann et al. 1982), and this is also true for the German-speaking countries (Möller et al. 1996). The quality of life of schizophrenic patients in particular needs to be dealt with (Kaiser et al. 1996; Lauer 1994, 1996; Stieglitz 1996). In the short time in which the subject has been discussed, however, a solid basis for research has been laid, especially as far as a theoretical basis for the quality of life concept in psychiatry is concerned, particularly in Europe (Angermeyer and Kilian 1996). In contrast to other fields, psychiatry has been substantially concerned with the concept of quality of life and has made a conceptual contribution to the clarification of the term.

On the other hand, the development of disease-specific scales for quality of life assessment of mentally ill individuals has only just begun. Many of the disease-specific methods that were developed in Anglo-American countries were originally not aimed to be applications of the quality of life concept, although now they are used as such. An assessment needs to be made of the extent to which these tools are an adequate representation of the entity "quality of life" (as a multi-dimensional concept including psychological, physical, social, mental and everyday well-being and functioning as reported by the patient). It also needs to be established to what extent detailed interviews are necessary for an assessment of quality of life or whether shorter and thus more time-saving and patient-oriented scales would make sense, at least in clinical studies. On the other hand, it remains unclear how the quality of life of psychiatric patient groups could be described qualitatively and/or to what extent the experience and behaviour of patients coincide with the aspects of quality of life that are being used. Furthermore, basic psychometric work has been done concerning internationally available scales; after being adequately translated and applied to German-speaking patients, these include a calculation of characteristic test theory values. Scales have so far only been employed in a few descriptive studies and on the question of patient care after immediate treatment, although the studies usually only involve small numbers of patients. Epidemiological and clinical studies

are almost entirely lacking, although they would be necessary for the assessment of the need for medical care and of treatment effects with respect to the criterion of quality of life. The question of whether psychiatric patients can judge their quality of life themselves can be answered affirmatively. With the exception of severe clinical symptoms or mental retardation, according to the study results available, patients give consistent and adequate information on their well-being and functioning.

The fact that patients suffer from psychiatric symptoms does not mean that their subjective experience of their current state is irrelevant with their symptoms distorting their well-being. With the exception of only a few psychiatric states, such as acute psychosis or progressive dementia, patients are willing and able to supply information about their experience and their perception of the world. Self-reporting by patients needs to be taken seriously, especially with respect to the search for tolerable medication with fewer side effects.

As the interviewer's assessment of quality of life (observer rating) usually differs from the self-report made by patients (Gater et al. 1995), these data should also be dealt with separately: the interviewer's assessment should not be regarded as an external criterion of validity for the experience of the patient but as an independent source of information.

In view of the current state of research, work is still necessary as far as quality of life assessment in psychiatry is concerned – in theoretical, methodological and practical terms. This work will only be meaningful if the quality of life concept is oriented towards the patient and is accepted as relevant in its multi-dimensionality by physicians, patients and family members, i.e. as a way to describe the patient's condition and as a criterion for therapeutic action (Strauss 1996). This basic decision for (or against) psychiatric research that is oriented towards the concept of quality of life is desirable and has implications for health policies that cannot be decided by quality of life research, although a solid basis for discussion can be laid by developing concepts, methods and possibilities for application.

It is generally true for the field as a whole that quality of life is a concept that involves value judgement. Generic quality of life scales, in particular, are implicitly derived from norms set up for a physically fit, mentally healthy, socially integrated and functionally competent person who – at least in our culture – would be highly respected. If such judgements on quality of life form the basis for treatment decisions, it needs to be considered whether patient groups are not to some extent being systematically discriminated against (e.g. physically handicapped or mentally ill patients). A way out of this dilemma is certainly not to exclude the subject of quality of life from psychiatry, but to face the inherent ethical problems involved with the definition of treatment goals, something which also applies in principal to clinical data. The question that needs to be answered within society is which kind of therapy will lead to which results with what kind of financial profit – not only with regards to the traditional classically defined state of health (e.g. measurement of laboratory parameters), but in the subjective experience of the patient as well (health-related quality of life). Further efforts are necessary in research in order to include conceptual and ethical aspects above and beyond the methodological and practical aspects of research on quality of life that are already being treated.

CHAPTER

8

L. Eisenberg

Prevention of Psychiatric Disorders

1 Definitions

The public health approach to prevention distinguishes between three levels of disease prevention: primary, secondary, and tertiary prevention.

Primary prevention is designed to preclude the development of disease among susceptible populations; it employs health promotion (e.g., the teaching of hygienic practices, universal education to promote cognitive development, the provision of optimal nutrition to enhance resistance, social support for family life, peer programs in public schools to diminish the onset of health injurious habits) and specific protection (e.g., immunizations, iodinization of salt, eliminating lead from gasoline).

Secondary prevention is designed to shorten the duration of illness once it occurs, reduce the likelihood of contagion, and limit sequelae by means of early diagnosis and prompt treatment, i.e., the use of psychotropic drugs and psychosocial interventions to abort acute psychotic states. Treatment (secondary prevention) of the first disease in a causal series constitutes primary prevention for those conditions which would otherwise follow in its wake, i.e., medical control of hypertension to reduce the likelihood of a cerebrovascular accident or treatment of hypothyroidism to avoid the onset of myxedematous madness.

Tertiary prevention is directed at individuals with irreversible disease; its goals are to limit disability (i.e., reform of institutional programs to avert the chronic social breakdown syndrome), to minimize exacerbations of the underlying disease (i.e., psychosocial education for the families of schizophrenic patients), and to promote rehabilitation (i.e., social skills training, vocational guidance, sheltered workshops for the chronically mentally ill).

In the first instance, the goal is to prevent the development of disease; in the second, to shorten its duration after it has occurred; and in the third, to preserve function so far as is possible when no effective treatment for the disease itself is available. This chapter will focus on primary prevention, but will also consider the other two levels briefly.

2 Is It Possible to Prevent Mental Disorders?

The concept of prevention in psychiatry is commonly met with skepticism. It is argued that so little is known of cause and treatment that "prevention" can be no more than a pious, vague, and perhaps even meddlesome notion. However, such a response underestimates the power of public health methods and the legitimate scope of psychiatry. Effective measures of prevention need not wait upon precise knowledge of disease etiology; programs of control can be devised from epidemiologic data on susceptibility and transmission. To cite the classic example, in 1854, by studying the distribution of cases of cholera in London, Snow was able to indict the contaminated water citizens were drawing from the Broad Street pump as the source of the epidemic, 30 years before Koch isolated and cultivated the cholera vibrio. The fact is that effective prevention of *some* psychiatric disorders is not only possible, but is substantially complete for *certain* disorders in *some* countries; what is not possible now, or in the foreseeable future, however, is the prevention of *all* mental disorders.

Pellagra and paresis are telling examples of primary prevention. Patients suffering from pellagra crowded the orphanages and the mental hospitals in the United States in the early decades of this century. Well before it was shown to result from niacin deficiency, but after it was recognized as a nutritional disease (Sydenstricker 1958), pellagra was eliminated in the United States by improvements in diet (reduction in the dependence on milled corn as a food staple). In the first decades of this century, the wards of mental hospitals were crowded with patients suffering from general paralysis of the insane. Now paretics are hardly to be found in industrialized countries. Effective programs to treat syphilis with penicillin have eliminated the tertiary disease manifestations of spirochete infection. Neither of these preventive measures is "psychiatric." However, what matters is not the mode of action of the agent, the venue in which it is applied, or the academic discipline of the practitioner, but the effectiveness of the measure in preventing diseases causing disturbed mental function (APA Task Force on Prevention Research 1990).

Moreover, secondary and tertiary prevention (clinical care) has led to even more impressive gains for the recurrent and chronic mental disorders. This is reflected in the progressive reduction in the need for psychiatric beds during the last half of this century. Between the mid-1950s and the mid-1990s in the United States, the number of inpatient mental hospital beds (public and private combined) fell by more than half (public beds by more than 90%), although the U.S. population increased by more than half over that time span. The reduction in the need for hospitalization and in the average length of stay when hospitalization is necessary are a product of changes in sociomedical administrative policy (the "open hospital" and "community mental health") and the sequential development of more effective treatment methods, e.g., psychopharmacology, new methods of psychotherapy, psychoeducational groups for families, social skills

training for patients, partial hospitalization and day care, sheltered workshops, and group residences in the community.

The emphasis in this chapter is on validated means for preventing mental disorders. The measures are presented in a life cycle perspective beginning before conception and continuing into old age. Primary preventions head the list; secondary and tertiary measures applicable in clinical settings are discussed briefly; and the chapter concludes by considering health policy.

3 Preventive Interventions

3.1 Family Planning and Prenatal Care

The more numerous and the more closely spaced the pregnancies in the reproductive lives of women, the greater the risks for maternal and infant mortality and the worse the developmental outcome for the children (World Bank 1993). Studies in developed countries have demonstrated that the larger the number of children in a family (other variables such as socioeconomic status having been controlled for), the lower their educational attainment (Blake 1989). Unplanned and unwanted teenage pregnancies are associated with a high risk for mother and child (Brown and Eisenberg 1995). Taken together, these findings indicate the importance of family planning services to reduce the number of offspring and to lengthen interbirth intervals in order to optimize the ability of parents to care for their children. The health risks associated with modern contraception are far less than those associated with pregnancy and childbirth (DaVanzo et al. 1990).

Family planning provides an opportunity to improve outcomes for mother and baby by identifying and managing risks *before* conception. Ordinarily, prenatal care begins weeks or even months into the pregnancy when the conceptus has already implanted in the uterus and begun to develop its central nervous system. Pre-conception planning, in contrast, focuses on optimizing health and avoiding controllable risks before pregnancy begins. Topics typically addressed in pre-conception care include diet and weight, exercise, smoking, alcohol and drug use, reducing environmental risks, bringing vaccinations up to date, and managing sexually transmitted diseases (STDs) if they are present, as well as bringing chronic medical conditions such as diabetes, hypertension, and cardiovascular disease under as much control as is possible. Because maternal diabetes is associated with complications of pregnancy, strict metabolic control before and during pregnancy has been shown to reduce the risk to the developing fetus (Fuhrman et al. 1984).

Family planning makes it possible to minimize toxic effects on spermatogenesis by optimizing nutrition and by reducing alcohol and drug use and exposure to chemicals (Cefalo and Moos 1995). It permits the identification of vulnerability to genetic diseases through early diagnosis. Carrier detection coupled with prenatal testing and access to abortion allows families at high risk to give birth to healthy children of their own by enabling them to abort defective fetuses (Milunsky 1992; D'Alton and DeCherney 1993). This can sharply reduce the incidence of inherited disease of the central nervous system (though without affecting carrier rates). A telling example is provided by Tay-Sachs disease, a gangliosidosis resulting from a deficiency of hexosaminidase A. It is manifest by motor weakness beginning in the first 6 months of life and progressive motor and mental deterioration, with the development of feeding problems, deafness, blindness, convulsions, and spasticity; the patient usually dies of bronchopneumonia before the fourth year of life. The disorder occurs principally in a defined population group, i.e., Ashkenazi Jews (Jews from Eastern Europe and their descendants). The carrier rate in this population in the United States and Canada is about 1 in 31 (in contrast to a rate of about 1 in 280 among non-Jews). Voluntary enrollment of American and Canadian Ashkenazi Jewish populations in screening programs made it possible to reduce the number of newly diagnosed cases of Tay-Sachs disease from an average of about 60 per year in the 1960s to 13 by 1980 and to three to five cases per year in the decade that followed (Kaback et al. 1993).

Comprehensive family planning services should include education about contraceptive choices and access to contraceptives. Safe abortion must be available as a backup for contraceptive failure. Adolescents use contraception irregularly; even when used faithfully, every contraceptive method has a failure rate (lowest for the pill). Major morbidity and mortality from back-alley abortions is inevitable if legal and safe abortion is denied (Brown and Eisenberg 1995).

Inadequate nutrition, cigarette smoking, alcohol consumption, drug abuse, and inadequate prenatal care during pregnancy are all associated with increased hazards to the fetus, including higher rates of low birth weight infants. Low birth weight, in turn, is associated with higher neonatal mortality rates (NMR) and developmental impairment among survivors. The high technology of the neonatal intensive care unit (NICU) results in greater salvage for very low birth weight infants, but at much greater monetary costs and far less satisfactory developmental outcomes than that achieved by improving the physical and social

condition of the mother during pregnancy (Shiono and Behrman 1995). Thus, although NICUs in the United States have lower birth weight-specific NMRs than those in Sweden, the overall Swedish NMR is lower than the U.S. NMR because the proportion of low birth weight infants born in the United States is half again higher than that in Sweden (Guyer et al. 1982). The limits to technology are indicated by the outcomes in U.S. NICUs. The addition of pulmonary surfactant and dexamethasone therapy has doubled the rate of survival for very low birth weight infants (less than 750 g), but at the cost of survivors handicapped by subnormal cognitive function and neurosensory abnormality, including cerebral palsy, blindness, or deafness (Hack et al. 1996).

Where feasible, screening for elevated blood levels of α-fetoprotein, for chromosomal anomalies by cytogenetic methods, and for morphologic abnormalities by ultrasonography can permit the detection and abortion of abnormal fetuses carried by mothers at risk. Spina bifida and anencephaly are related neural tube defects which are major causes of morbidity and mortality in infancy and childhood. Mid-trimester screening by measuring maternal serum α-fetoprotein or by ultrasound examination can identify more than four fifths of affected pregnancies. The application of screening and abortion of affected fetuses has led to a fall in the prevalence of these defects.

There is now strong evidence that neural tube defects are caused by inadequate intake of folate in the periconceptional period (Czeizel et al. 1994; Medical Research Council 1991). Only in the case of planned pregnancies can women deliberately increase their intake of folic acid before conception. Thus it has been proposed that all fertile women take a supplement until menopause or that food for the entire population be fortified with folate. The principal concern about fortification is that individuals in the population with untreated vitamin B_{12} deficiency (but without a clinically evident anemia) may develop an irreversible neuropathy from folate supplementation if diagnosis is delayed (Bower and Stanley 1996; Dickinson 1995).

3.2
Newborn Screening

A number of congenital metabolic abnormalities can be detected by routine screening of newborns. Notable among the correctable conditions are phenylketonuria (PKU), galactosemia, and congenital disorders of thyroid function, all of which result in severe central nervous system pathology if treatment is not instituted in the first weeks of life and maintained thereafter. The clinical manifestations of the first two can be prevented by appropriate diet, and of the third by extrinsic thyroxin. The fact that they occur at low frequency in Caucasian populations – 1 in 3600 to 1 in 5000 for disorders of thyroid function, 1 in 10,000 to 1 in 25,000 for PKU, and 1 in 60,000 to 1 in 80,000 for galactosemia (American Academy of Pediatrics Committee on Genetics 1989) – makes newborn screening a practicable public health measure only in countries with highly developed health services. Although the cost of case detection is relatively high because the conditions are rare, so are the lifetime costs to the community in caring for severely affected children. Screening programs are, however, of little or no value in the absence of a comprehensive follow-up program to ensure that the infant at risk receives optimal care (Rowley and Huntzinger 1985; Holtzman et al. 1986).

3.3
Childhood Immunizations

According to UNICEF (1996), 20 million deaths in children under the age of 5 have been prevented since 1980 by means of immunization against diphtheria, pertussis, tetanus, measles, polio, and tuberculosis; however, there are still some 2 to 3 million deaths each year from vaccine-preventable diseases because of the failure to extend the vaccination program to all susceptible children. Moreover, mortality data underestimate the magnitude of the public health burden because they do not tabulate the morbidity from central nervous system pathology and from the psychosocial consequences of chronic handicap among survivors. Full implementation of the WHO Expanded Program of Immunization would not only yield enormous gains in further reduction of mortality in childhood (and thus make parents more willing to forego large family size) but spare compromised brain function and psychosocial disability among survivors. Measles encephalitis, subacute sclerosing panencephalitis, and mental retardation from congenital rubella syndrome or hemophilus B meningitis are rapidly disappearing from the clinical scene in countries with comprehensive immunization programs (Gruenberg et al. 1986).

3.4
Preventing Malnutrition

Deficits in the intake of specific micronutrients as well as in overall protein-calorie intake can impair brain development with major consequences for cognitive and emotional function.

Iodine deficiency disorders (IDD) constitute the most pressing instance of micronutrient deficiencies which lead to brain malfunction. IDD affects between

600 million and one billion people in the world (Hetzel 1989). Clinical manifestations include still births, abortions, and congenital anomalies; endemic cretinism, characterized by mental deficiency, deaf mutism, spastic diplegia, and other forms of neurologic defect; and impaired mental function associated with goiter. IDD in individuals at risk can be prevented for 3–5 years with one injection of 2–4 ml iodized poppy seed oil, a treatment that can be given by primary care workers. To prevent fetal IDD, iodized oil must be administered before conception (another benefit of planned childbirth); treatment even as early as the first trimester of pregnancy is not fully effective. Oil injections are both feasible and practical as an immediate means to control endemic IDD. For reasons of costs and convenience, the long-term goal must be the introduction of an iodized salt program for the entire population. Program success is dependent upon public education to elicit the full support of the population (Hetzel 1986, 1989).

Worm infestations in children result in retarded physical stature and cognitive ability. It is now possible to treat very effectively 19 of the 23 major human helminth infections with one of three drugs taken orally: albendazole, praziquantel, or ivermectin. In principle, it should now be possible to treat for iodine deficiency, vitamin A deficiency, and worm infestations by oral medication administered at school. Such programs are now being tested in the field (Warren 1991).

Severe protein-calorie malnutrition, life-threatening in itself, increases the likelihood that exposure to infectious agents will result in clinical disease; malnutrition impairs host defenses. Furthermore, malnourished individuals show increased systemic manifestations of diseases which are more limited in those who are well nourished. Gastrointestinal diseases, made more likely by malnutrition, increase nutritional stresses on the host by increasing caloric requirements at the same time as food intake and absorption are impaired. Traditional "treatments" for diarrhea by reducing intake of food and fluids worsen the threat. UNICEF has taken the lead in minimizing harm from diarrheal disease in children by promoting oral rehydration with an easily prepared solute solution.

The conjoining of chronic malnutrition with disadvantageous family circumstances results in retarded cognitive and social development. Studies of malnourished children indicate that it is the interacting and multiplicative effects of the simultaneous biological and social insults that result in damage (Dobbing 1987). Grantham-McGregor et al. (1978, 1991) have shown that nutrition plus social stimulation for hospitalized malnourished children, maintained after hospital discharge by parents who have been educated by home visitors, result in greater developmental gains than renourishment alone. Effective remediation must be targeted at the entire complex of social and nutritional deprivation.

Monitoring the growth of young children, a simple method well within local resources, permits the early detection of developmental failure. It is one of the four components of the UNICEF "GOBI" initiative: growth monitoring, oral rehydration, breast-feeding, and immunization (Grant 1995).

Insuring universal education for women is the common denominator in measures to improve child health. National infant mortality data show a stronger inverse correlation with years of education women receive than they do with the gross national product (Caldwell 1986). The intervening behavioral mechanisms include later age of marriage, fewer and more widely spaced children, and use of hygienic health-promoting behaviors among educated women (Hobcraft 1993).

3.5 Injury Prevention

Vehicular accidents are a major source of head and spinal cord injuries among survivors. Such injuries are preventable by vigorous enforcement of lower speed limits (Wagenaar et al. 1990), by better highway design, traffic regulations, vigorous prosecution of drunken driving, automatic seat belts, child safety seats, and air bags. Cycling is a major cause of hospital admissions for head injuries. In recent studies (Thompson et al. 1989, 1996), cyclists wearing helmets had an odds ratio for brain injury after vehicular accidents of 0.35 compared to those without helmets.

Poisonings in children can be minimized by laws requiring "child-proof" safety caps on bottles of medication and toxic chemicals for domestic use (Walton 1982). Blood lead levels in children can be reduced by effective public controls on the lead content of gasoline (Centers for Disease Control 1982a).

3.6 Home Visiting and Enriched Day Care

Olds and his colleagues (Olds et al. 1986; Olds and Kitzman 1990) have shown that pre- and postnatal home visitation, transportation for health care, and sensory and developmental screening were effective in preventing abuse and neglect among children born to socially disadvantaged primiparas. The women visited by nurses made better use of community services,

experienced greater social support, improved their diets, and reduced their smoking. Length of gestation and newborn birth weight were improved, and there were fewer verified cases of abuse among poor, unmarried teenage mothers.

Studies in both developed and developing countries have shown that children growing up under deprived circumstances exhibit deficits in cognitive development, lower levels of academic achievement, and increased rates of behavioral and antisocial disorders (Eisenberg and Earls 1975). These disastrous outcomes can be made less likely through enriched day care programs which involve parents as active participants. Several long-term outcome studies have demonstrated that children enrolled in day care exhibit better occupational history, fewer out-of-wedlock pregnancies, and lower rates of academic and behavioral pathology (Berrueta-Clement et al. 1984; Jordan et al. 1985; Lazar et al. 1982).

Day care programs can facilitate the attainment of a second goal, namely the teaching of parenting skills to adolescents by having them participate in the care of toddlers under supervision. The effectiveness of this strategy has not been formally demonstrated, but its desirability is indicated by the fact that experience in child care within the family, the traditional way these skills have been transmitted, is becoming ever less available. With smaller family size and fragmentation of the family, it can no longer be taken for granted that such "naturalistic" education is available to all children.

3.7
Community- and School-Based Programs

Pierson et al. (1983) introduced a parent education and diagnostic screening program with periodic developmental examinations from 6 months, weekly play groups from 2 years, and daily prekindergarten from 3 years of age. Classroom observation demonstrated that experimental children had less learning difficulty and fewer reading problems in the second grade. Ramey and Campbell (1984) evaluated a child-centered prevention program emphasizing language, cognitive, perceptual-motor, and social development in children aged 18–54 months. The enrolled children scored significantly higher than controls on a series of tests of mental ability. Botvin et al. (1984) assessed a school-based 12-unit curriculum delivered by peer leaders or classroom teachers (with periodic booster sessions in subsequent years). The goal was to give junior high school students the skills to resist pressures to smoke and use drugs, to help them develop self-esteem, and to cope with social anxiety. The outcome was a reduction in the onset of smoking in the experimental students, both by self-report and saliva tests.

These and other model programs have been reviewed by an American Psychological Association Task Force on Prevention (Price et al. 1989). The Task Force noted that the common features of successful programs include "careful targeting of the population, the capacity to alter life trajectory, the provision of social support and the teaching of social skills, the strengthening of existing family and community supports, and rigorous evaluations of effectiveness" (p. 57).

3.8
Can Dementia Be Prevented?

The prevalence of dementia increases with age, from a rate of less than 1% in those aged 60–64 to a rate as high as 40% in those aged 90 and older. Prevalence increases each year both because of an increase in the size of the population at risk (i.e., the "graying" of the world population), but also because of an increase in the survival time of patients with dementia. Epidemiologic studies (Katzman 1993) in countries as different as the United States, France, Italy, Sweden, Finland, Israel, and China reveal a negative correlation between the amount of schooling received in youth and the prevalence of dementia in old age. Not only is this evident in cross-sectional studies, but lack of formal education also predicts a decline in cognitive function in a community population of individuals aged 65 and over (Evans et al. 1993). If these findings are not merely an artifact of tests for dementia (and careful analysis of the data suggests that it is not), it is possible that school-related intellectual activity results in an increase in synaptic density during development, just as a stimulus-rich environment does for the brains of other mammalian species (Eisenberg 1995). The additional "brain reserve" may delay the appearance of clinical symptoms, even though the early pathological changes of Alzheimer's disease may be present (Mori et al. 1997; Alexander et al. 1997). Thus it is an appealing extrapolation from the evidence to suggest that increasing access to public education could minimize the occurrence of dementia in the developing world, an initial approach to "primary prevention of dementia." This proposal, however fanciful, is worth implementing in and for itself. Education is an engine for development, both personal and social. This chapter has already noted the reduction in infant mortality associated with greater schooling for women (Caldwell 1986). Measures such as universal public education that have great general usefulness merit implementation, even when a direct effect on the prevention of a particular disease (in this case, dementia) is only inferential.

4
Clinical Settings: Secondary and Tertiary Prevention

The iatrogenic diseases resulting from inappropriate prescription can be reduced by training primary health care workers in the recognition and treatment of psychosocial disorders. A recent WHO 19-country study has revealed the high frequency of psychiatric morbidity among patients in general practice and the fact that health workers recognize only half of these problems (Üstün and Sartorius 1995). Similar findings have been demonstrated in child health care in the developing world (Geil et al. 1981). Training in the recognition and management of psychiatric disorders in general practice can not only reduce unnecessary diagnostic examinations and inappropriate medication, but also make effective mental health care available and thus reduce morbidity (Eisenberg 1992; Goldberg and Huxley 1992).

The "treatment gap" in epilepsy (i.e., the percentage of patients with active epilepsy who are *not* in treatment) in less developed countries has been estimated to be as high as 70%–90% (Shorvon and Farmer 1988). Because untreated epilepsy is associated with increasing psychosocial impairment worsened by the stigma associated with the disorder, improving the skills of primary health workers in the recognition of the disorder and its treatment can markedly diminish psychosocial handicap (Eisenberg 1997). Furthermore, improvement in obstetrical care, more effective accident prevention, and prompt treatment of central nervous system infections can reduce the incidence of symptomatic epilepsies.

The primary prevention of the schizophrenias is beyond present capacities. If anything, according to Kramer (1989), there will be an inexorable increase in cases of schizophrenia in the developing world because the population at risk is increasing (i.e., young adults between the age of 20 and 40). However, secondary prevention through the use of neuroleptic drugs for patients, psychoeducational training for family members, and social skills training for patients can reduce the duration of treatment episodes and the likelihood of relapse (Brown et al. 1972; Leff et al. 1982; Hogarty et al. 1986; Tarrier et al. 1989). Tertiary prevention, by keeping hospital stays to a minimum, redesigning institutional programs, and providing social skills training in sheltered workshops, can avert chronic social breakdown syndromes among patients with chronic disorders (Gruenberg and Kennedy 1988). Systematic research in China has demonstrated the remarkable effectiveness of community-based interventions in enabling chronic schizophrenic patients to be maintained in the community (Phillips et al. 1994).

In similar terms, although we lack a knowledge base for the primary prevention of affective disorders, the use of tricyclics, selective serotonin reuptake inhibitors (SSRIs), lithium, and interpersonal and cognitive psychotherapy (Frank et al. 1989) can shorten morbid episodes and reduce the likelihood of recurrence (Quality Assurance Project 1983; NIMH Consensus Development Conference Statement 1985). In view of the long-term morbidity associated with depressive illness (Kiloh et al. 1988) and the evidence that the incidence of depression in successive birth cohorts has been rising (Cross-National Collaborative Group 1992), emphasis on the diagnosis and treatment of depression in primary care merits high priority in public health programs.

The U.S. National Institute of Mental Health has developed a Depression Awareness, Recognition and Treatment (DART) Program in order to improve the ability of health workers to identify and treat depression. O'Hara and colleagues (1996) evaluated a series of DART programs at 18 sites across the United States by comparing participants' knowledge about depression before and after 2-day workshops. The findings demonstrated increases in levels of knowledge as well as a high degree of satisfaction with the program on the part of the health professionals who attended. Six-month follow-up evaluations indicated a continued positive evaluation. What is still to be established is the impact of the increased knowledge on actual behavior in clinical practice once the participants have returned to their own workplaces.

Similarly to the DART Program, the World Psychiatric Association in collaboration with the International Committee for Prevention and Treatment of Depression has initiated an Educational Program on Depressive Disorders (WPA/PTD 1997; Linden 1998). It goal is to distribute worldwide present knowledge on the diagnosis and treatment of depression and to foster clinical awareness of this widespread and disabling disorder.

Indeed, suicide prevention provides the most telling psychiatric example of prevention by treating an antecedent disorder. Depression is the most potent risk factor for suicide. Given that there are effective treatments for depression, making such treatment widely available should lead to lower rates of suicide in the population. Empirical evidence of such an effect has been reported in two studies. Rutz et al. (1989) reported a statistically significant reduction in suicide among women (and hence in the total rate) on the Swedish island of Gotland 1 year after all general practitioners on the island had completed an educational program on the recognition and care of depressed patients. The sex difference may reflect

differences in the willingness to consult doctors or in greater physician diagnostic sensitivity to depression in women. Similarly, Rimer et al. (1990) reported a negative correlation between rates of suicide and rates of treated depression in administrative districts across Hungary.

Ahrens et al. (1995) reanalyzed data on more than 800 patients who suffered from affective disorders and who had been maintained on long-term lithium prophylaxis. Whereas the mortality risk for untreated patients is three times greater than that for an aged-matched population sample, the ratio of observed to expected deaths in the treated population was the same as that for the general population. The effects of lithium indicated a reduction in deaths from suicide and cardiovascular disease.

5
Is Prevention Always Preferable?

Having shown that prevention of some mental disorders is possible, we must still ask whether it is always preferable. From the standpoint of the individual who would otherwise have become ill, avoidance of illness is almost always more desirable than treatment, because it avoids the morbidity associated with illness and its care. However, when prevention requires changing habitual behavior and particularly when change causes withdrawal symptoms (as in smoking cessation), the "cost" of prevention may deter its acceptance. Moreover, the time lag between risk taking and its pathological consequences, a matter of decades, reinforces public skepticism, because smoking cessation reduces rather than altogether eliminates the probability of disease. Although the risk of lung cancer is far greater among smokers than nonsmokers, not all smokers develop cancer and lung cancer also occurs in nonsmokers. Ways of detecting those at greatest risk (presumably because of genetic susceptibility to the carcinogens in cigarette smoke) have not yet been uncovered. The relatively slow progress of antismoking campaigns attests to the strength of social forces which reinforce cigarette smoking.

From the standpoint of the community, in contrast to that of the individual, decisions about undertaking preventive measures require weighing up competing social objectives. To pursue the instance of smoking, its elimination involves the loss of jobs in tobacco farming and cigarette production, the loss of revenue from taxation, and the loss of foreign exchange from exports. These factors do not gainsay the extraordinary benefits from smoking cessation, i.e., significant reductions in rates of cancer, ischemic heart disease, chronic obstructive pulmonary disease, prematurity, and other health hazards; however, they do highlight the magnitude of the political challenge (Director General's Report 1986).

5.1
Weighing Risks and Benefits

Prevention is so attractive a concept that, all too often, little thought is given to the potential for "toxicity" that may be associated with implementing putative preventive programs. Methods to identify individuals at risk can harm those incorrectly labeled. Programs can fail. They can cause disease in those who are not enrolled as well as harm those who are included. Paradoxically, they can have an overall negative effect on health in the community even when they benefit target groups.

Population screening to identify individuals at increased risk for disease inescapably carries with it dual hazards, i.e., that of being incorrectly labeled as being at risk (false positives) and that of being incorrectly reassured of safety (false negatives). The likelihood of error is a function of test sensitivity (the proportion of affected individuals who test positive), test specificity (the proportion of unaffected indivduals who test negative), and the a priori probability of being affected (the proportion of individuals in the population with the condition).

Ineffective measures carry two kinds of costs: first, the waste of resources which could have been used to provide other services; second, a negative impact on public opinion. When unrealistic promises are made in the name of prevention, the failure to redeem these promises makes the public cynical about other public health proposals.

An effective measure can be counterproductive when it does not reach a sufficient proportion of the population. If the uptake of rubella vaccine among susceptible children is less than 90% (the level necessary for herd immunity), an immunization program can lead to an increase in rates of congenital rubella syndrome (CRS) in the next generation because it postpones the age at natural infection among the unvaccinated. Even though CRS rates among the vaccinated population will be close to zero, rates will increase disproportionately among the offspring of the unvaccinated (Knox 1984).

An incompletely implemented prevention program can harm those it is designed to benefit. Newborn screening for sickle cell anemia poses risks for the infants positive for the disease and those positive for the trait. Infants with sickle cell anemia will benefit only if parents are thoroughly informed about the significance of the finding and if appropriate medical care is available from physicians knowledge-

able about managing the disease (Rowley and Huntzinger 1985). Infants at greatest risk for harm without offsetting benefit are those with the sickle cell trait. Undue parental apprehension may lead to a vulnerable child syndrome (Green and Solnit 1964); as an adult, the individual may be denied employment or insurance if trait is mistaken for disease. Further, as in the case of every recessive genetic disorder, testing parents carries the risk of discovering that the husband is not the father of the child, information which compromises the relationship between the parents.

That premature introduction of programs purported to prevent disease can be hazardous to health is not an argument against prevention, but it does emphasize the need for careful review of potential hazards before undertaking new initiatives and rigorous evaluation to assess both negative and positive effects after programs are introduced.

5.2 Setting Priorities

Given the fact that the resources available for health programs are finite and that assigning them to one use precludes their availability for another, the challenge is to assess the competing claims of various proposals for prevention and to decide on the proper balance between prevention and treatment. Decisions must be based on a close analysis of the extent and distribution of disease on a country by country basis and the resources, both internal and external, available to each for public health measures. The criteria to be employed in weighing up competing options include the illness burden produced by the disease, effectiveness of the intervention, its toxicity, its feasibility, and the opportunity cost (see below).

The illness burden resulting from a specific disease (i.e., senile dementia of the Alzheimer type) or a category of diseases (i.e., all mental disorders) is a function of the following: (a) the prevalence of the disease or diseases, (b) the severity of the morbidity and mortality resulting these diseases, and (c) the distribution of the ages at onset. That burden includes the cost of providing medical and social services for the ill, the losses to economic productivity resulting from sickness and death, the encumbrance on the family from caring for the sick, and the pain and suffering experienced by sick individuals and their families. Because they are more easily measured, the first two indicators (health care costs and output losses) are the ones employed when attempts are made to quantitate illness burden.

Black and Pole (1975), in a pioneering study in the United Kingdom, measured burden in terms of inpatient days, outpatient referrals, sickness benefits, and mortality. On the basis of 1972 data, they reported that mental illness accounted for 31% of all inpatient days (and mental handicap for an additional 15%), 4% of outpatient referrals, almost 8% of general practitioner consultations, and almost 10% of sickness benefit days; just over 1% of life years lost was attributable to suicide.

Rice et al. (1976, 1985, 1992) have pioneered U.S. studies of illness burden; they employed an analogous set of measures, but, in addition, they computed direct (costs for care) and indirect (losses of output from sickness or premature death) economic costs of illness. As in the United Kingdom, mental disorders accounted for many inpatient days, were a major cause of disability, and exacted considerable economic costs and life years lost. In an assessment based on 1980 data, the Board on Mental Health and Behavioral Medicine of the Institute of Medicine (1984) noted that mental illness accounted for about $20 billion in direct health care costs, about 8% of all direct health care expenditures in that year. Indirect expenditures were estimated as eight times as great. A recent Institute of Medicine study of child and adolescent mental disorders (Institute of Medicine 1989) estimates that about 16% of inpatient and 23% of outpatient pediatric insurance costs incurred by dependents in the United States were attributable to psychiatric problems.

According to the World Development Report (World Bank 1993), mental health problems make up 8.1% of the global burden of disease. Notably, this figure does *not* include brain trauma, mental retardation, or neurotic disorders; thus it is a considerable underestimate. The WHO World Health Report (WHO 1995) lists the ten leading causes of morbidity and of disability. Neurotic, stress-related, and somatoform disorders together make up the third most important cause of morbidity; in terms of chronically disabled individuals, mood disorders are the most important single cause; mental retardation is fourth, epilepsy sixth, dementia seventh, and schizophrenia ninth. The most striking data of all were provided by a recent analysis completed by Murray and Lopez (1996) from the Harvard Center for Population and Development Studies. The unit they employed in their statistics was the disability-adjusted life year (DALY). This takes into account years of life lost (by subtracting age at death from remaining life expectancy) and the handicap imposed by chronic disease by discounting the value of the years so affected. In 1990, depression was the fourth leading cause of DALYs, exceeded only by lower respiratory infections, diarrheal diseases, and perinatal conditions. In the year 2020, depression will be second only to ischemic heart disease as a cause of world disease burden. However,

despite the fact that neuropsychiatric conditions account for five of the ten most important causes of long-term disability and the fact that depression alone is currently the fourth most important cause of DALYs and will be the second leading cause by 2020, mental health is largely missing from the international health agenda.

The potential toxicity of an intervention must be weighed against its efficacy in reducing the risks posed by the disease to be prevented; in other words, although every effort must be made to minimize toxicity, even substantial side effects are tolerable if the intervention is highly effective in averting serious morbidity and mortality. The decision, however, cannot rest upon expert opinion alone. The public must have accurate information about benefits and risks set before it and must be persuaded that the one outweighs the other. Distorted publicity on side effects can lead to an increase in avoidable morbidity and mortality. Such has been the case with pertussis immunization in the United Kingdom (Centers for Disease Control 1982); concern about vaccine side effects reduced parental compliance and resulted in a substantial increase in cases of pertussis.

The feasibility of a program depends upon whether the necessary infrastructure for implementation is in place, i.e., personnel with the requisite competence to administer it, appropriate geographic distribution of such personnel, and a health system able to coordinate their activities. Thus, even a potentially effective intervention may not make sense for a particular community if it requires a level of skill and an administrative system not to be had in that community. The simpler the method and the more compatible it is for use by primary health care workers, the more likely it can be implemented in a less developed country.

Finally, it is necessary to take into account the opportunity cost (i.e., those programs forgone because funding and energy have been committed to the program under review). Because health care resources are finite, a decision to embark on a prevention program will entail diversion of resources from other health programs. The allure of cost saving from prevention is so attractive to governments that treatment facilities may be closed down on the mere assumption that disease will be avoided. Such has been the case in the United Kingdom and the United States, where the illusory promise of "community" mental health, with its claim of averting iatrogenic illness arising from hospitalization, has led to the wholesale closing of psychiatric hospitals, leaving many chronically ill mental patients without any care because community alternatives were not made available (Weller 1989).

6 Need for Epidemiologic Intelligence

Policy decisions can be no better than the quality of the information on which they are based. In the absence of reliable data on the extent, distribution, and social burden of mental disorders in the population and of time trends in prevalence, decisions on the allocation of resources can be no better than shots in the dark. It is essential to develop information centers capable of collecting and feeding back data on the nature and magnitude of the health problem in each country and on the results from treatment and prevention programs. All new public health initiatives should therefore include a mandatory set-aside of funds to pay for epidemiologic surveillance in order to facilitate periodic reassessments of effectiveness and to permit midcourse corrections in resource allocation.

General Principles for Psychiatric Treatment

Translator: S. Johnson

1 Benefits of Establishing General Principles for Psychiatric Care

A chapter on general principles of care has been a notable omission from previous editions of *Psychiatrie der Gegenwart.* In the past few decades, there have been impressive developments in psychopharmacology, and psychosocial treatment programmes have become widespread. These developments seem to have focused attention so much on specific treatment strategies for particular diseases and even symptoms that there has been little place for consideration of fundamental principles which apply for all disorders.

1.1 Historical Developments

In 1861, W. Grieser's textbook on the pathology and treatment of psychiatric illnesses set out the following general principles for psychiatric treatment: the fundamental principle of respect for humanity; the recognition that one should understand "madness as an illness" and "abnormal psychological phenomena as cerebral processes"; the absolutely equal validity of psychological and physical methods of treatment, with strong adherence to the principle of "adapting the treatment of the insane to the needs of each individual"; the need for both early intervention and patience where the course of illness is long; "protection from damaging influences" and "a properly regulated balance between rest and activity"; and finally, a rapid "move to a good asylum".

In 1929, a substantial chapter of Bumke's *Handbuch der Geisteskrankheiten* ("Handbook of Mental Disorders") was still devoted by Nitsche to "General Treatment and Prevention of Mental Disorders". Interestingly, this chapter accorded the basic principles primacy over specific measures:

> As the treatment of mental illnesses . . . remains mostly symptomatic, what we can learn from general principles of psychiatric treatment still constitutes a very fundamental part of our therapeutic equipment. . . . Variations of the general principles of treatment provide the only ways of managing individual psychiatric illnesses.

Indeed, treatments such as bed-rest, prolonged bathing or even Simon's treatment programme based on activity were hardly designed for specific clinical presentations. Compared with the rest of medicine, the discovery of treatment methods targeting particular psychiatric disorders came very late (Degkwitz et al. 1982).

1.2 Problems of Contemporary Psychiatry

The reappearance of general principles of treatment in this volume seems to me to be attributable to the following needs and problems in contemporary psychiatry:

1. In National Socialist Germany, the psychiatrically ill and mentally handicapped were victims of appalling acts of murder, sacrificed to a politically fanaticised social Darwinism as "empty human shells, unworthy of life". In the former USSR and the other states of the old Eastern bloc, psychiatry was abused in the service of political oppression. Following these events, there is again a pressing need for consideration of the basic values which should underpin all psychiatric care (Heimann 1991). The current emphasis on individual civil rights embedded in recent liberalisation movements provides a further impetus to this, as does the growing emphasis on the "healthy aspects" and demands for autonomy of even the severely mentally ill. The ethical and legal problems arising from processes such as the compulsory admission and treatment of the mentally ill are discussed in Chaps. 15–18 (Vol. 1, Part 2).
2. In the course of history, there have been continual changes not only in views of the nature of mental illness, but also in the fundamental concept of the human being on which psychiatry is based (Benedetti 1959). Recently, there has been particular pressure for change in traditional concepts and expectations of human behaviour, which are now becoming less and less tenable as world-wide migrations of peoples create culturally very mixed societies, especially in Western industrial countries. There is an increasing danger of misunderstanding the ways in which psychological distress is expressed by people from cultures with which we are not familiar, or of treating them wrongly because of prejudice or unconscious defence mechanisms. This creates new challenges for doctors in fulfilling their obligation to adhere to a concept of the individual which entails a commitment to ethical treatment.
3. More and more biological, psychological and social factors which may influence human experience and behaviour have been identified. In some areas, tensions and alienation have developed within our (as yet still) shared profession between a neurobiological and scientific psychiatry, allying itself increasingly with physical medicine, and representatives of more psychotherapeutic or social

psychiatric perspectives. In this climate, principles which are generally accepted need to be clearly established and stated, so as to prevent a fissure in clinical psychiatry between biological, medication-based treatments for the severely ill and psychological therapies for less severe disorders (Gabbard and Goodwin 1996). Because of the divergence of these movements, there is a need for integrating models and for tasks in which they can be united (Andreasen 1996) so that once again communication is possible using a common language within a shared framework.

4. Clinical practice in psychiatry is now increasingly pervaded by pressure for detailed analysis of performance, a pressure which originated in industry and has grown as business management models have become influential and health costs have risen. This requires searching consideration of the relationship between costs and benefits in our treatment measures. Political committees, funders of hospitals and health insurance companies expect more detailed disclosure of the details of our daily work with patients. This performance analysis must be linked to efforts to safeguard and optimise the quality of our treatment and also to incorporate into basic and specialist training knowledge gained through this process. In reasoned debates with the funders of health care and with those with political responsibility for it, our position is strengthened by the formulation and adoption of general treatment guidelines and by establishing standardised quality requirements and using these a basis to make claims for the resources which are absolutely necessary for their fulfilment.

So that these needs can be met, two questions need first to be addressed: Which fundamental concepts and models currently underlie psychiatric treatment, and which *should* underlie it?

2 Fundamental Models Underlying Current Psychiatric Treatment

La vray science et la vray estude de l'homme c'est l'homme.
CHARRON (1601, as quoted in SCHRENK 1973)

Especially when one considers efforts to establish theoretical foundations for it, psychiatry is obviously a medical discipline which is especially susceptible to being influenced by the current cultural climate and by changing ideologies. This is a result of the endless diversity of human destinies and the accompanying variations in the forms taken by psychological disturbances, the mysteries surrounding the major mental illnesses and the powerful emotions which the mentally ill can provoke in those around them. Finally, and of particular current relevance, it results from the mind–body problem, which has not so far been satisfactorily resolved (see Vol. 1, Part 2, Chap. 1).

However, the effects of theoretical concepts and of the ideological battles between their sometimes fanatical advocates seem to me much less striking when one considers the old pragmatic methods for "care of the insane" and also the modern practice of psychiatry. Calming the agitated patient, enlivening those who have sunk into apathy or melancholy and guiding the isolated back into an active life within the community are unavoidable necessities. These remain the constant tasks of the doctors and carers of the mentally ill, as they have been for centuries.

Except in the terrible periods of political abuse of psychiatry under National Socialism or Stalinist communism, psychiatric care has – at least since the time of the Enlightenment – aimed for care of the mentally ill which is humane and not determined by ideology. The ideological battles between the psychically and the somatically oriented, between adherents of orthodox psychoanalysis or extreme social psychiatry and the pharmacologically and biologically based psychiatric units died down some 20 years ago. The last great tide of ideology in our speciality was unleashed in the 1960s and 1970s by the antipsychiatry movement, a "late Romantic" movement (Glatzel 1975) which lacked internal coherence and, apart from the justified critique of the large psychiatric hospitals, has had little impact on psychiatric practice.

The previously dominant model in medicine was very much a mechanical one, fundamentally derived from Descartes and over-emphasising structural defects and linear causality. Currently, a paradigm shift away from this can be observed to varying degrees within medicine, towards a theory and practice in which psychological and somatic processes are understood as interdependent and multiply linked aspects of the functioning of a complex living system. The subjective experience of the patient and his or her "individual reality" are further essential elements in this model (von Uexküll 1986), which has in the last few decades also found its way into psychiatry.

2.1 Biopsychosocial Model

The great majority of types of psychiatric treatment are today based on the biopsychosocial model of human health and illness, which was first proposed for medicine as a whole by Engel (1970). According to this model, our behaviour and experience develop

from a genetic basis, follow individual predispositions, are modified by learnt behaviour patterns and conscious and unconscious strivings, and are shaped by interpersonal relationships and the influences of the environment.

Thus care which seeks to alter only somatic events, only processes which can be understood in psychological terms or only the social environment must be rejected as inadequate.

Extensions of this model to the theory of psychosis have given rise to widely accepted basic models for management of schizophrenia, in the forms of the vulnerability–stress model (Zubin and Spring 1977) and a further development from it, the vulnerability–stress-coping–social competence model (Nuechterlein and Dawson 1984; Ciompi 1986; Brenner 1989). Subsequently, this concept has also been applied more and more to depression and anxiety disorders. More recent psychosomatic theorising has produced other potentially fruitful models, such as the "functional" and "situational circle model" proposed by von Uexküll (1986), the systematic–ecological conceptual framework, which has not yet been very sharply formulated conceptually but whose content is very promising (Bertalanffy 1974; Ludewig 1992; Böker and Brenner 1996), chaos theory (an der Heiden 1992; Prigogine and Stengers 1981) or also Maturana's exposition of a biology of cognitive processes (Maturana and Varela 1987). In future, the benefits of these new directions in thinking will probably be seen not so much in individual treatment methods as in the formulation of integrating approaches to psychological disturbances.

2.2 Medical Historical Foundations

When one considers the biopsychosocial model from the perspective of medical history, it becomes obvious that it is a revival of much older concepts which go back as far as Arabic and Greek antiquity. These are the rules for living found in the *Diaita* of antiquity, which extend across many aspects of human functioning and represent a quest for "good order" and balance in human existence, both within the microcosm formed by each individual and in the individual's relationship with their natural environment and with the macrocosm (Lain Entalgo 1982; Garcia-Guillen 1982). The recommendations on the conduct of life which are derived from this relate to the six *res non naturales*: (1) light and air, (2) food and drink, (3) work and rest, (4) sleep and waking, (5) excretions and secretions and (6) stimulation and balancing of the mind. These are contrasted with the *res naturales*, i.e. the biological nature of man, and the *res contra naturam*, i.e. diseases. In the Middle Ages, these ideas were further developed and popularised as the *regimen sanitatis* (Schmitt 1982). The ultimate goal of this regime is a balanced and harmonious life, and this should be "the first and noblest interest of the doctor" (Schipperges 1962). The task is the "productive moulding of the tensions between the physical forces of nature and the creative and ordering mind of man" (Schrenk 1973). The concept of the *regimen sanitatis* was also at the root of "moral treatment" in the eighteenth century, and guidance towards a regulated order in life is a theme which has continued to appear in institutional regimes up to the present day. In this connection, links between psychological treatment and education, not least through the bridge formed by learning theory and cognitive psychology, obviously take on increasing significance. In this age of electronic data analysis, it is important not to lose sight of the biographical method as a way of approaching the individual patient.

Attempts to reinstate the ancient *Diaita* for modern therapeutics and to adapt it so that it may again become a fruitful method are potentially of great value, but such attempts are still very much at an early stage (see Tellenbach 1982). Finally, a question which arises here is whether in addition to biological, psychological and social dimensions one should consider a spiritual level. This area plays scarcely any role in modern treatment, apart from the pastoral care provided within psychiatric in-patient units, generally a very marginal aspect of these services.

3 Need for a Basic Philosophy of Treatment

In common with all professionals who work with the mentally ill, confidence with scientific models and concepts and skilfulness in implementing them are not the only attributes required of good psychiatrists. Their interactions with others need to be marked by a particular professional attitude, an inner attitude which is a product of attentiveness, self-criticism and a feeling of responsibility.

Attitudes to the mentally ill have fluctuated continually in the course of history between the poles of compassion, blame ("mad or bad") and fear. All these are feelings which we still encounter in relatives, but also in ourselves:

Christian humility and brotherly love, abhorrence of cripples and monsters, fear of madness, amusement about the stupidity of the insane, concern for the moral education of those fallen into sin, bureaucratic approaches to organising care, scientific curiosity, exclusion of the chronically unproductive, and solidarity

with the mad as sacrifices to an illness-producing society (and an illness-producing hospital) can be identified as attitudes which have determined the practical management of the mentally ill in the hospital, and which in varying mixtures still do determine it (Böker 1986).

Transference and counter-transference give rise to powerful feelings, which people without adequate training often cannot cope with. There is a great danger that they may lead to unhelpful acting out of inner tensions, such as aggression, or that in psychotherapy they encourage overstepping of boundaries, even to the point of sexual contact. We need to consider what characteristics the basic professional attitude needs to have in order to be faithful to the fundamental principle of humanity which was already to be found in Griesinger's work. This section will outline a series of precepts and recommendations of which even the experienced professional should always remain aware.

3.1
Respect for the Patient

We should always approach patients with sincerity, listen to them impartially and not intentionally lie to or deceive them. Even behind manic excitement or autistic withdrawal into a world of bizarre delusions, when control has been lost or in the intellectual disintegration of a dementing illness, the worth of the patient remains intact and is to be respected (the concept of individual worth is embedded in German basic law, which upholds the fundamental rights of every individual to attention, respect and self-determination and refers to the basic rights of every individual to attention, respect and individual development, regardless of behaviour, earnings or current state).

Each episode of psychiatric care should limit the patient's right to lead his or her own life as little as possible, so that there should be no unnecessary isolation, physical restraint or other use of force and no unnecessary segregation of the sexes, or unnecessary restrictions, e.g. on visits and outings. The patient's view of life and fundamental religious ideas are to be respected.

3.2
Reinforcement of Autonomy

A major goal of treatment is to help patients to help themselves. The only restrictions on patients taking responsibility for themselves in all private matters and on their right to a degree of privacy should be those clearly required because of the illness. This is relevant, for example, to the hospital and ward regulations that apply to in-patients.

3.3
Minimal Use of Intrusive Forms of Treatment

Both in diagnostic investigations and in therapeutic interventions, attention should be paid to differences in the degree of intrusiveness between methods. Each treatment should be as unintrusive as possible, so that out-patient treatment is to be preferred to in-patient, care on open wards to be preferred to locked wards, and each intervention with medication should use the minimum effective dose. *Primum nil nocere!*

3.4
Clear Definition of Treatment Goals and Measures

We owe it to patients and relatives to explain our judgements, intentions and actions in a comprehensible manner, at an appropriate time and after rational consideration. One must therefore:

- Formulate at an early stage a clear, realistic overall treatment plan
- Strive for close collaboration between all professions and with all those who have an important role in the patient's life
- Be able to define precisely the individual indication for each therapeutic measure

3.5
Critical Self-Examination

Everyone working in psychiatry has an obligation to constant critical self-scrutiny and continuing professional education. Supervision and peer supervision provide advice, clarification and protection against boundaries being overstepped in problematic patient–therapist relationships. They should prevent therapists from losing touch with the community of their colleagues and withdrawing into an isolated ideological position.

4
Development of a Therapeutic Alliance

For a course of treatment to succeed, especially when, as often occurs in psychiatry, it is carried out over a long period, a robust patient–therapist relationship needs to develop, i.e. an explicit or unspoken treatment

alliance needs to be formed. The first contact often has a decisive influence on the success of this relationship. If a sensitive therapist is able to adopt the basic professional attitude described above, an attitude permeated by respect and concern, he or she will quickly come to set great store by the success of this encounter. However, problems can arise. The therapist and the patient do not necessarily inhabit a common world, even if they come from the same culture and linguistic community. Both patient and therapist always have been and remain compelled to adapt their way of responding to the demands of their environment and to their personal aspirations and experiences. This gives rise to endless diversity in "individual realities" and different subjective understandings of the world. von Uexküll (1986), who placed this perspective at the centre of a psychosomatically oriented treatment method, stated that:

People realise themselves not only through the development of their bodies, but also by means of a creative achievement through which the environment they encounter is transposed into an individual reality.

What happens in medicine when these different concepts of reality encounter one another? When a patient has a fairly simple, objectively demonstrable disorder of health such as a fractured wrist, an open wound or a skin abscess, doctor and patient tend to unite quite quickly to form a treatment alliance. They bend together over a piece of work, in which assessment of the condition and management give rise to little in the way of problems of interpretation.

The situation already becomes considerably less clear in the case of general medical illnesses with complex patterns of symptoms, such as heart failure or multiple organ disorders, where there are greater difficulties in achieving a clear focus on an objectively defined piece of work. Here, phenomena such as illness gain and exaggeration or dissimulation of symptoms come into play. Thus the patient's subjective evaluations and attribution of meaning influence von Uexküll's "diagnostic–therapeutic circle". Nevertheless, doctor and patient do generally manage to reach agreement on a diagnosis of an "illness", and the patient agrees to enter a treatment alliance so as to be cured of his or her malady.

The situation in psychiatry is generally more complicated, most of all in the case of psychotic patients. Here, patients' perceptions and the functioning of intrapsychic schemata are adversely affected. Cognitive disturbances or disordered emotions impose a particular interpretation on patients' view of reality, which may then deviate to an especially glaring degree from the individual reality of the therapist. "Insight into illness" and consent to treatment cannot be taken for granted. In any case, the experience of change or disturbance reported by the patient is not necessarily characterised by suffering (e.g. in mania or ecstatically uplifted states in people with schizophrenia). So as to establish a working alliance, the therapist must first get to know the individual, psychotically transformed reality of the patient and must use patient attention to attempt to find a way into this. The scientific illness concept of the doctor (who, for example, diagnoses a psychosis of a schizophrenic type) and the private logical interpretation of the psychotically ill person (who, for example, understands the shift in his experience as the result of hypnotic influence) are in no way congruent.

However, serious consequences for necessary treatment can follow from this incongruence, so that a careful piece of negotiation must be carried out with the aim of constructing a new shared reality which allows a therapeutic relationship to be established and accepted. Particularly once the acute psychotic phase of disorganisation has subsided and stability is being re-established, this work becomes essential to pave the way for rehabilitative measures and effective relapse prevention. A plausible explanatory model needs to be introduced, allowing the subjective experience of the patient to be fitted into a scientific concept (e.g. a readily comprehensible explanation of the vulnerability–stress-coping concept of schizophrenia). This allows a patient who is at risk of relapse to comprehend and integrate into his or her individual reality sensible prophylactic measures such as the prescription of neuroleptics which are effective in preventing relapse and a low-stress lifestyle, as well as early intervention for prodromal symptoms. Patients thus also learn to communicate with therapists about their illnesses in a common language.

According to the conceptual framework of the cognitive biologist Maturana (1982), different forms of life exist in a "network of structural linkages", which as humans we constantly construct through oral communication about our behaviour ("lingolaxis"). These structural linkages create "consensual areas", for whose development a "sense of mutuality" is required. Psychiatric treatment should thus be particularly successful if it is based on a "common reality", which opens up new consensual areas between therapist and patient. In the light of such observations, therapy takes on a wider significance, as one must constantly seek opportunities to fit the structures better to one another, or – in the therapist–patient relationship – to achieve better links between individual realities. Thus treatment involves something which reaches deeper than simple technical application of methods of intervention. It comes much more to involve a shared journey, taking place over a shorter or longer period of treatment, in which the various

reciprocal interactions also produce changes in the therapist. In some ways, earlier treatment concepts have already prepared the ground for such a view of treatment: examples are the concept of empathy, the psychoanalytic transference and counter-transference constructs, the concept of "co-evolution" as the "art of growing together" (Willi 1985), the "collaborative empiricism" of Perris (1989) or the aspiration of establishing a "therapy based on partnership" (Böker 1990, 1992). The problems raised in medico-legal and ethical deliberations about how to meet requirements for "informed consent" are closely related to the issues of medical practice discussed above (for an overview, see e.g. Lidz et al. 1984).

In conclusion, a general treatment principle of great importance in psychiatry is that therapists must strive to attain a framework of understanding shared between themselves and their patients within which a productive working alliance can develop.

To achieve this goal, it is not enough to devote adequate interest and time to the patient, to tell and discuss with him or her results of examination and investigations, diagnosis and treatment plans and to involve family members – all of which unfortunately is all too often not achieved satisfactorily. We must get to know precisely the subjective reality of the patient and his or her individual values and concept of reality, so that we can build a bridge over which he or she can walk into a joint reality shared by therapist and patient. Of course the patient must collaborate in this constructive communication process and is likely to do so all the more willingly if he or she is aware of our efforts. Thus patients expect us to keep them company for a stretch of their journey. To this end, we must also change. We have to adapt rigid learned schemata to the living diversity of our patients and will thus experience the widening step by step of our horizons of understanding and our creative possibilities. Currently, the training of prospective psychiatrists unfortunately takes far too little account of these requirements.

5
Fundamental Assumptions Behind the Major Approaches to Treatment

Factors identified as possible influences on psychiatric disorders and treatment programmes for such illnesses have long since become too numerous to be readily reviewed or enumerated, and considerable difficulties arise in trying to fit them all into a set of categories based on the biopsychosocial model. The problem of numbers alone means that such an enterprise is doomed to be incomplete. The close association of biological and psychological mechanisms in many or probably in the end in all methods applied and their often substantial dependence on socio-cultural context again mean that such a categorical classification is very questionable. Many complex programmes of treatment are based on several basic principles. Other treatment programmes have been eclectically assembled or are based on therapists' personal preferences, so that basic principles cannot always be clearly identified. Practical psychiatry as a "healing art" allows for as great a variety of ways of providing care to others as there are therapists.

Bearing in mind these difficulties, for the purposes of discussion and because such a division is customary, the following section adopts a classification of the very diverse range of treatments into three domains: biological (somatic) treatments, psychological treatments and social treatments.

The universally valid principal which most of all needs to be remembered is the fundamental statement in the Hippocratic Oath, *primum non nocere*, and the fundamental therapeutic attitude described in Sect. 2 is also always applicable. A further universal principle is the obligation of the therapist to respect the ethical ground rules of his profession, such as the Hippocratic Oath for doctors, and to practice according to the *lege artis*, i.e. using established methods with a clear scientific basis (evidence-based medicine). This last requirement is taking on increasing significance with recent work on quality assurance (Gaebel 1995; Haug and Stieglitz 1995) and with an improvement in the quality of life of the mentally ill (Möller et al. 1996).

5.1
Biological (Somatic) Treatments

Attempts to alter the behaviour and experiences of humans by physical means are legion and have a thousand-year-old tradition. There are probably literally no methods involving the body which have not been tried out on the mentally ill at some time.

They range from the measures which are closely related to basic care (bed rest, cold compresses, plaster, bath cures, massages, mechanical restraint), various shock treatments (immersion in water, blows, the application of hot iron, cardiazol shock and electroconvulsive therapy), regulation of food intake (diets), coarse methods involving the whole organism (vomiting cures, purges, sweating and fever cures, insulin coma), surgical interventions (leucotomy, stereotactic neurosurgery), methods altering autonomic functioning (exhaustion, sleep deprivation, light therapy) to the use of natural medicines (cabbage teas) and industrially synthesised drugs, the psychotropic drugs which in the last few decades have become particularly

sophisticated and have become the most widely applied method.

From examination of the indications and goals for the application of these methods, they can be classified into methods for dampening agitation, promoting sleep, influencing biorhythms, lifting mood and dispelling anxiety, suppressing acute psychotic symptoms, arresting epileptic fits and diminishing vulnerability to these, stimulating (stimulants) and loosening (psychedelics) of intrapsychic connections, blockade of neuronal overactivity and hyperarousal processes (neuroleptics) and many more. The difficulty of somatic approaches and the way in which they still remain unsatisfactory is their lack of specificity. Even now, the newest psychotropic drugs are still burdened with unwanted side effects. We still know too little about the natural laws underlying the development of psychopathological symptoms to be able to plan optimal somatic interventions on the basis of mechanism of action and dosage. Our treatment is not based on causes, but on symptoms or, at best, syndromes. The following general principles for somatic treatments are widely accepted as basic rules for their use.

5.1.1 Clarification of Indication

Should a sleep disturbance be treated with hypnotics, tranquillisers or low-dose neuroleptics? Which neuroleptics are to be preferred in the acute phase and which for maintenance treatment? Is it best to subdue withdrawal symptoms from illicit drugs with medication, or does a better prognosis result from a "cold withdrawal", alleviated by massage, teas and baths? Guidelines derived from international consensus conferences will in future contain more and more advice on indications and dosage. The essential foundations for these are and will continue to be delivered by carefully evaluated clinical experience (see Vol. 1, Part 2, Chap. 10).

5.1.2 Weighing Up of Effects and Side Effects

Particularly in the use of psychotropic drugs, desired therapeutic effects are often not achieved because of ignorance of the range of effective doses, lack of care in monitoring effects or inappropriate polypharmacy, so that more harm results than good. The art is not to undermine the organism's capacity for self-regulation through wrong dosage or excessively long periods of administration (e.g. in the use of hypnotics). With electroconvulsive therapy, there are "side effects" of a social kind, in the form of the widespread aversion to it among the public. Together with the biological inadequacy of explanations for its efficacy, this has led to a very marked, albeit empirically ill-founded, decline in the use of this method and to the range of accepted indications for it becoming narrower.

5.1.3 Following Rules for Application and Dosage

Should a drug be administered orally or parenterally, in immediate release or in depot form? Each of these means of administration has advantages and disadvantages. Is a sleeping drug more effective before or after midnight? The dosage determines degree of efficacy and extent of side effects. Low dosage and a shorter period of administration of neuroleptics reduce the incidence of tardive dyskinesia, but increase the relapse rate. Extra-pyramidal side effects restrict patients' compliance, etc.

5.1.4 Attention to Interactions

When given in combination, many psychotropic drugs interact with one another in desirable or in undesirable ways. For example, monoamine oxidase inhibitors cannot be given with many other anti-depressives, and clozapine should not be given with carbemazepine. In cases of multiple morbidity, drugs are prescribed for different types of indication, and attention must then be paid to their interactions. Increasingly, dependence or self-medication for psychiatric symptoms leads patients to use drugs which potentiate the intended effects of psychotropic drugs (e.g. potentiation of the effects of sedatives with alcohol) or which counteract these (e.g. amphetamine counteracts the effects of hypnotics). In order to avoid harmful effects, doctors need to elicit carefully details of self-medication which patients may not initially volunteer.

5.1.5 Attention to the Legal Framework

Lack of insight is bound at times to lead to a need to implement against the patient's will somatic interventions such as compulsory injections, restraint and forcible feeding; the legal implications must be examined before these are used.

5.2 Psychological Treatments

Psychological methods of treatment have a history just as long as that of physical forms of care. Obtaining an overview of the whole field is perhaps even more

difficult than with biological treatments. Here, one encounters a vast number of more or less clearly distinguishable methods, which are used in bewildering diversity and varying combinations by professional therapists and natural healers, but also by lay people. The spectrum extends from magical procedures (sleeping in the temple, religious dances, magic), approaches using suggestion (group attainment of ecstatic states, individual suggestion, hypnosis), relaxation methods (catharsis, autogenic training, systematic muscle relaxation), so-called exploratory methods (psychoanalysis and the various developments from it), humanistic therapy and counselling, gestalt and imaginative therapies through to practical methods of directly influencing behaviour (behaviour therapies, biofeedback) and the newer cognitive methods. Individual, group and family therapies have each established their own practitioners and preferred types of indication.

5.2.1 Definitions

Avoiding a very restricted definition of psychotherapy as the treatment of disorders of health by psychological means, a definition such as that given by Wolberg (1967) demonstrates what an extraordinarily broad range of requirements psychotherapy seeks to meet:

Psychotherapy is the treatment of emotional problems by psychological means, in which a specifically trained therapist carefully establishes a professional relationship with the patient. Possible goals are first to remove, modify or make milder current symptoms, second to change disturbed ways of relating, and third to encourage the attainment of maturity and the development of the individual (cited in Kind 1982).

Thus the ends to which psychotherapy has been applied are not only the treatment of disturbing symptoms (the so-called medical model of psychotherapy), but also the development of the individual in ways which go far beyond this, encompassing philosophical and educational values and concepts. That the sphere with which the provider of this type of care becomes concerned extends beyond the usual professional one is one of the special characteristics of psychotherapy, but also one of its dangers. Thus, in considering this category within the biopsychosocial classification of approaches to treatment, general principles of care take on a particular importance. What are the premises, characteristics and difficulties to which special attention is needed in psychotherapeutic treatment?

5.2.2 Task and Role of the Therapist

As the danger of overstepping boundaries is greater, the task of defining the working relationship between the therapist and the person seeking help before treatment begins is even more important here than with biological treatments. The therapist must view himself or herself not as a "paid friend" or as a secret partner in love or founder of a religion, but as an expert who applies conscience and knowledge as best he can to taking a position of trust and working on an assignment for a limited period of time. Training and competence must be equal to the treatment task. Where a social insurance scheme is paying for the treatment, there is an obligation not to burden this inappropriately.

5.2.3 Clarification of the Nature of the Relationship

Closely related to the above requirement is the need to establish reasonably clearly the nature of the relationship from each perspective: does the person seeking help see himself or herself as a patient, who expects from a medical therapist the alleviation of particular disturbances or disabilities, or is it more a matter of tasks such as finding meaning, maturing or getting help with unsuccessful interpersonal relationships, tasks which a non-medically qualified therapist can also undertake? Certainly, a holistic model of psychosomatic functioning makes these goals rather difficult to distinguish and might even finally remove the separation. However, in considering problems arising in the therapeutic relationship, it is helpful to devote some thought to this issue.

5.2.4 Clarification of the Indication and Choice of Method

To be able to answer the question of which method of psychotherapy should be applied for which disturbances, deficits, disabilities or needs, the therapist must have made a careful overall study of the working principles and theoretical foundation of the various methods. Obviously a few principles are effective elements in many methods (review by Grawe et al. 1994). However, experience suggests that some methods work better than others for particular disturbances, e.g. behaviour therapy for phobias and analytic treatment for long-term difficulties with relationships. In addition to factors relating to the patient's personality, the quality of the relationship between therapist and patient is of particular importance for the outcome of treatment.

The person seeking help has the right to be treated by a method which is recognised and established from the perspectives of usual practice in the therapist's profession and the current scientific consensus ("good clinical practice"). Where therapy ventures onto new territory, the therapist must inform the patient of this and seek his or her consent.

5.2.5 Clear Specification of the Setting

Clear specification of the setting includes arrangements about the place (out-patient practice, hospital unit, patient's home), form (out-patient, in-patient, individual or group therapy), duration and frequency of therapy and the context in which third parties will be involved (relatives and others with significant relationships with the patient). If these aspects of the framework for therapy are not firmly established, uncertainties arise in the therapist–patient relationship, and the danger of boundaries being overstepped (e.g. sexually) or of acting out behaviour becomes greater.

5.2.6 Awareness of Transference and Counter-transference

Not only in full psychoanalysis and psychoanalytically oriented treatment, but in all close, long-term therapist–patient relationships, feelings are evoked or reinforced whose direction and dynamics are influenced by past emotional experiences. It is an error of professional judgement to deny their existence or to underestimate their force. As discussed in Sect. 2, one of the obligations of the therapist is to use supervision and peer supervision to seek advice and help with crucial developments.

5.2.7 Clear Specification of Breaks and of the End of Therapy

Just because of the strength of the explicit or unspoken feelings which are evoked, breaks in treatment, e.g. during holidays, and the end of the therapeutic relationship are to be handled with care. Intensive weekend meetings such as take place with primal scream therapy, encounter groups or rebirthing are dangerous in that they discharge the participant, who is sometimes in an emotionally churned-up state, back into the everyday world with no follow-up care of any sort. Practical behavioural or relaxation methods with a strong educational orientation are less problematic in this respect.

5.3 Social Treatment

The deliberate use of environmental influences in the form of practical social psychiatry or specific milieu treatments has only really become prominent in this century. Before this, people did of course consider whether and in what way a particular environment might affect the development and care of the mentally ill. Isolation of the patient played a central role in this context.

5.3.1 Isolation

The view found in the work of Esquirol and his contemporaries is that the mentally ill should "be separated from his habits and usual way of life and from the people with whom he lives, and should be moved to an unknown place and entrusted to the care of people he does not know." This is a view which was accepted until quite recently and is derived from observation of the effects of pathogenic families and unfavourable living circumstances. In such an unfamiliar environment, the doctor could "more easily win the trust of the patient, in that he encounters him with no preconceptions". The author continues: "Thus consideration and experience indicate that isolation should be seen as a central method in the rational management of mental illness" (Esquirol 1869). Following the comparative study of three English psychiatric hospitals by Wing and Brown and their colleagues between 1960 and 1968 (Wing and Brown 1970), the damaging effects of years of isolation and social understimulation in often overcrowded asylums have finally been recognised. Social psychiatry, which developed as a reform movement in the post-war years, has thus worked to open the doors of psychiatric hospitals and to make these hospitals smaller in size and sometimes to close them completely, with the aim of preventing damage due to hospitalisation and returning the mentally ill to community-based treatment.

Recently, the negative effects of certain family environments for certain types of illness have been demonstrated. For example, the Expressed Emotion (EE) studies have shown the damaging effects on prognosis for rehabilitation of intrusive expression of feelings. Happily, however, this has not now led to the re-adoption of the isolation principle, but to work aimed at helping families to adopt a style of interaction less characterised by tension or to placement of patients in the care of open facilities such as day hospitals and therapeutic residential care.

What should be understood today as constituting social treatment? Are there particular methods which can be associated with this term? Clearly no interaction with mentally ill or mentally handicapped individuals and no physical or psychological treatment of any sort can happen in a complete vacuum – there is always a social milieu of some form. Making use of this milieu for treatment purposes (for a review, see Heim 1985) is a matter not so much of specific and clearly defined individual treatment methods or techniques as of overall reflection on the social context. Social treatment is a matter of learning or relearning social behaviour and social skills under the restrictions imposed by mental illness, vulnerability or disability.

5.3.2 Applications

In in-patient treatment, spheres where there are opportunities for practising such skills include the ward meeting, in which patients have the opportunity to practice conducting relevant arguments in the group and have a say in the life of the ward. In-patients may sometimes also take on particular responsibilities, strengthening their autonomy and feeling of responsibility, or they may participate in activities such as communal cooking and leisure activities, which provide training in co-operation and communication. Outside the in-patient unit, life in social care settings such as day facilities and residential care gives rise to many situations in which patients are given realistic practice in dealing with social demands (e.g. using public transport, shopping, interacting with people in official positions or job interviews). Thus initiative, social behaviour and awareness of reality are strengthened. There is currently a fluid boundary between these methods and the methods employed in behavioural therapies such as social skills training.

Social treatment reinforces the elements in the individual which are normal, well-regulated, general, everyday and healthy – that is the elements which are free and are not linked to illness. . . . The goal of all these efforts is to allow the patient to realise fully his potential in the social sphere (Dorner and Plog 1978).

Complex concepts concerning the realisation of these goals are to be found in the specialist literature on subjects including milieu therapy, occupational and social rehabilitation, occupational therapy, work training and support in employment, community-based psychiatry, work with family and network, voluntary work.

5.3.3 Treatment Principles

With such a broad set of goals, it is not easy to formulate general principles for social treatment. A few basic principles should be set out:

1. Social treatment is invariably relevant and is indicated as a basic part of every course of psychiatric treatment. No treatment takes place without a social context, but only a structured social milieu is therapeutically productive.
2. Mental illness and handicap lead to different patterns of limitations of social behaviour, which social treatment should take into account through clear targeting.
3. Group activity (community therapy) and, if desired, temporary retreat into solitude should be balanced so that they are appropriate for the individual and the illness.
4. Psychiatric work now takes place to a large extent in teams with members from various professions. Use of skills which are specific to a particular profession must be combined appropriately with the setting of joint goals, so as to avoid role diffusion or the setting up of parallel or competing treatment programmes.
5. Milieu treatment projects are sometimes in danger of degenerating into a separate pseudo-egalitarian world, and social treatment groups must therefore not lose contact with the surrounding reality to which the patient has to return.
6. Following the basic principle of "helping patients to help themselves", social treatments must not deprive patients of their right to make decisions. Care must be gradually and carefully balanced with allowing self-determination, so that each patient's potential for autonomy is realised.

6 Need for an Integrated Treatment Framework

The results of the rapidly advancing neurosciences, genetic studies which take into account environment and behaviour, and psychopharmacosocial treatment studies reinforce more and more the belief that biological, psychological and social factors interact much more closely than earlier evidence suggested (for reivews, see e.g. Gabbard 1995; Roth 1994; Roth and Menzel 1996). Thus environmental influences are of great significance for the expression of genes; the growth of synapses and the dendritic network of brain cells is a function of cognitive and emotional demands. Recurrent powerful external stimuli (psychostressors)

trigger psychopathological reactions of increasing frequency and severity, thus clearly lowering the vulnerability threshold (the so-called kindling-sensitisation concept; Post 1992):

The neuroscience revolution has now reached a level of sophistication that allows it to serve as a bridge between biology and the psychosocial environment: we are referring to the emerging understanding of the myriad ways in which even subtle changes in the environment can produce biological changes in the brain (Gabbard and Goodwin 1996).

Thus the division made above between types of psychiatric treatment - as mentioned, made mainly for purposes of clear discussion - becomes more and more questionable, and integrative thinking and treatment in psychiatry, as in modern psychosomatically orientated medicine as a whole, becomes indispensable.

6.1 Interactions Between Types of Treatment

It has long been known that there can be interactions between many therapeutic interventions, indeed between all forms of treatment. The great variety of possible interactions has, however, received insufficient attention, although their consequences are very significant. This will be illustrated with some examples.

Even at the initial interview, where the main aim is diagnosis, the foundations are established for a psychotherapeutic relationship if "consensual areas" can be discovered (sympathy can grow from empathy) and a readiness indicated to move into the "diagnostic-therapeutic cycle". The admission of acutely psychotic patients to in-patient treatment not only removes them from a family environment which may be pathologically highly charged (a "high EE" environment), but also restructures the course of their days and thus influences biorhythms such as sleeping pattern as well as capacity for social contacts. In psychotherapeutic relationships with clearly defined conceptual frameworks, the influences of other methods also have effects; thus psychoanalysis has elements of behaviour therapy, and behaviour modification "technologies" must also take account of motivational and psychodynamic factors. Neuroleptics subdue central nervous arousal and thus facilitate patients' efforts at cognitive restructuring and promote the coping abilities which they still retain. Even psychotropic medications are a convincing example of the principle of interaction of biological and psychological influences; in his critique of modern pharmacotherapy, Blankenburg (1982) rightly points out that a sharp distinction cannot always be drawn between the "purely pharmacological", chemically and physically understood "efficacy" of a drug and the much broader "effectiveness" of a medication, to which, additional placebo effects, for instance, may contribute. A further question to be considered is

. . . how far counter-regulation, which occurs in an organism to which a particular substance is administered should be taken fully into account in assessing the 'efficacy' of that organism. In prophylaxis against relapse in schizophrenic psychosis the combination of neuroleptics and social skills training has proved to be clearly more effective than the administration of medication alone. One would also suspect that the amount of medication required in programmes which aim at low neuroleptic dosages provided in combination with psychoeducational interventions would vary with the intensity of a concurrent family therapy intervention, and that variations in requirement for medication might also show clear differences related to premorbid adjustment and prevailing family atmosphere (Blankenburg 1982).

Thus, from these considerations, one may conclude that the effects of the simultaneous use of a variety of types of intervention are not simply additive, but that the whole (a therapeutic system) is more than the sum of its parts (the treatment components). A systemic way of thinking therefore leads to new insights and possibilities for therapeutic improvements, a subject which cannot be further discussed within the scope of this chapter.

6.2 General Treatment Principles

An overall general principle of treatment which should be promoted is that we should convert our knowledge about narrowly defined biopsychosocial factors which influence human development into a multi-dimensional, integrated therapeutic framework. So that this ambitious project does not lead to conceptual confusion and fuzzy classification, it seems necessary, as before, to distinguish between different levels of treatment and interpretation. However, the artificially separated treatment components must always be brought together in the context of the fundamental biopsychosocial model and considered jointly. Psychiatrists' training should already have equipped them with the knowledge required to manage such a synthesis. In this process, they must beware of the dangers of grandiosity as much as those of biological and psychological reductionism.

CHAPTER

10

G. Andrews

Evaluation of Psychiatric Treatments

1 Introduction

In an ideal world, no new treatments should be introduced into medicine until they have been shown to be more effective, safer or less expensive than existing treatments (Cochrane 1971). In the real world, once new treatments have been shown to be effective, they are quickly promoted by their makers. The methods of the marketplace, rather than scientific argument about effectiveness, safety and cost, are used to encourage clinicians to adopt the new treatments. Before 1936, psychiatry, like much of general medicine, had few treatments that were specifically effective. Even so, the advice of clinicians was highly prized – at best, people did well with sage advice and encouragement, and at worst, people with serious disorders could be shown how to lessen the impending tragedy, while people with disorders likely to remit could be shown how to manage until the remission occurred. Even today, when we have proven and effective treatments for most mental disorders, providing considered advice about prognosis and the management of disability is an important part of medical practice. Skill in providing good clinical care (Andrews 1993), especially care for disorders for which there are, as yet, no proven or specific treatments, distinguishes good clinicians from those who are only mediocre. However, this chapter is not so much about such non-specific good clinical care. It is more about identifying specific treatments which have been proven to be effective for particular disorders and then about how to incorporate those treatments into good clinical practice.

2 Identifying Effective Treatments

A treatment is a procedure, which may be pharmacological or psychotherapeutic, prescribed to a patient in the belief that it will lessen the patient's symptoms, disability or pathology due to a mental disorder. The problem lies in deciding which treatments are of specific benefit and which are merely palliative. If a new treatment were shown to be effective in an open study with a large number of carefully diagnosed subjects who were typical of people with that disorder, would that be sufficient evidence? If the subjects were randomly allocated either to the new treatment or to treatment with placebo or standard treatment, and symptoms and disablement were reliably measured at the end of treatment and the new treatment were still superior, would that evidence be more satisfactory? If, in addition, the new treatment were sufficiently specified so that others could either make or obtain the compound, or replicate the procedure, and the study had been independently replicated, would that be sufficient evidence? There certainly would be less argument, particularly if the superiority of the new treatment over placebo was substantial. Yet there is always discussion about the effectiveness of a new treatment, simply because the above criteria are seldom adhered to. The essential steps in investigating a new treatment are discussed below.

2.1 Specification of the Disorder to Be Treated

No treatment is good for all disorders. The first step in evaluating a treatment is to specify which type of disorder and patient for whom this treatment is designed. Usually this is specified in terms of the *International Classification of Diseases*, Tenth Revision (ICD-10) or the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV), but sometimes a greater specificity is indicated. For example, the evidence about clozapine comes from trials with patients with schizophrenia who have not responded to other treatments. It is important that studies specify the characteristics of the people treated, and it is equally important that clinicians do not generalise beyond the evidence. For example, the studies that show that paroxetine is of benefit in F32.1 and F32.2 (moderate and severe depressive episodes) do not automatically mean that it will be of benefit for depressive symptoms occurring in F41.2 (mixed anxiety and depressive disorder). Paroxetine might be effective in mixed and depressive disorder, but these studies do not demonstrate this. Studies should therefore specify the reliability and validity of the diagnostic process. "Patients with depression seen at the clinic" is not enough. Clinical judgment, plus evidence from a structured diagnostic interview or rating scale, would be preferable. For instance, "patients who met criteria for moderate and severe depression, both clinically and according to the Composite International Diagnostic Interview (CIDI)" would be sufficient.

2.2 Specification of the Elements of Treatment

If a report of an effective treatment is to inform clinicians, it must specify both the characteristics of the new treatment and the implementation regime. If the new treatment is a medication, then the compound or components of the medication must be specified, together with the levels of purity and the form of the

final preparation. In most countries, this level of specification is required by the licensing authority before the medication can be marketed. Non-drug treatments, such as psychosocial interventions and other psychotherapies, are not subject to such constraints, and it is essential that the procedures to be undertaken are fully specified. "The therapist should facilitate the resumption of growth and increase the understanding of self and other . . .", for instance, does not specify what the therapist should actually do. Many psychotherapies, especially the cognitive behavioural therapies, are now fully specified in manuals which describe exactly what the therapist should say, e.g.: "As part of this programme, we are going to examine the way you think about yourself and others. It is likely that you have some unrealistic and therefore unhelpful beliefs which . . . ." Only if a treatment is fully specified can it be replicated by others. Treatments which are effective, but unspecifiable must necessarily die with their originators.

2.3 Specification of How the Treatment Was Administered

Specification of the elements of the treatment is only one part of the story. Each description of a treatment must also specify the process of implementation: dose, route and frequency for medication, frequency and duration of sessions for a psychotherapy. It is also important to specify the setting of treatment and the use of ancillary treatments, e.g. "prescribed as part of a comprehensive in-patient rehabilitation programme" is clearly different to "prescribed monthly in outpatients". Specification has two purposes: (1) to allow others to use a proven treatment with their patients and (2) to allow the elements in the treatment to be identified if there is discussion about which element in the programme is the essential element.

2.4 Measuring the Change in Symptoms

The purpose of treatment is to reduce symptoms and complaints, reduce disability and improve the quality of life and, if one is really fortunate, reduce risk factors so that relapse becomes less likely. Measures need to be applicable, reliable, valid and sensitive to change. A list of common measures that meet these criteria is displayed in Table 1.

2.4.1 Applicability

The measures chosen must meet the broad aims of the study; certainly all clinically relevant outcomes must be measured and reported. Thus a study of depression needs to use a symptom measure that identifies the symptoms of depression, and a general symptom measure alone will not suffice. If the study is a long-term study, then the number of people who commit suicide should also be reported, because depressive symptoms and suicide would both be clinically relevant outcomes. A study in which the primary aim is the maturation of personality needs to use measures of personality maturity, and again a general measure of well-being will not suffice if it is the only measure used. Measures should be matched to the aim of the treatment. While symptom measures must be specific to the diagnosis of interest, disability and quality of life measures can be more general, applicable to all mental disorders or even to all disorders.

2.4.2 Reliability

A measure should be a reliable measure of the characteristic being measured, i.e. it should return the same value when re-administered on two occasions or by two different people to subjects whose status has not changed. The more reliable a measure is, the better. There are a number of ways of measuring reliability. *Internal consistency* refers to the assumption that items in a scale should be measuring the same general phenomenon and should be correlated. Cronbach's alpha is the statistic used, and values greater than 0.8 are desired. *Inter-rater reliability* refers to the consistency with which two raters record the information being elicited at one interview. Agreement should be close to perfect, and the kappa statistic should be close to 1.0. *Test-retest reliability* refers to the consistency of the scores on two administrations at different times when there has been no change in the state of the individual being measured and is also estimated using the kappa statistic. Test-retest reliability is always less than the inter-rater reliability, because it includes that element, and values of 0.8 are to be desired.

2.4.3 Validity

Validity refers to the extent that a measure accurately measures what is being measured. Reliability sets an upper limit on the validity of a measure and if, for instance, the kappa statistic for test-retest reliability is 0.8, the kappa statistic for validity must be less than this. Estimating validity should be quite simple: we merely have to estimate the degree to which the measure correlates with some perfect measure of the characteristic of interest. Unfortunately, there are very

Table 1. Outcome measures

Title	Time (min)	Description	Reference
Beck Anxiety Inventory	10–40	Self-rated questionnaire 21 symptoms, rated on a 4-point scale; symptoms covered include: numbness or tingling, unable to relax, unsteady, terrified, hands trembling, fear of dying, indigestion	Beck et al. (1988)
Beck Depression Inventory	5–10	Self-rated questionnaire 21 symptoms rated on a 4-point scale, with behavioural anchors provided; symptoms covered include: pessimism, sense of failure, self-dissatisfaction, guilt, self-dislike, suicidal ideas, social withdrawal, indecisiveness, body image change, insomnia, fatigability, weight loss, somatic preoccupation, loss of libido	Beck et al. (1961)
Behaviour and Symptom Identification Scale	20–30	Interviewer-administered interview, or self-administered questionnaire 32 items with five subscales: relation to self and others, daily living and role functioning, depression and anxiety, impulsive and addictive behaviour, psychosis	Eisen et al. (1994)
Brief Psychiatric Rating Scale	18	Clinician-rated scale following interview 16 symptom constructs rated on a 7-point scale: somatic concern, anxiety, emotional withdrawal, conceptual disorganisation, guilt, tension, mannerisms and posturing, grandiosity, depressive mood, hostility, suspiciousness, hallucinatory behaviour, motor retardation, uncooperativeness, unusual thought content, blunted affect	Overall and Gorham (1962)
General Health Questionnaire	6–8	Self-rated questionnaire Initially developed with 60 items covering four areas: depression, anxiety, objectively observable behaviour, hypochondriasis. Revised versions have 30, 28, 20 and 12 items	Goldberg (1972)
Health of the Nation Outcome Scales	15–30	Clinician-rated rating scale 12 scales: aggression, self-harm, alcohol and drugs, memory/orientation, physical problems, mood disturbance, hallucinations and delusions, other mental, social relationships, social environment (housing and finance), overall severity	Wing (1994)
Hamilton Anxiety Rating Scale	15 (estimate)	Clinician-rated semi-structured interview 14 symptoms rated as none (0) to severe (4): anxious mood, tension, fears, insomnia, intellectual, depressed mood, somatic (muscular), somatic (sensory), cardiovascular, respiratory, gastrointestinal, genito-urinary, autonomic, behaviour at interview	Hamilton (1959)
Hamilton Depression Rating Scale	20 (estimate)	Clinician-rated semi-structured interview 21 items with 3-, 4- and 5-point scales used; behavioural anchors provided; symptoms covered include: feelings of guilt, suicide, insomnia (early, middle, late), agitation, genital symptoms, loss of weight	Hamilton (1967)

Medical Outcomes Study Short Form-36	5–10	Self-rated questionnaire (can also be given to an informant or administered at an interview) Eight multi-item scales: physical functioning, physical and emotional role limitations, bodily pain, mental health, social functioning, vitality, general health perceptions, reported health transition	Ware and Sherbourne (1992)
Mental Health Inventory	10–15	Self-rated questionnaire 38 items with five subscales: anxiety, depression, behavioural/emotional control, general positive affect, emotional ties	Veit and Ware (1983)
Role Functioning Scale	Few minutes	Clinician-rated rating scale Four single scales: working, independent living and self-care, immediate social network relationships, extended social network relationships	Goodman et al. (1993)
Scale for the Assessment of Negative Symptoms	20–30	Clinician-rated rating scale 24 items with five subscales: alogia, affective flattening, avolition-apathy, anhedonia-asociality, attentional impairment	Andreason (1982)
Scale for the Assessment of Positive Symptoms	20–30	Clinician-rated rating scale 34 items with four subscales: hallucinations, delusions, bizarre behaviour, formal thought disorder	Andreason and Olsen (1982)
State-Trait Anxiety Inventory	10–20	Self-rated questionnaire Two scales with 20 items each: state anxiety (A-state) and trait anxiety (A-trait)	Spielberger (1983)
Symptom Checklist 90 (revised)	10–20	Self-rated questionnaire 90 items covering nine primary symptom dimensions: somatisation, obsessive compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, psychoticism; three global indices: lobal severity index, positive symptom distress index, positive symptom total	Derogatis (1977)
WHO Psychological Impairments Rating Schedule	5–10 after interview	Clinician-rated rating scale 97 items covering ten areas: psychic tempo, attention, fatigability, initiative, communication by facial expression and by bodily language, affect display, conversation skills, self-presentation, cooperation. Item behaviours rated as absent, present, or present in a more severe form. Cost unknown; extensive training required	Jablensky et al. (1980)

few perfect or "gold standard" measures, and one must compare the measure with the best of the other measures. Ideally, the correspondence between a measure and the "gold standard" for estimating the characteristic should be very high; however, the validity of a measure will be limited by unreliability in both the criterion measure and the present measure.

Clinical judgment is often used as the gold standard for psychiatric measures, but this is inherently unreliable and kappa statistics for this type of validity are often quite low. We must remember that if two clinicians disagree, one or both must be wrong; both cannot be right. *Face validity* refers to whether the questions on a scale look as though they are measuring what they are supposed to be measuring (this is really a component of acceptability, not validity). *Content validity* refers to the extent that the measure covers the domain of information to be measured adequately. Agreement with a panel of experts is one method for assessing this characteristic. *Criterion-related validity* refers to whether or not the measure is able to predict scores on an independent and direct measure of the characteristic. *Construct validity* refers to the extent to which the measure may be said to estimate a theoretical construct or abstract attribute such as health or quality of life. Demonstration of construct validity depends on the accumulation of information from a number of sources, both those measuring the same construct (convergent validity) and those measuring different constructs (discriminant validity).

2.4.4 Sensitivity to Change

Measures used to identify effective treatments must be capable of registering change due to treatment in the target symptoms or disorder. Measures with multiple response options are more likely to be sensitive to change, but there are two additional issues, i.e., whether the measure covers the new range of scores and whether the characteristic has had time to change. For example, measures designed to cover severe psychosis commonly fail when the person has recovered, because there are no questions to describe being well. Secondly, different characteristics take different times to change, and the timing of measurement must allow for this. Symptoms may change within a week and can be measured and show change after that time. Changes in disablement require that the patient has time to experience the lessened handicap and cannot be measured for some time after the improvement in symptoms has taken place. Changes in risk factor measures take even longer to become manifest.

2.5 Ensuring that Improvement Is Due to Treatment

One might think that if reliable and valid measures showed a significant change in symptoms when a well-specified treatment was applied to a carefully diagnosed group of patients, then it could be safely assumed that the treatment was responsible for the improvement. It might be, but we cannot be certain, because three other factors that are very likely to be present can mimic the beneficial effects of a treatment. These are spontaneous remission, regression to the mean and the placebo response.

Some disorders run a phasic course. Major depression is a good example, and symptoms remit spontaneously some months after the onset of the disorder. As people seldom come for treatment until the disorder has been present for a few months, remission can be expected within some months whatever is done.

Regression to the mean is a special variety of the spontaneous remission phenomenon and applies to disorders that are chronic and do not remit. Even in such disorders, the severity of symptoms fluctuate, being worse at times and better at times. People try to manage their chronic diseases as best they can. When the symptoms have lessened in intensity, they are less likely to seek help, being more likely to go for help when their symptoms seem to have worsened. Thus, among patients who consult doctors, even if no treatment is given, it is more likely than not that the period of severe symptoms will be followed by a return to the average level of symptoms or even a move to mild symptoms. In both these circumstances, when spontaneous remission is likely or regression to the mean probable, the response may mimic a true treatment response. "Waiting list" and "no treatment" control groups can measure the change due to these phenomena, i.e., the spontaneous remission occurring in remitting conditions and regression to the mean occurring in chronic conditions.

"Waiting list" and "no treatment" control groups do not, however, control for another important confounding factor known as the placebo effect. When people believe they are being treated by an effective remedy, when in fact they are being treated by an inert remedy, a response related to the expectation of getting better may mimic the effect of treatment. People in treatment are encouraged to capitalise on each improvement trend and to minimise each setback. Improvement is experienced as progress due to treatment and setbacks as mere random phenomena of minor import. Placebo-controlled trials, in which one group is treated by a treatment which the experimenters but not the patients

know to be inert, can estimate the extent of both the placebo effect and the other two phenomena, spontaneous remission and regression to the mean. In some disorders, such as obsessive compulsive disorder and schizophrenia, the magnitude of these non-specific treatment effects is small, while in other disorder, such as depression or generalised anxiety disorder, the changes seen in the placebo group can be quite considerable and equal in magnitude to the changes resulting from the specific treatment itself.

When a group of patients are treated with any effective treatment, the resulting improvement can be decomposed into two elements: that due to the non-specific effects of being in treatment (i.e. to the result of spontaneous remission, regression to the mean and the placebo effect) and that due to the specific power of the treatment to lessen the severity of the disorder. Thus the observed clinical change in any patient who is being effectively treated will be greater than that due to the specific treatment being used, although in clinical practice it is conventional to attribute the change to the specific treatment being used and to ignore the contributions that the non-specific effects of being in treatment may be making. Sometimes, as when carrying out cost–benefit calculations, for example, it is helpful to distinguish the two components, and this is another reason why placebo-controlled trials are so helpful.

There is another element of treatment that is helpful to define. Some treatments are designed to relieve or control symptoms. Antipsychotic drugs in schizophrenia would be a good example. Treatment is thus designed to be long term and should be continued throughout the natural history of the disorder. Other treatments actually seem to end the disorder, e.g. graded exposure in agoraphobia, and treatment can be discontinued once the patient is better because they will then stay better in the absence of any contact with the therapist. Follow-up studies in agoraphobia show stability of improvement for 5 and 8 years following behaviour therapy, as though the person were cured. Cure, of course, not only means that the symptoms are relieved and disability lessened, but also that the person's risk of once again developing the condition is similar to that of the normal population. Follow-up measurement should thus specify whether the measurements were made while treatment was continuing or after treatment had been concluded. Again, such a differentiation between the control and cure effects of treatment is important in costing studies, because treatments that cure are intrinsically less expensive in the longer run, even if they might appear to be more expensive in the shorter term.

2.6 Randomised Controlled Trials

We began this chapter with the idea that no new treatments should be introduced into medicine unless they had been shown to be more effective, or as effective but safer and cheaper, than existing treatments. The randomised, controlled trial is the key to this set of decisions. Conceptually very simple, such trials are very difficult to conduct once they involve more than the short-term comparison of one drug against another. It is essential that such trials be conducted on all specific treatments used in psychiatry, and this is increasingly being done. They should also be conducted on all treatment programmes, but these are very seldom tested (see Kluiter and Wiersma 1996).

The idea behind a randomised, controlled trial is that a group of people with a specific disorder are carefully assessed and, if deemed suitable for treatment, they are informed that there are two possible treatments: usually one that has been in use for some time and a new treatment that is believed to be equally safe, but is possibly superior. They are asked to consent to either treatment and are randomly assigned to one or the other. They are then measured again prior to treatment commencing and at the end of treatment if treatment is believed to "cure" or when the effect of treatment is deemed to be maximal if the treatment is believed to control symptoms. Finally, they are measured at follow-up. Ideally, all people who entered the trial are followed up, even those who may have dropped out of treatment for one reason or another. The difference in scores of the two groups at the end of treatment or at follow-up are compared. Any difference is attributed to the differences in the two treatments, as all other sources of variation are believed to be controlled.

It is ethically unsound not to determine the efficacy of a treatment or treatment programme. If public or private money is being used to support it, and if people who are sick are accepting it on the basis that it is the best treatment available, then it must be evaluated, preferably by a randomised controlled trial against placebo or other treatment. Awkward as it may be, clinicians have a duty to evaluate all unproven treatments unless the evidence is as compelling as the examples listed below (see Sect. 2.7). Nevertheless, many proponents of unusual therapies claim that their therapies are so distinctive that unbiased assessment is impossible. Evaluation of those therapies will therefore have to depend on patient self-reports, not so much of symptoms, but of a lessening in the disability and handicap in those receiving the treatment as against

those receiving treatment as usual. There are no treatments that should be exempt from scientific scrutiny.

Getting patients to agree to enter trials is often very slow and time-consuming. Most have been referred for specialist treatment, and the fact that they might now "be experimented upon" is of real concern to them. Sometimes inducements are offered – treatment is made free or immediately available – but the effect of inducements is to narrow the type of people entering the study to those that cannot afford to go elsewhere. There is no easy answer, one can only present the truth in either of the two scenarios. The patient information for the randomised, comparison-controlled trial should state that there is a proven treatment and another about which there is reason to believe that it will prove superior (otherwise the trial would not be carried out), although it cannot be guaranteed that the effect will not be the same or worse than the standard treatment. In contrast, the patient information for a randomised, placebo-controlled trial should state that there is no proven treatment for the patient's disorder but that there is reason to believe that a new treatment might work, but again it cannot be guaranteed that the new treatment will be better than a continuation of good clinical care.

The purpose of randomisation is simply to ensure that all factors likely to influence outcome are equally distributed across the two treatment groups. As we cannot know which factors might prove of prognostic import with a new treatment, people are randomised without knowledge of their characteristics or the characteristics of their illness. While the idea is simple, the process is complicated, and tossing a coin is not enough. Experimenters have been known to bias the allocation of people with a good prognosis to the favoured treatment (Sackett et al. 1985). Thus it is essential that randomisation is carried out by a process that does not allow the allocation to treatment group to be biased by the experimenter. When the trial is complete, it is necessary to demonstrate that randomisation resulted in groups that were equivalent in relevant characteristics; otherwise, in the final calculations, some statistical corrections for the imbalance will be necessary, even if this method is not as satisfactory.

If experimenters with full knowledge of the allocation to group are asked to complete rating scales, it is very difficult for them not to be swayed in the direction of their hypothesis. Judges completing open rating scales should therefore be blind as to which patient is allocated to which group; neither therapists nor patient should know which treatment the patient is receiving, and raters of the outcome should not know either. It is possible to achieve this level of blinding in short-term drug trials, whether comparison or placebo-controlled, but impossible to manage the latter steps when the treatment involves a psychological or social intervention. Having unblinded raters who are ignorant of the purpose of the study is one solution, but the more usual solution is to use highly structured patient questionnaires and interviews that minimise the subjective element in the ratings. If allocation to group is truly random, then the only information required is the status of each patient at the end of treatment, although it is usual to measure prior to randomisation, when treatment begins, at the end of treatment and at follow-up. The pre-treatment information is valuable should randomisation not be effective and some correction by analysis of covariance be required.

As both groups are being treated, one by the experimental treatment and one by placebo or standard treatment, and as both groups are being measured at the same time after treatment begins, then spontaneous remission, regression to the mean and the placebo response should be the same in both groups. However, it is very easy for the patients in the control groups to realise that their treatment is not deemed important by the experimenter and to reduce their expectation of improvement. Unless the identity of the experimental treatment is clearly masked, as in a placebo-controlled drug trial, it is essential that each patient's perception of the adequacy of treatment be measured to identify any such bias. When programmes of treatment are being trialled, such as in-patient versus day-patient care, the views of the staff can be very influential in controlling the adequacy and the perceived adequacy of treatment. It is therefore important to ensure that treatments are carried out as intended. It is usual to measure this by tape recordings or ratings of the process of treatment. While it is important to specify treatments, it is equally important to demonstrate treatment integrity.

The analysis of a randomised, controlled trial is relatively simple. Having decided before the study begins which is the key outcome measure, the simple question is whether the scores on that measure are significantly different in the two groups. The probability of a significant finding depends on three things: the size of the difference, the variability of the scores and the number of subjects in the trial. No study should be commenced unless a power analysis shows that there is at least an 80% chance of showing a significant difference ($p < 0.05$) given the expected effect size in standard deviation units (SD). The effect size is the difference between the group mean scores at the end of treatment divided by standard deviation of the control group scores. If there are large numbers in the trial, then it is likely that the difference will be

significant even if it is of no clinical utility – essentially a false-positive finding. If the numbers in the trial are small, there may be a clinically significant difference between the groups that does not reach significance because of lack of power – essentially a false-negative finding. The relation between the number of subjects required in a study and the effect size is curvilinear; only seven subjects per group are required if the effect size is likely to be 1.5, 14 subjects if the effect size is 1.0, and more than 50 subjects per cell if the effect size is likely to be 0.5 SD. The clinical significance of a measure also depends on the nature of the measure. A one-third standard deviation difference in scores on a measure of depression is probably not clinically significant, but the same change in suicide rate would be. Lastly, all the subjects who were randomly allocated should be included in the analysis – the intention to treat rule – simply because drop-outs are more likely to occur when the treatment is more onerous or less immediately effective and hence, if ignored, would inflate the result associated with the less satisfactory treatment.

2.7
In the Absence of Randomised Controlled Trials

Sometimes a trial is not necessary to know that a treatment is effective. Streptomycin in children with tuberculous meningitis eliminated certain death, and no trial was required. Few improvements are so obvious, but this example does highlight the obvious issue: if the effect of treatment is sufficiently strong for all to see, it is unlikely to be due to faulty measurement or to the other confounding factors. Many new treatments are first evaluated by doing an open trial in which patients with a defined illness are given the treatment and measured at the beginning and the end of treatment. This will demonstrate whether the improvement might be statistically or clinically significant. If it is, then examination of the magnitude of the placebo effect, spontaneous improvement and regression to the mean that are likely in this disorder can be judged from other trials. After subtracting the placebo effect size from that obtained in the pre-post trial, it will be obvious whether the change due to the specific treatment is still likely to be clinically significant. It is then that the investigator should proceed to a randomised, controlled trial.

There are three circumstances in which evidence from open trials in a disorder should be taken seriously. The first is if there is a substantial body of evidence from pre-post trials in which the change due to treatment is large while the evidence from other trials makes it likely that the response to placebo is small. As always, independent replication of results reduces the likelihood that selection, measurement or experimenter biases could account for the positive result. Behaviour therapy for obsessive compulsive disorder was almost totally reliant on evidence from pre-post trials, yet the efficacy of this treatment is well accepted. Fortunately, there is now evidence from randomised controlled trials that supports the extensive data from the open trials. The second attribute is a dose–response curve in which small doses or hours of treatment produce only a little improvement and increasing improvement is associated with increasing doses or hours of treatment. Theoretically, the placebo response should also show a dose–response curve, but there seems to be a plateau after a certain time with no further benefit thereafter. The third circumstance in which open trial data can be convincing is when there is replicated evidence of the effectiveness of treatment from baseline pre-post trials with a long follow-up, i.e. trials in which the duration of the baseline and follow-up are both many times longer than the period of treatment. Such long baseline and long follow-up trials are common in cognitive behaviour therapy and are respected because a long baseline serves to measure the effect of spontaneous remission and regression to the mean, while the long post-treatment follow-up without continued contact with the therapist means that any sustained improvement is unlikely to be due to a placebo response. Nevertheless, despite this type of evidence, critics will only finally be convinced by evidence from randomised placebo- or comparison-controlled trials.

3
Aggregating the Results

3.1
Systematic Reviews of the Literature

There are three traditional sources of information when reviewing the evidence of treatment effectiveness: information from experts, from current practice and from treatment trials. All sources can be valuable. When all else fails, the opinions of experts are very valuable in delineating what is the best practice and in identifying the shortcomings in research. Provided the experts are representative of the profession, then their considered opinion is important; "three wise men" have always been better than a single ill-considered opinion. In like vein, a careful delineation of what is current practice among the majority of clinicians is likely to be more balanced that the view of zealots. Nevertheless, despite the value of expert opinion or a consensus among practitioners, there is a profound respect for the evidence represented by the

scientific literature. Sometimes this respect can be misplaced.

Reviews of the literature have very low status. They are merely expressions of opinion supported by a selective review of the literature. A systematic review of the literature defines how the articles were identified, the basis on which they were selected for review and the system used for collating their findings. Sometimes a complex field can be simplified if attention is confined to replicated findings. This can be further systematised if the degree of replication is identified. For example, multiple replications in independent clinics with no negative findings are more convincing than independent replications with some negative findings (the reviewer should seek to explain the differences), which are in turn more likely to be stable than evidence based on replications confined to one centre. This ranking of the confidence that can be placed in a "fact" allows the reviewer to confine his or her attention to such facts and to relate the findings to a causative theory (see Andrews et al. 1983). While useful in demonstrating the reliability of the finding, such reviews fail to estimate the strength of the association, information which is especially important when treatment studies are being reviewed.

3.2 Meta-analysis

It has always been possible to aggregate the results of studies that used the same measure of outcome. One simply reported that the average improvement to be expected across the trials on a certain measure was such and such a value. The problem for psychiatry is that there are few commonly agreed measures, so that even in one disorder, such as depression, trials will very probably use one of the ten or so reliable and valid depression measures. Aggregating the results of these trials was difficult until Glass (1976) introduced the Cohen effect size estimation to clinical practice. Using this procedure, the difference between the experimental and control group mean scores on any outcome measure is standardised by dividing the difference by the standard deviation of the control group scores. The resulting measure of benefit or effect size is, theoretically, independent of the scale from which the effect size was derived.

The rationale for meta-analysis is as follows: symptoms of patients coming for treatment will range from mild to severe and be distributed about the scores of the average patient. Random allocation of patients to experimental and control groups should result in groups with similar distributions of symptoms. After effective therapy, the condition of the experimental group will have changed more than the control group, and a measure of this effectiveness is the distance between the distributions of the experimental and control group symptom scores at this time. This can be measured in standard deviation units and is called the effect size. From the area under the normal curve, it can be calculated that, given an effect size of 1.0, the average person in the experimental group will be better than 84% of people in the control group, a gain of 34 percentile ranks. Effect size superiority over placebo of less than 0.5 is associated with weak treatments, whereas an effect size superiority of more than 1.5 is associated with strong treatments. Most established treatments in psychiatry show effect size superiority over placebo of between 0.5 and 1.5 SD.

Given that the effect size is theoretically independent of the scaling properties of the measure used, be it symptom checklist, rating of severity of disorder or evidence of disability, then the comparability of the effect size derived from different outcome indicators allows studies to be compared statistically. Furthermore, details of patients, treatments, measures and study design can be assigned numerical values and related to the effect size. Calculating the effect size is simple when means and standard deviations are reported by the authors of a study. All authors should report these statistics, but only some do. The effect size can often be calculated in the other cases, but the procedures are complicated. Nevertheless, clinicians should become used to making effect size calculations, if only to be able to standardise their understanding of the power of a treatment.

3.3 The Cochrane Collaboration

Cochrane (1971), whose ideas were used to begin this chapter, also called for a regularly updated critical summary of all relevant randomised, controlled trials. While the first meta-analysis of interest to psychiatry, and indeed to medicine, was Glass's study of all reports of psychotherapy (Glass 1976), the first meta-analyses of clinically relevant material were the re-analysis of the Glass material now confined to clinical cases (Andrews and Harvey 1981) and the meta-analysis of the treatment of depression (Quality Assurance Project 1983) published as part of an early best practice protocol initiative. Ten years later, the first Cochrane Centre was established in the United Kingdom, and there are now centres in many developed countries. This network of international centres is called the Cochrane Collaboration. The centres have established registers of randomised, controlled trials and regularly publish reviews of trials in electronic format. At present, the principal task is to hand-search hundreds of journals for trials, because MEDLINE and PsychLIT

databases do not allow all randomised controlled trials to be identified. Nevertheless, the Cochrane Collaboration has already published reviews of important and difficult topics, such as family intervention and case management in schizophrenia, comparative efficacy of anti-depressant classes and the efficacy of critical incident stress debriefing. These are being continually extended and updated.

3.4 Evidence-Based Medicine

On the basis that good practice usually means more than the application of a single treatment agent, many countries have convened meetings of experts to determine what best practice for particular disorders might be. Usually the experts review the literature, acquaint themselves with current practice and make consensus recommendations that are science based in terms of identifying which treatments have been shown to be effective in clinical trials, and practice based in terms of which treatments and clinical procedures are likely to prove efficient in a particular treatment setting. Most clinicians should now have access to a wide range of such treatment protocols and manuals. Many clinics have taken the standard protocols and modified them to suit both the practice conventions of the clinic concerned and of their patient clientele, thus ensuring that they use proven effective treatments in the most efficient manner.

The move towards consensus-based treatment protocols began 15 years ago with two initiatives, one when the U.S. National Institutes of Mental Health convened a number of conferences on clinical problems of the day, and another when an Australian group began writing treatment guidelines for the ten most common mental disorders (see Quality Assurance Project 1983). These initiatives were initially resisted, because many practitioners feared that guidelines for treatment of certain disorders would limit a physician's freedom to do what was best for a patient. An additional worry was that the physician would be legally liable for any mishap when or if such guidelines were departed from. In effect, even physicians who use such guidelines find that they are constantly changing the actual treatment guideline to meet the needs of each individual patient. Thus the guidelines inform and expand the clinician's competence; they do not limit or restrict. The change in atmosphere about guidelines means that both government agencies and professional associations are currently developing guidelines for practitioners. Both the U.S. Agency for Health Care Policy and Research and the New Zealand Department of Health are producing guidelines for general practitioners, while the American Psychiatric Association, the American Psychological Association and the British Royal College of Psychiatrists are producing guidelines for their members. That this is a general trend is evident from the World Health Organization's initiative to review the effectiveness of treatments for mental disorders (Sartorius et al. 1993), which followed the publication of ICD-10, but whether such best practice protocols will result in preferred funding for practitioners who adopt them remains to be seen.

4 Applying New Treatment Data in Practice

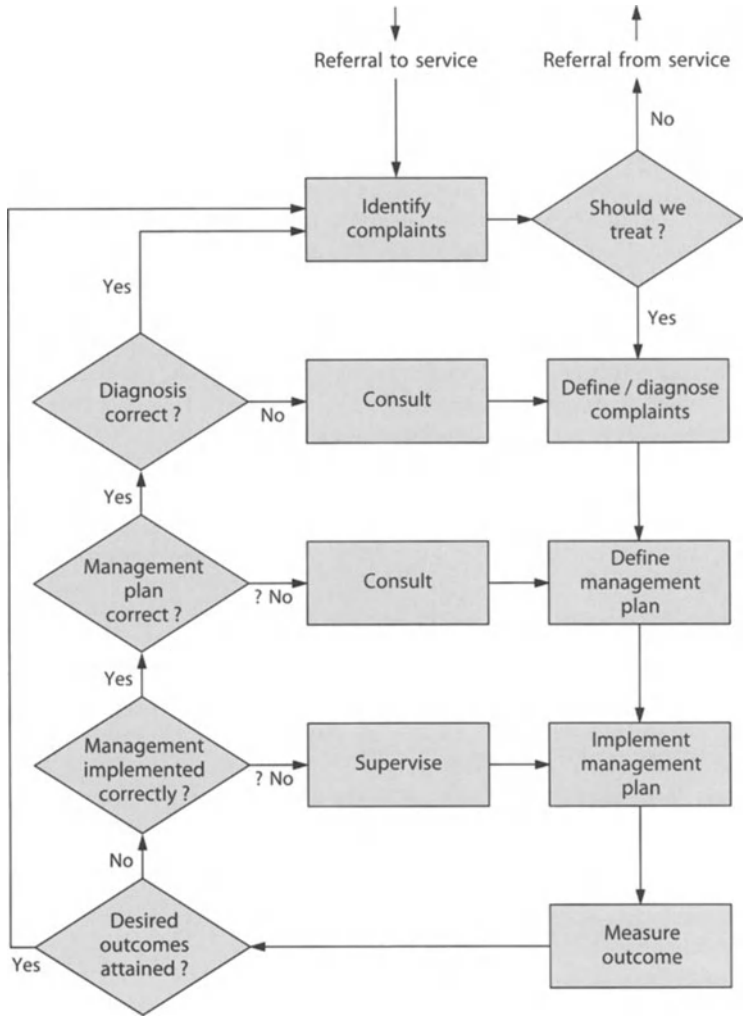
4.1 Learning About New Treatments

Good clinical practice is about absorbing the best information from the literature and then applying it to the care of an individual patient. Sackett et al. (1985) published strategies for busy clinicians to use when reading clinical journal articles. While the general issues are dealt with in the preceding sections, the specific questions that an individual clinician should ask about any article reporting an advance in treatment are somewhat different. According to their strategies, an article about treatment should not be read unless there is clear evidence of random allocation of patients to treatments, the results are statistically and clinically significant and all patients who entered the study are accounted for in the conclusion. If these provisos are met, the next set of questions concerns applicability to one's own practice, i.e. whether all clinically relevant outcomes were reported, whether the study patients were recognisably similar to one's own and whether the therapeutic manoeuvre is feasible in one's own practice with the training one has or could obtain. If the answers to these questions are positive, then one should consider using this therapy with the next suitable patient, which is a serious responsibility. There is a belief that the patients included in randomised, controlled trials are not typical of those seen in clinical practice. This is true in two ways. Patients in clinical practice tend to span a greater range; some have milder variants of the disorder, and their need for treatment would not cause them to volunteer for a trial, while others have more complex disorders and would often be excluded from a trial because of the presence of these exclusion criteria. However, on balance, there is no evidence that the patients in clinical trials are especially easy to treat. This is certainly a topic that should be investigated, because on present evidence it seems likely that the

results of randomised controlled trials are atypical in that both mild and complex cases will be underrepresented but the results will suffice for the average run of cases. Clinicians, however, are adroit at personalising therapy for the exceptional patient.

Because of clinicians' ability to personalise therapy, some discussion of the steps in good clinical care is in order whereby the results of the literature are integrated into the care of an individual patient. In fact, in order to understand the role of any specific treatment, it is helpful to have a model for good clinical practice (see Fig. 1). When patients go to a doctor or attend a mental health service, they have the right to be seen by a skilled clinician who can assess whether the service is competent to treat their complaints. People whose complaints are mild can be advised about self-care, while those with complaints that are outside the competence of the clinic can be referred elsewhere. Patients whose complaints are consistent with a disorder that the clinic is competent to treat should then be further investigated, the disorder diagnosed and symptoms, disability and risk factors measured. Once the diagnostic formulation is complete, the management plan is selected and implemented. During and at the end of treatment, the symptom, disability and risk factor measurements should be repeated, the change in scores indicating the outcome. If the desired outcome has been obtained, then the patient can be discharged from care. If the desired outcome has not been attained, then the decision tree makes it clear how to determine whether the diagnosis, management plan or implementation procedure is likely to need revision so that the desired outcome can be achieved. Paradoxically, measurement of outcome can also be useful for identifying people who do not improve even after the best clinical investigation and treatment. Normally, such people are excluded from the system, whereas regular follow-up can lead to good care and considered advice about how to manage the chronic disorder until specific treatments do become available.

Fig. 1. Model of good clinical practice



4.2 Establishing the Diagnosis

The first step in treatment is always the identification of the correct diagnosis, and this is especially important when treatments have a specific indication or a narrow therapeutic range. ICD-10 lists the criteria that must be satisfied before a diagnosis is made, yet few clinicians ask about each criterion in a systematic way. After listening to the patient's complaints at presentation, most quickly establish a probable diagnosis and spend the remainder of the interview asking questions to prove or disprove their initial hypothesis. This is a good use of scientific method, but because each clinician has idiosyncratic ways of developing the initial hypothesis, of asking the subsequent questions and of weighting the diagnostic criteria according to the answers received, it is not surprising that such clinical diagnoses are unreliable, both between clinicians and when made by the same clinician over time.

If effective treatment depends on an accurate diagnosis, how can accuracy be improved? The traditional method is to ask another clinician to review the case before starting treatment, but given the scarcity of skilled clinical staff, increasing use is being made of structured diagnostic interviews and standardised assessment questionnaires. The Composite International Diagnostic Interview (CIDI) is composed of questions that have been designed to illuminate each diagnostic criterion in Chap. V of ICD-10 (see Chap. 2, this volume, Part 2). It can be administered by non-clinical staff or, in the computerised version (CIDI-Auto), it can be self-administered. The results are then processed by a scoring programme and the exact ICD-10 diagnoses determined. It is reliable and valid and is available in most European languages (World Health Organization 1997).[1]

4.3 Measuring Symptoms, Disability and Risk Factors

There are many symptom scales, both interviewer-administered rating scales and self-completion questionnaires. While global symptom scales exist, it is preferable to use scales designed to measure the symptoms associated with a specific diagnosis (see Fig. 1). Measures of disability should be more general and cover a wide range of activities, a range that includes impairment in productive work, self-care and personal and social relationships. Examples of such general scales are listed in Table 1. In some disorders, it is also possible to measure risk factors such as neuroticism and coping in anxiety and depressive disorders. Information from measures of symptoms, disability and risk factors is important collateral information which can support the diagnosis and which, when compared with data obtained when treatment has been concluded, can produce measures of outcome.

[1] See http://www.unsw.edu.au/clients/crufad/cidi/htm

4.4 Selecting a Management Plan

Good clinical practice presumes that most management plans will comprise more than one single effective treatment. Most begin with education about the nature of the disorder and a discussion of the prognosis and the likely response to treatment. The clinician will then select a particular treatment and discuss the reasons for choosing this with the patient, ensuring that the patient understands the rationale behind the main treatment, the importance of compliance and the likely side-effects and factors that could interfere with efficiency of the treatment. The clinician should then discuss the use of any additional therapies to improve outcome, whether ancillary drug or psychological therapies, interventions to support relatives or training in social skills or rehabilitation. Finally, the clinician should make clear the expected time course of the improvement and be explicit about whether the treatment is intended to control the symptoms, in which case treatment may have to be prolonged, or to actually treat the condition to the point at which the patient can expect to be well, and remain well, after treatment has been concluded. Many texts on the management of mental disorders have sections that can be photocopied and handed to patients (Treatment Protocol Project 2000).

4.5 Ensuring Implementation

Prescribing a management plan is only half the task. One has to ensure that it is correctly implemented by patient and staff. Patients are more likely to comply with treatment if they understand the rationale behind the treatment and have a reasonable awareness of the likely side-effects or difficulties so that they can persevere with treatment when these occur. They should also have a detailed understanding of the duration of treatment and of the changes in their status that will lead to a revision of the dose or a change in the treatment. In New Zealand, best practice protocols for depression are published in popular magazines in

the hope that patients will know what is expected and that they will ensure that doctors comply with the details of the protocols. The simpler the dosage regime, the more likely patients are to comply. Similarly, the simpler the treatment regime, the more likely doctors are to administer it. Therefore, complex treatment programmes need to be written down in patient treatment manuals which both patient and doctor can follow.

4.6 Measuring Outcome in the Individual Patient

The measures of symptoms, disability and risk factors which were taken at the first assessment should be repeated at points during treatment, certainly at the end of an episode of care and at regular points during treatment in the same setting if the treatment is long term and the disorder chronic. The difference in the scores – especially changes in symptom scores – represent the outcome of treatment. These scores are of the greatest value if the difference in score is available during the consultation, because, when compared with benchmark data for this type of patient with this diagnosis and treatment combination, it will be clear whether the expected degree of improvement has occurred. If it has, then the treatment plan can be continued until the patient is relieved or cured. If the expected degree of improvement has not occurred, then the clinician can consider why this is so, e.g., whether the prescribed treatment was correctly implemented and complied with. If not, measures to improve compliance can be implemented. If compliance was not the issue, the next question is whether the treatment plan was appropriate for this patient. If review of the diagnosis and assessment information suggests that the treatment plan was not appropriate, then a more appropriate plan should be implemented. In the absence of improvement, one should be prepared to consider alternative treatments. Not everyone responds to the same treatment for their condition. If the treatment plan does match the diagnosis, then the evidence for the diagnosis should be reviewed; if no errors are discovered in that formulation, then a second opinion should be obtained from an experienced clinician. Second opinions are commonly requested in medicine, and they should also be a regular feature of psychiatric practice.

The routine measurement of outcome serves two purposes. Firstly, it informs the clinician about the progress of treatment in individual cases, which is very useful in difficult patients who are slow to improve and with whom so much time is spent. The second purpose is to allow the clinician to evaluate his or her effectiveness across a range of patients. Clinicians commonly believe they are less effective than they really are. This "clinician's illusion" results from the fact that they judge their effectiveness on the basis of the patients they are currently seeing. Clinicians spend the majority of their time with patients who are difficult and slow to improve and quite forget the patients who responded quickly and did not need to be seen again. Thus the routine review of outcome will show the clinician that, while their typical work-load is with people who are chronic, their typical patient is someone who responds quickly.

5 Conclusions

The methods for identifying effective treatments are well established. They include specifying the disorder to be treated, specifying the elements of the treatment, measuring the change in symptoms and ensuring that the observed improvement is actually due to the treatment, either by using a randomised, controlled trial or by carefully aggregating evidence from open trials. Information from trials is commonly aggregated, by systematic review, by meta-analysis and especially by the work of international consortia such as the Cochrane Collaboration. The ability to aggregate the evidence of treatment research has led to the development of best practice treatment protocols and encouragement for all clinicians to practice evidence-based medicine.

A model of good clinical care is outlined. The steps used in the care of an individual patient parallel the steps used in evaluating a treatment. It is important to be systematic about diagnosis and assessment, to use and properly implement proven treatments and to measure outcome appropriately. Such behaviour will accomplish two things. Firstly, it will inform the clinician about the progress of the individual patient, and secondly, it will allow any necessary modification of the treatment plan. Aggregating outcome data from all patients will demonstrate that the clinician's level of effectiveness is greater than that which is apparent from the progress of the patients who form the principal work-load. The routine evaluation of the outcome of treatment is an important clinical tool.

Systems of Psychiatric Care: Principles and Desiderata of Good Services

1 Introduction

Systems of psychiatric care can be conceived of as complex, multi-dimensional frameworks or matrices which do not exist in isolation but are firmly rooted in and influenced by prevailing mores, political climate and culture. Any analysis of the principles and desiderata of good services therefore needs to examine the relationships between the different layers of national policy, regional support and local implementation of service delivery; between the different sectors of health care, social care, housing, social security benefits and the criminal justice system; between the complicated infrastructure of primary, secondary and tertiary care; between research, evidence-based medicine and education and training; and between the different strands of resource allocation, particularly public and sector funding and contributions from the voluntary sector. Adequate interfacing arrangements between components of the infrastructure are as crucial for successful functioning of mental health care as adequate inputs into each component to ensure maximum effectiveness of the service and high standards of efficiency and equity.

Countries around the world face a number of common challenges, whether they be in the industrialised or the developing world. These include the high burden of mental disorders, the general shift in ethos from institutional to community care, relative resource constraints and a fluctuating balance between primary and secondary care.

It is important to recognise that individual outcome is affected by public policy and social norms at a national and international level, by how care is organised, financed and delivered and by how access and treatment are provided at the level of the individual. The definition of "need" is influenced by factors at all levels and is not an absolute, but rather reflects cultural norms, resources available, alternative demands on intellectual and fiscal resources, and the real and perceived benefits. Thus it depends not only on societal definitions and public policy, but also on the services that are potentially available.

Any discussion of systems of psychiatric care need to acknowledge that the quality of the care provided is a critical issue, because efficiently linking together multiple ineffective services will not result in positive patient outcomes. That said, this chapter will focus on issues of particular relevance at the level of the service system.

2 Overarching Principles

There are a number of overarching principles which should be outlined at this stage.

2.1 Needs-Led Service

It is critical to ensure that decision-making about services is led by needs rather than supply. Thus it is important not to start with existing services but to base estimates of needs on absolute levels of disease, disability, severity, chronicity and risk in the context of some assessment of social and political concerns, real or perceived efficacy and option appraisals of the alternative use of resources, i.e., that it is predicated on accurate information about the epidemiology of mental disorders, their prevalence, course, outcome and accompanying disability, social and economic costs and the opportunity for treatment rather than simply on pre-existing service use (Stevens and Gabbay 1991). This is often quite difficult, especially in systems that are underfunded in which demand for existing services exceed supply. It is an easy, but incorrect, conclusion to draw in cases of this sort that the currently available services are the best ones to provide based on the fact that demand is high and excess resources to start up new service options are scarce or even nonexistent (Goldberg and Gater 1991). Epidemiologic surveys show clearly that demand is not a good indicator of need. Other services than those provided might well be more needed or effective or efficient. Segments of the population that are hard to reach might have greater need than those who are more likely to seek treatment. It is critical that procedures be developed to monitor need for services independent of demand for currently offered services if a treatment system is to evolve (Griffiths et al. 1992; Jenkins and Griffiths 1991). It is a challenge to develop national monitoring procedures, but models do exist. Besides collecting national mortality data, it is possible to carry out repeat national health surveys. Furthermore, a number of countries have developed a system of reporting the need for specific health problems, e.g., the DAWN system in the United States whereby a national sample of emergency rooms reports every drug overdose case, allowing the federal government to monitor trends in serious drug problems.

2.2 Explicit Values

Mental health policy also needs to take account of – although not necessarily follow – public beliefs, assumptions and attitudes. Likewise, local decision-making will need to involve a wide constituency of user and carer, professional and public interests. It is therefore important that mental health care is based on an agreed set of values and principles which are explicit and open to scrutiny. The Reed principles (Department of Health 1994b,c; Royal College of Psychiatrists 1996) provide an excellent example. Patients should be cared for:

- With regard to the quality of care and proper attention to the needs of individuals
- As far as possible, in the community, rather than in institutional settings
- Under conditions of no greater security than is justified by the degree of danger they present to themselves or others
- In such a way as to maximise rehabilitation and their chances of sustaining an independent life
- As near as possible to their own homes if they have them
- With respect for their rights as citizens

At the same time, the mental health care system can have an agenda-setting function in changing values and perceptions. This is especially important in the case of mental health care, as stigma is a serious barrier to seeking care for psychiatric problems around the world. Furthermore, stigma affects objective assessments of need at all levels, including public policy, attribution by organisations and individual assessments. There is evidence that this situation is changing in developed countries in response to major public education and outreach campaigns in conjunction with unprecedented attention in the mass media over the past decade of new pharmacological treatments. Even so, needs assessment surveys in even the most "enlightened" countries continue to find that the major self-reported reason for not seeking professional treatment among people who have a psychiatric disorder is that these people believe that this is a private matter, the kind of problem they should handle themselves. Breakthroughs in our understanding of the genetic basis of many mental disorders and the development of new and effective pharmacotherapies create an opportunity to correct this misconception by making people recognise that mental disorders are illnesses, not personal failings, and that effective and safe treatment is available.

2.3 Range and Severity of Disorders

Policy needs to address both the range and severity of disorder. Firstly, policy needs to encompass not only people with severe mental illness, but also the more common mental disorders and the sub-threshold disorders which also cause personal dysfunction, social problems and economic costs and alcohol and drug abuse; it should also focus on the promotion of mental health more generally in the whole population, including in schools (Bond and Compass 1989) and workplaces (Jenkins 1994b). Otherwise the care of people with severe mental illness by specialist teams will be compromised by the large burden of the more common disorders if such patients are not adequately dealt with in primary care, workplace employee assistance programmes, school-based services and housing- or social service-based programmes. The prevalence, chronicity and severity of minor to moderate mental disorders is so great that, unless their needs are adequately met in primary care, patients with such disorders will be referred in huge numbers to secondary care and impede attempts to target specialists to the more severe disorders (Jenkins 1992; Lloyd and Jenkins 1995; Lloyd et al. 1996; Paykel and Jenkins 1996). This means that primary care teams, occupational health teams, social service professionals and teachers need to be appropriately trained and supported.

Secondly, it needs to be remembered, in cautioning against neglect of non-severe disorders, that many severe disorders start out as comparatively mild and much more tractable conditions. Indeed, the typical person with a mental disorder does not seek treatment until many years after onset and a number of episodes (Kessler et al. 1998). Given that initial treatment-seeking is slow and that many psychiatric disorders begin early in life, we need vigorous outreach to young people still at school. There are many young people with clinically significant disorders that are risk factors for the subsequent development of severe disorders in adult life. Such outreach programmes in schools, if they exist, often target juvenile delinquents, but more emphasis is needed on shy/depressed/anxious children. These are not children who cause trouble in school, so they are often overlooked; targeting them early could, however, be a very powerful and cost-effective way of reducing morbidity in later life (Rotheram 1982; Bierman 1986; Kellam and Rebock 1992; Hawkins et al. 1992; Mubbashar 1997; Sampaio Faria et al. 1997).

3
Principles Used in Decision-Making

3.1
Equitable Allocation of Resources

Resource allocation to local areas should be proportionate to the health and social care needs of that area, and hence it will be important to develop funding formulae which take account of those needs on an equitable basis. Such formulae will need to include factors such as prevalence rates of illness, social deprivation, homelessness and high rates of high-risk groups, e.g., refugees and immigrants.

As noted above, it is important that this allocation formula is not determined primarily by differential demand for services, as such an approach will lead to a cumulation of inequity by resources flowing disproportionately to areas that already have well-developed systems of care that are visible to their communities and successful in attracting people in need of services.

Investment in areas that have underdeveloped systems of care is critical, even though this allocation of resources will necessarily be comparatively inefficient in the short run, if equitable allocation of resources is a long-term goal. It is important to make clear and explicit the processes for identifying and allocating resources, to establish who is "legitimately" involved in such decisions, to understand how rapidly or slowly resources within the system can be reallocated and to determine who is accountable for increasing or reducing access to services.

There are many difficult decisions in resource allocation that we will need to confront as we attempt to rationalise delivery of services. If we have ten disorders to address, each with a different prevalence, different accompanying disability, different cost of treatment and different treatment effectiveness, should we aim at equal treatment outcomes even if one disorder is much more expensive to treat or maximise the reduction in total population impairment/disability? These are difficult decisions which need to be explicitly tackled in the context of public debate.

3.2
Quality Assurance

Governments need to think about putting systems in place to ensure quality of service inputs and processes and to measure the health and social outcomes achieved. Quality assurance of inputs and processes can be achieved by a combination of inspection systems, auditing and empowering users and carers to have certain specific expectations. In order to be successful, these functions need to be centralised at the administrative level responsible for resource allocation rather than shunted off to the treatment centres as tasks they are required to perform in order to maintain funding. Time and again, it has been shown that self-audits of the latter sort are perfunctory and aimed primarily at creating an administrative paper trail that justifies treatment decisions post hoc rather than providing accurate information on quality of care. Different models for using novel auditing procedures to monitor quality need to be studied, implemented, evaluated and revised if optimal treatment quality and cost-effectiveness are to be achieved (Farrar 1996; Miller et al. 1995; Commonwealth of Australia 1996; Ministry of Health 1997b; Rosen et al. 1995).

3.3
Evidence-Based Medicine

As far as possible, it is helpful for governments to set a policy that aims to be as evidence based as possible. We are now uniquely positioned to develop such an evidence-based approach, using reports from national morbidity surveys, capitalising on the advent of routine outcome measures and information on effective interventions. It is not always politically possible or indeed desirable to wait for all the possible evidence to be accumulated before government action is taken. Often, it is important to take some preliminary action and then to fine-tune the policy with specific research evidence at a later date (Conway et al. 1996).

4
Desiderata for National Policy

Mental health policy at a national level comprises the government's mission statement and strategic objectives for the mental health of the country.

4.1
Goals

Many countries are now starting to focus much more on the central goals of improving health and reducing morbidity, disability and mortality, with improved processes seen not as main goals in themselves but rather as intermediate steps towards real health gains (Jenkins 1990). England's Health of the Nation strategy set some specific targets to reduce morbidity, disability and mortality (Department of Health 1992, 1994a; Jenkins 1994a, 1996a,b), and Australia is another example of a country which has set national goals,

targets and strategies for better health outcomes into the next century (Commonwealth of Australia 1994). As a general principle, the overall framework can be summarised in five principal goals:

1. Promote good mental health
2. Prevent illness
3. Reduce morbidity (improve health and social functioning) of people with mental illness
4. Reduce disability associated with mental disorders and their ensuing discrimination
5. Reduce mortality (from suicide and physical illness) of people with mental illness

4.2 Needs Assessment

Mental health policy should be rooted in and supported by accurate information about the health and social care needs of the country, either by using national surveys of psychiatric morbidity or extrapolation from a combination of local surveys together with national surveys from other countries in order to obtain accurate estimates of the range, frequency, severity, chronicity and accompanying disability and mortality and their relationship to sociodemographic variables, including geographic variables. National surveys need to collect information on variation in local need to help decide which areas need more resource per capita. They cannot micro-manage local services, but they can provide some comparative information which may be helpful to local areas, and they can provide help for local needs assessment (Jenkins et al. 1997a,b; Meltzer et al. 1995a–c, 1996a–d; Wing 1992; Croghan et al. 1998). Mental health policy will also need to take into account information about the existing accessibility, quantity, quality, costs and outcomes of services (Jenkins and Knapp 1996; Glover and Gould 1996; Glover 1996; Goldberg and Gater 1991; Griffiths et al. 1992; Knudsen and Thornicroft 1996). Furthermore, it will need to take account of the existing resource infrastructure of the country in terms of the available capital, revenue, trained personnel and untrained staff in the context of managing any kind of transition to a new style service. Other inputs such as public beliefs and opinions, publicity about specific incidents and the political inclination of governing parties are crucial. Thus mental health is not just an issue for health and social care, but also for the general population, schools, workplaces, rural areas and cities.

4.3 Coherent Interdepartmental Policies

National policy needs to be coherent and complementary across the different government departments or ministries of health, social services, housing, social security, employment and finance. Ideally, any major policy move in any one sector needs to be preceded by the production of a mental health impact statement, analogous to an environmental impact statement. Many examples exist of national policies that are internally inconsistent and so lead to suboptimal resource allocation and treatment effectiveness due to conflicting intra-sector rationalities. The only hope of solving this problem is to empower an administrative team with an oversight of the departments in which coordination is sought. Interdepartmental coordination is unlikely in the absence of such a structural arrangement. National policy also needs to be coherent across the local geographic units where it is implemented, and these local planning units need to be coordinated and targeted as national priorities. Within each of these levels are multiple agencies and departments requiring coordination and common fiscal strategies (Department of Health 1995).

4.4 Support for the Voluntary Sector

The voluntary sector, encompassing as it does consumer and family organisations and charitable donations of time and money to the health service, needs to be encouraged, stimulated and supported. Governments play a vital role in pump-priming this system. The voluntary sector is also important because of its links with the wider community and hence its capacity as an agent for influencing public attitudes. In some countries, the voluntary sector is the largest part of the de facto mental and addictive services treatment system. This is the case, for example, in the United States, where there are more visits per year to self-help groups for psychiatric problems than to all professional speciality mental health services combined. Opportunities for increasing coordination between the voluntary sector and the professional service sectors need to be explored as one way of extending the limited professional resources available in even the most resource-rich society in treating psychiatric problems (Kessler et al. 1997a).

4.5
Strategies for Research and Development

It is vital to invest adequately in research and development to support policy and service developments and to ensure that we adequately research different methods of organising and financing care and different methods of service delivery. If money and activity are to be efficiently spent, it is important to have some degree of national coordination, oversight and stimulation.

4.6
Strategies for Manpower Training

Human resources are fundamental to the operation of psychiatric services, and it is essential to have national strategies for ensuring adequate flows of sufficient personnel for relevant disciplines, taking account of projected demographic trends; national strategies are also necessary to ensure appropriate professional training and continuing professional development. This includes not only specialist mental health personnel, but also generic staff in primary health care teams, social services, etc.

Manpower training is also a major opportunity for dealing with the issue of stigma. Training should include multi-disciplinary components so that there is increased awareness of the activities of other agencies and specialities (Mohit 1997).

4.7
Strategies for Mental Health Promotion

National government policy can affect the mental health of the population, e.g., through policies on poverty, unemployment, social exclusion, alcohol availability and restriction of firearms. Furthermore, there are some strategies for mental health promotion that need to be directed at the whole population, i.e., universal measures which, if they are to be implemented, will require some kind of national policy support (Jenkins and Üstün 1997), e.g., home visiting for the newborn; general measures to encourage health policies in the workplace that address both mental and physical health (Jenkins and Coney 1992; Jenkins and Warman 1993); teacher training as prevention intervention for school disruption, the encouragement of mental health promotion education in schools and physical health promotion, requiring liaison between the government, teacher-training bodies and schools (Durlak 1995).

4.8
Strategies for Suicide Prevention

Suicide is a major cause of avoidable death across the world (Murray and Lopez 1996). Those countries which have adopted a national plan for suicide prevention, e.g., Finland, Holland and the United Kingdom, are showing an encouraging decline in suicide rates, even in young men - thought to be the most difficult age-group to influence - and there are some aspects of suicide prevention that require action at a national level (Jenkins 1994a; Kingdon and Jenkins 1995). These measures include the following:

- Action to reduce access to means of suicide, e.g., measures on gun control, restricting the sale of certain prescribed medicines such as barbiturates, restricting pack size and availability of over-the-counter medicines such as paracetamol
- Action to support high-risk occupational groups by liaison between the government and the relevant occupational organisations
- Specific suicide prevention programmes in prisons and police cells, where suicide rates tend to be very high
- Research into the causes and prevention of suicide and action to ensure that all suicides and psychiatric homicides are investigated to learn the lessons for prevention and to disseminate them
- Action to ensure adequate continuing professional training programmes in the assessment and management of mental illness, especially depression, and of suicidal risk for both primary and secondary health care professionals, e.g., the United States' DART programme; the training programme for practitioners in Sweden for the prevention and therapy of depression (Rutz et al. 1996) and the World Psychiatric Association's educational programme on depression
- Working with the media to ensure that individual suicides are reported responsibly, without glamorising the victim and without reporting the specific method (Schmidtke and Hafner 1988).

Suicide prevention strategies should be a major component of the overall framework of government goals in order to reinforce the commitment of all the relevant sectors (Department of Health 1994a; Ministry of Health 1997a).

In the United States, there is an increasing focus on trying to reduce risk, which is done both through public policy as well as by formal coordination of professionals and by increasing the informal support systems.

5
Desiderata of Local Service Delivery

5.1
Goals

There is a need for individual service providers to establish their goals and targets, to monitor their success in achieving these outcomes and to make adjustments to reduce the negative outcomes. These local goals might include prevention of episodes, shortening duration of episodes, increasing duration between episodes, reducing residual impairment from mental disorders and reducing the amount of co-morbidity. Even less severe disorders can be disruptive to work and social relationships and entail considerable costs for society, employers and individuals.

5.2
Needs Assessment

Therefore, local geographic needs assessment has to be carried out for health and social care within which individual agencies can contribute to integrated assessment and management (Johnson et al. 1996). In order for overall mental health goals to be met, many other agencies besides traditional mental health providers need to be involved and managed in an integrated way.

When local health planners, commissioners or purchasers assess the health needs of their local population, they need to consider the epidemiological evidence, both national and local, on the prevalence of the different disorders, their severity and chronicity. The consequences of mental disorders – particularly disability and the degree of risk to self and others – also become more salient in determining the need for services and specific actions. Local planners also need to consider the policy context, again both national and local, and the current state of the specialty services, together with the current levels of in-patient and residential provision and the existing pressures on them. In particular, they need to examine the extent to which the full spectrum of health and social care is being provided to people with mental illness and the extent to which there are problems with the interfaces between the different agencies providing health and social care, the criminal justice system, etc. It is also important to examine local suicide rates (both those officially identified by the coroner and the "undetermined" deaths that are epidemiologically likely to be suicides). People with severe mental illness have highly standardised mortality rates from physical illness such as cardiovascular disease, malignancy and respiratory disease. Purchasers should therefore ensure that they also pay attention to assessing and meeting the physical health needs of their population with mental illness.

Variables which contribute to high rates of mental illness in local areas include social deprivation, urbanicity and the combination of deprived inner city areas, marital breakdown, family breakdown, single-person households, single-parent families, unemployment and levels of substance abuse. The presence of major rail termini within a service catchment area can aggravate the effects of the geographical drift of people with severe mental illness from more rural areas to inner city areas. Particular markers of high mental health needs are high proportions of homeless people, alienated, ethnic communities, refugees, children "at risk", children "in care", young males aged 15–45 and people who are single, divorced or widowed. Some of these variables may be influenced by public policy and general economic developments, while others may be influenced by clinical interventions.

Aspects of the specialist services where there are likely to be pre-existing heavy pressures include secure provision for mentally disordered offenders, acute beds, 24-h nursed care for "new long-stay" patients, supported housing, occupational rehabilitation, mother and baby units, eating disorder services and drug and alcohol services.

Local needs assessment should also include the need for primary health care, firstly to tackle the less severe disorders; secondly to deliver physical health promotion and physical health care to people with mental illness; thirdly to contribute as locally agreed to a shared care programme for people with severe mental illness; and fourthly to deliver primary prevention to high-risk groups such as the socially isolated, bereaved, physically disabled, unemployed and elderly.

Local planners/purchasers should ask themselves whether there is equity in their existing provision, with people from different geographic areas, cultures, social class and the homeless all having their needs met to an equal extent. They need to know what costs are associated with the current provision, what obstacles currently exist to planning coordinated and comprehensive services and how the services might be improved.

5.3
Education, Support and Deployment of Primary Care and Links with Specialists

Mental disorder is extremely common, and no country can afford sufficient specialists to cover everyone with

a mental disorder. The WHO multi-site study (Üstün and Sartorius 1995) has shown that around one third of general practice patients have a psychosocial problem and that the most common of all chronic disorders (physical or psychological) in general practice is depression. The essential goal of primary care is to tackle the majority of individuals with a mental disorder, and most people with a mental disorder will need to be seen by primary care teams, leaving highly trained specialists free to deal with those patients with disorders that are more severe and difficult to treat (Kingdon and Jenkins 1996).

Members of the primary care team, especially doctors and nurses, must be trained to assess, diagnose and manage common mental disorders and to know how to refer patients to specialists. This requires addressing undergraduate, postgraduate and continuing education of primary care doctors and continuing training of primary care nurses to ensure that adequate attention is given to mental disorders. It is relevant to mention here some innovative "cheap" strategies that there is reason to think might work. Computerised self-therapy programmes, for example, are very intriguing and have the potential to be an enormous boon in extending the number of people a single practitioner can "treat". The adjunctive use of self-help groups is another potentially useful strategy in which the amount of time the professional spends with each patient alone is reduced and the group is given the resources (e.g., educational tools) to assume some of the education and support and possibly even therapeutic functions that would otherwise be met by the professional. These kinds of initiative are important if we are to come close to having enough resources to meet the massive need for services that exists in the population.

The primary care team needs to consider the appropriate balance of doctors, nurses, counsellors and others and the appropriate division of labour, to ensure that the caseload is tackled within the resources available. A number of innovative models have evolved over the past two decades to coordinate primary care and specialty treatment of psychiatric disorders. These include the placement of mental health specialists (psychologists and social workers) within primary health care settings. It is important that these models be studied, evaluated and modified as necessary so as to increase the efficiency of coordination across service sectors. It should be the responsibility of the specialty sector to take the lead in developing these systems, as they are in a better position than their colleagues in primary care to evaluate options for innovative treatment along these lines (Jenkins and Field 1996).

Primary care teams need backup support from the specialist services (e.g., opportunities to agree on clinical guidelines and discuss cases; opportunities to learn additional psychological skills such as behaviour therapy techniques). This is a special challenge in the many parts of the world in which the population in need of treatment lives predominantly in rural areas. Problems of distance and communication and lack of availability of specialists in rural areas conspire here to create very serious problems, especially for patients with problems that are not sufficiently severe to warrant moving them to distant cities for in-patient treatment. Innovative models need to be developed here. New developments made possible by breakthroughs in communication technology, such as telepsychiatry and Internet consultation networks, need to be considered here. However, what is most crucial is that those involved in primary care should feel supported by the specialists and should feel they have adequate specialist backup. Failure to communicate effectively is often aggravated by stigma and leads to poor patient care and misunderstanding about the respective roles of primary and secondary care teams.

Primary health care teams need to have a certain amount of basic information about local mental health services, including an organisation chart of the local services (with the names of key clinical and management staff and maps of geographic or other boundaries) and an information booklet of therapies available together with named contacts for advice on appropriate referrals. Agreed criteria are required for referral to the specialist services, taking into account diagnosis, severity of symptoms, duration and risk of harm to self or others – and also evolving safe methods of shared care, whereby the primary care team can participate, e.g., with medication, physical health care and health promotion (Strathdee and Jenkins 1996; Lloyd and Jenkins 1995). Secondary care teams need specific information in the referral letters, including background family and social history, details of the presenting problem, interventions tried so far with outcomes, the reason for the present referral, the specific role that is being requested of the specialist team and the anticipated continuing role of the primary care team. Likewise, primary care teams need specific information in the reply from the specialist, which should include the following: a clear management plan with objectives and expected outcomes; an indication of the risk of suicide; what the patient has been told about his or her condition; the prognosis and likely continuing disabilities and influence of the patient's life style; the role that the primary care team is expected to play in the management plan; the role that the specialist staff will play; and who will be responsible for doing what and within what time schedule, including prescribing and monitoring roles and responsibilities.

5.4 Development of Comprehensive Health and Social Services

Countries vary in their capacity to afford the full scope of comprehensive specialist local health and social services, but even the richest will never be able to afford sufficient specialists to cater for the complete spectrum of mental disorders. There must therefore be explicit public policy and local availability of supportive and nurturing family and community environments as well as an appropriate balance of specialist services and primary care services which will need to be thought through in relation to the specific needs and resources available within each country (e.g., Wig and Murthy 1994; Murthy 1997). There is also a need to establish developmentally appropriate responses and services for children, adolescents, adults aged 16–65 and older people in terms of the opportunities for effective interventions and for reducing compounding factors.

Now that research has demonstrated the long-term damage to health and social functioning which prolonged institutionalisation can bring, most countries are attempting to transform services reliant on old, large asylums into services where people with severe mental illness are cared for in their own homes or in homely environments, as close to home as is compatible with the health and safety of the patient and the safety of the public. However, some people with severe mental illness will need to be admitted to acute beds in hospital for short periods of time for intensive assessment and management of acute episodes of severe illness; in addition, a proportion will need supported accommodation for long periods of time, and a small proportion will need very intensive skilled nursing care for long periods of time in order to enable regular supervision of medication and daily monitoring of their mental state. Thus every locality will need a range of services to supply the gradation of needs of people with mental illness for psychological treatments and medication, supported accommodation, work and occupational rehabilitation, leisure activities and day care (Ministry of Health 1997b; Commonwealth of Australia 1996; Department of Health 1994a). The use of these services needs to be carefully evaluated so that their predictors are well understood (e.g., Kessler et al. 1997a, 1998).

There is a risk that politicians, planners and health service managers may misuse de-institutionalisation programmes to divert resources into other areas of expenditure instead of re-investing the money from the institutions into local community mental health care. Table 1 gives the spectrum of care that needs to be available locally for people with mental illness. Multidisciplinary teams are needed to look after clients in both hospital, residential and home settings.

While many countries are making arrangements for the "old long-stay" patients in the old, large asylums to move in a planned and supported way into the community, most countries have not yet made adequate provision for the so-called new long-stay clients, i.e., that small number of very severely mentally ill people who, for a variety of reasons and despite excellent treatment, will nonetheless continue to need intensive, skilled, round-the-clock nursing for many years. In the absence of such provision, these clients either inappropriately "block" acute beds because there is nowhere else for them to go or they receive no or inadequate support in the community (either in inadequately supported hostels, unsupported in their own homes, homeless or in prison or secure units). The provision of 24-h nursed accommodation would release acute beds for those who require them and would provide a more homely and more socially rich and stimulating environment for those who need

Table 1. Range of care

	Acute/emergency	Rehabilitation/continuing care
Home-based	Sector teams Sustainable out-of-hours cover Intensive home support	Domiciliary services Key workers Care programme approach
Day care	Day hospitals	Drop-in centres Support groups Employment schemes Day care
Residential support	Crisis accommodation Acute units Local secure units	Ordinary housing Unstaffed group homes Placement schemes Care schemes Mental nursing homes 24-h nursed NHS accommodation Medium secure units

ongoing skilled nursing for long periods of time. This group includes those who need daily monitoring of their mental state, frequent monitoring of the risk of harm to self or violence towards others, storage, administration and supervision of medication which will usually be necessary on a daily basis, assistance with self-care and daily living skills, supervision and support to attend day care or rehabilitation activities, crisis intervention at night if required, skilled management of challenging behaviour and possibly skilled management of dual or even triple diagnosis.

There is an equivalent problem at every level in the service system, where those who are inappropriately at that level reduce the availability of services for those in need, thus resulting in diversion to more intensive or inadequately intensive services. In addition to attending to when a more intensive service is needed, systems are needed to determine when services can be discontinued and when less intensive services can be substituted for more intensive and usually more expensive services.

5.5
Development of Good Inter-agency Collaboration

There needs to be public policy and practice at each level that focuses on individual and family needs. Health professionals (doctors, nurses, psychologists, occupational therapists) will have to work closely with social workers, voluntary workers, probation officers and the police to ensure that care is properly coordinated (Kingdon 1994a). This can be very difficult, since all the separate agencies involved in the care of severely mentally ill people will have their own sets of principles and priorities which guide their work. However, it is essential that they work well together, and there are certain basic requirements without which working together can be very difficult. These include the principles of a commitment to working together at all levels of the agencies involved, including senior management; an agreed and jointly "owned" strategy for the care of severely mentally ill people; agreed and well understood principles for accessing services; appropriate and effective arrangements for inter-agency information exchange; joint commissioning, wherever possible, to maximise the use of available resources; a commitment to training, on a single and multi-agency basis, in order to encourage a better understanding of other agencies' roles and structures; and regular review and evaluation of arrangements for inter-agency working. One very appealing strategy that has been adopted in many systems is the use of a case manager to coordinate care across multiple service sectors – to interface with and optimise on a patient-by-patient basis the allocation and delivery of such diverse services as those involving public housing, income maintenance, social services, health and mental health. Although systems that have adopted one or more of the widely used case manager models have, perforce, an additional layer of administration than those without such an approach, experience has shown that the savings introduced by reduced inefficiency and coordination costs more than make up for the costs and complexity of this innovation.

5.6
Development of Mental Health Information Systems

Mental health information systems are valuable adjuncts to planning the delivery of specialist services to a defined population, assisting the coordination of care between a variety of professionals and helping to ensure that clients do not get lost to care. At their simplest, they comprise names, addresses, age, sex and date of referral to specialist services. However, many places are now developing data sets which include a common core of helpful clinical and sociodemographic data to assist health professionals in reviewing and coordinating care. These minimum data sets, which include measures of health and social functioning, allow health and social outcomes to be monitored.

It is essential that such information systems be developed in consultation with users and carers, to satisfy concerns about data protection and confidentiality and to develop sensible procedures for accessing information. Common information technology standards allow local information systems to "speak" to each other should a client move from one district to another with accompanying transfer of care. Interfacing information systems are also essential to examine the coordination of care at the population level. It is important to continue to evaluate these systems in terms of direct patient benefits against the costs of implementing and maintaining them (Wing et al. 1996).

5.7
Development of Good Practice Guidelines

As well as ensuring adequate quantity and quality of the inputs to the service in terms of beds, staff, housing, etc., it is also necessary to ensure adequate quantity and quality of the processes of care in both specialist and primary care services, to bring levels of care across the board up to the best standards. Good practice guidelines are a key method of implementing evidence-based services (Armstrong 1997; World Health Organisation 1996; NHS Executive 1996a,b).

Where possible, good practice guidelines should be developed in collaboration with the relevant professional bodies and should address the multi-axial elements of care, namely physical and psychological health care needs and social needs including housing, employment and benefits (Kingdon 1994b,c), as well as continuation of care (Tessler et al. 1986; Tessler 1987; Test 1979).

5.8 Prevention of Suicide

As well as the national measures to reduce access to means of suicide, research and audit of suicides and national measures to support high-risk occupational groups, it is also necessary for services to take a number of local steps to reduce suicide (Jenkins et al. 1994; Kingdon and Jenkins 1995). These include ensuring that primary and secondary health and social care professionals are regularly educated about the assessment and management of suicidal risk; that local arrangements are in place to support high-risk occupational groups, e.g., doctors, nurses, farmers, vets and pharmacists; and that local alliances are made with the media to ensure more responsible reporting of individual suicides whereby the specific method used is not reported and the event is not glamorised.

There are some important misconceptions that need to be dispelled about suicide. These include the belief that those who talk about it never do it; two thirds of people who commit suicide have mentioned their suicidal ideas and a third have expressed clear suicidal intent. Conversely, many also believe that asking about suicide might make it more likely. Good risk assessment and management are essential. The second misconception is that suicide is often a "rational choice". In fact, most people who kill themselves are mentally disordered at the time, usually with depression but also alcoholism and schizophrenia. Treatments are available for each and need to be utilised, but sometimes lack of knowledge of the skills of other professionals can mean patients are not referred. As Goldberg and Gater 1991 have cautioned, "those who work only in the environment of their own profession, (or in isolation) tend to develop the idea that if someone cannot be helped by their own brand of intervention then they cannot be helped at all and can therefore be discharged to suffer on their own." A further important message which is not clearly understood, even by general practitioners, is that mood can be significantly improved and suicidal risk reduced even in the face of seemingly overwhelming life events and circumstances such as severe physical illnesses.

The final major and particularly important misconception is that "if they want to do it, they will do it anyway." Unavailability of "acceptable" means, treatment of depression, life events and social support can all intervene and remove, or significantly reduce, risk. Patients who have been fortuitously intercepted during a determined suicide attempt and who have recovered and gone on to lead a meaningful existence are relatively common in clinical practice.

5.9 Mental Health Promotion and Prevention

Within primary prevention, there are three principal strategies (Mrazek and Haggerty 1994):

1. Preventing the occurrence of the risk factor
2. Improving the coping response
3. Altering environmental settings

The first strategy assumes that it is possible to control or prevent the occurrence of the causal agent and is called proactive primary prevention, while the second strategy assumes that the agent, if unavoidable, can be resisted and is termed reactive primary prevention. Thus reactive primary prevention can occur before or after the stressor, but it is aimed at preparing the individual to react effectively to the stressor. In contrast, proactive primary prevention attempts to avoid the stressor altogether.

Potentially targetable stressful life events include both predictable transition points or "normal" crises which are potentially periods of lengthened stress (e.g., starting school, moving school at 11, job entry, retirement) and which may be judiciously prepared for by parents, schools and workplaces if supported and educated to do so.

Unpredictable events or crises, such as unemployment, physical injury or war, cannot usually be anticipated or avoided, but social support can nonetheless be delivered in a variety of ways, including promoting existing natural support systems, creating new but natural support systems, educating carers, consulting specific organisations such as schools (Leaf et al. 1997; Sampaio Faria et al. 1997; Mubbashar 1997), police, the criminal justice system and social services, developing local community alliances and, last but not least, establishing a public education programme about mental health and illness.

Research indicates that local residents often have minimal knowledge about mental health services offered in their vicinity. It is particularly important to reduce stigma, and schools and the media have an important role here. Such mental health education aims to develop important competence within normal groups and groups at risk in order to improve the capacity to cope both with predictable life transitions and with less predictable stress factors.

5.10
Introduction of Mental Health Policies in the Workplace

While employers have long valued the physical health of their work force, and more recently have paid particular attention to reducing the health problems associated with alcohol, drugs and the human immunodeficiency virus (HIV), they have tended to ignore mental health problems. The reasons for this lack of attention to mental health are mixed – the stigma attached to mental illness, the fact that the common mental disorders of depression and anxiety are often hidden, the relative paucity of concrete research data on the full economic and social costs of mental health problems in the workplace – and employers have historically taken the view that, since they do not cause the majority of mental health problems, they do not need to address them. However, whether or not employers cause mental health problems, the economic burden of mental health problems in the workplace (reduced performance, labour turnover, sickness absence, accidents) is very great (Jenkins 1985a,b; Kessler and Frank 1997), and this burden is borne by both employers and society.

Health policies in the workplace are systematic statements of action on health agreed between staff, management and appropriate bodies such as unions. Mental health components may include a commitment to a healthy workforce; placing a high value on both physical and mental health; acknowledging that mental health problems have many causes, including stresses in the workplace and in the outside world; listing factors which may lead to increased stress in the organisation (customised based on discussion with staff and needs assessment); recognising that domestic factors (such as housing, family problems and bereavement) may add to levels of stress experienced by employees; and stating that the organisation is committed to an explicit course of action. This course of action might include increasing understanding of the causes of mental health problems in the workforce; action to combat workplace stresses and helping staff to manage stress; managing mental health problems that occur effectively through early recognition and appropriate management (including early access to counselling, providing advice on sources of help); and taking action to manage the return to work of those who have suffered mental health problems to ensure that their skills are not lost to the firm. Once employers recognise the cost to their businesses of inefficiency caused by mental disorders and employee turnover, they can became advocates for more effective services and greater access to services.

5.11
Development of Good Processes of Care

There needs to be a systematic approach to the care of mentally ill people, based on a systematic assessment of needs, both health and social; the production of a plan to meet those needs; the coordination of care by a nominated health or social professional; and regular review as appropriate until the person is better.

5.12
Risk Assessment and Management

A full assessment of risk should be part of the assessment process, covering both risk to the patients themselves and risk to others. Any risk identified will need to be managed appropriately. The key principle of risk assessment is to use all available sources of information – a proper assessment cannot be made in the absence of information about a patient's background, present mental state, social functioning, or past behaviour. In addition to the treatment team and the patient, sources may include relatives, carers, friends, the police, probation officers, housing departments, social workers, local press reports and concerns expressed by neighbours.

It is often possible to identify circumstances under which, based on past experience, it is likely that an individual will present an increased risk. An assessment can then go on to indicate what must change to reduce this risk, to propose how these changes might be brought about and to comment on the likelihood of interventions successfully reducing risk. An example might be when a patient stops medication or abuses alcohol or drugs. As well as undergoing training in these areas, team members will need to be aware of the underlying risk factors for suicide and be able to ask patients about possible suicidal intent. The period immediately after discharge from hospital is a time of particularly high risk of social withdrawal or violence and suicide, emphasising the need for proper assessment prior to discharge and effective follow-up afterwards.

5.13
Auditing

Even in the best-run service, the possibility remains that something may go wrong. It is essential that all those involved in planning, purchasing and providing mental health services investigate any serious assault involving a mentally ill person quickly and objectively and learn the lessons from any inquiry.

Optimal audits require separate and joint focus on intake (the decision of who to treat and who not to treat as well as decisions regarding allocation of patients across diverse service offerings), processes, outcome and follow-up. As noted earlier, it is important that these audits are genuine efforts to provide independent evaluation of quality at each of these critical phases of the treatment process. It is all too common that this is not the case and that ostensible auditing degenerates to a sleight-of-hand exercise that does more to justify current practice than to provide an independent review that might lead to necessary changes in the system.

Audit reviews should be comprehensive and multidisciplinary, involving everyone associated with the patient's care, including the primary care team and the patient's family. The purpose is not to find culprits, but to identify any lessons that can be learnt to prevent such incidents in the future. Auditing is of course only part of the picture, and all auditing should take place within the context of systematic monitoring of outcomes.

5.14
Use and Disclosure of Patient Information

The use of information is a sensitive issue for mental health services. There have been serious incidents where failure to pass on information, e.g., about a particular patient's previous acts of violence, has put a patient, member of staff or the public at risk. As a matter of good practice, it is vital to share information if multi-disciplinary and inter-agency care is to function effectively. Joint planning across agencies needs to specifically address this need for exchange of information. At the same time, mentally ill people are entitled to the same confidential handling of information about their health and care as any other patient or client.

Patient information is covered by a duty of confidentiality. As a general note, information given by the patient for one purpose should not be disclosed to a third party or used for a different purpose without the consent of the patient. However, this requirement need not be so rigidly employed that it disadvantages the patient or the public interest. Thus the patient should be made aware that, in order for health and social services (or others such as probation, housing or voluntary agencies) to plan and provide effective care, personal information may need to pass between them as part of the normal processes of assessing and meeting needs. However, any information passed on should be restricted to that in which the recipient has a legitimate interest. The recipient should not transmit it to a third party unless the latter is entitled to it or the patient has explicitly consented or is aware that information needs to be passed on to enable care to be coordinated properly. There may be particular circumstances in which disclosure of information is required by the court or, exceptionally in the absence of consent, can be justified in the public interest (e.g., in certain circumstances, this may be so if someone has a history of violence). Disclosures based on public interest involve weighing that interest against the duty of confidentiality in the particular set of circumstances. The balance can be delicate and it may be necessary to take legal advice. It is important to share the right amount of information with those who need to know. For example, telling staff that an individual is violent is likely to be less helpful than detailing in what circumstances he or she is likely to be violent and how such situations can be avoided.

5.15
Local Manpower Strategies

It is important to develop and retain sufficient manpower to deliver good mental health services. This prompted the German government, for example, to issue legislation in 1991 stipulating the minimum number of doctors, psychologists, nurses, social workers and occupational therapists in psychiatric hospitals according to the individual requirements of each hospital. Important aspects in retaining good staff include attention to induction processes, mentoring schemes and occupational health services. They also include sufficient flexibility in the job plan to allow the development of specific management expertise, involvement with professional bodies, development of research and academic skills, e.g., protected time for teaching and research, appropriate links to academic institutions and development of clinical expertise in special areas such as psychotherapy and forensic work.

6
Conclusions

Good services are those which show respect for individuals and their social, cultural, ethnic, religious and philosophical principles; where individuals' needs are taken fully into account; where treatment is provided in the least restrictive environment possible and is aimed at promoting each individual's self-determination and personal responsibility; and where care and treatment aim to achieve each individual's highest attainable level of health and well-being. Success depends on a critical analysis of where we are now, a vision of where we want to be, a strategy of how to get there and commitment from politicians, professionals, managers and the general public.

Quality Assurance in Psychiatry

Translator: S. Johnson

1 General Principles

Attempts to regulate the quality of clinical practice date back as far as medicine itself. The Hippocratic Oath includes as fundamental principles that doctors should use their ability and judgement to benefit patients as much as they can and that they should refrain from any harmful or mischievous course of action. Safeguarding and improving existing standards of practice is now accepted as a central priority. The introduction of measures aimed at quality assurance (QA) is in part a response to the growth of knowledge and to increasing specialisation. However, it also reflects increased public scepticism about medical practice and, last but not least, pressures to contain costs because of increasingly restricted resources in public sector health services (Eichhorn 1997).

Medical care encompasses not only diagnosis and treatment, but also prevention, rehabilitation and aftercare. Planning, organisation and co-ordination of this whole field requires an overall framework of health policies. However, the starting point for the safeguarding and, where possible, improvement of medical care needs to be the definition of quality standards. Following this, methods need to be developed for implementing these standards and for continuously monitoring how far they have been attained. Quality assurance in medicine should provide patients with a guarantee that they will receive treatment which is rational according to the current status of specialist knowledge. This applies in psychiatry as in all other areas of health care.

In psychiatry, a systematic approach to quality assurance is particularly necessary. This is because psychiatric disorders are common and their predisposing, precipitating, maintaining and modifying factors are complex, so that diagnosis, treatment and rehabilitation need to be multi-dimensional and to be provided in a diverse range of care settings. This chapter will set out the conceptual, methodological and organisational framework required for such a systematic quality assurance.

1.1 Concepts and Definitions

The starting point for a concept of quality assurance in medicine must be a definition of quality. Outside medicine, in manufacturing and service industries, quality control and quality assurance are familiar concepts. Here the Deutsche Institut für Normung (DIN; the German Standards Authority) defines quality as the "whole set of characteristics of an entity which determine its suitability to fulfil specified and predetermined requirements" (DIN ISO 8402; DIN 1992). Within the field of medicine, Fifer (1980) gives an operational definition of quality as "the degree of adherence to a standard", thus making it clear that one can only assess quality in relation to clearly defined standards.

The main ways of defining standards are on the basis of statistical/quantitative norms and/or of qualitative norms; these two should generally be combined so that they complement each other. Examples of quality standards in medicine are those published by the American Medical Association (1986):

- Emphasis on health promotion, prevention of illness and disability, early recognition and treatment
- Treatment provided in a timely manner, without inappropriate curtailment or unnecessary delay, discontinuity or prolongation
- Achieving the informed co-operation and participation of the patient in the care process and in decisions about that process
- Treatment based on accepted principles of medical science and proficient use of appropriate technologies and professional resources
- Sensitive care that takes into account the anxiety and tension which illness causes; concern for the welfare of the whole family
- Attainment of a good treatment outcome through efficient use of technologies and other health system resources
- Sufficient documentation of the patient's condition to allow continuity of care and peer evaluation

These standards are fully applicable to psychiatry.

Specific treatment standards should increasingly be based on the results of empirical evaluations of treatment, taking into account modifications needed to apply these experimental treatments in clinical practice.

"Evidence-based medicine" (Ellis et al. 1995; Naylor 1995) or in this case evidence-based psychiatry (Goldner and Bilsker 1995) starts from the assumption that medical practice should be based on the best possible information. This will be the results of studies which satisfy appropriate scientific standards, evaluated through meta-analysis. This requires a paradigm shift:

Evidence-based medicine places less weight on intuition, unsystematic clinical experience and pathophysiological basic principles than on having adequate foundations for making clinical decisions. The emphasis is on seeking empirical evidence by means of clinical research (Evidence-Based Medicine Working Group 1992, as quoted by Goldner and Blisker 1995).

With this aim, practising clinicians should make great efforts to achieve a better balance between the use of clinical experience and acumen (*phronesis* in the Aristotelian sense) and the application of scientific knowledge (Aristotle's *techne*) (Goldner and Bilsker 1995). Thus doctors must become well acquainted with scientific ways of thinking and must be in a position to inform themselves about currently available empirical knowledge. Study results, meta-analyses or guidelines available via modern information systems can provide the necessary foundation for this (e.g. see Antes et al. 1995; Cochrane Collaboration Working Group 1996).

The basic concepts in quality assurance are described – not always in a uniform way – by the expressions "norm", "criterion", "standard", "indicator", "threshold value" and "guideline" (Bertolote 1993; Donabedian 1982; Fauman 1989; Wilson and Phillips 1992c; see Table 1).

According to this terminology, the dosage specified in a psychopharmacological formulary is an example of a quality *norm*, established by empirical and statistical means. An example of a corresponding quantitative *criterion* is the range of doses across which a drug is effective for the average subject. A *standard* is the normative specification of a particular range of doses which indicates optimum quality. For various reasons, total unanimity cannot be expected (see below). A *threshold value* or reference range therefore needs to be specified, above or below which a review of quality (audit) should be triggered. Possible methods for evaluating quality of treatment based on a particular formulary include assessing the extent of deviations from this dosage standard. The goal for *guidelines* for treatment with a particular formulary would be to provide instructions on how to achieve optimal treatment. The guidelines would need to include practical explanations of indications, dosage and duration of treatment, investigations which must routinely be carried out, contra-indications and modifications required for particular individuals or situations.

Standards are thus the reference points for medical care based on the principle of high quality. They indicate the current status of medical knowledge and clinical practice and thus also provide foundations for basic and higher training and for continuing professional development. They establish the scientific foundations on which the quality assurance process should be based (Gaebel 1995a).

In applying standards, the risks, benefits and costs of trying to achieve particular goals need to be weighed, and standards need to be adapted to varying needs at different stages in treatment (see Linden 1994). Standards are not rigid prescriptions, and their applicability is limited by doctors' freedom to make decisions and practice according to their own clinical judgement (Buchborn 1993). Finally, an important principle is that, in certain individual cases, it will be reasonable and necessary to depart from the principles which have been established statistically as valid for groups. Unless this principle is recognized, the "art" of medicine will diminish into a merely mechanical process, and the development of innovative treatments will cease to be possible. Because of its lack of clarity – and the overtones of strict obligation and of a threat of being held legally accountable – it might be best to abandon the use of the expression standard (see Selbmann 1996).

In medico-legal terminology, the term "regulation" is applied to the binding rules governing medical

Table 1. Fundamental concepts in quality assurance

Concept	Definition
Norms	The general precepts on the basis of which quality is defined (Donabedian 1982)
Criterion	A quantifiable characteristic which can be used in assessing quality of care (Donabedian 1982)
Standard	The precisely defined level of quality which is deemed adequate, acceptable or optimal (Donabedian 1982)
Indicator	The variables measured in order to detect deviations from standards (Bertolote 1993)
Threshold value	The predetermined value of an indicator at which an intensive assessment is triggered (Fauman 1989)
Guideline	Systematically developed sets of precepts which provide health professionals and patients with a basis for provision of appropriate care in particular clinical situations (Agency for Health Care Policy and Research, as quoted in AWMF 1995)
Structure (structural quality)	The physical, organisational and other characteristics of the system of care and of its context (Donabedian 1966, 1986)
Process (process quality)	Encompasses all the activities which contribute to the care of the patient (Donabedian 1966, 1986)
Outcome (outcome quality)	What is achieved: generally an improvement in health, but also improvements in practice and knowledge which may benefit health in future (Donabedian 1966, 1986)

practice. Guidelines are formulated on the basis of diagnostic and therapeutic standards, while recommendations and statements of opinion simply provide information and suggestions for management (Klinkhammer 1995).

Guidelines (see below) are not absolute rules, but doctors do have some obligation to take account of them. They must correspond to the current state of knowledge. According to Sect. 70 of the Fifth Book of the German Social Welfare Code (see below), they must also be confined to the basic steps which are necessary to achieve the goal and must take account of economic viability.

1.2 Domains of Quality

More detailed discussions of quality and of quality assurance measures are usually based on Donabedian's (1966) model, which distinguishes between structure, process and outcome domains of quality (see Table 1).

Ideally, one might expect outcome quality to reflect the combined effects of structure and process quality in care, so that it would be the fundamental domain for evaluation of the whole process of care. However, even given state-of-the-art treatment, the relationship between intervention and outcome is not necessarily a straightforward linear one. A great many modifying variables, including variations in the natural history of disorders, co-morbidity and compliance, also influence outcomes, which may thus be suboptimal with ideal conditions and inputs. These modifying variables must therefore be taken into account in any evaluation of outcomes (Fauman 1989), e.g. when comparing institutions whose patient populations have markedly different initial characteristics. Essentially, the attainment of the best possible structure and process quality through implementation of valid standards can only increase the *likelihood* of an optimum outcome (Schybe and Prevost 1990). Few investigations of these relationships have so far been published.

1.3 The Quality Improvement Cycle

Quality control and quality assurance are elements in a cyclical process whose goal is quality improvement: the Plan–Do–Check–Act (PDCA) cycle (Fig. 1) (see Selbmann 1995). Thus planning related to quality (problem analysis), monitoring (problem recognition, evaluation) and implementation of solutions to problems and of safety measures make up a continually repeated series of stages.

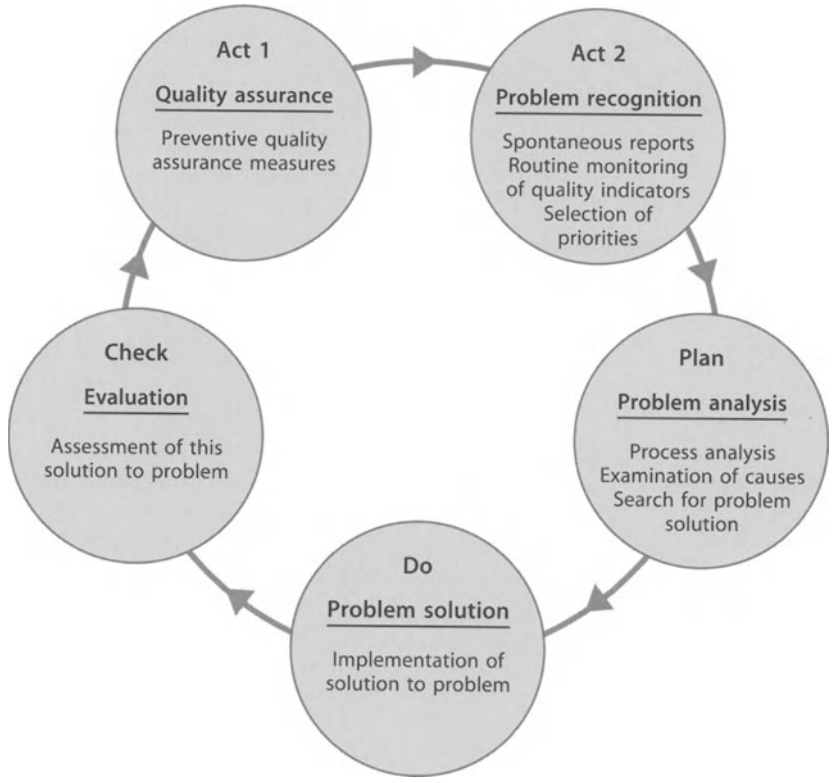

Fig. 1. Problem-oriented quality assurance

From a production engineering perspective, quality control can be understood as the whole procedure through which the actual value of a particular target variable, e.g. an actual treatment process, is compared with its *desired* value, as defined by a guideline. Applying the domains of quality outlined above, structural parameters, ways and levels of functioning and outcome criteria are all variables which can thus be used as starting points for such analyses.

Quality assurance consists of the problem analysis which takes place when a deviation is found from a fixed range of acceptable values and of the corresponding problem solution (Fifer 1980). The terminology of the German Standards Authority characterises quality assurance as "all the planned and systematic activities which are necessary to achieve reasonable confidence that a product or service will fulfil the quality requirements specified for it" (DIN ISO 8402; DIN 1992). "Confidence through quality" is also the motto of a quality assurance programme in a Munich hospital (Piwernetz et al. 1991).

In North America, a distinction is drawn between quality assurance and utilisation review (UR). Quality assurance is concerned with the question of whether care is in keeping with accepted medical standards and thus whether it fulfils specific quality criteria. In contrast, utilisation review investigates the cost-benefit relationships which may be arrived at within existing resources (Sederer 1991). Utilization review is carried out by specific organisations and involves exercises such as peer review of cases identified by specific criteria (e.g. length of stay). Together with the Health Maintenance Organizations (HMO), it is a component of managed care (see Arnold et al. 1997). Indirect cost control through examination and review of clinical practice (utilisation review), control of service budgets and, in the case of HMO, restricting the choice of doctor to certain practitioners with contracts with the organization are mechanisms used to switch from a fee-for-service system to a system of flat rates. The principle is insurance and service delivery from a single provider (Selbmann 1997), and the patient becomes a partner in the insurance company and must thus be involved in judging the quality of services. To guard against deterioration in quality, systems for accreditation and quality management need to be put in place. Advantages of HMO are the possibilities of better horizontal (between different treatment facilities) and vertical (between levels of care) integration in health care provision (Selbmann 1997).

The central idea behind the concept of "continuous improvement of care" is that of a continual process of quality improvement, which is decentralised and self-regulating as opposed to centrally controlled.

1.4 Current Status and Models

In planning and implementation, a distinction should be made between internal and external quality assurance measures. Internal quality assurance programmes are independent and specialty specific, have explicit criteria, are based on sampling frames which are as representative as possible and apply to specific illnesses or specific situations. They are to be preferred to purely external types of programmes (Eichhorn 1987).

However, fulfilling legal requirements (see below) largely involves external quality assurance measures. Without internal measures, external programmes cannot be effective; in practice they need to complement each other in a meaningful way.

In U.S. health services, external models of quality assurance have a longer tradition than in Germany (see Kaltenbach 1991; Sederer 1991). Methods of investigating quality such as utilisation review and quality assurance originated in the early 1960s. Following the introduction of the Medicare programme and the funding of the Community Mental Health Care movement by the U.S. Government, mechanisms needed to be developed for controlling rapidly escalating costs. In 1972, organisations called Professional Standard Review Organizations (PSRO) were established by law. These were local medical organisations within the public health service entrusted with control of resource allocation in inpatient and occasionally also outpatient services. Conflicts between cost control and quality improvement led in 1977 to the PSRO being placed under the scrutiny of the Health Care Financing Administration (HCFA), a division of the Social Security Administration, with a view to more vigorous cost control. Because costs continued to escalate in the public health service and medical organisations continued to oppose the PSRO, they were replaced in 1982 by bodies called Peer Review Organizations (PRO). These were organised at state level and have been associated with a system of flat rates per case, based on diagnosis. In psychiatry, flat rates per case have not so far been introduced. PRO are now generally set up and maintained by state medical associations. Their main task is to use utilisation review and quality assurance to control the costs of Medicare, but also of Medicaid and other funders. The goal is to reduce the use of expensive methods, e.g. outpatient treatments are favoured rather than hospital admissions. Over the years, their remit has developed to encompass quality assurance as well as cost control. Utilisation review has become an element in managed health care systems, in which HMO make use exclusively of selected doctors, their own protocols and accredited institutions. The

work of the Joint Commission on the Accreditation of Hospitals (now the Joint Commission on Accreditation of Health Care Organizations) has defined and operationalised quality assurance, making use of guidelines. This forms the basis on which these clinics are obliged to identify and resolve problems in care. Initially, use was mainly made of structural and process measures, but outcome-oriented quality criteria play an increasing role in a system of care which is now more tightly regulated. For some years, the American Psychiatric Association (APA) played a substantial role in development of quality assurance standards. However, it withdrew from this activity at the end of the 1980s because of the increasing economic interests of the bodies involved (Hamilton 1992). Its main activities now lie in the development of practice guidelines (see below).

In the Federal Republic of Germany, the development of quality assurance measures in medicine dates from the mid-1970s, when quality assurance programmes were initiated in neonatology, gynaecology and general surgery (Eichhorn 1987). These have subsequently been implemented nationally. Other examples of activities aimed at external quality assurance are found in laboratory medicine, radiology, nuclear medicine, pathology, cardiac surgery, neurosurgery and paediatric cardiology.

In these programmes, special multi-centre surveys take place during an annual study period examining characteristics relevant to quality. For example, for the surgical treatment of gallstones, patient characteristics, risk factors, treatment procedures, intraoperative diagnosis, results of operation and outcome at follow-up are recorded. Survey statistics are used to record trends and to compile a profile for each clinic. The position of each clinic can then be evaluated in relation to the average or to a fixed standard, and this is reported back to a central project office. Thus identification of weaknesses in particular places, initially on an anonymous basis, can serve as a starting point for the analysis of deficiencies in treatment and of how these may be remedied (Baur-Felsenstein 1994).

1.5 Range of Application

Quality assurance can be applied at a variety of levels of planning and of care (Bertolote 1993). Health policy and programmes are the highest level at which quality standards can policy be established. They are implemented within a health care system, which is made up of treatment facilities (inpatient/partial hospitalisation/outpatient and community/social care services), in which particular treatment procedures are available, which are applied for specific illnesses. The domains of quality discussed above can usefully be applied within each of these levels.

A variety of legal requirements also need to be observed, and many of these are specific to a region (*Land*) in Germany. German law regulating medical practice requires all doctors to implement measures for quality assurance in clinical practice. The law regulating doctors who treat patients under insurance schemes stipulates further measures aimed at quality assurance, and here groups known as quality circles (see below) have a particular significance. Finally, regional laws regulating local hospitals require internal and external quality assurance in the hospital. The fifth book of the Social Welfare Code is specifically concerned with quality assurance and includes regulations relating to care by doctors with health service contracts (Sect. 135), to prevention and rehabilitation in community care (Sect. 135a) and to hospital treatment (Sect. 137). For example, Sect. 137 states that "hospitals registered under Sect. 108 are obliged to implement quality assurance measures. These measures must encompass quality of treatment procedures, of the process of care and of treatment outcomes. They should be designed so to allow comparative investigations." Thus this section relates to external quality assurance. Section 70 states that the basis of service provision of appropriate quality is that "health insurers and care providers should guarantee to insured patients service provision which is appropriate to needs, equitable and reflects the generally agreed status of medical knowledge." Treatment must therefore be "adequate and goal-directed", "must not go beyond what is necessary" and must be "carried out economically".

The following section will discuss in greater detail specific applications of quality assurance in psychiatry.

2 Applications in Psychiatry

In psychiatry, the range of application for quality assurance measures includes all aspects of multidisciplinary mental health care, from diagnosis to identifying indications for and carrying out treatment, prevention, rehabilitation and aftercare. Institutional structures and the administration and organization of care also fall within their scope.

Concepts, methods and applications for quality assurance have been discussed in a series of reviews (Liptzin 1974, 1991; Mattson 1984; Fauman 1989; Bertolote 1993; Gaebel 1995a) and collections of papers (Gaebel 1995b; Haug and Stieglitz 1995; Berger and Gaebel 1996). Statements on this topic have been published by the Royal Australian and New Zealand

College of Psychiatrists (1982) and the Canadian Psychiatric Association (Cahn and Richman 1985). The Committee on Quality Assurance of the APA has issued a *Manual of Psychiatric Quality Assurance* (Mattson 1992a), which includes criteria for reviewing quality in different types of psychiatric treatment facility and methods of therapy (see below).

The specialist medical associations have played a particular role in the development and implementation of quality assurance measures (see below). Organizational elements of quality assurance programmes include the following (adapted from Eichhorn 1987):

1. Framework for quality assurance
   - Internal–external
   - Within specialty/across specialties
2. Extent of organisation of quality assurance
   - Improvised/institutionalised
3. Degree of autonomy in programme implementation
   - Autonomous/regulated by government
   - Optional/compulsory
4. Domains for assessing quality
   - Outcome/process/structure
5. Method of sampling for quality assessment
   - Total/representative group/based on selected examples
   - Random/non-random sampling
   - Selection based on illness type/based on situation
6. Degree to which indicators of quality and quality requirements are formally specified
   - Implicit/explicit
7. Timeframe for quality assessment
   - Prospective/concurrent/retrospective
8. Strategies for promoting quality
   - Organisational development
   - Training
   - System of incentives
9. Organisational and technical infrastructure for quality assurance
   - Analysis of single cases/statistical methods
   - Study of documentation/direct observation/ surveys and interviews

Particularly in psychiatry, quality standards are not the only basis for clinical judgement and care. As well as economic resources, local social and cultural norms have an important role at all levels of service planning and treatment (Bertolote 1993). As required by the World Health Organization (WHO), the views of those directly (patients) and indirectly (relatives) affected by psychiatric care are increasingly taken into account in the development and implementation of quality standards (the "community participation" and "consumerism" movements). This can also be seen as a significant step towards greater "consumer protection" in psychiatry.

The domains of quality discussed above are not fully separate and distinct in their range of application. However, for the sake of clarity, structural process and outcome quality will be described separately in the following sections.

2.1 Structural Quality

The term "structure" is used here to describe all qualitative and quantitative aspects of mental health policy and service organisation and of the buildings, rooms, staffing and equipment resources whose function is to enable needs for psychiatric care to be met. Levels of psychiatric morbidity and of those forms of social deprivation which are known to be associated with psychiatric illness can be used to assess need for psychiatric services in a region (Wing et al. 1992).

The sole basis for the humanitarian approach to care is assessment of the needs of suffering individuals. The realistic approach, on the other hand, also takes into account the degree to which a method of treatment is available and effective and can be funded. Recent expert opinion concludes that needs for care should be assessed on the basis of epidemiological data. Calculations should take into account the prevalence of psychological disorders and the evidence on their treatability as well as current levels of demand for services.

Needs-led delivery of health care is based on specific treatment goals and is provided within a structured care system. Goals are formulated in the context of health policies which provide overall guidelines for care, such as the following recommendations formulated by the *Psychiatrie-Enquete* (enquiry into German psychiatric services; BMJFG 1975) and by the 1988 Expert Commission which followed this (BMJFFG 1988; see Rössler and Salize 1995a):

- Needs-led, community-based systems of services should be established.
- There should be equity between the mentally and physically ill in terms of legal provisions and rights, financial entitlements and social status.
- There should be co-ordination and collaboration between the elements in the care system.

For the individual patient, what this should provide is a guarantee of diagnosis, treatment and rehabilitation which are tailored to his or her illness and disability, personality and living circumstances and which are the best possible on the basis of current knowledge. Reaching this goal requires the implementation of explicit guidelines within satisfactory care structures. Thus there is increasing emphasis on an approach to care which is goal-directed and tailored to individuals rather than centred on institutions.

The quality of a system of care (see Vol. 1, Part 2, Chap. 11) essentially depends on how far needs for treatment can be met in a way which is satisfactory according to clearly defined criteria (Rössler and Salize 1995b). In the Federal Republic of Germany, the 1975 *Psychiatrie-Enquete* provided a decisive impetus to improvement in the structural quality of the psychiatric care system. This was partly evaluated through model programmes and was modified and carried further in the recommendations of the 1988 Expert Commission.

Care takes place within a system with several levels, as summarised in Goldberg and Huxley's (1980) filters of care model. These levels encompass non-professional (self-help, neighbourhood, volunteer-based schemes) and professional types of help. The latter can further be divided into non-specialist, community-based primary care services (general practitioners, community nursing schemes, social services) and specialist services. Specialist services may be categorized as community and outpatient, inpatient, partial hospitalization or social care and include independent outpatient psychiatrists, social psychiatric services, day hospitals, outpatient clinics, specialist psychiatric hospitals, university units, departments in general hospitals, hostels, group homes, workshops and day centres. A variety of quantitative statistics can be used as indicators of the quality of a health care system. Examples include levels of provision of inpatient beds, the size (total number of beds) of psychiatric hospitals and the average length of stay in inpatient care.

Comparing European countries, the number of psychiatric beds per 1000 inhabitants in the period from 1987 to 1991 ranged from 0.55 in Italy to 2.6 in Luxembourg. In Germany, the average was 0.94 in 1994, with figures for different regions ranging from 0.8 to 1.5. When elderly patients were included, the figure was approximately 1.4 (Rössler et al. 1993; Rössler and Salize 1995b).

The deinstitutionalisation process has involved a restructuring of the care system in almost all Western countries. Psychiatric hospitals have diminished in size, while departments of psychiatry have been developed within general hospitals. In some areas, considerable deficits remain in the provision of day hospital places and in social care services such as community residential facilities, work schemes and day and drop-in centres.

Checklists and glossaries for evaluation of the quality of treatment facilities were published by the WHO following testing in 13 countries (Bertolote 1994). In the United States, "generic quality screens" have been developed in the course of the work of the HCFA (Mattson 1992b). These are used to examine aspects of quality of care in psychiatric hospitals on which accreditation is conditional. Likewise in Germany, criteria for structural and process quality have been published for psychiatric inpatient units (Bundesarbeitsgemeinschaft der Träger Psychiatrischer Krankenhäuser 1990; Landeswohlfahrtsverband Hessen 1991, unpublished; von Cranach 1994) and for child and adolescent psychiatric units (Bundesarbeitsgemeinschaft der Leitenden Ärzte kinder- und jugendpsychiatrischer Kliniken und Abteilungen 1993). These can be operationalised and applied in the quality assurance process.

The development of guidelines for the structural quality of other components of the care system, such as partial hospitalisation, outpatient and community programmes and social care services, has not so far been satisfactorily achieved (Spengler 1991; APA Task Force 1992; Wilson 1992; Wilson and Phillips 1992a; Bertolote 1994). This applies also to specialist units within adult psychiatry (Böhme et al. 1994; Gaebel 1995c), child and adolescent psychiatry (Bundesarbeitsgemeinschaft der Leitenden Ärzte kinder- und jugendpsychiatrischer Kliniken und Abteilungen 1993, unpublished), geriatric psychiatry (Moak 1990) and addictions (Miller and Phillips 1992). Here, the continuing discussions about the advantages and disadvantages of integration, specialisation and sectorisation are of particular relevance. Evaluative studies which have compared outcomes for hospital and community-based settings, including some which have involved health economic evaluation, have arrived at some controversial results (Häfner and an der Heiden 1994; Brenner 1995). There is also controversy about whether single or multiple levels are needed in inpatient psychiatric care systems and how tasks should be divided between general departments and specialist clinics (Rössler and Salize 1993). Currently, these ideologically charged controversies tend in any case to be resolved through a pragmatic "anything goes" approach, mainly based on local factors (Finzen 1994).

Finally, the area in which research is most markedly lacking concerns the effect on outcome quality of the architecture and design of treatment facilities, the equipment available and the organisational structures. This also applies to issues concerning appropriate planning and decision-making processes and appropriate legal frameworks for service provision (Kukla 1995).

Psychiatric treatment and care is based on a team of professionals. In outpatient care, the number of independent practitioners providing psychiatric care to outpatients under insurance schemes (*niedergelassene Nervenärzte*) rose continuously up to 1993, when the number in Germany was around 4145 (Rössler and Salize 1995a). Since then, the social welfare legislation has prescribed a level of provision of care of one such practitioner for every 17,348 inhabitants. The nature of

the reimbursement system is such that the extent of ancillary professionals working in these practices cannot be adequately assessed.

In inpatient and partial hospitalisation programmes, a significant step towards optimising process quality was made with the appearance of the 1991 decree on psychiatric staffing levels (the *Psychiatrie-Personalverordnung*), which set out a method for calculating multi-professional staffing requirements on the basis of service activity (Kunze and Kaltenbach 1994). So far, no evaluation is available of the effects on quality of this method of calculation, but Sect. 4 (4.2) of the decree (*Verordnung über Maßstäbe und Grundsätze für den Personalbedarf in der stationären Psychiatrie*. Bundesgesetzblatt 1990, part I, pp 2930–2939) does make this a fundamental requirement:

> The contracting partners have agreed on a framework of criteria which allow assessment of whether the staffing patterns stipulated in the decree result in satisfactory service provision.

Under Sect. 275 of the German social welfare code, the *Medizinischer Dienst der Krankenversicherer* (MDK; medical advisory staff of the health insurers) has an advisory and regulatory role in matters of quality assurance. This function applies to determining which treatment groups patients fall into for the purposes of calculating staffing requirements according to Sect. 4 of the *Psychiatrie-Personalverordnung* and also to ways of applying this decree in such a way that quality is improved (Banaski et al. 1993). Draft versions of a checklist for improvement of quality of care using the additional staff input for which the decree provides have been devised (Kunze et al. 1994).

There have also been discussions of the staffing structures needed in social care services, such as residential facilities and day centres, in order to be able to provide treatment and rehabilitation adapted to individual needs (Kruckenberg et al. 1994).

The qualifications of health care staff constitute a further aspect of structural quality. Appropriate higher specialist training is a requirement for good process quality (Klieser et al. 1995). A recent example is the improvement of the quality of medical training through the reorganisation of specialist training organisations, which has given doctors the option of training as specialists in psychiatry and psychotherapy (Berger 1993). Establishing new subspecialties besides those which already exist (psychotherapeutic medicine, psychotherapy, psychoanalysis) not only requires co-ordination of service provision (Deutsche Gesellschaft für Psychiatrie, Psychotherapie und Nervenheilkunde 1996, unpublished), but must also be subject to critical scrutiny from the point of view of the European harmonisation of specialist medical training which the Union of European Medical Specialists (UEMS), the European specialist medical body, is currently trying to bring about. A law regulating the involvement of psychologists in psychotherapeutic practice has not so far been passed.

Another important issue in quality assurance is the provision of psychiatric training to medical students, currently being discussed in the context of the review of basic medical education. Obviously, similar considerations apply to basic training in the other health professions as to the specialist training of members of the various mental health professions. There needs to be an investigation of ways in which continuing professional development for specialists could be made more intensive, following the example of continued medical education (CME) programmes in the United States and the recently introduced compulsory further training in Switzerland. Under medical professional regulations, continuing professional training is an obligation, and doctors must be able to demonstrate to medical associations that they are undertaking it. It includes attendance at appropriate meetings, further clinical training, study of specialist literature and use of audiovisual teaching and learning materials.

2.2 Process Quality

The term "process quality" refers to all diagnostic, therapeutic and rehabilitative activities and particularly to the extent to which the identification of indications for these and the way they are carried out conforms to guidelines. Treatment and care are increasingly needs-led; thus selective provision of services, which is determined by the types of services and staff available, is giving way to adaptive provision, which emphasizes fitting treatments to individual needs.

In considering indications for particular treatment settings within the health care system, the development of operational criteria, such as those for inpatient admission or for determining length of stay, has particular importance (Prunier and Buongiorno 1989). The availability of alternative forms of treatment is a particularly central issue for quality evaluation where compulsory inpatient admission is concerned. Community rather than inpatient care is not valid as a principle in all cases. Even where there is no immediate danger to self or others, inpatient treatment may in certain cases prevent further damage, e.g. if it protects a patient from a pathogenic environment or relieves relatives of burden.

According to Sect. 112 of the Fifth Book of the Social Welfare Code (see above), two-way contracts regulate admission and discharge of insured parties and determination of need for and duration of hospital

treatment. Section 301 sets out requirements for the contents of admission documents, including reason for admission and initial diagnosis. Section 115a regulates hospital care preceding and following hospitalisation. The purpose of care prior to admission is to establish whether admission is necessary or to prepare for it, while care following hospitalisation safeguards or consolidates improvements made during the hospital stay.

Inappropriate placement and multiple episodes of care are to be avoided and continuity of care needs to be safeguarded, extending, if necessary, over several treatment facilities. This requires a functional network between the various components of the care system. In response to the small-scale fragmentation of the regional system of care, with gaps in provision, inappropriate provision and overprovision, the concept of the community psychiatric association has developed. This includes a community outreach service, a drop-in service and a day service and has been realized in the form of social psychiatric service with a single funder or as associations in which functions are divided between facilities with a more complex funding structure. The concept of care co-ordination through case management has been applied in this context, and in retrospect it has not been clearly established that it is effective in preventing repeat admissions to inpatient services (Rössler et al. 1992). Looking to the future, there is likely to be increasing emphasis on developing differentiated services which have different main focuses but are linked in a functional network within the health care system.

The introduction and further development of operationalised diagnostic systems, such as DSM-IV (APA 1994) and ICD-10 (Dilling et al. 1992) and of clinical interview instruments has been an important advance in improving diagnostic process quality. Because of the multi-dimensional nature of causes, presentations and treatment strategies for psychiatric disorders, supplementary diagnostic methods generally also need to be applied, in keeping with advancing understanding of aetiological factors and the development of modern diagnostic methods. This means applying scales measuring symptoms and psychological tests, such as intelligence, personality and neuropsychological tests, and above all establishing a clear general medical and neuropsychiatric diagnosis, e.g. by use of imaging techniques (see Gaebel 1995c). Quality assurance in diagnosis involves supervision, specialist training meetings and case conferences as well as regular psychopathological and diagnostic rater training.

Psychiatric treatment takes a wide variety of different forms, conventionally classified into physical, psychological and sociological forms. Quality monitoring measures are needed to ensure that indications for each are properly identified and that they are combined in appropriate ways and carried out correctly (Gaebel 1995c). Psychiatric treatment here also includes prevention and rehabilitation as components included in the overall concept of care in a structured health care system (Wig 1993). As well as treatment methods whose high level of effectiveness has been empirically demonstrated, a variety of inadequately evaluated methods are still in use (Grawe et al. 1994). This applies particularly to evaluation of different service models, so far undertaken only to a limited extent within German university psychiatry, not least because of the methodological difficulties involved (Rössler and Meise 1993). In psychiatry, progress has so far been greatest in establishing treatment standards and methods of quality assurance for drug treatment. In order to develop evidence-based medicine, a task for the future will be to establish a rational basis for the use of other medical and non-medical interventions or else to abandon them if there is no clear evidence for their effectiveness.

Donabedian (1988) distinguishes between technical and interpersonal aspects of therapeutic activity. Technical aspects include scientific knowledge and specialist judgement and skills. These are a central element in practice guidelines (see below), which are based on empirical findings and on establishing an expert consensus. In psychiatry, there is a particular requirement for this technical competence to be applied in combination with interpersonal competence, which has its own kind of "technical" quality and needs to be learnt.

Most notably in psychotherapy, a series of treatment manuals have been developed. The APA has published brief guidelines on various forms of treatment, including psychotherapy (Gray 1992), psychopharmacotherapy (Kane et al. 1992) and electroconvulsive therapy (ECT) (Weiner et al. 1992). These allow a more clearly goal-directed choice of treatment, which is a basic requirement in quality assurance programmes.

In the management of individual disorders, all therapeutic measures need to be co-ordinated within an overall treatment plan (Munich 1990; Munich et al. 1990). This structures the content and timing of the therapeutic process, taking into account treatment prognosis. Practice guidelines enable the professional to carry out diagnosis and treatment according to the valid rules of the art, but allow medical freedom to make modifications in treatment where required in particular individual cases. Guidelines must themselves fulfil a number of quality requirements. The principle characteristics of effective and efficient practice guidelines are as follows (Field and Lohr 1990, cited in Selbmann 1996):

- Validity: demonstrated effectiveness and efficiency
- Reliability when applied
- Clinical flexibility: allowing deviations

- Clearly written
- Clinical applicability: indications clearly specified
- Monitoring of effectiveness and efficiency: planned deadlines for revision
- Reproducibility: process of development reliable
- Balance and acceptability: product of a multidisciplinary development process
- Adequate documentation of development process and of guidelines

Practice guidelines, which – unlike textbook recommendations – are the product of a special procedure for establishing consensus (see below) have been published for a variety of illness types. These include schizophrenia (Andrews et al. 1986; Kissling 1991; Frances et al. 1996), depression (Armstrong and Andrews 1986; Rush 1993), eating disorders (Wilson and Phillips 1992b) and personality disorders (Royal Australian and New Zealand College of Psychiatrists 1991a,b). The APA has published guidelines for major depression (APA 1993b), bipolar affective disorders (APA 1995b), eating disorders (APA 1993a) and substance dependence (APA 1995a), with further guidelines on dementia and schizophrenia in preparation.

Introduction of practice guidelines will obviously have a greater impact on outcomes when accompanied by the use of internal educational programmes which are directly relevant to patient management and to specific illness types (Grimshaw and Russell 1993). An example is the linking of a clinical quality review with measures for postgraduate training, e.g. in clinical psychopharmacology (Awad 1987).

In setting up guidelines, certain ground rules should be observed and should prevent groupings which are not clearly recognised within their specialties from producing their own sets of guidelines on which an adequate consensus has not been established (see Gaebel and Falkai 1996). The specialist medical associations should take a lead in formulating professional standards in collaboration with relevant specialist organisations, established experts and practitioners and in deriving from these standards regulations, guidelines and recommendations (Selbmann 1996). This process must itself satisfy methodological standards.

In consensus development, one can distinguish between *non-formalised* procedures, such as statements from single experts (e.g. in text books) or groups of experts, and *formalised* procedures (Ellis and Whittington 1993; Deutsche Gesellschaft für Chirurgie 1995 as quoted in AWMF 1995). Formalised procedures are the most effective way of developing consensus statements. There is now substantial literature on methods of establishing consensus in groups (for an overview, see Ellis and Whittington 1993). Where there is a need for rapid development of simple guidelines, an expert group is adequate (AWMF 1995). For longer-term development of more detailed guidelines, other techniques for consensus formation should be added, particularly the Delphi conference and the use of focus groups (Ellis and Whittington 1993; AWMF 1995; Deutsche Gesellschaft für Chirurgie 1995 as quoted in AWMF 1995).

Practice guidelines should be incorporated in basic and higher training, and corresponding specific indicators issued for quality assurance measures (Fauman 1989).

2.3 Outcome Quality

Outcome quality can be defined as the degree of congruence between the treatment goal (ideal) and treatment result (reality). Outcome quality reflects the interaction of structural and process quality in care and is thus undoubtedly the most important dimension in judging quality. As already explained, outcome quality does not have a simple, direct relationship to these input variables. If the outcome of treatment is suboptimal, an investigation should generally take place of whether the assumptions behind treatment and the way it has been carried out satisfy defined quality criteria. In practice, in contexts such as quality assurance programmes, such an investigation will generally be initiated if the treatment outcome falls outside a defined tolerance zone.

A thorough discussion of outcome quality in psychiatry needs to take into account the multidimensional nature of outcome in psychiatric illness. The various outcome characteristics (such as symptoms, rate of recidivism and social adaptation) constitute independently valid criteria for assessment, which are related to partially correlated, relatively stable longitudinal functional systems ("open linked systems"; Strauss and Carpenter 1977). Conceptualisations of quality of life (e.g. see Awad 1992; see also Vol. 1, Part 2, Chap. 7) principally emphasize the patient perspective on outcome quality. Patients' views play an increasing role in quality assurance (Leimkühler 1995). The relationships which may exist between patients' diagnoses and their views need to be taken into account and have not so far been elucidated (Kelstrup et al. 1993).

It is increasingly assumed that consumer expectations must be taken into account in establishing treatment goals. Ways of doing this include surveying satisfaction with treatment among patients and relatives, routine provision of patient advocates so that patients' interests are more effectively represented, setting up bodies such as complaints commissions and canvassing patients' and relatives' experiences when treatment structures are planned, set up or modified. In

this process, uncritical agreements should not be reached and role conflicts should be discussed; in addition, it needs to be accepted that illness-related restrictions on capacity to judge and decide mean that psychiatric treatment to which the patient does not consent will sometimes be required and can be legally enforced. There is a considerable need for research regarding the complicated relationships which exist in this area.

Research on prognosis and outcomes are important prerequisites for quality assurance measures (Möller et al. 1995).

Length of stay in psychiatric institutions is a global indicator of efficiency. Worldwide, length of stay in inpatient units has fallen, while admission rates have risen. For example, between 1991 and 1992, the average length of stay in Germany is reported to have fallen from 70.1 to 60.6 days (Rössler and Salize 1995b).

Obviously, this outcome marker has multiple determinants and cannot therefore be viewed as an unambiguous indicator of outcome quality (Gaebel 1995c). Short stays do not necessarily reflect a more successful treatment than longer stays. Patient population and peculiarities of the regional care system play a modifying role, and if this is not taken into account, false conclusions are inevitable (see Böhme et al. 1994). As a variable on which data can quite readily be collected, this indicator can however be used in an internal quality assurance process as a starting point for an "auditing" process. In such a process, certain situations can be examined more closely, such as very long stays within particular diagnostic groups.

Because of the complexity of outcome quality, a risk management approach is often preferred, which focuses on serious adverse incidents involving patients. Surveys are conducted of events such as violent incidents among inpatients, accidents and complications of treatment (Liptzin 1991; Way et al. 1985), with the aim of preventing further such events (Clements et al. 1985; DGS 1993; Kibbee 1988; see also Gaebel 1995c). Obviously, indicators of this type allow only a broad, global estimate of quality of care, and with retrospective analysis quality improvement is only possible after quite a long delay. The same applies to the drug monitoring process (Cole and Katz 1988; Helmchen et al. 1985; Molnar and Feeney 1985), unless it is carried out "online" with a capacity to trigger changes immediately.

3 Framework for Quality Assurance

This concluding section will describe the framework which needs to be in place for effective implementation of quality assurance measures.

3.1 Organizational Framework

Various institutions are involved in the development and organisation of quality assurance in Germany. In 1993, the 96th Deutscher Ärztetag (German doctors' conference) declared that assurance of the quality of medical work is an integral part of medical activity. The Bundesärtzekammer (national medical association), the Kassenärtzliche Bundesvereinigung (national association of doctors treating patients under insurance schemes), the Deutsche Krankenhausgesellschaft (German association of hospitals) and the Spitzenverbände der Gesetzlichen Krankenkassen (associations of providers of statutory health insurance) have increased their activities in quality assurance since the 1989 health reforms, including work in the field of psychiatry. In 1993, they founded a working party for the advancement of quality assurance in medicine.[1,2]

The specialist medical associations and their parent body, the Arbeitsgemeinschaft Wissenschaftlich-Medizinischer Fachgesellschaften (AWMF; federation of specialist medical associations), are taking a leading role in the development of specialty-specific quality assurance measures. In each region, associations of hospitals, doctors' associations and providers of health insurance collaborate in a working party, whose main project office is located within the regional doctors' association (Baur-Felsenstein 1994; Kolkmann 1995). External quality assurance programmes are carried out here.

Within institutions, "quality policy", "quality management", "quality assurance system" and "quality control" are key expressions in the organisation and implementation of quality assurance measures (DIN ISO 8402; DIN 1992). All those involved need to understand and accept the obligation to carry out internal quality assurance programmes. In literature on quality assurance in the hospital, quality assurance is presented as an element in a "total quality management" programme (Eichhorn 1987; Kaltenbach 1991). According to DIN ISO Standards 8402 and 9000–9004, quality management encompasses "all the activities by means of which quality philosophy, goals and responsibilities are established and are implemented through quality planning, quality control, quality assurance and quality improvement" (see Selbmann 1995). This

[1]Gesetz zur Strukturreform im Gesundheitswesen (Gesundheits-Reformgesetz - GRG) 1988, Bundesgesetzblatt, part 1, no 62, Bundesanzeiger, Bonn.

[2]Gesetz zur Sicherung und Strukturverbesserung der gesetzlichen Krankenversicherung (Gesundheitsstrukturgesetz, GSG) 1992, Bundesgesetzblatt, part 1, no 59, pp 2266–2334, Bundesanzeiger, Bonn.

process involves the use of specific forms of organization, such as the introduction of quality officers and commissions and of quality circles based on participatory group work (Antoni 1990). The development of a quality assurance system should progress from simple to more complex types of indicator. The concepts on which multi-organisational external programmes are based need to be quite simple, while internal programmes can be more complex.

In inpatient care, models of external quality assurance have been developed on the basis of Sect.137 of the Fifth Book of the Social Welfare Code and have followed other medical specialties in being based on particular tracer diagnoses (on depression, see Wolfersdorf et al. 1996; on schizophrenia, see Janssen et al. 1998). Specific screening criteria can then be applied to all patients or to a random sample who fall outside a defined tolerance zone, e.g. related to length of stay.

Models of internal quality assurance are currently being evaluated in outpatient care in the form of quality assurance circles made up of outpatient psychiatric practitioners (Berger et al. 1995; Härter and Berger 1996). In inpatient care, a "primer of quality assurance in psychiatric clinics" has been published as a basis for internal quality management programmes (BMG 1996; Gaebel 1996).

3.2 Documentation and Data Processing

A prerequisite for effective quality management is documentation that meets the recognized quality criteria (reliability, objectivity and validity), permitting analyses which are sufficiently precise and concurrent with treatment. In inpatient settings, the psychiatric case notes are the major instrument of documentation of all interviews and observations relating to the patient and of therapeutic measures and results of treatment (see Gaebel 1995c).

However, lack of standardisation limits the usefulness of case notes in quality analyses ("medical audit"). In charting the course of symptoms, it is valuable to incorporate the use of standardised instruments such as the AMDP (Arbeitsgemeinschaft für Methodik und Dokumentation in der Psychiatrie; Schaub 1994). A basic psychiatric form for recording basic psychiatric data has been developed so as to generate a minimum data set for analyses (*Basisdokumentation*, BADO; Dilling et al. 1983). However, the implementation of this in Germany has been patchy, and its suitability for quality assurance is limited as it does not include process or outcome measures (see Cording 1995).

The Deutsche Gesellschaft für Psychiatrie, Psychotherapie und Nervenheilkunde (DGPPN, German Psychiatric and Psychotherapeutic Society) has recently published an extended version of this form, aimed specifically at collecting data required for quality assessment (Cording et al. 1995). As well as information on structure (e.g. catchment area, type of hospital, structure of regional care system, characteristics of patient population), it incorporates process data (e.g. diagnosis, treatment) and outcome data (e.g. progress of treatment, outcome). Where initial conditions such as characteristics of patient populations are similar, an instrument of this type allows the external quality comparisons required by law to be made. The addition of such a set of instruments would greatly increase the usefulness of centralised health monitoring, which is essential from the point of view of service planning but remains weak in the area of data on process quality (Rössler and Salize 1995a).

Further requirements for both internal and external quality assurance are the availability of satisfactory data analysis techniques together with expert data management (Craig and Mehta 1994; Smith 1992; Schröder 1993). To this end, appropriate hardware and software need to be installed, allowing prompt and user-friendly processing of data. Only when these conditions are met will a satisfactory information base be available for prospective quality planning and control.

3.3 Needs for Evaluation and Research

Quality assurance should not be equated with research (Selbmann 1995). Without research, there is no possibility of progress in medicine, so that quality of care cannot be improved. On the one hand, research is the source of advances in scientific knowledge, while on the other hand there is a constant need for research evaluating the implementation in clinical practice of guidelines based on scientific knowledge (Fauman 1990). Research must itself satisfy specific quality criteria (Falkai et al. 1995).

There are particularly prominent gaps in research available in the area of service evaluation, especially regarding groups of patients who are cared for in non-university facilities (Klein 1994). This restricts not only the development of empirically based practice guidelines, but also their implementation in practice, as the generalisability of research results is uncertain. In principle, the introduction of systems of documentation and quality assurance structures should open up opportunities for research in non-university institutions. The quality assurance process may itself foster a more research-friendly culture, providing a basis for a more rational understanding of the treatment process and thus for the improvement of this process.

3.4 Ethical Aspects

Ethical principles such as those set out by the APA (1973) require medical practice to have a scientific basis. This is also the fundamental principle underlying evidence-based medicine. Practice guidelines developed to reflect the current status of scientific knowledge should enable doctors to follow this principle in their practice. Through its commitment to the principle of applying empirically developed standards to clinical practice, quality assurance thus has an ethical justification which protects it from misuse in the service of purely economic interests.

3.5 Economic Aspects

The fundamental purpose of quality assurance is the maintenance and improvement of quality of care. Economic considerations are secondary, but not necessarily irrelevant. Rational treatment involves a willingness to analyse costs and benefits. This process is best initiated by clinicians themselves through peer review rather than it being imposed on them from outside based on standards which are not acceptable to them. Where measures labelled as quality assurance involve examination of the treatment process with the sole aim of making it cheaper and more uniform, there will necessarily be negative consequences from the perspective of patient management which aims at the best possible treatment. Effective opposition to such developments requires clear identification of situations in which treatment standards that have been reached or could in principle be reached have had to be abandoned for economic reasons. Explicit and evaluated quality standards are needed so that a consensus can be reached on the standard of treatment which a society is able and willing to afford.

4 Future Directions

A central requirement for the further development and implementation of quality assurance measures is the co-ordination at the levels of content and methodology of the work of different committees and organisations. Formulation of guidelines which are illness specific and which take into account the modifications required for different settings is a priority. A practicable system of documentation which includes sections recording service activity of specific types needs to be introduced, and frameworks need to be established and evaluated for internal and external quality assurance. In the work on these tasks, counterproductive competition and unrealistically high goals need to be avoided.

Without quality assurance, accountable and responsible further development of the public health service cannot be envisaged (Deutscher Ärztetag 1994). This principle is entirely valid for the field of psychiatry.

Psychiatric Disorders in Primary Care

Translator: S. Johnson

1 Epidemiology of Psychiatric Disorders

Epidemiological studies carried out in recent years both in Germany and internationally have shown that between 15% and 25% of the population are suffering from psychiatric illnesses for which treatment is currently indicated (Bebbington et al. 1981; Henderson et al. 1979; Dilling et al. 1984; Häfner 1978; Schepank 1987; Robins and Regier 1991). In industrial countries, around two thirds of all the people in the population regularly consult general practitioners because of a variety of illnesses and complaints or else for preventive health care measures (RCGP and OPCS 1979). Thus, on the basis of these facts alone, it is clear that many patients in general practices are suffering from psychiatric disorders. If we take into account the further observation that people with chronic illnesses, and especially those with psychiatric disorders, consult doctors about twice as often as other patients (Finlay-Jones and Burvill 1978; Williams et al. 1986; Goldberg and Huxley 1980), then it is not surprising to find that surveys on this topic demonstrate that about every fourth patient in general practices is suffering from a psychiatric disorder.

Following the early work of Shepherd and his colleagues (Shepherd et al. 1966), a series of studies have been published reporting investigations of the prevalence of psychiatric disorders among service users in primary care (Burvill 1990; Üstün and Sartorius 1995; Dilling et al. 1978; Zintl-Wiegand et al. 1978; Gastpar 1984; Schulberg and Burns 1988; El-Rufaie and Absood 1993; Leon et al. 1995). These studies indicate that the overall proportion of patients who have psychiatric illnesses lies between 11% and 36%. Around two thirds of these patients can be seen as having chronic disorders and a third as having new episodes of illness. The degree of variation between the studies cited may be explained in terms of differences in prevalence between different settings and regions, different definitions of the threshold for "caseness", different study instruments and variations in sample inclusion criteria. Even so, the basic order of magnitude is in keeping with the values which would be predicted on the basis of population epidemiological studies. There are further substantial areas of agreement between the various studies. Throughout this literature, women, divorced people, middle-aged individuals and those of low social status are found to have raised rates of psychiatric disturbance (Goldberg and Huxley 1980; Jenkins and Shepherd 1983).

Comparisons between industrialized and developing countries are also interesting. They indicate that in poorer countries the rate of psychiatric disorders among patients receiving primary-care treatment is of a similar order of magnitude or in some instances may be even higher than in richer countries (German 1987; Ndetei and Muhangi 1979; Gautam et al. 1980; Harding et al. 1980; Mari and Williams 1984). This is despite the greater difficulties which are sometimes encountered in obtaining access to medical care (German 1987; Ndetei and Muhangi 1979; Gautam et al. 1980; Harding et al. 1980; Mari and Williams 1984).

A more recent study of psychological problems among patients in primary health care was carried out under the leadership of the World Health Organization (WHO) in parallel in industrialized and developing countries, encompassing a range of different cultures and health care systems (Üstün and Sartorius 1995). Despite language barriers, a central aim of the study was to examine patients using an identical research instrument, which allowed problems to be diagnosed in relation to current psychiatric classification systems. The structured Composite International Diagnostic Interview, Primary Care Version (CIDI) was used and diagnoses made according to ICD-10. Self-assessment questionnaires such as the General Health Questionnaire (GHQ) were also used. Figure 1 (Goldberg and Lecrubier 1995) shows that, according to ICD-10 definitions, 24% of practice attenders were suffering from a psychiatric disorder. Among a further 9%, clinically significant symptoms of illness were found without the requirements for an ICD-10 diagnosis being met. Finally, a further 31% suffered from two or more psychological symptoms without reaching the threshold for an illness being diagnosed. The results of the GHQ self-assessment scale indicated a similar picture. A total of 23.3% of practice visitors had a score of 5 or higher, suggesting the presence of a psychiatric disorder of clinical significance.

Table 1 shows the spectrum and frequency of the illnesses found (Goldberg and Lecrubier 1995). The most important psychiatric disorders are depressive illnesses, occurring in 10.4%, and generalized anxiety disorders, occurring in 7.9%, followed by neurasthenia (5.4%), alcohol misuse (3.3%), alcohol dependence (2.7%), somatization disorder (2.7%), dysthymia (2.1%), panic disorders (1.1%) and agoraphobia (1.0%). A total of 9.5% of the patients met criteria for more than one ICD-10 diagnosis, indicating a psychological co-morbidity.

The probability of suffering from psychiatric illnesses rises with the level of severity of physical illnesses. Patients whose physical health was classified as poor had a 1.4-fold risk of also suffering from a psychiatric disorder. This corresponds to the findings of a series of similar studies, which in some cases have indicated that the risk is as much as a 3.6-fold (Weyerer 1990; Leon et al. 1995). Causal mechanisms behind these associations may be psychiatric illness

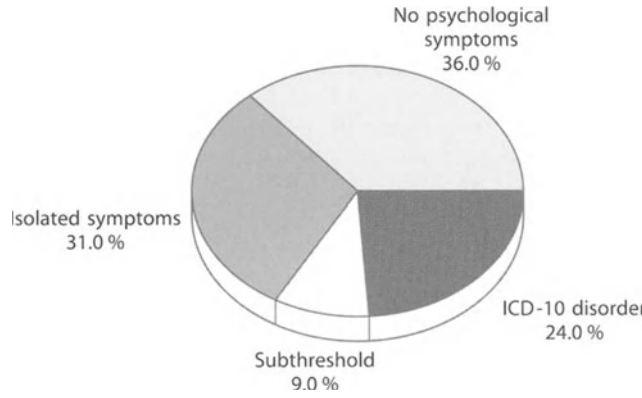

Fig. 1. Psychiatric disorders in primary care. (From Goldberg and Lecrubier 1995)

Table 1. Spectrum of psychiatric disorders in primary care (based on Goldberg and Lecrubier 1995)

Psychiatric disorder	Incidence (%)
Depressive episode	10.4
Generalized anxiety disorder	7.9
Neurasthenia	5.4
Alcohol misuse	3.3
Alcohol dependence	2.7
Somatization disorder	2.7
Dysthymia	2.1
Panic disorder	1.1
Agoraphobia with panic	1.0
Hypochondria	0.8
Agoraphobia without panic	0.5
At least one ICD-10 diagnosis	24.0

acting as a pathogenic factor in physical illnesses, organic illnesses manifesting themselves in partly psychiatric symptoms, or psychiatric disorder arising as a consequence of an organic illness such as a carcinoma (Brown and Parasekvas 1982; Massie and Holland 1984), a cardiovascular illness (Bass and Wade 1984), arthritis (Gardiner 1980) or a wide variety of other illnesses (Katon 1982).

The studies also provided some confirmation of a finding already mentioned above, which is that women suffer more frequently than men from psychiatric disorders and have different patterns of illness. Thus the prevalence of depression among women, for example, was found to be 12.5%, 1.9 times higher than the prevalence in men, which was 7.1%. However, if we take into account the full range of psychiatric disorders, including alcohol misuse, very little overall difference can be found. A total of 22.8% of men and 24.7% of women met criteria for an ICD-10 diagnosis. There was also an association with social class. If education is used as an indicator of social class, people who have had higher education have a lower risk of illness by a factor of 0.8.

So far, the results given in these international studies are summary results covering all the countries and cultures included. Depressive disorders and anxiety syndromes are the most frequent illnesses in the European countries, just as in Shanghai, Bangalore or Ibadan. Interestingly, the symptom profile of depression is also in essence the same across all centres. However, there are also significant differences between the various centres. For example, the overall prevalence of psychiatric disorders varies between 7.5% in Shanghai and 52.5% in Santiago. These differences provide further confirmation of the phenomenon of great inter-regional differences in diagnosis and treatment, a phenomenon which has already been frequently described in the literature. It is still an open question whether the explanation for these variations should be sought in differences between cultures, between health service structures or between the actual treatment facilities. An example of a difference related to culture is the finding that the rate of alcohol dependence among patients in Germany lies between 5% and 7%, while the corresponding rate in Ankara is only 1%.

2 Distinctive Aspects of Diagnosis and Classification

There is a long tradition of research on the extent to which general practitioners recognize and are thus in a position to treat their patients' psychiatric disorders. Studies which compare diagnoses of the general practitioners managing patients with psychiatrists'

diagnoses relating to those patients or else with the results of standardized surveys as a rule report a substantial rate of "underdiagnosis" (Blacker and Thomas 1988; Goldberg and Huxley 1980; Marks et al. 1979; Hankin and Oktay 1979; Skuse and Williams 1984; Casey et al. 1984; von Korff et al. 1987; Johnstone and Goldberg 1976; Shapiro et al. 1987; Zung et al. 1983; Hoeper et al. 1979). Goldberg and Blackwell (1970) applied the term "hidden psychiatric morbidity" to encapsulate this phenomenon. However, its origins do not lie, or at least do not principally lie, in a lack of specialist psychiatric knowledge among the general practitioners involved. Rather it is above all a reflection of the distinctive characteristics of the disorders concerned. The issues which give rise to problems relate to the specificity of presenting complaints, the particular ways in which patients present themselves and questions regarding the usefulness of making diagnoses in the usual standard ways.

Classification systems for psychiatric disorders have traditionally been developed in the context of psychiatric hospitals and have focused primarily on psychotic illnesses. In these very conspicuous illnesses, the principal symptoms guiding differential diagnosis, such as delusions of poverty or hallucinations, have a high level of validity and specificity. They are also not usually readily overlooked or misinterpreted. The situation is quite different for the disorders which predominate in primary care. They tend to be of mild to moderate severity and are not diagnosed on the basis of single characteristic symptoms so much as through a variable pattern of symptoms. Thus none of the symptoms to be observed has in itself a very marked pathological significance. Anhedonia, disturbances in concentration, lack of motivation, loss of appetite, sleep disorders or disturbances of energy may be manifestations of depression, but equally of many other psychiatric disorders.

Following the introduction of standardized assessment instruments and defined diagnostic algorithms, this marked lack of specificity of presenting symptoms has led to the phenomenon known as co-morbidity, with many patients fulfilling to similar extents the criteria for anxiety, depression, neurasthenia or somatization. Thus Stein et al. (1995), for example, found that the prevalence of mixed anxiety and depression was greater than that for pure cases of either, and as a result of this the mixed category has even been adopted as a distinct diagnosis in ICD-10. Moreover, the symptoms discussed here can also be manifestations of physical illnesses. In a study of older patients, Linden et al. (1995) were able to demonstrate that the average score on the Hamilton Depression Scale fell by half when they did not count as symptoms of depression those complaints which were seen by general physicians carrying out a simultaneous examination as symptoms of physical illnesses. Finally, the complaints discussed above can also be prodromal symptoms or indicators of relapse in a still wider range of disorders, so that it may only be possible to arrive at a valid differential diagnostic classification after more prolonged observation. This difficulty in establishing the boundaries of specific categories has resulted among other things in the WHO proposing a separate classification of psychiatric disorders for the field of primary care (Üstün et al. 1995a). Its principal characteristic is that diagnostic categories are broader.

Another problem which arises in assessing symptoms in general practice is how to establish thresholds for making diagnoses (Linden and Geiselmann 1996). The classical psychopathological symptoms already mentioned, such as hallucinations or delusions, are to a large extent categorical either/or phenomena, whose appearance always signifies illness and is always to be interpreted in psychopathological terms. In contrast, the symptoms of disorders which present in primary care are dimensional phenomena, which without any discontinuity make the transition from normal through to psychopathological, as with the fluid transition from excellent capacity for concentration via various gradations of limited concentration capacity through to a complete inability to concentrate. Epidemiological knowledge indicates that less severe manifestations of such symptoms are more common than severe ones. Minor alterations in the threshold at which a symptom is seen as being of clinical significance will therefore necessarily lead in primary care settings to substantial shifts in prevalence figures. The dimensional nature of the complaints encountered also has consequences for the recognition of disorders. Above all, it is the less severe disorders which do not yet impair social functioning that are not diagnosed (Coyne et al. 1995; Tiemens et al. 1996).

From such theoretical considerations, it follows that diagnostic conclusions regarding the disorders mainly seen in primary care settings must essentially carry a greater uncertainty than is the case in psychiatric settings and with more severe illnesses. Thus agreement rates between two observers or between observations based on different methodologies will necessarily be characterized by greater variability. We may even ask who is really coming closer to the "truth" when researchers and general practitioners arrive at different conclusions about diagnosis, since the lack of specificity of symptoms, for example, is not taken into account in using standardized survey instruments. In the WHO primary care study, the general practitioners arrived at a rate of psychiatric disorders among their patients of 23.4%, which is almost identical with the prevalence of 24.0% arrived at using the CIDI, but falls below the overall rate for the CIDI of 32.5%, arrived at when the subthreshold

CIDI patients were also included. However, agreement in making diagnosis was less satisfactory. Figure 2 (Üstün and von Korff 1995) indicates that only 13.3% of practice attenders were detected both by the doctor and the research interview (Üstün and von Korff 1995). Apart from the jointly detected patients, there are not only those who are ill according to the CIDI but are not recognized by the doctors, but also 10.9% who, according to the doctor's evaluation, are mentally ill without being detected by the CIDI. Interestingly, the correlation is greater between medical diagnoses and the self-rated instrument, the GHQ ($r = 0.83$) than between the CIDI diagnoses and the GHQ ($r = 0.73$).

Finally, another fundamental problem in the diagnosis of psychiatric disorders in primary care lies in the fact that, in less severe disorders, unlike for example in psychotic illnesses, patients themselves have a substantial influence on how a symptom is seen. It is up to them to decide which complaints they experience as burdensome and which they wish to report. Patients who go to a general practitioner will therefore as a rule be rather more inclined to report physical problems than those who seek help from a psychiatrist. Correspondingly, all studies in this area show that only few patients with psychiatric problems make direct reports of psychiatric complaints to general practitioners. Instead, they describe their somatic symptoms (Bridges and Goldberg 1985). Thus, in the international WHO study, 32.8% of the practice attenders presented with complaints relating to various physical conditions, and a further 29.3% complained about a variety of pains; 6.9% complained of tiredness and sleeping problems. Only 5.3% spontaneously talked about psychological problems and complaints (Üstün and von Korff 1995). Goldberg (1990) demonstrated clear variations between doctors in rates of recognition, which were independent of the patient's presenting complaint. However, the form of the presenting complaint also has a direct influence on the type of diagnosis made. Cremniter et al. (1995) found that, in depressive disorders, general practitioners did not see depressed mood as the primary problem, but sleep disturbance in 31.8%, lack of energy in 29.9% and anxiety in 24.6%. Finally, Tylee et al. (1995) also showed that the recognition rate was approximately eight times higher when psychological complaints were reported by the patient at the beginning of a consultation rather than first emerging later in its course. In explaining this phenomenon, we need to take into account the fact that the task of the general practitioner does not consist primarily of managing psychiatric disorders, but of considering the whole spectrum of illnesses. Thus it is understandable that, in patients who have known physical illnesses, the likelihood of psychological problems being recognized is lowest. In a study by Goldberg (1990), the recognition rate fell from 85% in the absence of other somatic illness to 33% with known physical illness. With tiredness in the presence of known diabetes, it is good medical practice to begin by considering whether a better insulin regime might not overcome the problem. Further, it needs to be borne in mind that, when patients present with particular complaints, they are also asking for treatment and are indicating what sort of treatment they expect. Someone who goes to the doctor because of headaches or muscle tension quite understandably expects that this complaint will be made the initial object of treatment. He or she will not expect to give information about personal problems. From this perspective, the role of doctors is to some extent to receive instructions. Doctors do not always have the right to go beyond the boundaries set and to try to see "behind the façade", as they may run the risk of infringing patients' rights to privacy and autonomy.

Alongside these basic problems in detecting and describing psychiatric disorders in patients in primary care settings and in transferring classification systems from psychiatry into primary care, there are also doctor-related factors which impede detection of such disorders. Studies of diagnostic techniques have repeatedly shown that general practitioners fail to collect significant pieces of information about current state and previous history and, for example, are too easily satisfied by explanations in terms of "problems in living" (Langwieler and Linden 1993) or focus too narrowly on the symptom initially reported, rather

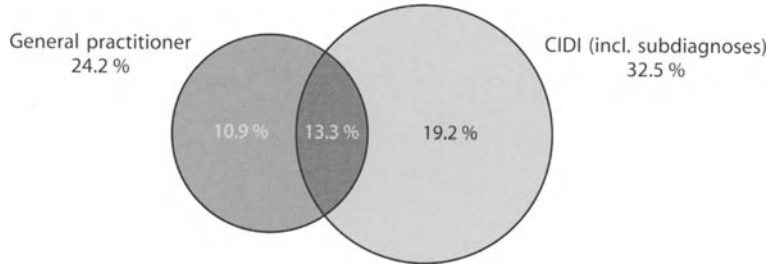

Fig. 2. Level of agreement between general practitioners' diagnoses and Composite International Diagnostic Interview, Primary Care Version (CIDI) research diagnoses. (From Üstün and von Korff 1995)

than enquiring further (Badger et al. 1994). A final fundamental problem which needs to be considered relates to the consequences which follow from making a diagnosis in a particular case. Given the uncertainty already discussed surrounding assessment of symptoms in this area, shifts in parameters such as the threshold at which a particular diagnosis is made will lead to substantial alterations in the sensitivity and specificity of whatever assessment criteria are being used to make this diagnosis. Thus a question arises about the clinical relevance of a false-positive diagnosis or of a failure to recognize a condition. While the spontaneous course of a severe psychiatric illness obviously has serious consequences for the person concerned and his or her environment and, in such a case, treatment can lead to improvements of obvious significance, this may not be true of the disorders encountered in general practice. At least on the basis of cross-sectional observation, it is an open question how far neurasthenic or somatoform complaints have really "serious" consequences. On the whole, we are only beginning to have scientifically evaluated and effective treatment methods for such disorders. Making a diagnosis which does not have treatment consequences may be of scientific interest, but from the general practitioner's perspective, it is on the whole contraindicated. This is not only because of the time and energy involved, but also because psychiatric diagnoses continue to be experienced as stigmatizing, so that if such diagnoses are to be made, there needs to be some clear prospect that the patient will benefit.

Goldberg (1979) was one of the first to show that an improved diagnosis which also influenced treatment plans could shorten the course of illness. This effect became more marked with increasing severity of disorder. Hoeper et al. (1984), who carried out an analogous study which was based only on giving doctors feedback about diagnosis, without making sure that some therapeutic action followed from the diagnosis, found that there was no alteration in the course of illness. Similarly, Tiemens et al. (1996) found that a higher recognition rate did not by itself lead to a better course of illness. On the other hand, Ormel and Giel (1990) reported that, in comparison to undiagnosed patients, diagnosed patients received psychotropic medication 4.5 times more often, psychotherapy 12.2 times more often and a referral to a specialist 3.3 times more often. This was accompanied by a sixfold better psychopathological state and a fivefold better level of social functioning.

3 Public Health Significance

With regard to the significance of psychiatric disorders in general and those encountered in general practice in particular, it is well established that to a greater extent than physical illnesses they are directly linked to a reduction in quality of life. Further, a series of findings have been reported showing that even the less severe psychiatric disorders which we have discussed have substantial social costs associated with them, above all because of the disturbances they cause in social adjustment and in the performance of work and family roles (Broadhead et al. 1990; von Korff et al. 1992; Wohlfarth et al. 1993; Hecht et al. 1990; Ormel et al. 1993).

Figure 3 shows data from the WHO study cited above regarding the association between severity of psychiatric disorder and the average number of days of sick leave. It shows that patients in general practice who have been diagnosed according to ICD-10 as having a psychiatric disorder have had around 6 days of sick leave in the previous month compared with 2 for the rest of the patients. As well as this tripling of days missed which occurs with clear-cut illnesses, it is of interest that even marginal disorders lead to a doubling of time off sick (Üstün et al. 1995b). This demonstrates the relevance from a public health

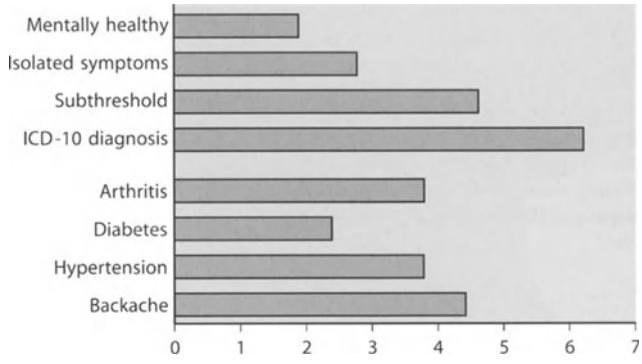

Fig. 3. Average days of sick leave in the last month in psychiatric disorders and selected physical illnesses. (From Ormel and Costa e Silva 1995; Üstün and Sartorius 1995)

perspective of disorders which may not seem especially impressive on cross-sectional study. The same result was also found when the Groningen Social Disability Schedule (SDS) was used as an indicator of illness-related disability or when global ratings made by the treating doctor were used as the basis of analysis. In all cases, a significant correlation was found between the degree of psychiatric disorder and limitations in the fulfilment of social roles.

It is of interest to consider to what extent physical co-morbidity plays a role in producing this effect, since, as already discussed, a correlation has been established between psychiatric and physical disorders. A logistic regression analysis was used to examine the relative contributions of physical and psychiatric disorders. As Table 2 shows and as would be expected, both physical and psychiatric disorders contribute to unfitness to work, but the relative influence of psychiatric disorders is certainly greater (Ormel and Costa e Silva 1995). To clarify this point, days of unfitness for work are twice as frequent in depressive as in comparable chronic physical illnesses. These unambiguously negative consequences of psychiatric disorders which on cross-sectional study might seem relatively mild may seem surprising at first glance. However, this finding is wholly in keeping with everyday clinical experience. Only a very small number of physical illnesses are clearly and directly linked to incapacity for activity, so that even where physical illness is present, interaction with psychological factors has a substantial mediating role in the extent of absence from work and sick leave.

Psychiatric co-morbidity also has a significant role as a determinant of the course and therefore the costs of treatment of physical illnesses. Sherbourne et al. (1996) found that patients with hypertension or diabetes who at the same time had a psychiatric disorder, particularly anxiety and depression, showed significantly worse health status on a health-related quality of life questionnaire for physical illnesses. Psychiatric disorders also lead to raised health care costs as a result of greater demands from these patients for general medical care. Wilkinson et al. (1988) observed over a 20-year period that every year 85%–90% of patients with psychiatric disorders consulted the general practitioner because of physical illnesses, compared with 60% of a control group. Similarly, Henk et al. (1996) used health insurance company data to show that, when a simultaneous questionnaire survey showed a raised depression score, an additional expenditure of on average US$ 1498 was incurred per year for patients receiving treatment from general practitioners for acute health problems. Simon et al. (1995) used a somewhat different methodology to calculate a corresponding additional expenditure of US$ 718, and McCombs et al. (1990) found additional costs of US$ 1043 for depressive patients who had not been successfully treated. These and other comparable studies (Manning and Wells 1992; Levenson et al. 1992; Widmer and Cadoret 1979; Greenberg et al. 1993) demonstrate that psychiatric co-morbidity is thus associated with substantial costs in health services.

The disabilities associated with psychiatric disorders are made more significant by the fact that in many cases the limitations imposed in various aspects of life are enduring. K.R. Lloyd et al. (1996) studied clinical histories in a follow-up study carried out 11 years after initial examination and found that 54% of patients were currently ill at the point of the follow-up examination and 37% could be classified as having chronic psychiatric illnesses.

Robins and Regier (1991) and Üstün and Sartorius (1993) have suggested describing the public health significance of illness according to criteria such as frequency, consequences (e.g. unfitness for work or treatment costs), public perception and possibilities for treatment. When this is done, psychiatric disorders of the type seen in general practice are of great significance and warrant increased awareness from the points of view of both treatment provision and research.

Table 2. Influence of psychiatric and physical disorders on unfitness to work: results of logistic regression analysis (Ormel and Costa e Silva 1995)

	Beta	SD	*p* value	Odds
Severity of somatic illness	0.39	0.08	0.001	1.47
Number of physical complaints	0.47	0.08	0.001	1.6
Number of psychological complaints	0.91	0.09	0.001	2.6
Number of ICD-10 diagnoses	0.92	0.09	0.001	2.52
Centre			0.001	

4 Selected Psychiatric Problems and Their Treatment

Some psychiatric illnesses are seen by the general practitioner and the specialist in psychiatry alike. However, there are also many disorders which are to be found almost exclusively in the general practitioners' practice and almost never in that of the specialist. Important examples in this latter category are generalized anxiety disorders, neurasthenia or somatoform disorders.

4.1 Psychotic Disorders

As already discussed, psychotic illnesses occur rather infrequently among patients in primary care. As they occur in the general population only with relatively low prevalences of around 1%–2%, they could not constitute a large patient group in general practice even if there were no specialist treatment. Severely mentally ill patients are also as a rule referred directly to specialists or hospitals, if these are available. However, general practitioners often remain involved in the physical management of these patients after referral, and in many cases they even play an important role in the management of patients with illnesses such as schizophrenia. Thus, in a study by Nazareth et al. (1995), 88% of the general practitioners interviewed felt that they had some share in responsibility for the treatment of their patients with schizophrenia. In 64% of patients, this took place in co-operation with a psychiatrist. On the other hand, 37% of these patients had no contact with a psychiatrist, so that their treatment remained exclusively in the hands of a general practitioner.

4.2 Depressive Illnesses

The most frequent psychiatric disorders in general practice are depressive episodes. They have the same symptomatic picture as is seen in psychiatric practice and described under the definition of "depressive episode" in ICD-10. Despite this prominent phenomenological similarity, there is evidence of some substantial differences between the depressive patients of psychiatrists and those of general practitioners. In a study of the distribution of patients between general practitioners and psychiatrists, it was found that in primary care the illnesses were less established as chronic and responded better to treatment with a serotonin-specific re-uptake inhibitor (SSRI) antidepressant (Dittmann et al. 1997). In addition, Blackburn (1984) reported that patients who were recruited for a treatment study from a psychiatric specialist clinic responded better to amitriptyline and less well to cognitive behavioural treatment, whereas the reverse applied for patients in general practices, which was attributed to differences in patient characteristics that exist between the two settings despite patients having the same diagnosis.

An impediment to the recognition of depressive illnesses is that they are typically linked with complaints about burdens experienced in life or experiences of loss. Depressive illnesses are thus seen as not requiring treatment because they can be understood. Such causal assumptions are, however, not scientifically as well-founded as they appear at first sight. Despite these links with difficulties in living, there is evidence that, when symptoms reach a moderate level of severity, depressive episodes should be treated regardless of their aetiology. Thus Zung et al. (1983) used a randomized design to show that patients in primary care who were diagnosed by means of a questionnaire as having depression showed an improvement in 64% of cases when an antidepressant was prescribed, whereas only 28% of untreated patients improved. This corresponds with the results of the many controlled trials on the effectiveness of antidepressants. As an alternative, specific psychotherapy, e.g. cognitive behavioural or interpersonal psychotherapy, can also be indicated. However, this is beyond the range of treatments generally available at a primary care level, and it will therefore require referral.

A problem which remains in part unresolved is how to treat mild depressive episodes or dysthymia, the label given to mild but chronic depressive mood. Paykel et al. (1988) found in a treatment study that antidepressants led to clinically significant benefits in more severe depressions, but could not bring about convincing improvements in milder ones. This finding fits with those of Blackburn (1984), cited above. Since the introduction of the newer antidepressants, there is however an increasing body of evidence that a course of treatment also makes sense for less severe but chronic depressive illnesses and that good results can be expected (Kocsis et al. 1995). Scientific evidence about the effectiveness in depressive illnesses of general counselling, addressing the psychological conflicts patients are experiencing, is lacking. However, this is not a reason not to give these patients the opportunity to talk about their feelings and living situation and to examine their depressive cognitions.

4.3 Generalized Anxiety Disorder

Generalized anxiety disorder is characterized by an increased level of tension, increased autonomic arousability and a tendency to constantly worry (Zubrägel and Linden 1997). Neither the doctor nor the patient may recognize these disorders for what they are, as the patient is of the view that his or her worries are justified. In psychological terms, worrying about something means always taking care and taking control of the situation (Butler et al. 1991). Thus patients do not identify the exaggerated worry as the problem, but rather the object of anxiety, whether it is that something could happen to a child on the way to school, that the washing machine might break down,

that the patient's husband might have a road accident etc. Patients therefore present because of the physical symptoms accompanying the anxiety, or because of worries about their own health or their children's, or with an "overwork" syndrome. Only by asking questions about the core symptoms can a diagnosis be made, while premature "understanding", as with depression, leads to a misdiagnosis.

Almost all psychotropic substances, prescribed and unprescribed, have effects on anxiety (Linden et al. 1988). This applies to alcohol, barbiturates and other sedatives, benzodiazepine tranquillizers or hypnotics, high- and low-potency neuroleptics and sedating and non-sedating antidepressants. However, none of the options mentioned can be seen as ideal, as each has significant limitations. Alcohol, barbiturates or benzodiazepines are ruled out because of the development of tolerance and dependence, as the nature of generalized anxiety disorder is such that treatment needs to be medium to long term. High-potency neuroleptics in low doses are in widespread use in Germany, for example (Lehmann 1989). However, empirical evidence on the effectiveness and risks of this treatment is largely unsatisfactory, so that it should currently be seen as an experimental treatment, which the prescriber must have particular reasons for employing it in an individual case. Further, even with a low dose, the risk of a tardive dyskinesia cannot be excluded. The sedating tricyclic antidepressants are also in wide use and can be used long term, lead to no problems of dependence, have positive effects on the depressive symptoms which sometimes occur with anxiety and also can have a positive effect on sleep disturbance. A disadvantage is that the anticholinergic and α-adrenergic side-effects can be experienced by patients with anxiety as an increase in the primary symptoms. Currently, the most promising pharmacotherapeutic alternatives are the 5HT-1A agonists (e.g. buspirone). These do not have an immediate effect, but, like antidepressants, only work after a treatment introduction phase. They are largely free from subjectively experienced side-effects and produce clinically significant reductions both in the primary psychopathology and in the dysfunctional cognitions associated with it.

In psychotherapeutic terms, clinically significant improvements can be achieved through behavioural therapy focusing on worrying as the problematic behaviour, in contrast to treatment measures which aim only at supporting patients in coping with problems (Durham et al. 1994; Butler et al. 1991). Even though the basis has not been scientifically worked out in detail, enough evidence is available to propose some treatment guidelines for psychological treatment by general practitioners. A central principle must be that not the problem, but the worry itself is the object of treatment. One must therefore work with the patient on developing more and more alternative ways of thinking, e.g. about their child returning from school a little later than usual. Patients must also be encouraged to take good care of their psychological health. This includes having rest periods which are free from any commitments, sufficient physical activity, care in the use of alcohol or coffee and regular sleeping times.

4.4 Chronic Fatigue Syndrome and Neurasthenia

Patients with chronic fatigue syndrome (Holmes et al. 1988; A. Lloyd et al. 1988) are seen almost exclusively by general practitioners and, because of the particular characteristics of their disorder, almost never by psychiatrists. There are a variety of very different views on the classification of this syndrome, reflected in synonyms such as effort syndrome (Wood 1941), exhaustion syndrome (Dowden and Johnson 1929; Macy and Allen 1934), fibromyalgia (Yunus 1989), neurocirculatory asthenia (Wheeler et al. 1950; Mantysaari et al. 1988), environmental hypersensivity disorder (Stewart 1987), post-viral or post-infectious fatigue syndrome (Behan et al. 1985; Bannister 1988) and more specifically chronic Epstein-Barr infection (Tobi and Straus 1985). The descriptions mirror the professional backgrounds of the authors concerned rather than really having a scientific foundation (Holmes et al. 1988; David et al. 1988; Wessely and Powell 1989). In any case, fatigue as a primary complaint produces substantial problems of differential diagnosis and, from a practical point of view, there are limits to the extent to which logical explanations can be provided under general practice conditions (Ward et al. 1996). Common characteristics are a physical and mental susceptibility to exhaustion not accompanied by the affective and cognitive indicators of a depressive illness, typically together with myalgic complaints in the absence of other somatic findings. The greatest diagnostic problem with this disorder is that tiredness is an exclusively subjective experience, so that in the study carried out by Jenkins et al. (1988) observers achieved a reliability score of only 0.02.

In around three quarters of cases, patients who present in specialist outpatient clinics with chronic fatigue syndrome suffer from clear-cut psychiatric disorders, and nearly half of these are depressive illnesses (Allan 1944; Manu et al. 1988; Morrison 1980; Sugarman and Berg 1984; Taerk et al. 1987; Wessely and Powell 1989; Wessely et al. 1996). This is true even when the sample is drawn exclusively from patients in whom blood tests have led to an Epstein-Barr infection being suspected (Katon et al. 1988; Kruesi et al. 1989).

Neurasthenia has a largely similar symptomatic picture as chronic fatigue. In contrast to the chronic

fatigue syndrome, which through nomenclature is conceptualized as a somatic disorder, neurasthenia is understood as a psychiatric disorder and included in ICD-10 among the psychiatric illnesses (Sartorius 1997). Nonetheless, in the first formulation by Beard (1869, 1880), it was described as an overtaxing of the nervous system which was to be understood in organic terms. Only in the writing of later authors such as Freud (1895) was it understood as a psychoneurosis (Linden 1991). Neurasthenic symptoms may also be an element in a depressive syndrome, so that, as with cases of chronic fatigue syndrome, the majority of cases of neurasthenia also meet the criteria for other psychiatric disorders, particularly depression (Kleinman 1982). For this reason, this disorder is no longer listed separately in DSM-IV, but is subsumed under dysthymia.

Despite this high co-morbidity or hierarchical incorporation into the categories of depressive and anxiety disorders, there still remains in all studies a group of patients who complain exclusively about exhaustion and easy fatigability and who therefore must be viewed as a distinct group. For this reason, the ICD-10 criteria allow neurasthenia (fatigue syndrome) to be diagnosed only when no depression or anxiety is present (Dilling et al. 1994).

Neurasthenia is by definition a chronic illness. According to a study by Kroenke et al. (1988), affected patients in general practice had on average already been suffering from their complaints for over 3 years, and around 70% still had them after a further year. This has been confirmed by the observations made by other authors (Nelson et al. 1987; Valdini et al. 1987).

These disorders are associated with substantial reductions in subjective well-being and are also chronic and not amenable to any other forms of treatment; thus, whatever the aetiological debates, the therapeutic challenge of trying to improve the well-being of the individual remains. Pharmacotherapeutic strategies have not so far been clearly established for this. Mild stimulants, e.g. nootropic drugs, such as piracetam or centrophenoxin, are probably worth a try. However, decisive factors are changes in patients' attitudes towards their own well-being, a greater tolerance of physical discomfort and above all a shift from a focus on their own internal state to an orientation towards action (Kuhl 1992). The significant pathogenic factor is the development of avoidance of unpleasant subjective states. This needs to be counteracted by establishing activity as a therapeutic measure. One treatment approach involves so-called paradoxical interventions. This means that the patient can withdraw and have a rest when he or she is feeling good, but that feelings of tiredness must be counteracted through activity. The therapeutic procedure thus has a similar form as for somatization disorders.

4.5 Somatoform and Functional Disorders

Somatoform disorders are defined as physical complaints for which there is no recognizable organic explanation or which can be described as exclusively functional disorders (Lipowski 1988). They include somatosensory misperceptions (somatization disorder), an autonomic dysregulation of organ functioning (somatoform autonomic dysfunctioning) or an anxious interpretation of normal or misregulated somatosensory perceptions connected with anxiety as indicating the presence of a particular physical illness (hypochondriacal disorder). Finally, combinations of all of these are also found.

In somatization disorders, patients complain of multiple non-specific physical symptoms, such as headaches, limb and joint complaints or heart complaints. If the patient is asked for further complaints, this generally results in a substantial increase in the number of complaints. Patients are firmly convinced that they are suffering from one or more physical illnesses, for which further investigative and treatment procedures are required (Samuels 1995). Negative test results do not reassure the patient.

In hypochondriacal disorder, the focus of complaints is not so much on a general and direct physical experience as on a particular organ, with a lack of confidence in this organ's functioning or fears that there is something major wrong with the organ. In autonomic functional disorders, there is a general autonomic instability or autonomic dysregulation, with an increase in dermatographism, sweating, palpitations and rise in blood pressure, stomach and bowel complaints, shaking and so on. These functional disturbances generally increase under stress.

The somatization disorders also present particular problems of differential diagnosis. Thus psychosomatic complaints are an integral part of the depressive syndrome, and various studies report that around 48%–94% of patients examined are suffering from a depressive disorder (Smith 1992). Other important differential diagnoses are anxiety and dependence disorders (Starcevic et al. 1992; Katon and Russo 1989).

In aetiological terms, both psychological and somatic factors are significant in somatization disorders. In psychological terms, somatosensory perception preferences (Barsky 1979), behaviour learnt from models in the family (Benjamin and Eminson 1992), attitudes to health (Tyrer et al. 1990), negative affectivity (Watson and Pennebaker 1989), societal sensitization (David and Wessely 1995) or attention from other parties, e.g. relatives and doctors (Mayou 1976, 1993), all play a role. From a biological point of view, there are indications of genetically determined

vulnerability (Bohman et al. 1984; Cloninger et al. 1984) and of a constitutional or acquired susceptibility to increased autonomic or hormonal arousal (Sharpe and Bass 1992).

The development of proven treatment strategies for these disorders is as yet only in its initial stages. Bass and Benjamin (1993) give general treatment recommendations, which can also be applied in general practice. One important principle is to recognize the disorder for what it is, so as to avoid mistaken physical management. A consistent relationship then needs to be built up, which also prevents patients from constantly changing their doctors. Patients should be given clear medical information about negative physical findings and about positive results regarding reactivity to stress. The suffering of the patient should be met with understanding and should never be devalued. To this end, the individual illness theories of the patient should not be dismissed too hastily, but seen as the expression of the experience and cognitions of the patient and taken seriously. The psychological factors in the patient's current situation and personal history which promote the disorder should be discussed with the patient and, where applicable, other ways of problem-solving should be examined.

In one of the few treatment studies, Real-Perez et al. (1996) report a brief family therapy, carried out by the general practitioner him- or herself. The patients had been suffering for at least 1 year from a somatization disorder. In 61% of patients, the results indicated some success which still persisted after 6 months.

4.6 Alcohol Dependence

In a survey by Roche et al. (1995), the overwhelming majority of general practitioners saw the treatment of alcohol dependence as one of their important tasks. Dependence disorders are treated by general practitioners and specialists as well. However, it is largely reserved for the general practitioner to see people with addiction illnesses which are in their early stages and not yet associated with grave damage. This gives the general practitioner opportunities for early recognition and possibly targeted early intervention to prevent problems becoming chronic.

The means by which this can be achieved are almost exclusively psychological. The first step is careful history taking. The second is to present the patient with a clear formulation of the problem without covert overtones of reproach. As a third step, self-monitoring and limits to the volume of alcohol consumed should be agreed with the patient. As patients with dependence problems on the whole cannot stick to these, the next step is to undertake an analysis of the circumstances which promote drinking and those which reinforce self-control. It is important to adjust to the fact that treatment success is not likely to be achieved by giving information on a one-off basis, but requires consistent, longer-term support (Schmidt 1997).

4.7 Dementia

With the increasing numbers of old people, illnesses associated with ageing, i.e. primarily dementing illnesses, represent a major care task. From around the age of 70, the prevalence of dementia rises in an approximately linear relationship with age, with the result that approximately half of those in their nineties are suffering from a dementing illness (Jorm et al. 1987; Reischies et al. 1997). Old people generally also have high levels of need for medical help because of other forms of morbidity, explaining the finding of Eefsting et al. (1996) that 5.2% of the patients of general practitioners are suffering from dementing illnesses.

Studies of the use of medical services indicate that old people have a tendency only to consult one doctor with their mostly chronic and multiple complaints and that they are less likely to be referred on to specialists (Ryynanen et al. 1997; Linden et al. 1996a). This means that general practitioners are responsible for diagnosis and treatment of psychiatric disorders in the elderly population (Cooper et al. 1992). There is also a danger that psychiatric disorders among old people are not recognized as illness (Eefsting et al. 1996; Pond et al. 1994), but seen as by-products of the accompanying physical multiple morbidity, as consequences of the social situation or simply as an unavoidable manifestation of old age. In around half of cases, the patients themselves, according to Newens et al. (1994), are not aware that they have a psychiatric disorder.

The focuses of general practitioners' treatment encompass not only the actual dementia syndrome, but also the other psychological and above all physical co-morbidity. Finally, support for relatives acting as carers is an important therapeutic task.

Currently, the possibilities for direct intervention in dementing illnesses are limited. However, the so-called anti-dementia drugs or nootropics represent important treatment possibilities, whose effectiveness can be seen as essentially established (Moeller 1991). The question is rather about when the success which can be expected is great enough to justify the treatment costs. Epidemiological treatment studies suggest that the current situation is that only a few per cent of those affected are treated with nootropics, and there are thus reasons for suspecting undermedication (Helmchen et al. 1996). After all, given the severity of the illness and the considerable costs incurred for care and nursing,

even small improvements or halting the progression of the illness may have great significance for those affected, their relatives and the wider network involved in supporting them. The same applies to the treatment of co-occurring physical illnesses. Here, too, epidemiological treatment studies indicate that, with increasing severity of dementia, less medical treatment is provided (Helmchen et al. 1996), even though overall physical state is of considerable significance for the development of the illness. Of all groups of doctors, general practitioners have the best basis for managing overall morbidity within an integrated treatment plan, and they can do this with a competence similar to that of specialists (Colenda et al. 1996).

General practitioners have a particular role in supporting the relatives of those with dementia. By their nature, these illnesses demand that patients are supervised and, at a later stage, also intensively nursed. Even among those with the greatest needs for nursing, the majority of patients are not cared for in nursing homes, but at home by relatives, which makes great demands both of them and of the treating doctors (Linden et al. 1996b; Tyler and Bourguet 1997). The ability of relatives to assume care depends among other things on the network of professional support (Vernooij-Dassen et al. 1997). General practitioners have a good knowledge of the social and family environment of the patient, and the work of the caring relative can therefore be facilitated not only through good provision of medical care, but also through advice and support on nursing aspects of care and in relation to social needs. Doctors' basic training gives them only limited education in areas which concern social needs. According to the studies carried out by Cheok et al. (1997) and Shah and Harris (1997), they feel less confident about advising on these areas than on other aspects of diagnosis and management, and relatives often expect more support than they obtain (Brodaty et al. 1994; Commissaris et al. 1995).

5 Primary Medical Care in a Complex Health Care System

5.1 Structures and Tasks of Primary Medical Care

The care provided for a patient is not only a function of medical knowledge, but depends just as much on the setting in which it is delivered and also on the treatment strategies which are permitted or available within a particular treatment setting. Economic considerations now have a greater influence on medical practice, it is not the doctor's task to do what is medically conceivable or optimal, but, as dictated by the law governing medical insurance, for example, only what is deemed to be necessary and sufficient, and sometimes merely what is practicable. In this respect, the general practitioner takes on a key position in many health care systems. He or she is responsible not only for basic care, but also for either mobilizing or avoiding the involvement of specialists and sometimes for co-ordinating specialist input. The significant facets of primary or general practitioner treatment thus include both the initial contact and first treatment and also continuing care following specialist medical intervention.

There are substantial international differences in the ways in which primary medical care is organized, depending both on the available material resources of a society and on political views. Thus the organization of the general practitioner system differs between Holland and Germany, for example, despite comparable standards of living. While in Germany a patient with any complaint is free to go to whatever doctor he or she chooses, in Holland the patient first has to go to a general practitioner and may then also see a specialist on referral from a general practitioner. This is the so-called gatekeeper function of the primary care physician and has direct consequences for service use pathways. In Holland, over 95% of patients who present anew in general practice have never been in treatment elsewhere for the problem concerned, whereas the proportion in Germany is only around 75% (Üstün and von Korff 1995).

Another aspect of the organization of primary care which is important in making international comparisons is the distinction between hospital and family doctor systems. These forms of care also exist alongside each other in a health care system in some cases. According to Starfield (1992), collective or hospital care can be differentiated from family doctor care in that patients consult the hospital and not an individual doctor, that the caring doctor in some circumstances may change from visit to visit and does not necessarily have prior knowledge of the patient, that a multiprofessional team and not a single doctor takes on the care of the patient and that the treating doctor as a rule does not receive direct reimbursement for this work. This way of organizing work has direct consequences for the diagnosis and treatment of the disorders treated. Thus the rate of diagnosed psychiatric disorders in hospital facilities is only around half as high as in family doctor practices, for example. This effect can be demonstrated even when corresponding facilities in the same city are compared (Üstün and von Korff 1995). The most plausible explanation is that, in the family doctor system, the doctor's longer acquaintance with both the patient and the relatives makes much more information available to him or her than in a hospital setting.

These structural characteristics of primary care medicine are paralleled by therapeutic tasks. These can be summarized as detection of the onset of illness, initial treatment and basic care, as well as the integration of specialist diagnostic procedures and treatment and referral for specialist treatment interventions.

The problems already outlined of non-recognition of psychiatric disorders have a particular relevance in relation to this description of the general practitioner's role in care. It is with just those patients who are least ready to accept the idea that they have a psychiatric illness that there is a particular need for the diagnostic and therapeutic skills of the general practitioner. He or she is the only person who can detect such cases and work to prevent adverse outcomes from illness such as suicide. In many cases, he or she is the only person in a position to treat those patients who find going to a psychiatrist an unacceptable idea. Thus in Great Britain, for example, the Royal College of General Practitioners has initiated a campaign together with the Royal College of Psychiatrists to fight the stigma associated with psychiatric illnesses and above all to improve awareness of such disorders in primary care settings (Sims 1993).

5.2 Co-operation Between General Practitioners and Psychiatrists

The next question to be considered in relation to the treatment of mental illnesses is the division of roles between general practitioners and psychiatrists, psychotherapists, psychiatric hospitals, social care services such as day centres, hostels and workshops and other providers of services for the mentally ill.

Williams and Clare (1986) have described three models of co-operation between general practitioners and specialists: the referral, the substitution and the consultation model. The referral model envisages the general practitioner as the primary treatment provider, who, depending on the type of disorder, may send the patient on to a specialist for additional and further treatment. In the substitution model, the specialist is seen as the primary doctor for illnesses which fall into his or her area of competence and is also approached directly by patients if they suffer from disorders in this category. The consultation model sees the treatment of a patient as almost entirely in the hands of the general practitioner, who in difficult cases presents the patient to a specialist for explanation and advice with regard to further treatment or else makes use of other groups of professionals such as social workers and psychologists for particular types of help. Which model is implemented depends partly, as already discussed, on the organization of the health care system. In many countries, all three models may be encountered at the same time. Which form of collaboration is chosen also depends not at least on the patients or general practitioners themselves.

Surveys in practices indicate that the current rate of onward referrals and co-operation is around 1%–2% of practice clients, with a great deal of variation not only between different general practitioners but also between regions and health care systems. This variation cannot be attributed exclusively to differences in local prevalence of psychiatric disorders. Around 10% of patients have had at least one contact with a specialist in the past (Zintl-Wiegand et al. 1978; Gastpar 1984; Dilling et al. 1978; Carey et al. 1994; Arreghini et al. 1991; Geiselmann and Linden 1989). Patient-related factors which make referral more likely are a known psychiatric history, psychiatric primary complaints, social problems and the family doctor making a relevant diagnosis. The latter, however, is of less significance than the primary complaints of the patient. The presence of clearly defined physical illnesses make referral less likely (Arreghini et al. 1991; Strathdee et al. 1990; Chithhiramohan et al. 1993; Verhaak 1993). Older patients also have a tendency to remain with their general practitioner and not to seek out the help of an additional doctor such as a psychiatrist (Lingg et al. 1995; Helmchen et al. 1996). Variables associated with the doctor are another contributing factor, as referral is less likely if the definition of the physician's role is narrowly confined to the management of physical disorders and is influenced by his or her view about whether he or she has the appropriate competence (Verhaak 1993; Fritzsche et al. 1993). Finally, referral also depends on organizational factors such as the structure, proximity and availability of specialist services (Dilling et al. 1984; Verhaak 1993; Arreghini et al. 1991).

Studies on needs for referral have as a rule tended to start out from the premise that the rate of referrals is markedly low (Dilling et al. 1978). Indications for referral identified by Helmchen (1991) are as follows: (a) doubts about psychiatric diagnosis and problems of differential diagnosis in multi- and co-morbidity, (b) severity of illness and threat of complications such as suicidality, (c) length of illness, degree to which it has become chronic and treatment resistance, (d) requirement for long-term medication, (e) unwanted side-effects of medication and (f) need for specific psychological treatments. In studies in which psychiatrists directly examined patients in family practices, half of the patients seen were in need of psychiatric treatment (Dilling et al. 1978; Zintl-Wiegand et al. 1978). In a newer study by Schulberg et al. (1995) on depressive illnesses in primary care, it was found that, among 283 patients with depression, 70% could be appropriately treated by the general practitioner, 13%

needed referral to a psychiatrist and 17% had other disorders in need of other forms of treatment.

Empirical studies on when general practitioners make referrals show that by then, as a rule, some treatment has already taken place (Maguire et al. 1995). In 61%, drug treatment had already been given, while 67% had received some form of advice or counselling. In 30%, the reasons for referral were for treatments not available in the primary care setting, in 20% because of treatment resistance and in 14% for a sharing of the burden of care in chronic disorders. This corresponds on the whole to guidelines for the management of depressive illnesses such as those issued by the Agency of Health Care Policy and Research of the USA (AHCPR 1993), which recommend that general practitioners should generally make a first attempt at treatment, including drug treatment. However, some psychiatrists are critical of such recommendations and advocate earlier referral (Munoz et al. 1994).

Empirical evidence is required as to when referral results not only in additional costs, but also in a better clinical outcome. According to the available studies, the types of disorders which are mainly managed in general practice are not necessarily managed better by a specialist than by general practitioners themselves. Jenkins and MacDonald (1994) randomly allocated 65 older depressive patients who had been detected in the context of a screening programme in general practices either to management over 9 months by a multiprofessional psychogeriatric team or to continued management as usual by the general practitioner. Their results indicated no significant differences between the two groups. In a study by Katon et al. (1992), half of a group of patients of 18 general practitioners who had in the past been heavy users of medical services were randomized to receive a psychiatric consultation. After 6 months, there was a significant increase in antidepressant prescriptions for the referred patients. However, there were no significant differences with regard to psychopathological status, degree of disability or the continuing use of medical services. In a similar study by the same authors (Katon et al. 1995), patients with depression were randomly allocated to joint management with a psychiatrist. At follow-up, the intervention patients were receiving significantly more antidepressants. Overall, there was a significantly better course of illness only for those with major depression, while the improvement rate for minor depression was the same in the intervention and the control groups.

In a study by Scott and Freeman (1992), 121 patients were randomized either to a psychiatrist, a psychologist behaviour therapist, a social worker or treatment by the general practitioner alone. After 4 and 16 weeks, independent raters detected clear improvements in all patient groups, but no clinically significant differences between the treatment groups. Meanwhile, treatment by a specialist rather than the general practitioners was associated with four times as much expenditure of time and twice as great a cost. Patients were most satisfied with the psychological treatment and above all management by the social workers (Scott and Freeman 1992; J. Scott et al. 1994). Thus undiscriminating referral of all those with psychiatric disorders from the general practitioner to the specialist cannot necessarily be expected to lead to a better course of illness. The question to be resolved is which patients it is appropriate to refer. Helmchen's (1991) proposed criteria, listed above, can be seen as practicable guiding principles which are supported by research evidence.

6
Specific Methods of Diagnosis and Treatment

When patients go to the general practitioner as the first port of call, the doctor's task is to clarify what the current problems are, to decide which diagnostic procedures and treatment measures need to be introduced now and, where feasible, to make an initial attempt at treatment. The diagnostic and treatment strategies which are typically available in primary care and the ways these are used will now be outlined.

6.1
Diagnostic Procedures

The particular difficulties of diagnosing psychiatric disorders among patients in general practice and the resulting failure to detect and thus to treat a significant sector of this patient group have already been discussed. The following are recommendations for improving the detection rate.

A factor which has a considerable impact on clinical detection of psychiatric disorders is the doctor's interviewing technique. Goldberg (1990) used video observation of doctors with better and worse recognition rates and identified a set of criteria which allow these groups to be distinguished:

1. Beginning of interview
   a) Eye contact
   b) Clarification of complaints
2. Interview style
   a) Reacts to verbal cues
   b) Reacts to non-verbal signals
   c) Can steer patient's flow of talk
   d) Can cope with interruptions
3. Style of questioning

a) Precise psychiatric questions
b) Supportive comments
c) Asks about domestic relationships

The successful doctors were also on the whole more experienced, had a greater interest in psychiatric questions and were happier in their practices. Interviewing technique is thus certainly dependent to a degree on personality and experience. However, as Goldberg et al. (1980a,b) were also able to show, it was possible through video feedback and targeted training to improve interviewer behaviour.

An option for improving the recognition of psychiatric disorders is routine use of diagnostic scales as screening instruments. The problems in implementing such a method are however substantial. According to Wittchen and Essau (1990), a screening instrument which could be used for all patients in general practice would need to fulfil a set of essential requirements. These include the criteria that it should be short and not time-consuming, simple to fill out, easily rated, useable in very different forms of practice organization, applicable with very different patient groups, e.g., young and old, and sensitive for the whole spectrum of possible psychiatric disorders. It also needs to be able to be interpreted without much training, to produce results which are sufficiently concrete to allow treatment to be initiated on the basis of it, to avoid false-positives results due to co-occurring physical morbidity, to have adequate psychometric reliability, specificity and sensitivity, to provide information as far as possible not only on the symptomatic but also the diagnostic level, to pick up disorders in their early stages and ideally also to encompass additional aspects, such as level of psychosocial functioning. It is clear from this list that such an instrument is not likely to ever exist.

The currently available screening instruments tend to cover a group of core symptoms which are very non-specific and can therefore occur in almost all psychiatric disorders. They do not allow diagnostic classification. An example is the GHQ (Goldberg and Williams 1988), which asks questions about general physical and psychological health, about a series of somatic complaints including sleep and about psychological complaints including suicidality. The questionnaire is available in a longer form of 60 items and shorter forms with 28 and 12 items. From the point of view of practicability, there would be no major problems in giving every patient who attends the practice such a questionnaire in the waiting room and having it rated by the clinic receptionist. From our own experience, we know that this is accepted by patients and in some cases even positively welcomed. With repeated administration, the questionnaire can also be used as an instrument for the documentation of course. Data about this are not available, but despite this basic practicability, it is the exception rather than the rule for such scales to be applied in general practices. One can only speculate that the problems of underdiagnosis may not be taken as seriously by doctors as the literature suggests, so that measures to address this are not seen as necessary.

Once it is established that a condition meeting criteria for a psychiatric diagnosis is present, starting properly targeted treatment will often require a precise diagnosis to be established. On the basis of the modern psychiatric classification systems ICD-10 and DSM-IV, it is now possible to distinguish between important psychiatric diagnoses with limited psychopathological knowledge, through structured questioning and use of the algorithms provided. In research projects, these structured interviews, e.g., CIDI (Wittchen et al. 1989), are sometimes also carried out by lay people after relatively short training. However, one cannot envisage this working in practices, as the interviews are time-consuming and commit the doctor or his or her colleagues to using up expensive time.

A possible alternative is the use of computer-supported interviews, whose suitability for application in general practice has to some extent already been demonstrated (Weissman et al. 1995; Olfsson et al. 1995a). The CIDI is also available in a computer version. The patient is seated directly at the computer and uses screen and keyboard to answer all the questions. At the end of the interview, diagnostic scores can immediately be generated using the computer. The patient needs only to be observed by a staff member from a distance, in case there are any queries or problems. From our own experience, such a procedure is feasible under practice conditions and is also accepted by patients. In each case, a doctor will need to check over the results of this questioning, but on the basis of the information available this can be done in a much more focused way.

6.2 Drug Treatments

For the disorders which are most significant for primary care, the most important pharmacological treatment strategies according to currently available literature have already been outlined. While in the initial years after the introduction of psychotropic drugs the treatment of psychotic illnesses was in the foreground, there is now increasing interest in the further development of psychopharmacotherapy for non-psychotic and milder disorders, such as anxiety disorders, dysthymia, somatization disorders or even personality disorders. The assumption that psychoses should be treated pharmacologically and never

psychotherapeutically, while the so-called neuroses should be treated psychotherapeutically and never pharmacologically, is no longer valid. Advanced understanding of the psychological and biological bases of these disorders permits understanding of why biological and psychological treatment may be effective in the same disorder and why in some cases combination treatments are also indicated. Thus drug treatment for those disorders which are on average milder is not merely an emergency solution or an inadequate substitute treatment, but is one of the core treatment strategies and, compared with alternatives, is relatively well evaluated. It should therefore play an important role in the armoury of the general practitioner. In the following, individual disorders and their management will not be discussed again, but rather we will look at the epidemiology of prescribing practices among general practitioners.

Pharmaco-epidemiological studies indicate that general practitioners rather than psychiatrists prescribe the largest total quantities of psychotropic drugs (Schäfer 1990).This can be explained in terms of the fact that there are around 20 times as many general practitioners as psychiatrists (Thust 1997), and per doctor they treat around twice as many patients. Considering the quantity of prescriptions per individual doctor or even per treated patient, psychiatrists clearly prescribe more psychotropic drugs than general practitioners, as would be expected. Psychiatrists also have a higher rate of prescribing a combination of psychotropic drugs (Meredith et al. 1994; Dittmann et al. 1997).

Pharmaco-epidemiological studies have repeatedly shown substantial differences both between regions and between professional groups. These are essentially related to differences in the prescribing behaviour among general practitioners (Wessling et al. 1991; Bellantuono et al. 1988; Friebel 1989). Such data show that choice of treatment and prescribing behaviour are basically not only dependent on medical factors in the narrower sense, but also on gender, attitudes of patients and doctors, organizational and political guidelines, and ethical and cultural context (Raynes 1979; Williams 1983; Hohmann 1989; Lloyd and Moodley 1992; Maslowski 1987; Linden 1994; Morabia et al. 1992).

In the WHO primary care study (Üstün and von Korff 1995; Linden et al. 1999), it was found across all international sites that 11.5% of practice attenders were treated pharmacotherapeutically for psychiatric disorders, with considerable variations from 2% in Shanghai to 29.6% in Santiago. Surveys by other authors have arrived at comparable or even higher rates (K.R. Lloyd et al. 1996; Joukamaa et al. 1995; Linden et al. 1996b). Among the patients who were mentally ill in the view of doctors, an average of 51.3% were treated with psychotropic drugs in the widest sense. Looking only at the patients meeting criteria according to the CIDI for an ICD-10 diagnosis, 27.6% were given appropriate treatment. These data firstly indicate that psychotropic drugs are a first-line method of treatment by general practitioners for psychiatric disorders. Secondly, they form a further basis for the premise which has already been discussed, and which is in fact obvious, that the recognition of such disorders is an indispensable requirement for treatment. Of the range of psychotropic drugs which are in use, tranquillizers and sedatives play the greatest role in 26.3% of patients recognized as mentally ill, followed by antidepressants in 15.0% and herbal and tonic substances in 13.2%. These data already give an indication that to some extent the treatments concerned are symptomatic and non-specific. This is confirmed by observation of patients with acute depressive episodes according to ICD-10 who were also diagnosed by the treating physician. Only 22.2% received an antidepressant. A further 27.6% received tranquillizers and another 23.2% other psychotropic drugs. On theoretical grounds, it could be concluded that treatment is largely non-specific in two thirds of cases.

6.3 Psychological and Social Treatments

In the conventional use of the term, psychotherapy is a specific treatment method which generally involves a 50-min interaction once a week with a specifically trained psychotherapist. Even if some general practitioners have a psychotherapeutic training and treat some individuals in a psychotherapeutic framework, the time requirements alone mean that this is not a form of primary care treatment. However, general practitioners often play an important part in directing people to such psychotherapy. They are also often asked to be joint participants in treatment in cases where drug treatment or another physical treatment is indicated in addition to psychotherapy in order to optimize the treatment outcome.

In addition to the traditional form of psychotherapy already discussed, there are various further forms of psychiatric and general practitioner psychotherapy. Basic supportive psychotherapy, as practised in many psychiatric contexts, is defined by the doctor having specific training, spending at least 20 min with the patient and, among other things, making some systematic use of the doctor–patient relationship in treatment. Thus it is a focused psychotherapeutic procedure for the treatment of different psychological disorders. "Syndrome-related verbal interventions" are brief psychotherapeutic interventions related to psychiatric disorders in which particular account is taken

of effects of psychopathology in limiting communication and functioning. Finally, basic care also involves the provision of general counselling and of specific counselling on particular problems arising from illness and treatment.

According to information provided by the doctors in the WHO primary care study (Üstün and von Korff 1995), 52.4% of patients recognized as mentally ill received relevant advice or counselling. Patients raise a great variety of topics in consultations with general practitioners. Zwernemann (1997) studied the types and frequencies of themes discussed during 100 general practitioner contacts. Table 3 summarizes these data, comparing patients with and without psychiatric disorders. In a further study, Olfsson et al. (1995b) studied the forms of psychological intervention used by general practitioners. They carried out some form of psychological intervention with 24.1% of all patients. Above all, these consisted of listening to problems (22.4%) and giving advice (19.0%). Such an intervention was used with 66.7% of patients with psychiatric disorders. According to the results of this study, advice and support with problems are an important aspect of the work of general practitioners, an aspect on which adequate scientific research has not yet been carried out.

A question of particular interest is the extent to which, in the treatment of psychiatric disorders by general practitioners, there is an inverse relationship between drug treatment and psychological intervention. An assumption sometimes expressed is that drug treatment is a substitute for personal attention and talk. In relation to this question, Fletcher et al. (1995) carried out a study in which they worked together with general practitioners to make targeted counselling available for patients to varying extents. Their results were unexpected and contradicted their initial hypothesis. The more counselling related to personal problems and other psychological complaints was offered, the higher the rate of prescription of antidepressants and tranquillizers. Apparently, detection of such disorders was associated with a greater overall intensity of treatment. These results were confirmed by a study carried out by Katon et al. (1996). This evidence thus indicates that conversations and counselling do not replace psychopharmacological treatments. Under general practice conditions, they are not alternatives, but complementary aspects of treatment.

Table 3. Themes of consultation for patients in general practice with and without psychiatric disorders (Zwernemann 1997)

Themes	Psychiatric diagnoses (%)	Physical diagnoses (%)
General topics	32	62
Brief pieces of advice given	18	2
Discussion of problems	20	6
Advice about problems	4	2
Psychotherapeutic intervention	6	0

A point that has already come up several times is that each course of treatment is necessarily influenced by the organizational context. This applies especially to the provision of counselling, which depends on the availability of time and relevant experience. In a study by Meredith et al. (1996), the type and range of counselling provision and psychological intervention for depression through general practitioners, psychiatrists and psychologists was investigated and examined in relation to the payment system. As one might expect, there were clear differences between the professional groups. While with psychiatrists and psychologists more than 90% of patients were counselled in some way, the corresponding rate for general practitioners was only around 40%–50%. Psychiatrists and psychologists more often made use of the methods of psychoanalytic psychology and of behavioural therapy, whereas doctors mainly gave advice. Across specialities, they found that doctors who received a global payment per patient rather than payment for each contact, as well as doctors who had greater numbers of patients to handle, were less likely to give advice and spent less time on this. The structuring of the remuneration system must therefore not only be considered in financial terms, but should receive as much scientific attention as the pharmacokinetics of drugs, as its influence on treatment is at least as great.

However, treatment in primary care does not only encompass the doctors' own activities, but also help for patients which is provided by other workers in the practice or polyclinic or by various other collaborators. The studies by Fletcher et al. (1995) and Katon et al. (1996) already cited involved increasing the availability of counselling and support by placing psychologists, social workers or nurses in the practices. A further example is a study by Blanchard et al. (1995) in which it was shown that, for older depressed patients, additional intensive care from a community nurse led to better depression scores than among a group of patients cared for solely by general practitioners.

6.4 Effects of Intensified Diagnostics and Therapy

In view of the particular characteristics of general practice already discussed, including the many factors apart from the nature of the disorder itself, empirical evidence is needed on the results of more targeted and

specific diagnosis and treatment. Goldberg (1979) was one of the first to show that an improved diagnosis which also influenced treatment plans could shorten the course of illness. This effect became more marked with increasing severity of disorder. In any case, there is no necessary connection between diagnosis and treatment. Hoeper et al. (1984), who carried out an analogous study based only on giving doctors feedback about the diagnosis, without making sure that some therapeutic action followed, found that there was no alteration in the course of illness. Similarly, Tiemens et al. (1996) found that a higher recognition rate did not by itself lead to a better course of illness. On the other hand, Ormel and Giel (1990) reported that, in comparison to undiagnosed patients, diagnosed patients received psychotropic medication 4.5 times more often, psychotherapy 12.2 times more often and a referral to a specialist 3.3 times more often. This was accompanied by a sixfold better psychopathological state and a fivefold better level of social functioning. Schulberg et al. (1996) carried out a comparative study on the treatment of depressive patients in primary care. A total of 92 patients remained in routine treatment (RT) as usual from the general practitioner, 91 were treated following the research protocol with nortriptyline (NT) at a daily dose of 190–270 mg over 8 months, and a further 93 patients received interpersonal psychotherapy (IPT). The results give clear support to a targeted course of treatment. After 8 months, 48% of the NT and 46% of the IPT active treatment groups were symptom free compared with 18% of the RT group. The differences are even clearer when only those who remained in treatment rather than all initially included are considered. The percentage of symptom-free patients was 67% in the NT group, 72% in the IPT group and 20% in the RT group, while the proportion of patients whose score on the Hamilton Depression Scale was just as high after 8 months as at the beginning of treatment (>12) was 13% in the NT group, 15% in the IPT group and 48% in the RT group. These data confirm that the specificity of the treatment, the adequacy of its implementation and the consistency with which it is carried out are important requirements for treatment success.

However, it should be borne in mind that, while these data refer to patients recruited in general practice, they were specifically selected for the research project and the treatment was also carried out by specialists. A rather more realistic study was carried out by Callahan et al. (1994), who randomized 103 general practitioners and 175 depressive patients aged over 60 in equal numbers between a routine therapy and an intervention group. The intervention consisted of the doctor receiving detailed information about their patients' depression and hints on treatment. In the intervention group, significantly more antidepressants were prescribed, but psychiatrists were not consulted about treatment more often. In contrast to Schulberg et al. (1996), they did not find a difference between groups with regard to mental status on longitudinal follow-up. With respect to the management of depressive illnesses in general practices, basic treatment was supplemented by Katon et al. (1996) by an offer of targeted counselling for patients. In comparison with the routine therapy group, the patients in the intervention group were significantly happier with treatment, were more likely to be receiving a prescription for psychotropic drugs and above all were significantly more compliant with this medication. Further, their status improved to a significantly greater degree in the course of treatment, above all in the more serious cases.

7 Conclusion

The primary care setting is an important setting for the treatment of patients with psychiatric disorders and is in fact where the greatest number of such patients are seen. Both theoretical considerations and evidence in practice indicate that knowledge from the narrower realm of psychiatry cannot be automatically transferred without further consideration to the primary care setting. Instead, there is a need for setting-specific knowledge about diagnosis and treatment. It also cannot just be assumed that all affected patients can or should be automatically referred to specialists. Instead, co-operation between specialists and general practitioners should be intensified and to this end new models of co-operation should be sought. Finally, this area needs to become a more prominent field for scientific research endeavours in psychiatry, so as to allow the best setting and type of care to be determined for different groups of patients.

Consultation and Liaison Psychiatry

Translator: S. Davison

1 Definitions

Increasing specialisation within modern medicine has meant that individual doctors are no longer able to have expertise in all areas and apply this to the benefit of their patients. When a doctor requires advice and help with a problem in a patient's management, he or she seeks the advice of a specialist who has particular experience and qualifications in the specialty in question (Schliack 1992). The discussion between several doctors, in this way, in the assessment and management of a single case has long been known as consultation.

In consultation psychiatry, therefore, a doctor who is not specialised in psychiatry enlists the help of a psychiatrist, who gives advice to his or her referring colleagues but is not actively responsible for managing the patient.

The term liaison psychiatry (from the French *liaison*, meaning relationship or connection), as currently used, was coined by Billings in the 1930s in the USA (Billings 1941). It describes a broader approach. It was originally used to describe the activity of a multidisciplinary team of psychiatrists and social workers who worked in a general hospital in the absence of an autonomous psychiatry department. However, the concept broadened in the following years, particularly in English-speaking countries. Liaison psychiatry differs from consultation psychiatry because of its more comprehensive and time-intensive integration within a particular area of somatic medicine. For example, a liaison psychiatrist may be present on a regular basis in a general medical or oncology department if he or she has not received a specific referral. Additional tasks of the liaison psychiatrist over and above direct patient contact include providing advice to the whole medical team on psychosocial issues, training and research (Strain 1996a; Lipowski 1992; Levy 1989).

2 Epidemiology and Effects of Psychiatric Co-morbidity in Physically Ill Patients in the General Hospital

It is known from community studies that members of the general population with a physical illness are at increased risk of suffering from a psychiatric disorder. The proportion of hospital patients with co-morbid psychiatric disorders is even higher. A series of methodologically sound studies from around the world have shown that between 30% and 50% of physically ill general hospital inpatients have co-morbid psychiatric disorders (Creed 1996). Three groups of diagnosis are significantly over-represented among general hospital in-patients in comparison to physically ill out-patients (Arolt 1997; Weyerer 1990). These are organic psychoses, alcohol and other addictions and acute stress reactions.

A German study of general hospital in-patients in the town of Lübeck showed the following prevalence rates of psychiatric disorder in surgical and medical in-patients: organic disorders 17.5%, depression 16.3% and addictions 11%. These figures are even higher in particular patient groups, such as patients on liver transplant programmes (Arolt 1997; Surman 1992).

Studies now show a significant association between psychiatric co-morbidity and more complicated illness courses, with longer lengths of stay in hospital and more frequent re-admissions. The presence of delirious states and depressive and dementing syndromes present particular risk factors in this respect (Saravay and Lavin 1994).

In a U.S. study, Levenson et al. (1990) diagnosed 27.5% of a population of general medical in-patients as very depressed, 27.5% as very anxious and 20.2% as having cognitive dysfunction. The median length of stay of patients with high levels of psychopathology was 40% longer, and the mean hospital costs 30% higher, than that of a comparison group with low levels of psychopathology.

These high rates of psychiatric co-morbidity leading to more complicated illness courses in physically ill general hospital in-patients are the "bread and butter" of consultation–liaison psychiatry.

It is important to know how many patients actually need either joint psychiatric care during their in-patient medical admission or out-patient psychiatric follow-up in order to plan the requirements of a consultation psychiatric service. There have, however, been very few studies in this regard.

In the Lübeck general hospital study, it was estimated using ratings by experts that 16% of acute hospital in-patients required a psychiatric intervention, whereas only a quarter of these patients had actually been referred to the psychiatrist (Arolt 1997). Wancata et al. (1998) reported similar findings. Swigar et al. (1992) found even more remarkable findings in older patients. They considered that 36% of older medical patients needed a psychiatric opinion, whereas the actual referral rate was 3%.

The only representative study at a national level was carried out in the USA and found that only about 0.9% of all in-patients admitted to general hospitals were referred to a consultation psychiatrist (Wallen et al. 1987). Higher referral rates of up to 10% of in-patient admissions (e.g. at Massachusetts General Hospital in

Boston) were noted and were attributed to particular local circumstances.

The discrepancy between estimated need and actual referral rates can be explained by the combination of multiple factors. Co-morbid psychiatric disorders are under-recognised by non-psychiatrists (Margolis 1994). This applies particularly to cognitive dysfunction and to depressive and anxiety disorders (e.g. Katon 1991). In addition, many doctors have negative preconceptions about what a consultation psychiatrist can achieve. Finally, in contrast to these individual factors, the organisational/sociological problems that may either facilitate or hinder the implementation of a consultation service have to be considered (Koch and Siegrist 1988).

3 Psychiatry in the General Hospital

The comparatively long tradition and well-established nature of consultation psychiatry in the USA can be traced back to the early establishment of psychiatric departments within general hospitals, a process that had already begun in the 1920s and 1930s (Greenhill 1977; Levy 1989; Panse 1964). The rapid growth of consultation psychiatry, with several journals and specialist associations, as well as its proposed status as a recognised sub-specialty within psychiatric training by the American Psychiatric Association would have been unthinkable without this development (Lipowski 1992).

In Germany, the issue of psychiatric departments in general hospitals was a "hot potato" for a long time (Panse 1964). It was only from the 1970s onwards that psychiatric departments were increasingly established in general hospitals under the influence of the *Psychiatrie-Enquete* (national inquiry into mental health services in Germany). The aim was to stop the discriminating segregation and poor treatment of psychiatric patients. The inquiry suggested the discharge of the chronically ill patients, predominantly suffering with schizophrenia, from institutions (Häfner 1991) and aimed overall to integrate psychiatry into the whole of medicine (Müller 1981). It was recognised that consultation psychiatry care could provide better treatment opportunities in general hospitals for physically ill patients with co-morbid psychiatric disorders (Winkler 1975). In addition, the inquiry called for the establishment of a consultation psychiatry service in every large hospital for the treatment of patients who had attempted suicide. It also suggested that it was important for consultation psychiatry services to be involved with primary prevention in high-risk groups within physical medicine, such as hospitalised accident victims, dialysis patients or transplantation patients (Deutscher Bundestag 1975, pp. 279–281, 392). However, these factors receded into the background compared with the improved medical management of psychiatric patients with co-existing physical illnesses through consultation with the medical and surgical specialties.

Bönisch and colleagues (Bönisch and Mayer 1975; Bönisch et al. 1986) had written at an early stage about extreme situations in medical management and had predicted the growing importance of liaison work. However, the impression prevailed that a consultation psychiatrist who was interested in psychosomatic medicine would be most likely to have to justify this interest (Blankenburg 1988). In Germany, consultation psychiatry remained an activity that individual psychiatrists had to take on in addition to their other work, leaving little space for scientific interests. In addition, German psychiatrists did not look back to their medical roots to establish their identity in the same way that their colleagues in the USA did: "There is no better way to establish medical identity than through consultation psychiatry" (Hackett and Cassem 1987).

The opportunity to use consultation psychiatry actively to demonstrate the usefulness of psychiatry in non-psychiatric departments in general hospitals, and in this way to drive forward the overall integration of psychiatry, was hardly taken. A survey of consultation psychiatry in Germany at the end of the 1980s thus pointed out that only the very few departments of psychosomatic medicine, principally within university settings, saw themselves as providing a consultation service; in contrast to departments of psychiatry (the two are separate specialties in Germany) (Herzog and Hartmann 1990). It should, however, be noted that this overview did not include consultation services provided by office-based psychiatrists and neurologists in private practice. The departments of psychiatry reported relevant consultation activities much less often, even though, in actual fact, they took on by far the major share of consultation patient care (Bender et al. 1983; Böker 1973). The results of this study were rather disappointing, if not altogether surprising: the extent and intensity of co-operation work was low among both general psychiatrists and, interestingly, psychosomatic specialists, and less than half of the psychosomatic departments and even fewer of the psychiatric departments held joint case conferences. Predominantly, the psychiatrists co-operated with all other departments (except neurology and psychosomatic departments), whereas only half of psychosomatic departments did so. On the other hand, psychosomatic departments were better staffed and saw their patients more frequently and for longer. Psychiatrists were more often available during the night and at weekends (24-h cover) and responded

more promptly to referrals than their counterparts in psychosomatic departments (Herzog and Hartmann 1990). At the time of this survey, there were 78 psychiatric departments situated in general hospitals in Germany. Since then, their number has risen sharply (125 departments in 1993; Rössler et al. 1996). In comparison, the USA had 1358 such departments in 1984 (the population of the USA is roughly just over three times that of Germany).

In Germany, although non-psychiatrists were increasingly recognising the importance of psychiatric consultation services in everyday clinical practice, it was not until the early 1990s (with a few notable exceptions; e.g., Möller and Lauter 1986) that psychiatrists increasingly began to devote their research to consultation psychiatry topics and to develop expertise in psychotherapeutic and psychopharmacological treatments for physically ill patients (e.g. Kapfhammer 1993; Möller and Scriba 1994; Saupe and Diefenbacher 1996a; Arolt 1997; Diefenbacher 1999).

4 Special Features of the Psychiatric Consultation

The classic psychiatric consultation on a medical ward is a complicated undertaking. In contrast to a surgeon providing an opinion to a physician or vice versa, the consultation psychiatrist is frequently regarded by his or her colleagues in physical medicine as an "unknown being". Conversely, psychiatrists carrying out such a consultation may well develop anxieties as to whether they can hold their own in the real or perceived hostile territory of physical medicine. This leads, not uncommonly, to reciprocal misunderstandings which jeopardise the success of the consultation (Spiess 1996; Greenhill 1977).

Meyer and Mendelson (1961) described three phases in a psychiatric consultation which are useful for consultation psychiatrists to be aware of. The initiation of the consultation may be the expression of non-specific uncertainty on the part of the referrer as to how to deal with a patient. This may not be explicitly verbalised. This requires the psychiatrist to work out independently what the actual question is. In order to arrive at his or her own definition of the problem, the psychiatrist's assessment should take into account the psychiatric examination of the patient; the inspection of the available findings and a corroborative history taken from third parties (such as the treatment team and relatives, if appropriate). The conclusion may be distorted if second-hand information is accepted uncritically. The ensuing intervention should take into consideration not only the patient, but also the whole system (e.g. the ward doctor, nurses, relatives). Consultation psychiatrists must see themselves as a catalyst who need the individual members of the system to mediate their work. This work will be unsuccessful if conducted in isolation and/or out of context (Saupe and Diefenbacher 1996a).

Although the consultation must take into consideration a series of environmental/situational factors in order to be successful, it is not usually the intention to bring about a change in the pattern of referrals of individual units, beyond the advice given in an individual case.

5 The Liaison Model

In contrast to the classic model of consultation psychiatry, the liaison model draws its foundations from the discrepancy between the high need for joint psychiatric care of general hospital patients and the low rates of referral for consultation.

According to the liaison model, the tip of the iceberg of psychiatric co-morbidity which is recognised by the general hospital doctor is merely the "numerator" of existing psychiatric disorder, whereas the unrecognised broad base is the "denominator" (Strain 1996a). Consultation psychiatry has to restrict itself of necessity to what is "counted" by the referring hospital doctor, such that the consultation psychiatrist is often only called at a late stage and is reduced to a "fire-fighting" function. In contrast to this, liaison psychiatry aims to have a substantial influence on the "denominator". To this end, two ways of accessing patients are employed over and above the classic consultation model: (1) referrals from nursing staff dealing with patients as well as doctors and (2) early screening of high-risk patients. This process is made easier by the more or less constant presence of the liaison psychiatrist (in contrast to the consultation psychiatrist) on the physical medicine ward.

As a result, emergencies and crises along the continuum from organic (e.g. acute states of confusion) to reactive disorders (e.g. preoperative anxiety states) are avoided as patients are more efficiently managed by the ward team. This approach is supported by empirical studies which show that not only does liaison psychiatry lead to an increase in the number of referrals, as can also be the case with the consultation model, but it also leads to changes in the pattern of referrals. Thus a drop in the number of referrals of acutely confused patients was observed following the establishment of a psychiatric liaison service as wards gradually began to manage them independently. On the other hand, there was an increased number of referrals of depressed patients, precisely the patient

group that non-psychiatrists frequently either misdiagnose or mismanage (Anderson and Philpott 1991).

Advice to medical and nursing staff and also to social workers with regard to diagnosis, therapy and guidance of patients is usually at the forefront of liaison work. The use of short rating scales for the identification of cognitive, depressive or anxiety disorders is recommended where relevant (Bass 1995). The early screening of high-risk patients by liaison psychiatrists has hitherto occurred predominantly in the context of research projects (e.g. Strain et al. 1991; John et al. 1996) or in specialist programmes such as transplant surgery (Sperling and Kalb 1995; Freeman et al. 1992). However, a European study is currently underway to develop a screening instrument for the detection of psychosocial risk factors in patients admitted to general hospital wards (Huyse et al. 1997).

6
Consultation and Liaison Psychiatry in Practice

Some of the different areas of practice in consultation psychiatry are presented below. The care of residents of old people's and nursing homes with psychiatric disorders is discussed in particular detail, as this area of consultation psychiatry is growing in size and importance.

6.1
Consultation Psychiatry in the General Hospital

Although Bönisch et al. (1986) found that the idea of consultation psychiatry as a psychiatric subspecialty in its own right had been only poorly taken up in the German-speaking world, and that the opportunity to integrate psychiatry fully in clinical medicine by interdisciplinary work had therefore been missed, there have been significant changes since that time.

Important papers describing the practice of consultation psychiatry in general hospitals that have since been published in the German-speaking literature are summarised in Table 1. A literature review by Hengeveld et al. (1984) is included to provide an international comparison. In addition, a consultation service provided by a university department of psychosomatic medicine is cited (Knorr et al. 1996). On the whole, German psychiatric consultation services lie within the scope of international psychiatric liaison activities, as described by Hengeveld et al. (1984).

In contrast to the German and international psychiatric consultation services described in the table, the psychosomatic medicine consultation service had some special features (Knorr et al. 1996). There were rarely referrals for psychosis, substance misuse problems or suicidal behaviour; approximately half of referrals were as a result of somatic symptoms in the absence of an organic aetiology, and psychopharmacological treatment methods were very rarely used. Unexplained physical symptoms occupied between second and fourth place in the order of frequency of referrals in the psychiatric consultation services and accounted for a considerable proportion of referrals in some services (Kapfhammer et al. 1992).

Psychiatric consultation services employ a wide range of treatment modalities. For example, Arolt (1997) reported the following recommendations for cases of alcohol-related problems: psychotherapeutic treatments in 44.8% of cases; psychosocial help in 34.5%; and psychopharmacological treatment in 25.9%. Bender et al. (1983) employed advice, behavioural psychotherapy, relaxation exercises and antidepressants most frequently. However, general doubts are expressed by psychiatrists as to whether the colleagues they advise act on that advice to a sufficient extent (see Sect. 9 for the problem of compliance).

Further details relevant to psychiatric work in medical specialties such as psycho-oncology, transplantation surgery, intensive care medicine and infectious diseases can be found in Vol. 2, Part 1 (see also Bönisch et al. 1986; Cravin and Rodin 1992; Breitbart and Holland 1993; Kopp et al. 1994; Rundell and Wise 1996).

6.2
Psychiatrists and Neurologists in Private Practice

A significant proportion of consultation psychiatry practice in German general hospitals is undertaken by office-based neurologists and psychiatrists in private practice (Fegers 1999). There is, however, inadequate data available describing the extent of this consultation work, particularly in nursing homes and homes for the elderly. This led the German Association for Psychiatry, Psychotherapy and Neurology (Deutsche Gesellschaft fur Psychiatrie, Psychotherapie und Nervenheilkunde, DGPPN) to order an overview of this area of practice within the framework of their section for health care delivery, which the German Task Force for Consultation Psychiatry and Psychotherapy (Arbeitsgemeinschaft Konsiliarpsychiatrie und -psychotherapie) also belongs to. A previous German study on the delivery of mental health care by office-based psychiatrists and neurologists, the so-called Psychiatrist-Neurologist Study (Nervenarzt-Studie; Bochnik and Koch 1990, pp. 54, 151), had not gone into this in detail.

In the USA, a survey of members of the American Psychiatric Association, conducted in 1991, revealed that 7.5% of the 36,000 or so members spent at least

Table 1. Consultation psychiatry in general hospitals in Germany and Austria

[h]Somatoform disorders about 16%, organic mental disorders (ICD-10F5) about 22%.
[i]Each entry gives the range of percentages in the reviewed publications.

25% of their working time engaged in liaison-consultation work, and 3.2% spent more than half of their time on such work. About 10.5% of members had a contractual arrangement with a consultation-liaison service. A greater proportion of general hospital psychiatrists than psychiatrists in private practice had these sorts of arrangements (Noyes et al. 1992).

A survey of neurologists and psychiatrists in private practice in Austria in the 1980s found that 41% and 21%, respectively, were engaged in consultation work in non-psychiatric hospital departments. A total of 87% of all hospitals, general and specialist, worked in collaboration with a consultation psychiatrist or neurologist; about 13% were served by specialists in private practice according to demand, and about 4% by a nearby psychiatric hospital. About 70% had at their disposal consultation psychiatrists employed by the hospital. However, the vast majority were part-time appointments for only a few hours each week. It was concluded on this basis that, overall, specialists in private practice undertook the greatest proportion of consultation work (Wancata and Gossler 1999).

6.3 Provision of Services to Homes for the Elderly and Nursing Homes

Since the 1970s, there has been a fundamental structural change in the composition of old people's and nursing homes. While 30% of residents were dependent on nursing care in 1969, this number rose to 70% in 1988 according to a German article (Vollhardt 1993). A large proportion of residents suffer from a mental disorder, usually in addition to at least one physical illness. Dementia is the most common psychiatric disorder.

Kim and Rovner (1996) found that 67.4% of the residents of a nursing home in Baltimore, USA, were suffering from dementia and a further 12.8% from a depressive illness. A total of 40% of the demented residents experienced additional psychiatric symptoms such as delusions, hallucination or depression which led to behaviour problems making their care more difficult (Kim and Rovner 1996; Burns et al. 1988). Similar figures have been found in German studies (e.g., 50% prevalence of dementia and 25% of depression in elderly nursing home residents in a Hamburg study; Wörle et al. 1992). The prevalence (57.5%) of psychiatric disorders in nursing homes has been found to be even higher than in residential homes for the elderly. In contrast, a prevalence rate of 24.2% was found in a German community sample of older people (Cooper and Sosna 1983).

During the 1980s, an expert commission set up by the German government confirmed once again that the provision of psychiatric services to mentally ill residents of homes was inadequate (Deutscher Bundestag 1975, p. 13). This had already been described by the German national inquiry into mental health services (*Psychiatrie-Enquete*). The inadequate provision of psychiatric and neurological care was condemned and the systematic introduction of consultation psychiatry services to homes was called for, among other measures (Bundesministerium für Jugend, Familie, Frauen und Gesundheit 1988; the BMJFG is the German Ministry for Youth, the Family, Women and Health). However, consultation psychiatry work in nursing homes and homes for the elderly remains rare, despite the pressing need.

A study of all nursing and old people's homes in the district of Gutersloh in Lower Saxony (Germany) described the psychiatric care of mentally ill residents as wholly insufficient; less than a half of the homes had nursing staff with psychiatric expertise at their disposal, and treatment by a specialist could only be guaranteed in about 25% of the homes. In contrast, the medical services from general practitioners were described as satisfactory (Steinkamp 1993). Similar findings have been published in the USA, where only between 2% and 14% of the mentally ill residents of homes are jointly managed with psychiatrists (Burns et al. 1988; Reichmann and Katz 1996, p. vii).

It is particularly those patients who are described by nursing staff as uncooperative (e.g., those who are described as manipulative or apathetic and withdrawn) who are not adequately assessed by psychiatric specialists with regards to psychiatric co-morbidity and therefore miss out on the possibility of more specific psychiatric treatments.

Rovner et al. (1992) compared "co-operative" and "unco-operative" patients and found a significantly higher rate of psychiatric co-morbidity in the latter group. They pointed out that the expert assessment of and differentiation between such behaviours facilitates more specific management; thus a demented patient whose delusional experiences lead to disturbed behaviour should be managed differently from a demented patient who is in pain or a dysphasic patient who does not understand instructions given by the nursing staff.

Non-specific management can lead to therapeutic nihilism and the development of a custodial milieu in which a pro-active nursing approach is lacking. Furthermore, such custodial management is associated with a high usage of sedative medication, in particular neuroleptics, despite the well-known associated risks such as falls and hip fractures. In contrast, psychosocial interventions are under-valued (e.g. modulation of the therapeutic milieu or supportive psychotherapy), although preliminary reports are promising (Wojnar and Bruder 1995).

Both the implementation of therapeutic milieu strategies in the management of dementias (Struwe 1995) and the offer of consultation from an out-patient old-age psychiatry service led to a significantly higher number of psychiatric consultations (Nißle 1994) and were associated with reduced use of psychotropic medication in nursing homes and residential homes for the elderly. In addition, such interventions were associated with increased use of anti-depressants instead of neuroleptics or benzodiazepines in the treatment of depressed residents, leading to significant clinical improvement in 60% of those managed in this way (Kim and Rovner 1996). Guidelines for such integrated care of demented residents of nursing homes have been drawn up in the German state of Nordrhein-Westfalen. Psychiatrists with experience of old-age psychiatry have an important role in the implementation of these guidelines (Höft and Paulus 1996; Vollhardt 1993).

The proposed models of co-operation all suggest a liaison psychiatry service which involves the regular attendance of a psychiatric specialist or neurologist in the homes for a specified number of hours per week, e.g., with regular weekly or fortnightly visits. The models require close co-operation with the doctor responsible for the general medical care of the residents. Emphasis is placed on the importance of giving advice about patients to nursing staff and regular contact with the management of the homes (Struwe 1995; Bienenfeld and Wheeler 1989; Sakauye and Camp 1992).

7 International Perspectives

Internationally, most consultation-liaison psychiatric services comprise elements from along a spectrum between classical consultation services and classical liaison services, the latter being provided to specialist areas (such as care of parasuicides, psycho-oncology, transplantation services). In most cases, consultation services account for the major share of the services provided. The exact balance depends on local conditions and the individual interests of the consulting psychiatrists. Where all services are provided, this is usually taken into account and the term consultation-liaison psychiatry is used. The British usually use the term liaison psychiatry (Guthrie and Creed 1996; Huyse et al. 1996a).

In English-speaking countries, the combined term "psychiatry and psychotherapy", which is used in German, is not in common usage because psychiatry includes psychotherapy (psychodynamic and/or cognitive/behavioural). The most important consultation-psychiatric organisation in the USA, the Academy of Psychosomatic Medicine, gave itself the additional name of Organization for Consultation-Liaison Psychiatry a few years ago to make clear its move away from classical psychosomatic concepts. There has since been discussion as to whether a further renaming to "medical-surgical psychiatry", for instance, might be more appropriate to reflect the increasing complexity of the field of consultation-liaison psychiatry (Thompson 1993). Although there are varying approaches in different countries (Greenhill 1977), the so-called German special way (A.E. Meyer 1992) must be mentioned separately because of its peculiarities.

Psychosomatic-psychotherapeutic theories were very influential in the USA in the 1930s and were very important for the development of consultation and liaison services within psychiatry. In contrast, in Germany in the 1920s, psychosomatic medicine developed as a discipline within general medicine, largely separate from classical German psychiatry (Lipowski 1992; A.E. Meyer 1992; Schwab 1989). Most other countries, such as the USA, have a unified model of consultation-liaison psychiatry. In contrast, the German "special way", with its two distinct medical specialties each with their own training, has led to a two-stranded system (psychiatric *and* separate psychosomatic consultation services), particularly within universities. In practice, the majority of consultation work is undertaken by the psychiatrists.

The dichotomous nature of consultation-liaison services in Germany is most evident where psychiatric and psychosomatic services co-exist in the same hospital (see Sect. 6.1). There is, for example, certainly a wide overlap in the care of patients with depressive symptoms. This would appear to be problematic given the differing therapeutic approaches, especially as there is no universally accepted way of allocating patients to one service or the other (Arolt et al. 1995; Knorr et al. 1996). In addition, an established trend has developed in Germany towards clinical psychology with the advent of behaviour therapy models in line with international developments. Behavioural medicine takes a genuinely psychological approach in the care of general hospital patients with psychiatric co-morbidity. The effectiveness of behavioural approaches can be proved in relation to a number of outcomes, including shorter hospital stays (Lupke et al. 1995; Friedman et al. 1995).

8 Benefits of Consultation Psychiatry Interventions

Consultation psychiatry care is seen overwhelmingly as positive by patients (Windgassen et al. 1997). It leads

to improved management of physically ill patients with co-morbid psychiatric disorder (Hall and Frankel 1996). Möller and Lauter (1986) reported that a psychiatric liaison service which provided out-patient follow-up of patients who had attempted suicide, which was provided by the psychiatrist who had first seen them, led to significantly higher compliance with follow-up appointments than in a control group.

The shortage of resources within health services has led increasingly to consideration of the issue of the costs of consultation psychiatry services (Hall and Frankel 1996). The argument in favour of the necessity of consultation psychiatry services on the grounds of cost-effectiveness was put forward early in the USA, as a result of the observation that patients with co-morbid psychiatric disorders had longer lengths of stay in hospital (Billings 1941). It was postulated that a psychiatric intervention might shorten the length of stay of these patients. Predominantly American research has tried to establish that consultation–liaison psychiatric services paid for themselves and furthermore led to cost savings (Schwab 1989; Strain et al. 1994).

Hip fractures are common in the elderly, so it is no wonder that the cost-effectiveness of consultation psychiatry treatment in this patient group was already being researched at the beginning of the 1980s. Strain et al. (1991) found that liaison psychiatry interventions in elderly patients with hip fractures were associated with an average length of stay that was 2 days shorter.

In a follow-up, 3 months after initial admission, patients who had been admitted during the study period had had fewer in-patient re-admissions than the control group. This suggested that the liaison intervention had not merely led to a transfer of costs from the in-patient to the out-patient sector. Lengths of in-patient stay are not conclusive as measures of the success of consultation psychiatry interventions as it is difficult to control adequately for the many confounding variables. Particularly in the field of hip fractures, other interventions have been described which are also associated with shorter admissions, e.g. where the most important factor has been found to be better co-operation with social services without any psychiatric involvement (Seyfarth-Metzger 1997). Whereas it has been convincingly established that patients with co-morbid psychiatric disorders have a longer length of stays on medical wards, study results of the effect of consultation psychiatry interventions with regard to shortening length of stay on medical–surgical wards must be considered as inconclusive, largely on methodological grounds.

9 Research

Some of the tasks and problems facing research in consultation psychiatry are outlined below (Guthrie and Creed 1996; Öhman et al. 1989). In recent years, there has been increasing discussion of the methodological problems involved in the diagnosis of mental illness in patients who are physically ill. For example, problems in the ascertainment of cases have been identified (problems with two-stage screening processes; see Clarke et al. 1993), as have problems in the diagnosis of depressive disorders. In the latter case, evaluation of the somatic symptoms (e.g. sleep disturbance, loss of appetite and weight) is very difficult in the presence of co-existing physical illness, such as malignancy (see Lagrhissi-Thode et al. 1996).

Despite the approaches that are available to understanding psychiatric problems in physically ill patients as a whole group, there has hitherto been no precise description of the phenomenology of psychiatric illnesses co-morbid with particular physical illnesses. No classification system has been developed to meet the specific needs of consultation–liaison psychiatry (Guthrie and Creed 1996; Diefenbacher and Saupe 1994).

Consultation psychiatry research in general hospitals should concentrate on common conditions, such as acute states of confusion in older patients, alcohol-related problems, depressive and adjustment disorders and post-traumatic stress reactions after accidents, with a view to improving diagnosis and treatment. In this respect, some relevant research findings already exist (e.g. Frommberger et al. 1996). Examples of further areas worthy of mention include the effects of modern high-tech medicine on patients in particularly stressful settings such as intensive care or during isolation following bone marrow transplantation (Schmidt-Degenhardt 1986; Andrykowski 1994), interactions of psychotropic medication with non-psychotropic drugs, as well as the psychiatric side-effects of non-psychotropic drugs, especially in older patients (Katz et al. 1994; Kasper and Jung 1995), and the prescription of psychotropic drugs for transplant recipients (Shapiro 1991).

The extent to which psychiatric co-morbidity during an admission for a physical illness is directly caused by the underlying physical illness and can therefore be expected to resolve with successful treatment of the physical illness is an important factor in determining the need for consultation services. This has been described in patients with depressive symptoms, for example (Pomerantz et al. 1992; Popkin et al. 1991).

The identification of risk factors is also important in planning consultation psychiatry interventions, as not

all psychiatric symptoms which develop in association with a physical illness resolve spontaneously once the physical illness improves. This would provide information about the necessity of providing psychiatric treatment to physically ill patients treated on medical-surgical wards (defining needs and planning services, Benjamin et al. 1994).

Treatment studies should aim to identify high-risk groups who benefit from consultation psychiatry interventions. This is important in view of the increasing restrictions on resources within the health service and the introduction of limited budgets and "carve-outs" that are likely to reduce the funds that third-party payers are willing to pay for particular conditions or particular treatment groups, especially if related to psychiatric co-morbidity in physically ill patients. If, for example, a psychiatric intervention was shown to contribute towards shorter lengths of stay in hospital, this might lead to savings.

The following points should be taken into account, among others, when planning relevant studies. Consultation psychiatry interventions can have differing effects on length of stay. They may be associated with shorter admissions (e.g. owing to joint triage by social workers and psychiatrists; Diefenbacher and Strain, in preparation), but in other cases they may be associated with longer admissions (e.g. due to the identification of depression and commencement of anti-depressant treatment; Callies and Popkin 1987). Poor compliance of the referring doctors in implementing the advice of the consultation psychiatrist may impair the success of the intervention. It has been found that only 70% of pharmacological treatment recommendations and 56% of recommendations for further investigations are followed (Popkin et al. 1991). Finally, the timing of the intervention should be considered. Early interventions are more likely to be associated with shorter hospital stays (Ormont et al. 1997).

Lyons and Larson (1989) have argued convincingly that it is not meaningful to measure such a complex phenomenon as the outcome of psychiatric consultations using a single parameter (e.g. length of stay). Instead, they propose a value matrix which takes multiple perspectives into account (e.g. the patient, the family, the psychiatrist, the medical team, the hospital, the medical insurance company, society), both clinical and economic.

Using this framework Strain et al. (1991, 1994) described economic outcomes (shorter in-patient stays, lower rates of re-admission), clinical outcomes (improvement in cognitive function and reduction of depressive symptoms), family/career outcomes (fewer relatives having to cut back on their work to care for the patient at home) and service-related outcomes (generation of funds from savings made). This demonstrates how important it is for every consultation-liaison service to consider how it wishes to affect each of the different parameters, all of which are relevant, more or less obviously, in every consultation.

While attempting to prove the economic benefits of consultation psychiatry, it should never be forgotten that the main goal of psychiatric consultation work is the alleviation of the patients' suffering in the hope that this will contribute towards an improvement in their quality of life (see Schmeling-Kludas 1995).

10 Training

The increasing integration of psychiatric departments within general hospitals will lead to a growing demand for medical care in collaboration with consultation psychiatrists (Creed et al. 1993). It is therefore necessary to develop a consultation-liaison curriculum within the framework of specialist psychiatric training in order to cover comprehensively the diagnosis and treatment of physically ill patients with co-morbid psychiatric symptoms. In addition to the acquisition of theoretical knowledge, practical experience should be provided during specialist psychiatric training, either in the form of rotation through a placement in a consultation psychiatry service or supervised consultation work during training.

Gitlin et al. (1996) suggest a tiered model for training in consultation-liaison psychiatry. They propose a basic compulsory core of knowledge that all psychiatrists should be taught, such as psychotherapy and psychopharmacology with physically ill patients. In addition, specialist centres would provide the opportunity to obtain further qualifications (e.g. transplantation psychiatry, psycho-oncology; e.g. see Craven and Rodin 1992; Breitbart and Holland 1993; Kissane 1993).

Furthermore, there is an urgent need to broaden and deepen non-psychiatric doctors' knowledge and experience of psychiatric issues, including psychosomatic ideas (Gask 1994). Consultation psychiatrists can therefore play an important part not only in training psychiatrists in the treatment of patients with physical illness, but also training general practitioners, physicians and surgeons in the care of patients with co-morbid psychiatric symptoms (Kathol et al. 1994).

There are interesting developments in the USA which provide joint training in somatic and psychiatric medicine. Combined medical-psychiatric specialist training has begun to be established in which a considerable portion of the programme (known as a

medical-psychiatric residency) takes place on so-called medical-psychiatric units.

Overall, there has been an increasing interest internationally in collaborative models in the outpatient and primary care sectors. Attempts are being made to integrate primary and secondary care of the general population better, with inclusion of other professional groups such as community nurses and social workers. Consultation-liaison models may have a useful role to play in this process (Gask et al. 1997; Creed 1996; Goldberg 1997; Hendriksche and Kroger 1997).

It should not be forgotten that the general hospital plays an important role in bringing patients whose psychiatric symptoms have hitherto gone unnoticed to the notice of specialist psychiatric services for the first time. Up to two thirds of patients seen by consultation-psychiatric services have never previously received psychiatric treatment (Saupe and Diefenbacher 1996b; Bass 1995; Creed et al. 1993). In this context, academic consultation psychiatry should strive to collaborate closely with academic departments of primary care and general medicine.

11 Further Liaison Models (Medical-Psychiatric Units)

Combined so-called medical-psychiatric units should be mentioned as an example of possible models of collaboration within the general hospital. They have experienced an increase in popularity over the last 10 years in the USA.

Kathol et al. (1992) have proposed a categorisation of in-patient units for the treatment of patients with physical and psychiatric problems. They suggest four types of unit depending on the level of what they describe as medical and psychiatric "acuity". Type I refers to the usual psychiatric in-patient units which treat primarily psychiatric problems, varying from very acute to less acute, but which can treat only a few non-severe medical problems. Type II units are their medical counterparts. These include general medical units or medical sub-specialty units that are associated with a psychiatric liaison service and provide low levels of psychiatric care to those admitted to the general medical setting. Medical-psychiatric units in the narrow sense are type III and IV units, as can be found in tertiary-care hospitals such as at the University of Iowa and the Emory University Hospital in the USA. They care for patients with concurrent and more severe psychiatric and medical problems in a unified setting. These patients would otherwise be frequently transferred back and forth between medical or surgical wards and psychiatric wards. Such medical-psychiatric units are run jointly by psychiatrists and physicians.

The following patients are given priority on a type III unit: delirious patients who cannot be managed on a medical ward, suicidal patients in need of acute medical treatment, patients whose physical state is unstable following intoxication etc. A type IV unit is a stage beyond that. It would be able to carry out more complicated medical procedures such as haemodialysis, peritoneal dialysis or parenteral treatment via central venous access (Stoudemire 1996).

In Germany, patients identified as having psychosomatic illnesses are referred to psychosomatic wards, mainly located in rehabilitation centres, and not in acute-care hospitals. Joint internal medicine-psychosomatic medicine units, corresponding to the American type II units, have seldom been tried (see Köhle et al. 1996, pp. 528–540). One should therefore avoid directly equating American medical-psychiatric units with German psychosomatic medicine units. Units similar to the American type III and type IV units can be found in Germany in such places as the Zentralinstitut für Seelische Gesundheit (the Central Institute for Mental Health) in Mannheim or the Wilhelm-Griesinger-Krankenhaus (Wilhelm-Griesinger Hospital) in Berlin. The latter is a neuropsychiatric intensive care unit.

12 Quality Assurance, Documentation and Further Reading

The following standards have been suggested for the organisation of consultation services in hospitals: consultation rates of 3%–5% of patients admitted to a general hospital; average time spent per patient about 2.5 h (including assessment and three follow-up appointments, advising the team and associated paperwork). If these standards were met, a psychiatrist employed by a consultation service would manage about 300 patients each year. Wherever possible, the psychiatrist should work with a multi-disciplinary team including social workers and specially trained liaison nursing staff (House and Hodgson 1994; Herzog and Hartmann 1990; Bönisch et al. 1986).

It remains to be seen to what extent the findings of the European Consultation Liaison Workgroup (ECLW) study can be usefully implemented (Huyse et al. 1996b). In this study, several hundred consultation psychiatrists throughout Europe documented their activities to provide empirical support for their suggestions.

Adequate documentation of consultation work is necessary for administrative purposes, but can also be

used for training, quality assurance and research. The American clinical electronic MICROCARES database provides access to a series of rating scales in addition to the individual service's consultation-psychiatric clinical data entry form. It exists in an optical pen entry form and can therefore be used at the bedside with a laptop computer without any extra time commitment (Hammer et al. 1995).

There is a specialist English-language consultation psychiatry literature with several journals (e.g. *General Hospital Psychiatry*, *Psychosomatics*, *International Journal of Psychiatry in Medicine*) and textbooks (e.g. Cassem 1997; Rundell and Wise 1996; Guthrie and Creed 1996; the only French textbook on consultation-liaison psychiatry is by Zumbrunnen 1991), covering the full range of psychiatric disorders and treatment possibilities. *Nursing Home Medicine - The Annals of Long-term Care* is a multi-disciplinary journal of great practical use for psychiatric consultation work in nursing and old people's residential homes. Strain (1996b) has produced a list of over 2000 consultation psychiatry references selected by experts. It is also available in electronic form on a 3.5″ disk with abstracts and, in some places, a commentary. It provides a comprehensive synthesis of relevant publications from recent years. It is helpful to both the consultation expert and the non-expert who wish to inform themselves about general or specific aspects of everyday clinical practice or about research in consultation-liaison psychiatry. The Academy of Psychosomatic Medicine has produced a collection of slides that are well suited to teaching and which include important data relevant to consultation-liaison psychiatry (Academy of Psychosomatic Medicine 1997).

Mental Health Legislation: International Trends

1 Introduction

1.1 Formal and Informal Norms

Communities worldwide have long developed norms, formal or informal, to deal with persons with mental disorders. In England, for example, formal legal instruments designed to govern mental health matters are documented as early as in the thirteenth century (Neugebauer 1978). It has become customary to refer to the ensemble formed by those binding norms as "mental health law", here employed in the sense of formal, binding, public and specific norms related to persons with mental disorders. However, due weight ought to be given to the legal tradition of a jurisdiction to appreciate the actual implications of mental health law provisions. Informal practices or usages concerning ways to deal with persons with mental disorders have also developed; they may have appeared in lieu of, in addition to or in opposition to formal laws.

1.2 Law and Mental Health: The Tradition

Perhaps to a significantly larger degree than elsewhere, mental health care is especially dependent on and affected by law. Social interactions of persons with mental disorders have traditionally raised two levels of concerns which appear to be the foundations for the development of early mental health norms.

The first level is directed at the individual affected in the first place, i.e., the person with a mental disorder. The very nature of a mental disorder will often make persons affected by them vulnerable in their dealings with society. This vulnerability typically affects persons with mental disorders in terms of decision-making and behaviour regarding their own health and safety and in terms of management of their property. Accordingly, measures have been designed to protect persons with mental disorders against themselves by removing a portion of their decision-making and management authority and by conferring it on someone else, to act as a "best friend." Typically, these measures have included involuntary hospitalization procedures, substituted consent to treatment procedures and the appointment of a legal guardian to manage property.

The second level of concern has been directed to family, neighbours, friends and other third parties in society at large who interact with persons with mental disorders. In a significant number of instances, actions or omissions by persons with mental disorders may affect others to the point that their health and safety may be jeopardized. This concern has justified lawmakers to adopt measures allowing designated authorities to limit the autonomy of persons with mental disorders felt to present a danger to the health and safety of others. Traditionally, this has been achieved through mandatory (involuntary) hospitalization.

Until recently, the purposes and patterns of legal instruments governing mental health have remained similar. They tended to be conceived as tools allowing societies to *react* to disturbing or unusual behaviours of persons with mental disorders (Curran and Harding 1978). Both levels of concern outlined above have traditionally rationalized and justified involuntary hospitalization. It is no surprise then that mental health laws have traditionally focused almost exclusively on this topic in the vast majority of countries in which formal enactments exist.

1.3 Modern Concerns and Trends

With the development of modern treatments for mental health disorders, the last two decades have witnessed a substantial shift in the pattern of some mental health laws. Many jurisdictions have adopted proactive legal provisions allowing or providing in some details for a new approach to mental health care, in particular through community-based mental health care.

In virtually all societies, persons with mental disorders are vulnerable in three ways in particular which now appear as modern justifications for mental health law:

1. They are ill and likely in need of treatment.
2. Their ability to understand, reason and decide may (or may not) be affected.
3. They tend to be stigmatized.

The need for their protection as a vulnerable group increases in contexts of civil disturbances and armed conflicts.

Justifications are also found with other groups. The families of persons with mental disorders typically bear an important portion of the burden associated with mental illness. Mental health professionals (e.g., psychiatrists, psychologists, nurses, occupational therapists, social workers), health care institutions and law enforcement authorities (e.g., the judiciary, the police) are all bound to face delicate situations involving persons with mental disorders. Ministries of health face the challenge of coordinating the above. The general public is entitled to be protected against threatening behaviour by persons affected by a mental disorder.

Formal rules governing these dimensions are warranted so that the rights and duties of all are known, rational, clear and predictable. Care for persons with mental disorders governed only by informal practices runs the risk of resulting in arbitrary decision-making and unbridled use of discretion.

1.4 International Norms

The international human rights movement set by the ratification of the Declaration of Human Rights in 1946 has had an impact on the development of specific international norms affecting the field of mental health. Three independent axes, explored below, have been of particular influence on national laws:

1. The adoption of reference principles by the United Nations
2. Rulings handed down under the European Convention for the Protection of Human Rights and Fundamental Freedoms
3. Norms put forward by non-governmental organizations (NGOs)

The first axis relates to UN norms. A number of international instruments affecting persons with mental disorders have been developed, including the following (United Nations 1994):

- *Declaration on the Rights of Mentally Retarded Persons*, United Nations General Assembly (UNGA) resolution 2856 (XXVI) of 20 December 1971
- *Declaration on the Rights of Disabled Persons*, UNGA resolution 3447 (XXX) of 9 December 1975
- *Principles for the Protection of Persons with Mental Illness and for the Improvement of Mental Health Care*, UNGA resolution 46/119 of 17 December 1991
- *Standard Rules on the Equalization of Opportunities for Persons with Disabilities*, UNGA resolution 48/96 of 20 December 1993

Three of these, described below, are indicative of current trends.

First, the UNGA unanimously adopted, in 1991, a set of 25 *Principles for the Protection of Persons with Mental Illness and for the Improvement of Mental Health Care*. Although, as mere principles, they are not formally binding on UN Member States, they are nevertheless seen as the main (and indeed the only) truly international set of modern principles on the rights of persons with mental disorders and the provisions of mental health care. Criticisms have been directed at these principles, essentially claiming that they are insufficient in their scope and poorly framed (Gendreau 1996; Rosenthal and Rubenstein 1993).

As part of its mandate to direct international health matters, the World Health Organization (WHO) has developed two documents to help disseminate the UN principles: a detailed set of questions aimed at delineating the potential scope of the UN principles (WHO 1995), and a brief working document, entitled *Mental Health Care Law: Ten Basic Principles* (WHO 1996), aimed to define, break down and help in the practical implementation of a core of ten very fundamental items drawn from the UN principles.

Secondly, stemming from the UN Decade of Disabled Persons (1983–1992) are the *Standard Rules on the Equalization of Opportunities for Persons with Disabilities*, a set of 22 proactive rules with annotations aimed at ensuring that persons with disabilities (including mental and intellectual) may exercise the same rights and obligations as others. Its stress on implementation in practice is reflected in Rule 15, entitled "legislation", which reads as follows: "States have the responsibility to create the legal bases for measures to achieve the objectives of full participation and equality for persons with disabilities."

Thirdly, the *Declaration of Caracas*[1] was adopted by a variety of legislators, associations, NGOs, mental health professionals, public health authorities and jurists at a conference on the Restructuring of Psychiatric Care in Latin America held in Caracas (Venezuela), 11–14 November 1990 under the auspices of the Pan American Health Organization. Innovatively, it calls upon various public institutions to support the restructuring of psychiatric care in accordance with six fundamental principles resulting from the premise that "[hospital-based] conventional psychiatric services do not allow for the attainment of objectives contained in a community-based care, that is decentralized, participatory, integrated, continuing and preventive." Importantly, in addition to declaring that the restructuring of psychiatric care should be performed on the basis of primary health care, this Declaration calls for any required redrafting of national legislation to safeguard human and civil rights of mental patients and to organize mental health services so as to guarantee the enforcement of these rights.

The second axis concerns case-law under the European Convention for the Protection of Human Rights and Fundamental Freedoms, which entered into force in 1953. Through this Convention, the European Court of Human Rights (ECHR) is given the authority to render rulings binding on States which have ratified it. The court has rendered a considerable number of opinions affecting persons with mental disorders,

[1] International Digest of Health Legislation 42: 336–338.

thereby contributing to influencing the trends of mental health law in Europe and beyond.

Revealingly, in its first ruling on the rights of persons with mental disorders, the *Winterwerp* case,[2] the Court opened the way to its numerous subsequent judgements on mental health, holding that confinement ("detention", under the meaning of the Convention) requires a government to show evidence of three items, known as the "Winterwerp requirements":

(1) "a true mental disorder has been established by objective medical expertise; and
(2) the mental disorder [is] of a kind and degree warranting compulsory confinement; and for any prolongation of detention the government must also be able to show that:
(3) the continued confinement is based on the persistence of the disorder" (Wachenfeld 1992).

As a result, confinement on account of a mental disorder in 40 European countries must be rationally established and documented, must be of a sufficient degree and must be persistent to justify deprivation of liberty.

The third axis consists of guidelines proposed by international NGOs. As an international consensus of interest groups, these guidelines provide useful references for lawmakers. Notable among the norms proposed are two documents: the Declaration of Madrid,[3] adopted by the World Psychiatric Association (WPA) in 1996, as an illustration of ethical guidelines adopted by a professional association and the Declaration of Caracas, to which several organizations contributed.

The Declaration of Madrid, adopted by the General Assembly of the WPA on 25 August 1996, reflects the perspective of the psychiatrists that the WPA represents. It supersedes the Declaration of Hawaii adopted in 1977 and updated in Vienna in 1983. It consists of seven main principles, is preceded by a preamble introducing the principles and is supplemented by five so-called Guidelines Concerning Specific Situations. These seven principles essentially do the following:

1. Delineate the purpose of psychiatry
2. Create a duty to pursue continuing education
3. Insist that patients should be made partners in the therapeutic process
4. Set out the exceptional circumstances under which treatment can be imposed on a patient against his or her will
5. Make it a duty to inform a patient if an intervention is conducted at the request of a third party
6. Delineate the duty to keep information disclosed in confidence
7. Spell out standards for research

The five guidelines governing specific situations concern euthanasia, torture, death penalty, selection of sex and organ transplantation.

2 Trends

2.1 Data and Methodology

The results presented here are largely drawn from a study conducted by the WHO from 1992 to 1995, the methodology of which is presented in the study report (WHO 1999). The study was based on a selected sample of 45 countries, several of which were selected for the intrinsic interest of their legal instruments. The study focused on specific legislation related to mental health care, as opposed to mental health in general. Topics falling outside this scope include, inter alia, criminal law and guardianship law.

Despite the bulk of international reference principles in the field, it appeared that, although not formally documented, a large proportion of competent jurisdictions worldwide operate without formal and binding norms governing mental health matters. Customary practices have likely developed in most of these jurisdictions, although little is known on these.

2.2 Terminology

The terminology found in national mental health legislation is an important variable to consider to assess world trends. In particular, it is indicative of the generation of laws from which a legal instrument was inspired and of the level of concern of lawmakers for contemporary concepts and schools of thoughts. One illustration is the "politically correct" movement which has recently emanated from the United States. Proponents of this movement advocate that expressions which, they feel, unduly label members of groups (e.g., handicapped, mentally ill) should be replaced by neutral and person-centred expressions (e.g., person with disability, person with mental disorder).

The consideration of terminology is inherently limited by an important dimension: the language. For the study, the consideration of terms was based on an English translation of terms found in legislation. Some

[2]Winterwerp Judgement, ECHR, Ser. A, No. 33, 24 October 1979.
[3]International Digest of Health Legislation 48: 240–241.

translations were official or formal translations, while other translations were unofficial private translations; in some cases, translations were done specifically for the study. While translators are presumed to have selected the English terms most suitable to translate the original expression, one cannot discount the risk of approximative or inaccurate translations. Moreover, in some cases, a concept in the language of origin may have no exact English equivalent. The present findings on terminology are therefore to be considered with the language caveat.

Consideration of the terminology used in mental health laws has revealed that the majority of countries considered have incorporated updated terms to refer to "persons with mental disorders" and to refer to "mental health care setting." With regard to the first expression, one finds "person with mental disorder", "person suffering from mental disorders", "mentally ill person", "mentally disordered", "patient" and "mental patient"; also found are "lunatic" and "person of unsound mind", but these are isolated examples. With regard to "mental health care settings", the following expressions were found: "psychiatric hospital", "hospital", "mental health establishment", "mental hospital", "establishment", "psychiatric facility", "facility" and "institutions"; in one isolated case, "asylum" was found.

The use of terms largely appeared to be in keeping with the age of legal instruments, i.e., antiquated terms were found mostly in older legislation. In conclusion, lawmakers seem, overall, to have given weight to the terminology aspect when updating legislation.

2.3 Age of Legislation

At a global level, the year of enactment of mental health law instruments is indicative of the magnitude of change. Although this indicator does not relate to the content of legal instruments, it provides some insight into the overall level of preoccupation of a jurisdiction with persons with mental disorders. Table 1 classifies the jurisdictions considered by the study according to the year in which the most recent significant legal instrument in the field of mental health that could be identified was enacted. It shows that, of the 45 countries reviewed, 21 have adopted significant legislation since 1978 (year of publication of previous WHO study), 12 countries apply pre-1978 legislation and 12 appear to apply informal systems.

Table 1 allows us to visualize three important features. The first is that a large proportion of jurisdictions included in the study (about 70%) have mental health legislation adopted after 1975, a year appears to be a cut-off point. Although of interest, this proportion may not, however, be representative of world trends. In fact, the data gathered for the review seem to suggest, on the contrary, that the majority of countries have either no formal mental health law or old (i.e., pre-1975) mental health laws.

The second feature is the association between the length of time a legal instrument has been in force and the level of resources available in the country in

Table 1. Period of significant mental health enactments

Period	Jurisdiction
1990–	Australia (Victoria), Brazil (Rio Grande do Sul), Canada (Quebec), Canada (Ontario), China[a], Costa Rica, Finland, France, New Zealand[b], The Netherlands[c], Tunisia, UK (England and Wales)
1985–1989	Australia (Queensland), Australia (Victoria), Finland, India (federal), Japan, Kenya, USA (IN)
1980–1985	Argentina (Capital), Barbados, Denmark, Germany (Bavaria), Ireland, Lebanon, Norway, Sweden, UK (England and Wales)
1975–1979	Italy, Norway, Senegal, Swaziland, Trinidad and Tobago, USA (MA), Zimbabwe
1970–1974	Ghana
1965–1969	Romania, Syrian Arab Republic, Fiji
1960–1964	–
1955–1959	Nigeria (Lagos), Tanzania
1950–1954	Malaysia
1930–1949	Brazil (federal)
1900–1929	Pakistan
Pre-1900	Benin[d], Sri Lanka
No enactment identified	Argentina (federal), Australia (federal), Canada (federal), Colombia[e], Ecuador[e], Ethiopia[e], Germany (federal), India (Karnataka), Jordan[e], Mozambique[e], Papua New Guinea[e], People's Democratic Republic of Korea[e], Thailand[e], USA (federal), Vietnam[e], Yemen[e]

[a] *Draft Mental Health Act* of September 1990 (Ninth Revision). In view of the concrete influence of this draft in several Chinese provinces, the principles of this draft have been considered in this publication.

[b] *Mental Health (Compulsory Assessment and Treatment) Act 1992*, entered into force on 1 November 1992. Review is of the *Mental Health (Compulsory Assessment and Treatment) Act 1989*.

[c] 1992 act was at draft stage at time of review.

[d] Law of 30 June 1838 adopted under French rule and reportedly inoperative; presumably Benin operates under an informal system.

[e] Countries presumably operating under informal systems.

question. Not surprisingly, older legal instruments are largely found in low-income countries.

Thirdly, an important proportion of the countries for which no formal legal instrument was identified seem to share socio-economic difficulties, suggesting an association between the absence of legal instruments dealing with mental health and the socio-economic context. If the adoption of a legal instrument or provisions dealing with mental health is indicative of the level of social priority assigned to mental health, it appears that countries in difficult socio-economic contexts give lower priority to mental health than other countries.

2.4 Scope of Law

Table 2 classifies countries in light of the scope embraced by their mental health law scheme. Considered for the purpose of this classification are the number and relative importance of the themes covered by policy statements and legal instruments, the substantive rights granted and the procedural safeguards enshrined in legislation. Among the relevant themes considered are rules governing hospitalization, rules governing treatment, rules governing guardianship (considered for this purpose only), community-based and integration principles, social support measures and other relevant themes.

Table 2 illustrates that the number of areas of concern addressed in legal instruments is also associated with the relative level of available resources in a country. The classification reveals that detailed legislative schemes are found almost exclusively in high-income countries. Moderately detailed legislative schemes are found in a mix of high-income and low-income countries, while basic legislative schemes are found in low-income countries.

Table 2. Scope of mental health law schemes

Scope	Jurisdiction
Detailed legal schemes	Australia (Victoria), Brazil (Rio Grande do Sul), China, Finland, France, Ireland, Japan, Norway, Senegal, UK (England and Wales), USA (MA), USA (IN)
Moderately detailed legal schemes	Argentina (capital), Australia (Queensland), Barbados, Canada (Ontario), Canada (Quebec), Costa Rica, Germany (Bavaria), Ghana, India, Italy, Kenya, Lebanon, New Zealand, Romania, The Netherlands, Tunisia
Basic legal schemes	Argentina (federal), Brazil (federal), Fiji, Nigeria (Lagos), Pakistan, Sri Lanka, Swaziland, Syrian Arab Republic, Trinidad and Tobago, Zimbabwe

Table 3. Decentralization of services reflected by mental health laws

Levels	Jurisdiction
High	Brazil (Rio Grande do Sul), Finland, Italy, UK (England and Wales)
Moderate	Australia (Queensland), Australia (Victoria), Canada (Ontario), Canada (Quebec), China, Costa Rica, France, Germany (Bavaria), India, Ireland, Japan, Lebanon, The Netherlands, New Zealand, Norway, Romania, Tunisia, USA (MA)
Low	Argentina (capital), Argentina (federal), Barbados, Brazil (federal), Ghana, Kenya, Nigeria (Lagos), Pakistan, Senegal, Sri Lanka, Swaziland, Syrian Arab Republic, Trinidad and Tobago, USA (IN), Zimbabwe
Insufficient data	Brazil (federal), Denmark, Fiji, Malaysia, Sweden, Tanzania

2.5 Decentralization of Mental Health Services

Decentralization has been identified as a leading theme of policy and social change over the last two decades. As a result, it was found relevant to assess the overall level of decentralization evidenced by legislation. Table 3 classifies countries in one of three categories representing the level of decentralization in administration and mental health care delivery that is reflected by the mental health law provisions. Variables considered for the purpose of this classification include: decentralization of powers, decentralization of implementation, composition and authority of decision-making authority, authority granted to personal representatives and other relevant variables.

Table 3 shows that overall decentralization efforts, if any, are not reflected very significantly in legal instruments. Only four countries (representing 12% of the jurisdictions reviewed) were found to have a mental health law incorporating a high level of decentralization.

Some level of decentralization can be achieved through private initiatives. For instance, in Quebec (Canada), a law passed in 1992 reforming the health care system stipulates conditions for private "foster family" initiatives eligible to some government funding.

2.6 Levels of Legislative Intervention

The legislative level of the lawmaker (i.e., federal, provincial, state, *Land*, canton, etc.) in charge of

adopting legal instruments in the field of mental health varies from country to country. In some countries, more than one level of government has the authority to adopt norms affecting mental health. In others, full jurisdiction to adopt legal norms in this field is vested in only one level.

Table 4 classifies countries according to the legislative level of the main mental health lawmaker(s). This account is limited to the legal instruments on which reporters were asked to concentrate their work, i.e., leading legal instruments governing mental health, to the exclusion of instruments only incidental to mental health. In a significant proportion of countries, mental health care is regulated by lawmakers of two levels of governments.

The type of powers granted to the various orders of government to adopt legal instruments is also indicative of the level of decentralization of mental health services. Some policy and legislative aspects may be best handled at federal or confederal levels, such as interstate cooperative efforts, the provision of financial support contingent upon compliance with specified basic standards, financial support to research and training, rules governing interstate issues and others. Such may also be the case for the redistribution of funds or the provision of services to regions most in need. However, norms adopted at local levels, which will tend to reflect the specific needs of the population, carry the best potential of being actually operationalized and enforced. This is true, in particular, of norms governing the delivery of mental health care or setting legal guarantees concerning involuntary hospitalization and treatment.

Interestingly, in a few jurisdictions, local authorities (as opposed to federal or federated authorities) are reportedly granted significant powers to adopt rules in the field of mental health care; these include China, Costa Rica, Finland, Italy and the United Kingdom (England and Wales).

Table 4. Level of main mental health lawmakers

Level	Jurisdiction
Unique, federal or confederal	Argentina (federal), Barbados, Brazil (federal), China, Costa Rica, Fiji, Finland, France, Ghana, Germany (federal), India, Italy, Japan, Kenya, Lebanon, Malaysia, Norway, The Netherlands, New Zealand, Norway, Pakistan, Romania, Senegal, Sri Lanka, Swaziland, Syrian Arab Republic, Trinidad and Tobago, Tunisia, Zimbabwe
State, provincial, *Land* or regional	Argentina (capital), Australia (Queensland), Australia (Victoria), Brazil (Rio Grande do Sul), Canada (Ontario), Canada (Quebec), China (Central), China (Shanxi), Germany (Bavaria), Ireland, Italy, Nigeria (Lagos), UK (England and Wales), USA (MA), USA (IN)

2.7 Increasing Differentiation Between Treatment and Hospitalization

Traditionally, provisions governing involuntary hospitalization were typically interpreted as including the authority to treat a person with a mental disorder even against the patient's will. It went without saying that a hospital stay was meant to be therapeutic. In most instances, no specific provision made this explicit.

The single most important legal aspect to notice with regard to treatment is the increasing distinction made by lawmakers and judges between involuntary hospitalization (deprivation of liberty) and involuntary treatment (interference with bodily/mental integrity). In this context, "treatment" encompasses any type of interference with the patient's bodily or mental integrity, such as drug treatment, electroconvulsive therapy and other types of interference. Two movements are noticeable which, although in opposition, both illustrate this differentiation.

In the first, found in a number of jurisdictions, the authority for the involuntarily hospitalization of persons with mental disorders does not extend to the authority to treat that person. Measures carried out to limit the autonomy of an aggressive patient in a crisis (emergency) situation, such as the use of physical or chemical constraints, are typically excluded from or constitute an exception to this definition of treatment.

An increased focus on human rights enforcement in the field of mental health care in recent years may explain the emergence of this new dichotomy. It no doubt challenges the traditional assertion that all persons labelled as mentally disordered are unable to understand, appreciate and decide for their own good. It seems to reflect an increasing acceptance of the principle that, while persons with mental disorders may occasionally be in a situation where they will be unable to exercise their right to consent or refuse treatment, it will not systematically be so, hence the conclusion that persons with mental disorders are not automatically incompetent for the purpose of deciding about their treatment.

The law in force in the United Kingdom illustrates this movement. Another illustration is the law in Canada (Quebec) where, under the Civil Code, a patient's wish not to receive treatment must be respected if care is categorically refused, except if purely hygienic or emergency care is involved.

The second manifestation of the increasing differentiation between hospitalization and treatment, quite

Table 5. Distinction between treatment and hospitalization

Distinction	Jurisdiction
Specific distinction made	Australia (Victoria), Canada (Ontario), Canada (Quebec), China, Germany (Bavaria), Italy, Japan, New Zealand, Norway, Romania, UK (England and Wales), USA (MA), USA (IN)
No specific distinction made	Australia (Queensland), Argentina (federal, capital), Barbados, Brazil (federal, Rio Grande do Sul), Costa Rica, Fiji, Finland, France, Ghana, India, Ireland, Kenya, Lebanon, Malaysia, The Netherlands, Nigeria (Lagos), Pakistan, Senegal, Sri Lanka, Swaziland, Trinidad and Tobago, Tunisia, Zimbabwe

in contrast to the previous one, is best illustrated by the legal scheme in force in Italy. Starting with the reform brought about by the 1978 Italian act, treatment, as opposed to hospitalization, is the only mandatory measure that is to be imposed on a patient found to fit legal criteria. In short, apart from exceptional cases, no hospitalization is to take place.

The extent of the growing treatment/hospitalization dichotomy is made explicit in Table 5, which highlights countries where this distinction has been specified in mental health legislation. Overall, nearly 30% of the formal mental health laws reviewed were found to carry this dichotomy.

2.8 Integration of Individuals and Legal Provisions

The social integration of persons with mental disorders is widely advocated. The idea is to allow persons with mental disorders to be integrated into the mainstream of life in society to the extent allowed by their health status, as opposed to having them taken care of *intra muros*, in closed institutions. Similarly, it is advocated that one way to remove the stigma traditionally attached to mental health is to incorporate the legal provisions addressing mental health issues into the mainstream of the legal system, i.e., by having legal provisions on mental health not singled out in a "mental health act" (Campbell 1994). It is useful to examine how these two facets of integration are addressed in current legal instruments on mental health.

Relatively few countries seem that have adopted legal instruments or provisions aimed strictly at integrating persons with mental disorders into the mainstream. Integration efforts in the form of community care laws were found in three of the seven countries visited during the study. Traces of efforts made towards the integration of mental health care into general health care are found in at least some legal instruments. In some instances, broad-based legal instruments have been adopted to foster the integration both of persons with physical disabilities and of those with mental disabilities. In at least a few cases, efforts to provide community-based care have been undertaken through national policy papers.

Efforts to integrate or reintegrate persons with mental disorders into society are also evidenced by the compatibility of standard mental health legislation with an integration strategy. In order to evaluate the impact of current mental health laws, an integration compatibility indicator was developed. The assessment takes into consideration features of mental health laws found to either foster or hinder the shift towards social integration of persons with mental disorders, such as whether the discharge procedure is burdensome, whether efforts or openings towards community care have been incorporated into the law and whether the least restrictive alternative principle has found its way into legislation. The results of this compatibility assessment are reported in Table 6.

A total of 11 jurisdictions were found to incorporate legal features fostering the integration of persons with mental disorders in society. The largest group of countries is found in a category described as including countries with mental health laws "compatible" with

Table 6. Compatibility of mental health laws with an integration policy

Compatibility level	Jurisdiction
Fostering (incorporates features to foster integration)	Brazil (Rio Grande do Sul), China, Costa Rica, Finland, France, Italy, Norway, Senegal, UK (England and Wales), USA (MA), USA (IN)
Compatible (incorporates features which allow integration)	Argentina (capital), Argentina (federal), Australia (Queensland), Australia (Victoria), Brazil (Federal), Canada (Ontario), Canada (Quebec), France, Ghana, India, Japan, Lebanon, New Zealand, The Netherlands, Trinidad and Tobago, Tunisia
Neutral (incorporates no features fostering or hindering integration)	Barbados, Germany (Bavaria), Ireland, Romania, Syrian Arab Republic
Incompatible (incorporates features hindering integration)	Fiji, Kenya, Nigeria (Lagos), Pakistan, Sri Lanka, Swaziland
Others (insufficient data)	Zimbabwe

reintegration. These first two categories account for about 71% of formal mental health laws reviewed, which is indicative of a significant policy trend. Few countries were found to have neutral legislation. Six countries have laws which incorporate features found to be incompatible with integration. The latter group is composed of countries with older laws.

The emergence of treatment arrangements allowing patients to live outside of mental hospital settings is another notable manifestation of the integration policy. Different modi operandi exist.

Firstly, it was found that the legislation of some countries authorizes the responsible authority to allow a patient to be discharged from hospital contingent on continued compliance with treatment requirements. Discharge may be subject to a time limit and renewals (e.g., in France, the law stipulates a 3-month maximum). In some countries, this is known as "supervised discharge". Typically, the patient's discharged status will be maintained as long the patient complies with the prescribed treatment, such as a monthly injection of long-acting neuroleptic medication.

Secondly, so-called mandatory community treatment procedures have been incorporated into legislation in a number of countries. Under this type of scheme, persons with mental disorders are to be treated in the community in which they live and maintain no link with standard hospital settings (e.g., New Zealand).

Obviously, arrangements for involuntary treatment in the community carries tremendous potential for least restrictive treatments. In contrast, they also carry some risks of human rights abuse. Special attention should be devoted to monitoring their operation. Their duration and a patient's right to regain full autonomy are critical issues for consideration. Table 7 lists jurisdictions (about 18% of the formal health laws reviewed) which have incorporated one type or another of these community-life arrangements into their laws.

It seems that little effort has been made to integrate mental health provisions in the mainstream of the body of law. This may be due to the fact that, in accordance with the protocol and research constraints, the current sample focused predominantly on mental health law provisions which are part of distinct "mental health" legal instruments, easier to identify and more accessible.

Lawmakers in the majority of countries selected for the study have adopted distinct mental health acts. In some cases, general constitutional provisions on health or liberty have been identified as the foundation of rules derived from it. Although not a country formally included in the present study, Spain is reported to have incorporated a large portion of the legal provisions addressing mental health issues into its Civil Code. In Quebec (Canada), key provisions governing the treatment and confinement of persons with mental disorders have been incorporated into the Civil Code in sections dealing with the integrity of these individuals, while a mental health act stipulates procedural guarantees in more details.

Table 7. Specific integration mechanism

Mechanism	Jurisdiction
Legal integration mechanism	Australia (Queensland)[a], Australia (Victoria), Canada[b], Canada (Ontario)[a], France, Italy, Japan[a], Lebanon, New Zealand, Norway, UK (England and Wales)
No legal integration mechanism documented	Argentina (federal, capital), Brazil (federal, Rio Grande do Sul), Canada (Quebec), China, Costa Rica, Fiji, Finland, Germany (Bavaria), Ghana, Ireland, Kenya, Malaysia, The Netherlands, Nigeria (Lagos), Norway, Pakistan, Romania, Senegal, Sri Lanka, Syrian Arab Republic, Trinidad and Tobago, Tunisia, USA (MA[a], IN), Zimbabwe

[a] A mechanism is reported but not documented.
[b] *1987 Model Act* of the Uniform Law Conference of Canada.

2.9 Legislative Features Encouraging Voluntary Care

It is widely acknowledged that health care of any nature yields the best results in individuals who endorse and support their treatment. This assertion has enhanced significance in the field of mental health care which, by nature, aims at treating disorders which may affect one's capacity to adopt a course of action. There is therefore a compelling interest to examine provisions dealing with care provided on a voluntary basis.

Mental health laws which govern voluntary hospitalization in an explicit manner are likely to entail an increased use of this mode of admission. In addition, this carries a potential of decreasing the use of involuntary hospitalization procedure in cases which do not warrant this mode of admission and hence do away with a potential barrier for accessing care. As a result, the level of incorporation of explicit voluntary admission procedures in mental health legislation is indicative of the tendency to prefer voluntary over involuntary admission whenever feasible.

The level of availability of voluntary care is an indication of accessibility to care and treatment in the least restrictive context. It also provides an additional instrument to determine whether integration with

Table 8. Explicit voluntary admission procedures

	Jurisdiction
Explicit voluntary admission procedure documented	Argentina (capital), Australia (Queensland), Australia (Victoria), Barbados, Brazil (federal), Canada (Quebec), Canada (Ontario), China, Costa Rica, Fiji, Finland, France, Germany (Bavaria), Ghana, India, Ireland, Italy, Japan, Kenya, Lebanon, Norway, Senegal, Swaziland, Romania, Sri Lanka, The Netherlands, Trinidad and Tobago, Tunisia, UK (England and Wales), USA (MA), USA (IN), Zimbabwe
No explicit voluntary admission procedure documented	Argentina (federal), New Zealand, Nigeria (Lagos), Pakistan, Syrian Arab Republic
Others (insufficient data)	Brazil (Rio Grande do Sul), Malaysia

Table 9. Grounds for involuntary hospitalizations

Criteria	Jurisdiction
Very strict	Australia (Victoria), Canada (Ontario), Finland, Ireland, Italy, The Netherlands, Norway, Tunisia, UK (England and Wales), USA (MA)
Strict	Canada (Quebec), France, Germany (Bavaria), India, Japan, New Zealand, Syrian Arab Republic, USA (IN)
Broad or none	Argentina (federal), Australia (Queensland), Barbados, Brazil (federal), China, Costa Rica, Fiji, Ghana, Kenya, Lebanon, Nigeria (Lagos), Pakistan, Romania, Senegal, Sri Lanka, Swaziland, Trinidad and Tobago, Zimbabwe

general health care is impinged by the lack of procedures allowing voluntary admission and treatment, as for other types of disorders.

A classification of countries according to the availability of an explicit voluntary admission procedure under the documented national legislation appears in Table 8. It shows that most of the legislative schemes (over 85% of the laws reviewed) now provides for the voluntary admission of mental patients, an issue which, in past decades, has been a key preoccupation (Curran and Harding 1978). However, the meaning attached to the expression "voluntary admission" or its equivalent was found to be heterogeneous, ranging from rules requiring explicit expressions of consent to others allowing for voluntary non-protesting individuals and cases of surrogate consent by third parties.

2.10
Grounds for Involuntary Hospitalization

Involuntary hospitalization is a common reaction to manifestations of mental disorders. Grounds specified in legislation as conditions for involuntary hospitalization tend to be related to the foreseeable dangerousness of individuals for self or others, although there is no consensus on a reliable method for foreseeing dangerousness with accuracy. Incidentally, several countries allow involuntary hospitalization regardless of an individual's potential dangerousness.

Table 9 classifies countries in one of three categories reflecting grounds for commitments, if any is specified in legislation. "Very strict" hospitalization criteria refer to the most demanding type of criteria, such as "expectation of imminent and serious danger", "prevent the chance of appreciable improvement in health status being lost" and other comparable conditions. "Strict" hospitalization criteria include intermediate types of conditions, such as "danger to self or other". "Broad" hospitalization criteria include conditions such as "disturbs the peace", "suffers from mental health disorder", "protection of others" and "patient's interest".

Table 9 shows that a large number of jurisdictions (about 50% of the formal mental health laws reviewed) rely on broad or on no criteria for involuntary hospitalization. This finding is disturbing in view of some of the 1991 UN mental health principles. The stricter criteria are found in systems derived from European law traditions, perhaps as a reflection of the influence of legal cultures.

2.11
Limited Periods of Hospitalization for Involuntary Care

It is advocated that the duration of involuntary mental health care (hospitalization or treatment) should be set to the shortest possible period to fulfil its raison d'être, i.e., should be as short as clinically required. It is further advocated that the length of involuntary hospitalization or treatment should be specified from the outset so that a reassessment of the appropriateness to maintain involuntary measures is performed upon termination of this period.

Typically, a time limitation of 90 days has been included in mental health legislation and has been found to provide a certain level of protection to persons with mental disorders involuntarily hospitalized. Hence, current laws have been examined from this perspective.

Table 10. Time limits for involuntary hospitalizations[a] and treatments[b]

Time limit	Involuntary hospitalizations	Involuntary treatments
90 days or less	Canada (Ontario), Finland, France, Lebanon, Swaziland, Tunisia, Zimbabwe	–
More than 90 days	Australia (Queensland), Australia (Victoria), Barbados, China, Germany (Bavaria), Ghana, Ireland, Kenya, New Zealand, Sri Lanka[c], The Netherlands, Trinidad and Tobago, UK (England and Wales), USA (MA)	New Zealand, Romania
No statutory time limit specified	Argentina (capital), Argentina (federal), Brazil (Federal), Canada (Quebec), Costa Rica, Fiji, India, Italy, Japan, Nigeria (Lagos), Norway, Pakistan, Romania, Senegal, Sri Lanka[d], Syrian Arab Republic, USA (IN)	Canada (Ontario), Canada (Quebec)[e], China, Germany (Bavaria), Italy, Japan, Norway[f], Pakistan

[a]Presumably extends to treatment in the absence of indications with specific regard to treatment.
[b]If addressed distinctively from hospitalization in legislation.
[c]"Hospitalization" status.
[d]"Detention" status.
[e]Courts tend to authorize treatment for a period of 1 year.
[f]One year.

Table 10 classifies countries in one of three categories to reflect the type of limitations, if any, imposed by legislation on the duration of long-term involuntary hospitalization and involuntary treatment. It indicates that nearly 45% of the formal mental health laws assessed carry no statutory time limit on involuntary hospitalization. Importantly, it also indicates that about 65% of countries whose laws make a distinction between hospitalization and treatment carry no statutory time limit to involuntary treatment.

2.12
Role of Health Care Providers

The involvement, at appropriate levels, of an enlarged range of mental health care providers – typically nurses, but also traditional healers, social workers and others – is an essential component of the primary health care approach to mental health. This is due to the fact that the delegation of some level of clinical authority to non-physicians carries the potential of increasing the availability of health care output at primary level and, as a result, of improving public health. In particular, low-income countries are likely to benefit greatly from this approach. In this context, the level of empowerment of non-physicians caregivers in mental health legislation may be indicative of a country's commitment to a primary health care approach. Further, the delegation of some managerial and decision-making authorities to non-physicians, such as career managers, jurists, clergymen and others, is indicative of an effort to balance the multiple dimensions of decision-making processes in the field of public health.

Table 11 classifies countries according to the level of authority conferred upon non-physicians in mental health legislation; this overall assessment considers both the types of powers and the number of different non-clinicians empowered. It shows that only a handful of jurisdictions (about 16% of the formal mental health laws reviewed) provide for the significant involvement of non-physician health care providers.

2.13
Emergency Care Procedures

Emergency procedures are essential to allow timely action in crisis situations. However, they carry the

Table 11. Involvement of non-physicians reflected by mental health laws

Level of authority	Jurisdiction
Significant	China, Italy, The Netherlands, Trinidad and Tobago, UK (England and Wales), USA (MA)
Moderate	Barbados, Brazil (Rio Grande do Sul), Canada (Ontario), Canada (Quebec), France, India, Ireland, Japan, Kenya, Lebanon, New Zealand, Norway, Senegal, Syrian Arab Republic, Tunisia
Low or none	Argentina (capital), Argentina (federal), Australia (Queensland), Australia (Victoria), Brazil (federal), Costa Rica, Germany (Bavaria), Fiji, Ghana, Nigeria (Lagos), Pakistan, Romania, Sri Lanka, Swaziland, Zimbabwe, USA (IN)

potential of serious human rights infringements. One risk lies in the systematic use of the exceptional rules applicable to emergency situations, which are typically less demanding. Another lies in repeated extensions of the emergency status so as to bypass the standard procedure. A third type of risk exists if no health care provider is involved in the emergency decision-making process.

Table 12 classifies countries according to the time limits imposed on the use of emergency procedures, whereas Table 13 classifies countries in terms of whether a medical assessment is explicitly made part of the emergency procedure process. These tables reveal that a large proportion of jurisdictions have incorporated time limit and medical assessment safeguards into their emergency care procedure.

Table 12. Time limits for emergency hospitalizations

Time limit	Jurisdiction
3 days or less	Australia (Queensland), Barbados[a], Canada (Ontario), Canada (Quebec), Fiji[b], France, Germany (Bavaria), India, Japan, New Zealand, Norway, Trinidad and Tobago, Tunisia, UK (England and Wales), USA (IN)
More than 3 days	Fiji[c], Ghana, Kenya, Nigeria (Lagos), Romania, Senegal, Sri Lanka, Swaziland, USA (MA)
No statutory time limit	Argentina (capital), Argentina (federal), Brazil (federal)

Assessment	Jurisdiction
Medical assessment required	Argentina (capital), Brazil (federal), Canada (Ontario), Canada (Quebec), Germany (Bavaria), Ghana, Japan, Nigeria (Lagos), Norway, Romania, Senegal, Swaziland, Trinidad and Tobago, Tunisia, UK (England and Wales)[a], USA (IN), USA (MA)
No medical assessment required	Australia (Queensland), Barbados[b], Fiji, France, India, Kenya, New Zealand, Sri Lanka

[a]In some but not in all cases.
[b]Observational hospitalization.

2.14 Overseers and Review Bodies

The need for a specialized authority in charge of monitoring the implementation and enforcement of legislative provisions is also largely advocated. Enforcement of norms specific to the mental health field is better supervised by a specialized body, as opposed to a court of law in charge of a host of other matters.

In this respect, three indicators have been considered:

1. Whether they are provided for in legislation (Table 14)
2. Whether they are composed of representatives of a variety of disciplines (Table 14)
3. What type of authority is conferred upon them and how the involvement of this authority can be triggered (Table 15)

Table 14 illustrates how widely in use overseers and review bodies have become; a significant proportion of jurisdictions rely on this safeguard (nearly 55% of the formal mental health laws reviewed). Further, it indicates that a large proportion of countries with overseers and review bodies (about 80% of the formal mental health laws with overseers or review body) require that they be composed of individuals with some diversity in backgrounds. These countries are mostly countries with recent enactments.

Table 15 classifies jurisdictions according to the types of authority conferred upon specialized overseers or review bodies and the mechanisms triggering their involvement. With regard to the type of authority, mandates conferred upon bodies have been classified into two categories: adjudicative or reporting in nature. Adjudicative mandates include the power to order an enforceable legal redress. For instance, it may include the power to order that a given patient be discharged or to order clinical or logistical changes. Although the nature of the legal redresses that adjudicative bodies can impose may vary significantly among jurisdictions, all are indicative of some level of decentralization of power and of independent human rights monitoring. Turning to reporting mandates, although they carry no authority to order a legal redress, they include the power to report and recommend courses of actions to a higher authority and, as such, may constitute an important safeguard.

With regard to the types of involvement, jurisdictions were classified into four categories: involvement upon the independent discretion of the body (power to investigate on their own); involvement at set periodical intervals; involvement upon the request of an interested party (such as a patient, a patient's parent or

Table 14. Overseers and review bodies

[a]Reportedly made explicit by special legislation unavailable to the study.

guardian or others); and involvement at the discretion of a state authority. This classification is indicative of the potential for compliance with legislative and human rights principles. Table 15 shows that about 27% of the formal mental health laws reviewed have granted an adjudicative/binding mandate upon an overseer or a review board, arguably the human rights monitoring mechanism which offers the highest protection.

2.15 Operationalization of Norms

The translation of the norms enshrined in mental health legislation from theory into practice has been identified as a prime area for concern. It was found that mental health laws are widely unimplemented and misinterpreted. Implementation failures may be the result of several different causes, two of which found to be of particular importance are explored below: that of the understanding of the norms by the participants in the health care system and that of the planning of the implementation of theory in practice.

Legislative Understanding

The unprecedented amount of new dilemmas which have appeared as a result of the evolution of clinical practice and of legal principles over the last decades have had an impact on the bulk and pattern of legal instruments in the field of mental health. As a result of advances in psychiatry and of increasingly demanding and complex legal standards, mental health laws have noticeably grown in size. It has become a challenge for law drafters to embody the substantive principles and procedural requirements involved in a comprehensive, yet intelligible format. Although most countries have been affected to some degree by this growth, mental health legislations have been designed in significantly different formats and size around the world. Legal traditions have of course also influenced this.

Table 15. Involvement and authority of overseers and review bodies

	Involvement by independent decision of body	Mandated periodical assessments	Involvement upon request of interested party	At discretion of State authority
Adjudicative/ binding mandate	Lebanon[a], The Netherlands	Australia (Victoria), Canada (Quebec), Norway, UK (England and Wales)	Australia (Queensland), Australia (Victoria), Canada (Ontario), Canada (Quebec), Ireland, New Zealand, Norway, Trinidad and Tobago, UK (England and Wales)	Brazil (Rio Grande do Sul)
Reporting/ recommendation mandate	Australia (Victoria), Canada (Ontario), France, Japan, New Zealand, Nigeria (Lagos), Sri Lanka, Swaziland	Australia (Victoria), France, India, Ireland, New Zealand, Pakistan, Senegal[b], Sri Lanka, Trinidad and Tobago, Tunisia	Australia (Victoria), France, Japan	Australia (Queensland), Australia (Victoria), Sri Lanka, Tunisia

[a]Reportedly made explicit by special legislation unavailable to the study.
[b]Available to patients admitted voluntarily only.

Two opposite trends seem to have emerged. In one of them, legal instruments have become very detailed as they are conceived to systematically address and regulate the multiple facets through various substantive provisions and procedural safeguards. This trend is the untamed result of the above-noted evolution. It is found mostly in countries influenced by the common law tradition, but also in other legal traditions. Good examples are Japan and in New Zealand. Legal instruments found in this category are reportedly widely perceived as complex sets of rules rather inaccessible to the lay person. They typically embody extensive legal definitions of terms and expressions used therein. Cross-references between sections are frequent. As a disadvantage, users' guides and visual representations are generally found to be required if the norms specified in this type of legislation are to be understood and followed by health care providers.

The second trend includes brief descriptive legal instruments which are only a few articles long. Legal instruments found in Italy and Tunisia exemplify this trend. In some cases (e.g., Spain), the provisions involved are no longer to be found in distinct acts, but have been integrated into the general body of health law or into a code, thus contributing to remove the stigma attached to a distinct group. This trend is found mostly in countries influenced by the civil law tradition. As a decentralization measure, operationalization efforts and regulation may have been delegated to local authorities, although this generally does not lead to overly detailed sets of legal instruments at a local level. Legal instruments found in this group tend to be less legalistic in their format and hence more accessible to non-jurists. This fosters operationalization and accurate enforcement. One criticism directed at the legal instruments in this group is their very variable level of precision, resulting in higher levels of discretion for the authorities in charge of their operationalization. Another is that the high level of abstraction may require complementary and incidental legal instruments. Some confusion as to the applicable norms may ensue.

As detailed and comprehensive as they may be, the substantive principles, procedural requirements and structures of authority specified in legislation have to be abided by if they are to mean anything. Unlike many other areas where non-jurists have the option and the time to defer to jurists to interpret legislative provisions, mental health legislation will often require immediate action and will seldom allow mental health care givers to obtain legal advice on the spot. They often have to be able to understand the legal mechanisms involved by themselves or they will resort to exceptional procedures (e.g., emergency procedures) or, more simply, to their common sense. Of course, training sessions and internal manuals specifying legal requirements, if they can be made available, will help. However, they may not cover the growing number of exceptional procedures. In the end, too complex or detailed mental health laws carry the potential of remaining significantly non-operationalized and unenforced, with entire portions systematically disregarded or ignored.

In order to depict world trends with regard to the issue of understanding, an indicator which evaluates the relative level to which legal instruments are accessible to non-jurists was developed. This indicator takes into consideration both the format of the instrument and its content. Although inevitably subjective in nature, the results of this assessment were found to be useful to identify tendencies. These results are reported in Table 16, which shows that a very significant number of jurisdictions (50% of the formal mental health laws reviewed) now apply legislative schemes in the field of mental health assessed as "complex"; these are mostly derived from the common law tradition.

Strategic Planning

It has been a recurring comment of national informants and experts that a leading cause explaining enforcement failures in mental health legislation lies in the way the entry into force of new legislative features is prepared and the way its continued enforcement is ensured. Typically, the conception of modern legal instruments in the field of mental health draws much energy and takes place over a process which may – and usually does – last several years. Task forces and/or commissions are set up. Attention is devoted, inter alia, to substantive rules, procedural guarantees, constitutionality and human rights as well as a variety of other aspects. In several countries, public participation also forms an

Table 16. Complexity of mental health laws

Complexity level	Jurisdiction
Complex	Australia (Queensland), Australia (Victoria), Barbados, Canada (Ontario), France, India, Ireland, Japan, Kenya, New Zealand, Pakistan, Sri Lanka, Trinidad and Tobago, UK (England and Wales), USA (IN)
Moderately complex	Canada (Quebec), China, Germany (Bavaria), Ghana, Nigeria (Lagos), Norway, Swaziland, The Netherlands
Simple	Brazil (Rio Grande do Sul), Italy, Senegal, Italy, Lebanon, Syrian Arab Republic, Tunisia
Insufficient data	Argentina (federal, capital), Brazil (federal), Costa Rica, Fiji, Finland, Malaysia, Norway, Romania, USA (MA), Zimbabwe

integral part of the process, contributing to enriching and prolonging it. Debates take place and consensus is reached or not. The results are increasingly detailed laws embodied in increasingly complex formats.

Yet, in comparison, a relatively insignificant amount of time and effort seems to be typically devoted to preparing the scene for the entry into force of a new legislative scheme or of amendments to any existing scheme. Although in some jurisdictions some level of preparation may be provided for the individuals involved in the operation of mental health laws prior to or at their inception, this appears to be exceptional and/or limited in scope. The few instances of preparatory efforts that are reported are typically limited to clarifying the more obscure or more problematic features of the legislative schemes. Little energy appears to be devoted to a number of facets, including informing people at various levels in the mental health care field about philosophical and practical changes in the law that should have an impact on their usual practices, giving due weight to the time variable, itemizing funds to prepare the operationalization (e.g., transition) as opposed to the application of the law and explaining the meaning of "the rule of law" (i.e., legal instruments are binding). In short, no global, coherent and rational strategic plan for the launching of mental health legislation appears to be generally followed despite increasingly detailed legislative features.

3 The Italian Experience

The Italian Public Law 180 on Mental Health, enacted in 1978, has become known worldwide for the radical shift in mental health care it envisaged: from institutional segregation and control to rehabilitation and reintegration into normal social life in the community. Influenced by leading psychiatrist Franco Basaglia and embodied in a brief 11-article format, it was essentially designed to do the following:

1. Phase out public mental hospitals by admitting no new patients
2. Move the treatment of persons with mental disorders to community-based mental health centres
3. Move any needed psychiatric hospitalization to general hospitals
4. Limit involuntary hospitalizations to cases where "(a) urgent intervention is required, (b) the patient refuses necessary treatment and (c) alternative community-based treatment is unavailable or not feasible"[4]

The implementation of Law 180 was delegated to regional governments.

Legal principles and mechanisms put forward in Law 180 towards these ends include the following:

- Setting out the principle that medical examinations and treatment shall, as far as possible, be voluntary (article 1 para. 1)
- Granting decision-making authority to the local mayor (article 1 para. 6)
- Setting out the principle that prevention, treatment and rehabilitation of patients shall normally be carried out by outpatient psychiatric departments and centres (article 6)

After two decades of operation, Italian Public Law 180 provides a good precedent for consideration by international observers. Four remarks on the wide-ranging reforms it has striven to bring about can be made:

1. Variations in the pace, extent and even existence of reforms are reportedly very high from one Italian region to another, with regions in the north generally more compliant and successful than regions in the south (Burti and Benson 1996). Explanations reported for this include difficult economic and political circumstances in the late 1970s and the early 1980s, difficulty in reallocating funds from mental hospitals to community services and severe cuts in social programmes during the 1980s. Clearly, the availability (or shortage) of funds and the level of commitment of local health authorities appear to be leading determinants of successes and failures in the regional implementation of Law 180.
2. Documented successes in several Italian provinces strongly support the theory advocated by Basaglia and his followers that a key to recovery and reintegration of mental patients lies in their empowerment.
3. Reported data suggests that the deinstitutionalization brought about by the reform in successful regions has not, as feared by some, entailed corresponding increases in the criminal justice system or in private mental health institutions (Barbato 1998).
4. On the finding by a Special Commission in 1989 that there were significant implementation failures a decade after its adoption, the Italian Senate recommended that an adequate budget be set aside for the *implementation* of Law 180, resulting in a national

[4]For an English translation of the Act, see International Digest of Health Legislation 30(1): 75–79.

plan passed by the Italian Parliament in 1994. Clearly, the Italian experience in translating a commendable yet ambitious mental health care reform into practice attests the need for early planning and budgeting in anticipation of the entry into force of a new mental health law.

4 The Situation in China

China has no nationwide legislation governing mental health matters. However, it cannot be said that the country operates through informal practices. There are two explanations for this:

1. Successive draft mental health acts have been considered by both the Ministry of Public Health (MPH) and the People's Congress for many years. The most recent version is the Tenth Draft Revision introduced in July 1991; although not formally adopted, informants report that it is widely observed.
2. Several provinces have adopted this Tenth Draft Revision (as submitted to national authorities as a report from a MPH/WHO National Workshop on Mental Health and Law, which took place in Chengdu, Sichuan, in October 1990) as their provincial law.

In addition to this draft, a number of laws relevant to the field of mental health have been adopted at both national and provincial levels. They include, inter alia, a *National Law on Experts' Assessment (Competence) of Mental Disorders* (1989), *Rules for the Assessment of Psychiatric Offenders* (1989), *Programme for Special Education for the Mentally Disordered* (includes mental retardation and other mental disorders) (1989), *Law on the Protection of the Disabled* (physical, sensorial and mental disability) (1990), *Programme for the Protection of the Disabled* (includes e.g., education, employment) (1991) and *Law on Maternal and Infant Health Care* 1994.

Since most of the Chinese still live in rural areas, the majority of mental health care is provided at primary health care level; psychiatric hospitals are available only in medium-sized and large cities, and psychiatric wards in general hospitals usually only exist in teaching hospitals. In view of the size of the population, the relative number of mental health workers is rather limited, making nursing aides a key player in the provision of mental health care.

Institutional mental health care in China does not seem to differ much from that found in other countries with a similar level of development. At community level, however, the persistence of the extended family, particularly in rural areas, favours the integration of people with chronic mental disorders into community and social life.

China's peculiar situation is further accentuated by two factors. The first is the inclusion of disabilities and handicaps due to mental disorders among all other disabilities (i.e., originating from physical and sensory problems). For historical reasons, persons with disability benefit from a series of laws and other measures for their protection.

The second factor is the importance given, in China, to the so-called second-generation human rights. Certain Western perceptions of China tend to be of generalized human rights violations, referring mostly to so-called first-generation human rights (i.e., civil and political rights). However, second-generation rights (i.e., social, economic and cultural rights) are largely abided by. These rights are important to persons with mental disorders. Chinese legislation referred to above is largely in pursuit of these rights, and site visits by the second author to three Chinese provinces (Yantai, Shanxi and Sichuan) have left little doubt that efforts are made to implement these provisions in practice. No signs of discrimination against people with mental disorders were found in the sites visited by the second author. In fact, people with mental disorders were generally treated with a respect similar to that demonstrated in relation to people with disabilities of other nature and the elderly.

It should be kept in mind that the predominance of the rural over urban population and of the extended family are changing quickly in China. This may have a heavy impact on the integration of people with mental disorders into community life.

5 Concluding Remarks

The reliance on binding norms protecting persons with mental disorders and facilitating their full participation in society as normal citizens has become the reference standard worldwide. Persons with mental disorders deserve the protection of the rule of law: "decisions should be made by application of known principles [. . .] without the intervention of discretion in their application" (Black et al. 1991).

Like other legislation, mental health legislation is a tool. To achieve the desired results, it must be handled with skill and care, especially when a vulnerable group is targeted. Most importantly, it must be used, i.e., its spirit and features must be implemented and specific provisions enforced in practice. It should not be left

lying in a statute book. Mental health legislation reforms which remain unimplemented turn into a formidable disservice to persons with mental disorders by creating a false sense of achievement.

Beyond legal provisions, the dignity of persons with mental disorders is also ours.

Forensic Evaluations for Civil and Criminal Competencies and Criminal Responsibility in German and Anglo-American Legal Systems

1 General Remarks

1.1 Two-Step Evaluation Process

A forensic evaluation to examine a person's mental state, where his or her mental state is of legal significance, should follow a two-step process. The first step determines whether a psychiatric illness or a serious mental disorder exists at all. Kurt Schneider (1948) formulated an approach in which the following two issues must be determined:

1. Whether a mental disorder exits and how the disorder is to be denoted according to psychiatric nomenclature
2. Proceeding from the clinical findings and diagnosis, how this disorder affects the mental capacity in question

This two-step process is basically equally valid for the assessment of competency to work, to earn a living, to practice a profession, to do business, to make a will, to consent, to be interrogated, to stand trial, to commit a crime (i.e., criminal responsibility), to drive a vehicle, and to serve as a witness.

1.2 Psychiatric Diagnosis

The first step consists of a comprehensive psychiatric evaluation that includes the medical history and the interpretation of available relevant medical, psychiatric, and legal documents to consider whether such materials produce evidence for mental illness. Based on the collected data, a psychiatric diagnosis is established that is consistent with the criteria and terminology of a currently valid classification system such as ICD-10 (World Health Organization 1992) or DSM-IV (American Psychiatric Association 1994). Forensic experts and lawyers must clearly understand that these diagnostic and classification manuals correspond to changing conventions and are therefore not final, permanent diagnostic authorities. Expert witnesses and lawyers should also appreciate that a psychiatric diagnosis per se is insufficient for direct testimony about impairment of competency.

1.3 Competency Assessment

The second step, i.e., application of the collected data in a particular case to the legal criteria for the competency to be addressed, is a separate and equally important task of the forensic psychiatrist as the collection of data. As a rule, unless there is reason to question the issue, any adult is presumed to be competent unless and until proven to be incompetent. Criteria for specific competencies are usually defined in concise legal wording, which in Germany is presented in the opinions of the highest court and in Anglo-American law can be articulated in either state or federal statute or appellate court opinion. The forensic psychiatrist must know how the absence of the relevant competency is legally defined. The psychiatrist's knowledge of the definition of competency will guide him or her in the specific, purposeful exploration and application of clinical knowledge about typical limitations in such pathological conditions. The nature and extent of such limitations should be clearly presented in the forensic report.

1.4 Principle of the Psychopathological Reference System

The principle of the psychopathological reference system (Saß 1985) is applied by comparing the evaluee's presenting symptomatology with the psychiatrist's extensive knowledge of psychopathological conditions. Assessment of mental phenomena is conducted with the background of biographical knowledge about the healthy and pathologically disturbed developmental stages of life, about the mechanisms of reaction to stressors, and about the influences of specific therapeutic efforts and the natural phases of maturation and aging. In contrast to a common misunderstanding in forensic discussions, the psychopathological focus should not limit the assessment to pathologically disturbed psychological phenomena alone, but rather the understanding of the person's psychopathology is clearly based on the psychiatrist's total knowledge of both pathological and atypical, but not abnormal mental phenomena in contrast to more or less pure mental health.

This chapter cannot replace any textbook of forensic psychiatry (Gunn and Taylor 1993; Nedopil 1996; Rosner 1994; Sadoff 1988; Venzlaff and Foerster 1994) or mental health law (Brakel et al. 1985; Perlin 1989; Slovenko 1973; Weiner and Wettstein 1993); it simply summarizes current guidelines for the forensic assessment of individuals whose competency in a specific area has come into question. The examining psychiatrist must be careful to order supplemental examination procedures when indicated to address specific questions and especially psychological testing to help clarify the diagnosis.

The following sections will discuss first civil competencies – legal competency, competency to sue, competency to make a will, competency to consent to

treatment, and related competencies – and then competencies in criminal law – competency to be interrogated/to confess, to stand trial, to commit a crime (i.e., criminal responsibility), and to be sentenced. Each competency will be explained from the perspective of the law and forensic practices in the Federal Republic of Germany followed by commentary of special relevance to forensic psychiatry in North America and England.

2 Civil Competencies

2.1 Germany

2.1.1 Legal Competency

In Germany, legal competency is the ability to autonomously bring about desired legal results through legal transactions or, more specifically, through legal documents and contracts. Legal competency is required in order to effectively conduct and conclude business actions. Children aged 6 or younger are not considered to be competent to enter contracts. Children aged 7 or older and adolescents up to the age of 18 have *limited legal competency*. To conduct legal acts, older children require the consent of their parents as legal representatives, provided that their parents do not themselves profit from the transaction. As will be discussed, testamentary capacity and competency to consent are basically special subtypes of legal competency.

2.1.2 General Legal Competency

Legal competency is presumed at majority. In Germany, legal competency is governed by the Sec. 104 *Bürgerliches Gesetzbuch* (BGB) (German Civil Code). According to the relevant statute, a person is legally incompetent if he or she (a) has not reached the age of 7 or (b) has a condition involving a pathological disturbance of mental processes that destroys free decisional capacity, provided the condition is not temporary in nature.

2.1.3 Temporary Conditions

For purely temporary conditions, e.g., temporary severe clouding of consciousness or loss of consciousness such as could occur with an epileptic attack, high fever, or an intoxicated state, the German Civil Code states the following: "A legal document that is proffered during a condition of unconsciousness or temporary disturbance in mental processes is therefore void" (Sec. 105(2) BGB). Once the condition has passed, the impairment in legal competency naturally no longer exists.

Individuals who are incompetent according to Sec. 104(2) BGB cannot participate in the business transaction themselves, but their legal representatives can act on their behalf. If it can be shown in retrospect that, at the time of the legal transaction, the individual concerned was legally incompetent due to a temporary pathological disturbance of mental functioning which eliminates voluntary decision-making capacity, any contracts concluded (e.g., rent, sale, loan contracts) can be voided. Competency to do business is presumed to exist until incompetency is proven.

2.1.4 Forensic Questions

Apart from appropriate treatment considerations, forensic issues concerning legal competency refer to two possible questions:

1. At the time of the legal transaction, did a temporary disturbance of mental functioning exist which eliminated the individual's voluntary decision-making capacity (Sec. 105(2) BGB)? Examples of such temporary disturbances include a partial complex seizure or a state of intoxication.
2. At the time of the legal transaction, did legal incompetency exist that was more than a brief pathological disturbance of mental functioning eliminating the person's voluntary decision-making capacity (i.e., according to Sec. 104(2) BGB)? This possibility usually arises as a result of a dementing process or a psychotic illness such as schizophrenia or manic-depressive illness, but not from an acute organic brain disorder. In principle, it could also apply to disorders such as personality disorders, abnormal reactions, and mental retardation, provided that these disorders are comparable in severity to a major mental illness.

2.1.5 Retrospective Assessment

Retrospective assessments to address legal competency should follow the same two-step process described at the beginning of this chapter. If a disorder did exist, the second step is then to determine whether it resulted in the elimination of the subject's ability to make autonomous decisions, i.e., the elimination of the "normal decision-making ability resulting from normal motivations" (Aschaffenburg 1906) or "normal decision-making ability through rational deliberation" (Federal Court decisions).

According to an opinion given by the *Bundesgerichtshof* (BGH, German Supreme Court of Justice) in 1918, individuals are considered incompetent to do business (according to Sec. 104(2) BGB) if their "deliberations and voluntary decisions are no longer based on a general opinion corresponding to an appreciation of external affairs and living circumstances, but rather are influenced through pathological feelings, pathological ideas and thoughts, or through influences by a third person of a lasting nature, (such) that they are in fact no longer free but follow the so-called contrary-to-rule actions without inhibition or restriction" (Diederichsen 1994). To address the question of whether the individual's ability to make autonomous decision has been impaired, the psychiatrist must retrospectively apply clinical knowledge about the person's volitional processes, decision-making, and behavior at the time of the business transaction.

Organic brain disorders which involve substantial impairment of the abilities to register and/or remember information (e.g., multinfarct or Alzheimer's dementia) can abolish legal competency by impairing requisite cognitive decisional foundations for the development of free choices or by pathologically altering the individual's emotional control. More or less purely affective disorders and organic brain disorders (e.g., with depressive or excitable moods) can impair volitional capacity and decision-making. This clearly also applies to abulia and conditions which can render the individual extraordinarily susceptible to influences such as can occur with some organic brain disorders, mental retardation, and schizophrenic illnesses.

2.2 United States

What is usually meant by civil competency in the United States is *competency to handle one's own affairs*. Competency to do business, though less frequent, occasionally has to be investigated by a forensic psychiatrist; basically, the criteria for competency to do business is the ability to understand the proceedings in which the individual is to become involved (Sadoff 1988). Much of what has already been discussed about forensic assessments would apply independent of political jurisdiction.

Criteria for competency to handle one's own affairs includes the capacity to know the extent of one's possessions and to handle one's affairs prudently (Sadoff 1988, p. 149). Depending on jurisdictional law, the person may be declared incompetent to handle some functions but not others. Related concepts are competency as to the estate and competency as to the person. A person who is found by the court to be *incompetent as to the estate* is barred from entering into business contracts (Weiner and Wettstein 1993, p. 285). Such transactions can be handled only by an estate guardian, appointed by the individual or by the court itself. Estate incompetency generally includes lack of competency to do business, to make a will, to sue, and to enter into contracts. In contrast, an individual who is declared *incompetent as to the person* also loses the right to make personal decisions which may include treatment decisions (Weiner and Wettstein 1993, pp. 285–286). The guardian then typically makes such decisions on behalf of this person.

2.3 Competency to Sue

A subcategory of competency to do business is competency to sue, which is in effect competency to do business in court. This refers to the capacity to conduct a lawsuit oneself or through a self-designated representative. Competency to sue is, however, quite different from competency to stand trial (see below).

2.4 Testamentary Capacity

Testamentary capacity is another special subtype of legal competency. Those who lack testamentary capacity are not capable of making a will or concluding an inheritance contract. According to the relevant section of the German Civil Code (Sec. 2249(4) BGB), a will cannot be made by someone who, due to a pathological disturbance of mental processes, mental retardation, or a disturbance in consciousness, is not in a position to recognize the meaning of the testament submitted by the individual and to act in accordance with such recognition.

2.4.1 Presumptions

According to an opinion given by the German Supreme Court, testamentary capacity requires that testators be capable of knowing that they are making a will and of knowing the content of the will. Testators must be in a condition to form a clear judgment about their will and the extent of their instructions, especially about the effects they will have on their personal and economic relationships. Testators must be able to act according to such formed judgment, free from the influences applied by third persons, although this does not preclude testators from strongly considering suggestions made by third persons in arriving at some of their decisions. In considering the suggestions of others, testators must retain the capacity to form

concepts on their own in determining and expressing the contents of their will.

2.4.2 Assessment Procedure

Some wills are contested after the death of the testator with the claim that the testator lacked testamentary capacity at the time he or she made out the will. Since the deceased person is not available for direct examination, the forensic psychiatrist must examine the contents of relevant documents and records and must methodically interview witnesses and acquaintances of the deceased to determine whether the testator had a relevant mental disorder at the time in question. The most frequent clinical basis for testamentary incapacity is progressive dementia. In such cases, the incompetency of the testator is usually not disputed; however, counterclaims of testamentary capacity can be asserted in cases where the testator was thought to have been in a "lucid interval" when the will was made.

2.4.3 Lucid Intervals

Intervals of Long Duration

The concept of the so-called lucid interval originated from the view that mental illness is an enduring process of mental decompensation (corresponding to Sec. 104(2) BGB). In the German Civil Code, the concept of a protracted lucid interval is based on the well-known clinical observation that some mental illnesses such as bipolar disorder occur in phases and are interrupted by intervals devoid of obvious psychopathology, intervals that can last for weeks or months or sometimes even years. During these lucid intervals, the individual is competent to do business and to make out a will (see also Diederichsen 1994).

Intervals of Short Duration

Invariably, however, forensic mistakes will occasion a challenge in court regarding a testator's competency to do business and to make a will, especially in those cases wherein the will was signed or a contract was finalized during a lucid interval of only a few hours or even a shorter period of time. From a psychiatric standpoint, this inquiry is meaningless, and forensic psychiatrists in Germany have expressed their concerns in recent decades (Rasch and Bayert 1985; Rose 1986; Foerster 1994). With irreversible progressive organic brain disorders, the lucid interval is no different from a relative improvement in the person's condition; this does not change the person's fundamental loss of memory and consequent loss of biographical and personal information for making appraisals. This also applies to schizophrenic and psychotic mood-disordered individuals, whose disorders may be authentically interspersed with brief disorder-free intervals.

2.4.4 United States and Great Britain

In Anglo-American law, three criteria are universally required for testamentary capacity. The testator must know and understand the following:

1. The purpose of the will
2. The nature and extent of his or her property
3. The recipients of his or her bequests, i.e., the natural beneficiaries of his property, usually family members (Sadoff 1988, p. 150; Weiner and Wettstein 1993, p. 285) or the claims others have on his property (Briscoe et al. 1993, p. 109)

A will can be invalidated based upon an "insane delusion" if the challenging party can prove that the will resulted from the testator's delusion (Ciccone 1994, p. 253). In the United States, a will can be challenged on the basis of a claim that a beneficiary had an "undue influence" over the testator. Once a claim of undue influence is made, the person who was left a bequest then has the burden of disproving that he or she exercised undue influence upon the testator (Slovenko 1973).

2.5 Competency to Consent

Competency to consent refers to the ability to give truly effectively consent for medical treatments, surgical interventions, participation in scientific studies, or invasive diagnostic procedures. The legal definition of competency to consent has only recently emerged from more general definitions of competency, and the rate of this development has varied even within Europe (Koch et al. 1996). Some overlap exists between the criteria for competency to consent and those for testamentary capacity and competency to do business. As for these other competencies, the two-step assessment procedure is required for the evaluation of competency to consent. After determining whether a mental disorder exists, the forensic psychiatrist has to assess the person's ability to do the following:

1. *Understand* certain facts
2. *Process* the information in a rational manner
3. *Assess* the information appropriately
4. *Determine* and *express* his or her own intentions on the basis of understanding, processing, and assessing

The assessment of these abilities demands that the grammar of psychological criteria are translated into a system of operationalized questions. This is usually

done by means of an informal psychiatric interview, but can also be carried out by using more elaborate and standardized techniques (Grisso and Appelbaum 1995). The capacity to consent has to be regarded as a specific and not as a global concept. This implies that the issue cannot be whether a person is competent to consent at all but whether he or she is competent to make a specific decision and to agree to or to reject a particular medical intervention; he or she may be competent to make certain decisions while at the same time being unable to accept or to reject a different medical proposal.

The concept of competency to consent is not only a relative concept, but also a dimensional one. Many patients will be rated as neither fully competent nor completely incapacitated. They may be unlikely to function perfectly in one or in all of the above-mentioned psychological areas and fall somewhere in between. Thus, whether or not a patient is evaluated as competent ultimately depends not only on the standard of assessment and the number of psychological dimensions that have actually been evaluated, but also on the borderline where the threshold between competency and incompetency is drawn. In general, this threshold will be determined by two variables: the risk–benefit ratio of the intended intervention and the direction of a patient's decision. In other words, if the risk–benefit ratio of the medical intervention is questionable or unfavorable, the standard of assessment and the threshold of competency must be high, while even the decision of a marginally competent patient may be honored if the individual consents to the application of a well-established procedure which is known to have a favorable risk–benefit ratio.

2.5.1 United States

In the United States, competency to consent to medical and surgical treatments requires that the patient knows the nature and consequences of the procedure and the consequences of accepting no treatment whatsoever (Sadoff 1988). Particularly with respect to psychotropic medication, this capacity is sometimes expressed in the negative, i.e., competency to *refuse* treatment (Sadoff 1988). A delusion concerning the procedure could impair a patient's understanding and ability to consent. With the psychiatric patient's right to refuse treatment being increasingly acknowledged and formalized over the last four decades, the law governing consent to psychiatric hospitalization, psychotropic medication, and electroconvulsive treatment (ECT) and a qualified right to refuse each of these procedures has become more extensive and more complex and certainly not uniform across state jurisdictions. Thus both treating and forensic psychiatrists have an obligation to familiarize themselves with the relevant mental health law governing competency. Some of these competencies are defined in the state health laws and other legal regulations (Weiner and Wettstein 1993). Some state mental health laws require a separate court hearing even if a guardian for an otherwise incompetent patient authorizes treatment with psychotropic medicine or ECT where the patient has not consented.

In *Zinermon v. Burch*,[1] the United States Supreme Court held that a Florida case could be litigated where a patient claimed he was mistakenly allowed to sign himself into the hospital when he was psychotic and incompetent to do so. Some states have a mental health law that requires patients to have competency to decide to enter the hospital before being allowed to sign themselves in voluntarily (Weiner and Wettstein 1993).

2.5.2 England and Wales

Competency to consent to medical treatment for a mental disorder in England and Wales is defined in the Code of Practice for the Mental Health Act 1983: "In order to have capacity an individual must be able to understand what the medical treatment is and why he needs it, its principal benefits and risks, and the consequences of not receiving the treatment, and he must have the capacity to make a choice."

3 Criminal Competencies

3.1 Competency to Confess or be Interrogated

3.1.1 Competency to be Interrogated in Germany

Competency to be interrogated in Germany is the capacity of a witness or defendant to undergo an interrogation by the police or legal authorities and to make a declaration. It presumes the capacity to follow the inquiry, to understand the intended meaning of the questions, and to offer clarifications with voluntary decision-making.

3.1.2 Competency to Confess in the United States

The concept in United States jurisprudence that is most akin to Germany's competency to be interrogated is competency to confess. However, unlike other

[1] 494 U.S. 113, 110 S.Ct. 975 (1990).

competencies in criminal law, competency to confess in the United States is essentially devoid of cognitive or functional capacities. In its 1986 *Colorado v. Connelly* decision,[2] the United States Supreme Court considered a confession to be voluntary and therefore constitutional if it was given without intimidation, coercion, or deception by others (i.e., the police). In that specific case, since the police did not obtain the confession by force or trickery, the suspect's cognitive competency was not considered relevant, even though he was quite psychotic at the time.

3.2 Competency to Stand Trial

As defined by commentaries on German criminal procedure law, competency to stand trial is the capacity of an accused, in or out of the court hearing, to perceive his or her interests rationally, to conduct his or her defense sensibly and in an intelligible way, and to give and receive declarations during the lawsuit.

3.2.1 Presumptions

Competency to stand trial covers the capacity to mentally follow court procedures concerning the court session, to conduct the litigation, and to fulfill procedural duties. The defendant should be capable of understanding the explanations of other participants in the court and of proffering his or her own requests in an understandable manner. Competency requires more than just passive participation; it requires the ability to actively look out for one's legal interests. Competency to stand trial is presumed for court hearings except for commitment procedures, as stated in Sec. 63 *Strafgesetzbuch* (StGB) (German Criminal Code). Anyone intentionally causing their own state of incompetency to stand trial (e.g., by voluntary intoxication) can be prosecuted in absentia.

3.2.2 Determination

Competency to stand trial can be eliminated by a psychiatric or physical illness. Whether or not an accused is incompetent to stand trial is a legal question to be decided by the court alone. The forensic psychiatrist merely provides potential reasons for the decision. According to Sec. 81 of the German Code of Criminal Procedure (StPO), the court can have a defendant admitted to a public psychiatric hospital for a maximum of 6 weeks in order to undergo a forensic evaluation to assess the defendant's competency to stand trial.

3.2.3 Expert Medical Reports

The forensic report, whether based on outpatient or inpatient assessment, must address the diagnosis, cause of the illness, foreseeable duration of the illness taking into account all possible therapies, effects of the disorder on the participation of the defendant in the main trial, and the danger this poses to the defendant's health.

Within the psychiatric realm, dementia and severe organic psychoses constitute possible reasons for lasting incompetency, while acute florid psychoses usually account for only a temporary state of incompetency to stand trial. There are no grounds for the assumption that the participation of a defendant or witness in a courtroom procedure generally presents a health risk if the person is already mentally ill or unstable; the clarification of a stressful situation through court participation can actually affect the defendant favorably.

3.2.4 Great Britain

In England and Wales, the concept of fitness to plead can include abilities to plead, comprehend the evidence, follow the court proceedings, advise one's lawyers, and know about challenging jurors (Briscoe et al. 1993, p. 44). In actuality, it is unusual for someone to be determined unfit to plead, affecting only about 20 defendants each year (Grubin 1991).

3.2.5 Canada

Until Canada's Criminal Code was revised in 1992, the Canadian Criminal Code did not specify criteria for fitness to stand trial, although criteria applied by courts were similar to the new standard (Davis 1993). The revised code now states that a defendant can be found unfit if he or she is unable to (a) understand the nature or object of the proceedings, (b) understand the possible consequences of the proceedings, or (c) communicate with counsel.

3.2.6 United States

In the United States, competency or fitness to stand trial is frequently assessed, affecting a large number of defendants. The criteria used by most jurisdictions in

[2] 107 S.Ct. 515 (1986).

the United States are known as the *Dusky* standard after the 1960 United States Supreme Court decision which established the minimal constitutional requirements for legal standards for competency to stand trial. According to the *Dusky* decision, the test of competency is "whether [the defendant] has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and whether he has a rational as well as a factual understanding of the proceedings against him."[3]

3.3 Competency to Waive Counsel in the United States

In the United States, competency to plead and competency to waive counsel are separate but related capacities pertaining to criminal defendants. Competency to waive counsel should logically include competency to represent oneself pro se, because any concern for fairness involves *functional* capacity at trial, not just *decisional* capacity when the defendant asks to release his or her attorney (see Felthous 1979, 1994; Perlin 1996). Although legislators and forensic psychiatrists are free to address such relevant concerns, in the *Godinez v. Moran* case,[4] the U.S. Supreme Court held that if the decision to waive counsel is knowing and voluntary, the *Dusky* criteria for competency to stand trial are constitutionally sufficient for competency to plead and competency to waive counsel.

3.4 Criminal Responsibility

3.4.1 Germany

Anyone who, when committing an act, is incapable of understanding that this act is wrong or of acting in accordance with this understanding due to a disorder of mental illness, a profound disturbance in consciousness, mental retardation or due to any other serious mental abnormality acts without guilt.

Since 1975, Sec. 20 StGB has been the standard for "lack of criminal responsibility due to mental disorders"; since then, possible reasons to presume mental disturbance have explicitly included psychiatric illness, mental retardation, and disturbance of consciousness. The concept "other serious mental abnormality" pertains to severe personality disorders, neuroses, and sexual deviations.

[3] *Dusky v. United States*, 80 S.Ct. 789 (782) (1960).

[4] 61 U.S. LW 4749; 113 S.Ct. 2680 (1993).

3.4.2 Consequences of Lack of Criminal Responsibility

Section 20 StGB provides the criteria for finding a defendant to be without criminal responsibility, which in turn results in *exculpation*, acquittal from criminal responsibility. The prerequisites for "*deculpation*," diminished responsibility, and corresponding diminished "punishability" are presented in Sec. 21 StGB: "[If], when committing the act, the capacity of the actor to understand that the act is wrong or to act according to this understanding, (is) substantially diminished by one of the reasons described in Sec. 20, the punishment can be reduced pursuant to Sec. 49(1)." Pursuant to Sec. 63 StGB, if the psychiatric disorder which led to the criteria of Sec. 20 or 21 being fulfilled persists and is expected to persist in the future, measures can be taken for hospitalization in a psychiatric inpatient facility.

3.4.3 Procedures for Forensic Examination

Examinations in forensic psychiatry follow the two-step process: First, through psychiatric exploration and examination, the evaluator must address whether the defendant has a disorder that corresponds to one of the four named legal concepts in Sec. 20 StGB. If a qualifying mental condition is diagnosed, the second step is to examine whether, at the time of the act, the condition resulted in a substantial impairment or elimination of the "capacity to understand" and/or the "capacity to control one's behavior." A general discussion about the capacity to control is not permitted without first determining whether one of the four prerequisite conditions was present.

In the context of retrospective examinations in forensic psychiatry, we shall discuss only persistent mental disorders, i.e., psychotic illnesses, severe personality disorders, and sexual paraphilias. Other qualifying conditions will be addressed briefly.

3.4.4 Profound Disturbance in Consciousness

The category of "profound disturbance in consciousness" is reserved for exceptional normal psychological conditions that are affectively intensified (Janzarik 1995) in which so-called expressive or affective crimes have been committed. A wide consensus has now been reached within the administration of justice concerning the criteria for assessing the existence and the effects of such a profound disturbance in consciousness (see Saß 1993).

3.4.5 Imbecility

Since the reformed German Penal Code of 1975, the legal concept of "imbecility" has played a more limited role than it used to in criminal forensic psychiatry evaluations. Imbecility is understood as a congenital intellectual deficiency with an intelligence quotient of below about 70, which is generally associated with a substantially defective ability to read, write, and calculate and with a clear impairment of social competence.

3.4.6 Brief Drug-Related Mental Disorders

Brief mental disorders, namely conditions of intoxication from alcohol or other drugs, frequently occur among otherwise psychiatrically healthy offenders and are thus of substantial practical relevance. The German Supreme Federal Court has attempted to simplify judgments by providing blood alcohol limits for which diminished (blood alcohol content of 2 per 1000th) or no (3 per 1000th) criminal responsibility are probable. However, these limits fail to take into account the wide range of reactions by different individual reactions to even comparable blood alcohol concentrations through habituation and the development of tolerance to steady drinking in contrast to episodic, social consumption (Kröber 1996). The German Supreme Court has since been modifying its policy on this issue, basing its decision more on psychological factors than on laboratory data.

The German Supreme Court has now corrected its guideline and formulated the following new basic principle (judgment of April 29, 1997):

There is no verified medical/statistical principle derived from experience according to which, without taking psychodiagnostic judgment criteria into account and only on the basis of a certain blood alcohol concentration at the time of the criminal act, considerably reduced ability of control as a function of alcohol can be assumed as a rule.

3.4.7 Evaluation of Mentally Ill Offenders

The evaluation of mentally ill offenders who suffer from a persistent "pathological mental disorder" was long substantially influenced by the agnostic position of Kurt Schneider (1948), who called for exculpation in the sense of the current Sec. 20 StGB in any case involving a defendant with a psychotic illness, since it is not always possible to distinguish the extent to which the illness alone influenced otherwise apparently normal premeditation and the decision to act. In previous decades, Janzarik developed and advanced a unified position that a graduation of impairment leading to the act is possible and that – particularly in moderately impaired schizophrenic patients – diminished or absence of criminal responsibility should be considered. On the other hand, if a delusional offender proceeds purposefully in a planned manner taking the situation into account, this does not preclude the absence of criminal responsibility; it is in fact characteristic for a particularly dangerous group of violent schizophrenic offenders (see Böker and Häfner 1973) whose external behavior is well organized and who are driven by a delusional system that guides their behavior.

Many crimes committed by individuals with schizophrenia are misdemeanor property offenses committed in the context of social marginalization. The crimes are suggested to these individuals because of their tendency to be easily influenced. In the psychotic context, the crimes may appear to be delusionally motivated calls for help or self-defense in a presumed emergency situation taken against imaginary threateners or persecutors. As a rule, the issue of criminal responsibility for misdemeanors is less compelling that the issue of whether serious offenses can be expected in the future such that hospitalization would be justified pursuant to the German Penal Code (Sec. 63 StGB), the state mental health code, or the law concerning people in need of care.

3.4.8 Crimes with Psychotic Mood Disorders

Patients with psychotic mood disorders such as unipolar depressive or bipolar manic depressive disorders are occasionally charged with criminal offenses. Crimes committed by manic patients, such as embezzlement, falsification of a legal document, or traffic violations, usually result from the diminished ability of the individuals to control their behavior, even though they appear to have been well organized with regard to the questionable transaction. The illness is manifested less by disorganized thought processes and more by pathologically altered mood with resultant abolition of the person's appraisal capacity.

3.4.9 Criminal Forensic Evaluations of Persons with Organic Brain Disorders

In forensic examinations of defendants with organic brain syndromes, the significance of the disorder essentially depends on its severity. These defendants can generally be classified according to a continuum of severity from very mild to extremely profound disturbances. This type of assessment is best performed by

someone with expertise in psychiatry or the treatment of nervous disorders; psychological test data alone, which portray only the defendant's intellectual functioning but not any severe changes in affect and critical capacity, are not sufficient.

3.4.10 Determining Severity

Since the current German insanity law became effective in 1975, determining the severity of any "other serious mental abnormality" within the context of the pathological reference system (Saß 1991) has been difficult. Not all personality disorders or character traits can be subsumed under this concept. Kröber (1995) reviewed the various interpretations of "other serious mental disorder" and proposed a corresponding classification whereby the regulation of self-esteem is constantly threatened by decompensation and persistently points to dangerous psychodynamic mechanisms, especially with flagrant borderline personality disorders and severe sexual paraphilias in which the sexual realm is distorted.

3.4.11 Dissocial Behavioral Pattern

With regard to dissocial behavioral patterns, Saß (1987) differentiated between dissociality as a behavioral pattern, psychopathy as a psychopathological personality construct, and sociopathy as a combination of personality disorder and dissocial behavior. In contrast, the Anglo-American psychopathological concept, at least as presented in DSM-III, DSM-III-R, and DSM-IV, is limited to a personality disorder that leads to criminal or socially destructive behavioral patterns. Of course dissociality only corresponds to the legal concept of "other serious mental abnormality" if it is accompanied by a profound disturbance of the personality and psychodynamic processes that are demonstrated to exist beyond the criminal behaviors alone. The possibility has to be considered that dissocial patterns of behavior can also represent precursors or accompanying phenomena of a psychotic illness. In addition to establishing the presence of other, similar disorders, it is the forensic psychiatrist's responsibility to carefully illuminate the entire spectrum of possible mental disorders from a psychopathological perspective.

3.4.12 Criminal Responsibility in England

The M'Naghten rule (also spelled "McNaughten") or "right-wrong test" derived from a case in England in 1843 by the same name. Still in use over a century and a half later, this standard criterion for the defense of insanity states the following:

> . . . to establish a defense on the grounds of insanity, it must be conclusively proved that, at the time of committing the act, the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or if he did know it, that he did not know what he was doing was wrong.[5]

In order to find a middle option between full responsibility and full punishment, which used to result in death by hanging, and not guilty by reason of insanity, England borrowed from Scotland the principle of diminished responsibility (Briscoe et al. 1993). Diminished responsibility was incorporated into England's Homicide Act of 1957:[6]

> Where a person is party to the killing of another, he shall not be convicted of murder if he was suffering from such abnormality of mind (whether arising from a condition of arrested or retarded development of mind or any inherent causes or induced by disease or injury) as substantially impaired his mental responsibility for his acts and omissions in doing or being a party to the killing.

The definition of "abnormality of mind" was given a broad interpretation by the Court of Appeal in 1960:[7]

> . . . a state of mind so different from that of ordinary human beings that the reasonable man would term it abnormal. It appears to us to be wide enough to cover the mind's activities in all its aspects, not only the perception of physical acts and matters and the ability to form a rational judgement whether an act is right or wrong, but also the ability to exercise will-power to control physical acts in accordance with that rational judgement.

The *Byrne* court opinion allowed less serious mental disorders such as neurotic and character disturbances to be considered for diminished responsibility and opened the possibility of arguing that an irresistible impulse can be used as a partial defense against the charge of murder (Briscoe et al. 1993). If the defendant can prove diminished responsibility "on the balance of probabilities" (equivalent to the U.S. standard proof of "preponderance of the evidence" or over 50%

[5] 8 Eng. Rep 718, 8 Eng Rep 722 (1843).

[6] 5&6 Eliz. 2, Ch. 2, Sec.

[7] *Regina v. Byrne* 2 QB 396 (1960); 3 All ER 1 (1960); 44 Cr App Rep 246.

certainty), the defendant can be convicted of manslaughter rather than the more serious offense of murder. Diminished responsibility is now more the rule and not guilty by reason of insanity the exception as a defense and verdict in England.

3.4.13 Criminal Responsibility in Canada

Unlike the United States, where states and federal jurisdictions have developed their own rather diverse insanity laws, Canada has a single insanity law that is followed in all provinces. In 1992, the aforementioned revised Criminal Code (see above) produced substantial changes. Whereas under the previous code, either the prosecution or the defense could raise the defense of insanity before the trial, to prevent potential abuses, the revised code restricts the prosecutor from raising the issue until after the defendant has been judged guilty of having committed the offense. The term "insanity" was replaced by "mental disorder" and "not guilty" by "not criminally responsible." The Canadian insanity verdict is now termed "not criminally responsible on account of mental disorder" (Davis 1993).

The criteria for not criminally responsible on account of mental disorder are not specified in the Criminal Code, because they have been established through case law which generally follows the *M'Naghten* right-wrong test. Until the Supreme Court of Canada's *Regina v. Chaulk* decision[8] in 1990, "wrong" was interpreted to mean legally wrong; however, in this decision, the High Court broadened the definition to include morally wrong as well.

3.4.14 Criminal Responsibility in the United States

Insanity jurisprudence in the United States is complicated by jurisdictional differences. Each of the 50 states, the District of Columbia, and the Federal Government has its own separate insanity law. To simplify, basically four standards or variants thereof have been codified or established by court opinion: the American Law Institute (ALI) insanity test, the M'Naghten test, the product test, and the *mens rea* approach.

Mentioned first because of its remarkable similarity to the two-pronged test of insanity in Germany, the ALI test was proposed in 1955 by the American Law Institute in its Model Penal Code:[9] "A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality (wrongfulness) of his conduct or to conform his conduct to the requirements of law." The second paragraph of the ALI test was intended to exclude antisocial personality disorder as a mental condition qualifying for the insanity defense (Elliott 1996): "As used in this article, the terms 'mental illness or defect' do not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct" (American Law Institute Model Penal Code). Twenty states and the District of Columbia use the ALI test or a modified ALI test (Steadman et al. 1993).

For the first half of the 20th century, the M'Naghten rule was essentially the law of the land in the United States, having been adopted by all but one jurisdiction, the state of New Hampshire (see below). Besides the United States, where 26 states now have a M'Naghten or modified M'Naghten test, England, Canada, Australia, and New Zealand also use the M'Naghten test for insanity (Elliott 1996).

In 1869, the New Hampshire Supreme Court adopted a product test of insanity in contrast to the more widespread acceptance of the M'Naghten test in other states. From the beginning of this century, when most states followed the M'Naghten test, up to the present, with a mosaic of different tests, New Hampshire has used the *product* test. According to this test, a murder defendant is to be acquitted if the homicidal act was the offspring or product of mental disease.[10] Since 1989,[11] however, the insanity test in New Hampshire is "whether insanity negated criminal intent";[12] and this insanity test leaves to the jury to formulate *how* mental illness negated *mens rea* in a particular case.

Finally, four states have now abolished a special defense of insanity: Idaho, Montana, Nevada, and Utah. In these states, at least theoretically, the defendant can still offer a mental illness-related defense by attempting to prove the absence of the requisite *mens rea*. Curiously, research by Steadman et al. (1993) showed that, at least in Montana, mental illness dispositions and diversions from criminal punishment continue unabated, even though a special defense of insanity no longer exists in that state, i.e., diversions are accomplished by a finding of incompetency to stand trial followed by dismissing the charge and civil commitment (Steadman et al. 1993).

It should be noted that the German insanity law would permit a severe personality disorder or a severe paraphilia as a condition which can satisfy the diagnostic criterion for the defense of insanity. In the United States, the second paragraph of the ALI test is

[8] 62 C.C.C. (3d) (1990).

[12] New Hampshire Statutes Annotated 628.2 (11).

intended to exclude personality disorders, and some state insanity laws explicitly exclude personality disorders. Likewise, some state insanity laws clearly bar paraphilias for consideration. It is the forensic psychiatrist's task to examine both the diagnostic and functional elements of the insanity test that pertains to the case in question and then to follow the two-step evaluation process.

3.4.15 Diminished Capacity

About one third of the states have adopted the diminished capacity principle (Slovenko 1995). Unlike diminished responsibility in England, Germany, and Scotland, which have a special diminished responsibility defense, diminished capacity is established by showing the defendant lacked the requisite *mens rea*. This approach is typically used as a defense against a murder charge, which requires specific intent to commit murder. If psychiatric testimony demonstrates that the defendant did not have the mental capacity to commit murder, i.e., the capacity to form the specific intent to commit murder, he or she may be convicted of the less serious offense of manslaughter instead. In California, the court-formulated diminished capacity doctrine fell into general disfavor and was replaced by the California legislature with the principle of diminished actuality. For a successful plea, the defendant must show that he or she actually did not form the specific intent. Because of the variation in rules governing diminished capacity and actuality in different jurisdictions, forensic psychiatrists need to familiarize themselves with the relevant statutory and case law (Miller 1994).

3.4.16 Heat of Passion and Extreme Emotional Disturbance Defense in the United States

The legal concept of "heat of passion" has long been used in the United States to reduce murder, a capital offense, to manslaughter or a similar, less serious offense. Defendants must establish that they were under the influence of heat of passion when they committed the act, that a normal person would respond similarly to the sequence of events that led to the heat of passion, and that there was no time from the provocation to the act in which to "cool off" (Goldstein 1989). It should be noted that no mental disorder is presumed because the emotional and behavioral reaction are considered to be "normal."

From this "heat of passion" concept, however, several states have adopted a broader and more formalized defense that allows for some degree of psychological disturbance, the "extreme emotional disturbance defense." New York's extreme emotional disturbance defense is often cited as an example. The state's revised penal code of 1967[13] allowed this defense where the defendant committed the act while under an extreme emotional disturbance, and "there must be a reasonable explanation or excuse, the reasonableness of which is to be determined from the viewpoint of a person in the defendant's situation under the circumstances as the defendant believed them to be" (p. 107). Pursuant to an opinion of the New York Court of Appeals (New York's highest court), a defendant could advance this defense if he or she suffered a "significant mental trauma" that can last for a while and then erupt unexplainably, resulting in the homicidal act.[14]

3.4.17 Guilty but Mentally Ill

About one quarter of the states (Slovenko 1995) have adopted a "guilty but mentally ill" verdict to address gray areas and ensure that defendants who were mentally ill at the time of the offense but did not qualify for the defense of insanity would receive both treatment for their mental disorder and punishment for committing the crime. Michigan was the first state to adopt this verdict, and its statute is the prototypical model, although significant variations are seen in the laws of other states on the verdict of guilty but mentally ill. Criteria for this finding of guilty but mentally ill in Michigan are as follows:

1. The defendant is guilty of an offense
2. The defendant was mentally ill at the time the offense was committed
3. The defendant was not legally insane at the time the offense was committed[15]

All three criteria must be proven beyond reasonable doubt. Even though one of the purposes of legislation on the verdict of guilty but mentally ill was to limit the number of insanity acquittals, most states with an option of a guilty but mentally ill verdict have retained the defense of insanity as well. Typically, a test of mental illness to establish whether a defendant is guilty but mentally ill is specified that is less stringent than the insanity test. For example, if the state uses the M'Naghten rule for its insanity test, the test used to establish presence of mental illness at the time of the act for a verdict of guilty but mentally ill is essentially the ALI test.

[13]New York Penal Law §125.25, subd. L. par. [a]; §125.27 subd. 2 par. [a] (1967).

[14]*People v. Patterson*, 383 N.Y.S. 2d 573 (1976).

[15]Mich. Comp. Laws §768.39; Mich. Stat. Ann §28.1059 (1985).

It should be emphasized that a verdict of guilty but mentally ill (unlike not guilty by reason of insanity, diminished capacity, and extreme disturbance defense) neither mitigates criminal responsibility nor reduces the punishment. Defendants found guilty but mentally ill must serve their complete prison sentence as if they had simply been found guilty of the offense. The fact finder, however, knows by the verdict itself that the defendant will be hospitalized as long as the severity of his or her disorder warrants this intensity of treatment, at least within the parameters of the prison sentence.

3.5 Competency to be Sentenced

3.5.1 Competency to be Imprisoned in Germany

In Germany, competency to be sentenced is, more specifically, competency to be imprisoned. This is "the capacity of an accused or convicted to be able to live in a facility within the prison system, to endure loss of freedom without special or serious danger to health or life, and to recognize the meaning and purpose of serving a prison sentence." Determining whether someone is competent to be imprisoned is a legal decision that is only partially based on medical findings.

A distinction should be made between illnesses that appear *before* pretrial confinement and those illnesses that begin during imprisonment. The issue is regulated by the German Code of Criminal Procedure (Sec. 455 StPO):

1. The execution of a prison sentence is to be removed if the convicted person becomes mentally ill.
2. The same is true for other illnesses if danger to the convicted person's life is expected to be caused by imposition of the punishment.

In these cases, lifting the order for detainment is therefore urgent. If the mental illness appears during confinement, then an optional regulation applies according to the German Code of Criminal Procedure (Sec. 455(4) StPO): The prison authorities *can interrupt* the execution of a prison sentence if (1) the sentence causes decompensation of the mental illness, (2) because of an illness, execution of the sentence would endanger the life of the convicted person, or (3) the convicted person becomes seriously ill and the illness cannot be recognized or treated in a prison unit or prison hospital, and the illness will likely continue to exist for a substantial period of time. If public safety is a compelling reason for continued confinement, then interruption of the prison sentence is not permitted (authors' italics). If public safety concerns contraindicate release from prison, treatment of the mentally ill prisoner must be carried out in a prison hospital.

The above-mentioned regulations are valid for convicted criminals. Psychiatrically determined incompetency to be imprisoned during detainment for pretrial investigation is to be substantiated with an illness which necessitates acute treatment in a hospital, such as florid psychosis or serious psychotic depression. If there is also substantial danger to the defendant, then admission to the psychiatric clinic of a prison or to a special security hospital should be considered in accordance with the German Code of Criminal Procedure (Sec. 126a StPO). The same applies for acute, potentially life-threatening alcohol withdrawal syndrome (delirium tremens) and conditions of intoxication requiring intensive observation that cannot be provided in a prison infirmary or prison hospital. For such serious conditions, treatment is more sensibly accomplished in a hospital setting. In contrast, conditions such as personality disorders, substance abuse, reactive depression, suicidality, and claustrophobia do not constitute incompetency to be incarcerated.

3.5.2 Competency to be Sentenced in the United States

Incompetency to be imprisoned is recognized in the United States but rarely applied in practice. In principle, if continued confinement would cause the individual's condition to deteriorate, he or she could be found incompetent to be imprisoned (Sadoff 1988). If a prison detainee requires psychiatric hospitalization prior to trial, this is more typically handled by one of the following actions: dismissal of criminal charges followed by civil commitment, adjudication of incompetency to stand trial followed by hospitalization to restore fitness, or transfer to a hospital under police supervision. In none of these examples is the defendant found by a court to be incompetent to be imprisoned. Prison systems typically have prison hospitals for mentally ill offenders. A court hearing is required before a prisoner can be transferred to a psychiatric hospital,[16] not to determine competency to be sentenced, but rather to establish legal criteria for hospitalization which correspond to criteria for involuntary civil commitment of nonprisoners. If a prisoner or a jail inmate requires hospitalization for surgical or medical treatment, this is arranged without a hearing to address competency to be sentenced. Occasionally, prisoners can be released prior to having completed their sentence if they suffer from a chronic, debilitating illness where near death is foreseeable, but this is handled more as a formalized act of mercy.

Thus, while the German model emphasizing competency to be imprisoned serves to protect the

[16] *Vitek v. Jones*, 445 U.S. 480 (1980).

mentally ill prisoner's right to necessary hospital treatment, the U.S. model protects prisoners from treatment that may not always be desired by the prisoners themselves.

3.5.3 Competency to be Executed in the United States

The United States Supreme Court held in *Ford v. Wainwright*[17] that the execution of an incompetent person violates the Eighth Amendment of the United States Constitution, which prohibits cruel and unusual punishment. The Council on Ethical and Judicial Affairs of the American Medical Association expanded the AMA ethical code's prohibition against participation in legal executions to include treating a prisoner for restoration of competency to be executed. An exception to this prohibition is if treatment is necessary to relieve the prisoner from "extreme suffering" caused by his or her illness. Although testimony regarding competency is not unethical, "a physician cannot be compelled to provide medical testimony as it relates to legal competency for execution if it is contrary to the physician's personal beliefs" (Council on Ethical and Judicial Affairs 1996/1997, p. 12).

CHAPTER

17

J. Arboleda-Flórez

Treatment and Care of the Mentally Abnormal Offender

1 Introduction

For centuries, there has been a relationship between medicine and law, specifically in relation to the treatment and care of the mentally ill offender. Ancient texts and codes such as the Baba Ramma, the Deuteronimus or the Justinian Code already make reference to individuals who, because of particular characteristics regarding their mental make up, had to be afforded special protection under the law (Arboleda-Flórez 1989). *Furiosus satis ipso furore punitor* ("the madman is sufficiently punished by his madness") is a dictum attributed to Marcus Aurelius. In the Nicomachean Ethics, Aristotle (1941) exhorted legislators to consider, when assigning punishment for an illegal action, whether the action was carried out by a madman, whom he called "ignorant". In English law, Bracton may have been the first legal scholar to attempt to identify the degree of legal impairment needed to exculpate an offender. In the first systematic treatise on English Law, written in the thirteenth century, he stated that "an insane person is one who does not know what he is doing and is lacking in mind and reason." Bracton's influence is still felt today, as his concept of "does not know" is the basic formula in the McNaghten rule. This rule, according to which an accused may be found not guilty because of a mental disorder, was developed in England in 1843 and has remained, with some variations, one of the most important medico-legal concepts in the majority of the commonwealth countries (Guttmacher 1968).

More recently, the growing number of legal cases involving individuals suffering from mental disorders or conditions that affect their emotional well-being has given rise to a body of jurisprudence that touches on practically every facet of the interface between psychiatry and the law. The study of this interface is the subject matter of forensic psychiatry.

Forensic psychiatry, as a subspecialty of psychiatry, provides methodologies for the assessment of individuals who are presumed to have some mental condition and who are caught in the midst of criminal or civil law proceedings. Among other topics, forensic psychiatry is concerned with the assessment of fitness to stand trial, criminal responsibility or dangerousness in criminal law and testamentary capacity, civil liabilities or the assessment of competency in civil law (Arboleda-Flórez and Copithorne 1996).

Past the legal entanglements, however, a number of mentally ill individuals end up in the correctional system, either detained while awaiting trial or after adjudication. The latter would include those found not criminally responsible because of mental disorder (NCRMD) or those who were simply found guilty and sentenced to a term of imprisonment, regardless of the existence of a mental problem. In addition, because prison environments tend to be pathogenic, mental illness might develop de novo while the person is incarcerated. In other cases, the natural history of mental disorders may interact with long sentences so that the probability of an inmate developing a mental illness at a particular age means that the illness will materialize while the person is in prison. Equally, a person with a history of mental illness who was well at the time of being sentenced to a prison term may experience a relapse while in prison. Thus prison environments contain individuals who were mentally ill at the time of arrival and individuals who were well on arrival, but subsequently relapsed from a previous mental condition or developed a mental condition while in prison.

Corrections, a branch of the criminal justice system, involves "all agencies of social control which attempt to rehabilitate and neutralize deviant behaviour of adult criminals and juvenile delinquents for the protection of society" (Kruzich 1982). The study of how the mentally abnormal offender is handled within correctional settings is the purview of correctional psychiatry, which in the strictest sense refers to psychiatric practice in the corrections system (Travin 1994). More specifically, correctional psychiatry could be defined as the branch of forensic psychiatry that studies the incidence, prevalence, determinants and management of mental disorders in prisons, the response of correctional systems to the mentally ill offender and the relationship between criminality and mental illness. The epidemiology of mental disorders in judicial/correctional systems is covered in the chapter by Konrad (Vol. 3, Chap. 20). The present chapter will deal more specifically with the management of the mentally ill within the system, including community corrections, and issues pertaining to the relationship between mental illness and criminality.

2 Relationship Between the Legal and the Mental Health Systems

The mentally ill and, by extension, mental health professionals interact with legal systems at practically every junction of the different components of the system, be it law enforcement, administration of justice or correctional systems (Fig. 1). The close relationship between the two systems is dictated by the intrinsic needs of the population served by both psychiatry and corrections. In some communities, the transfer of patients back and forth between the two systems

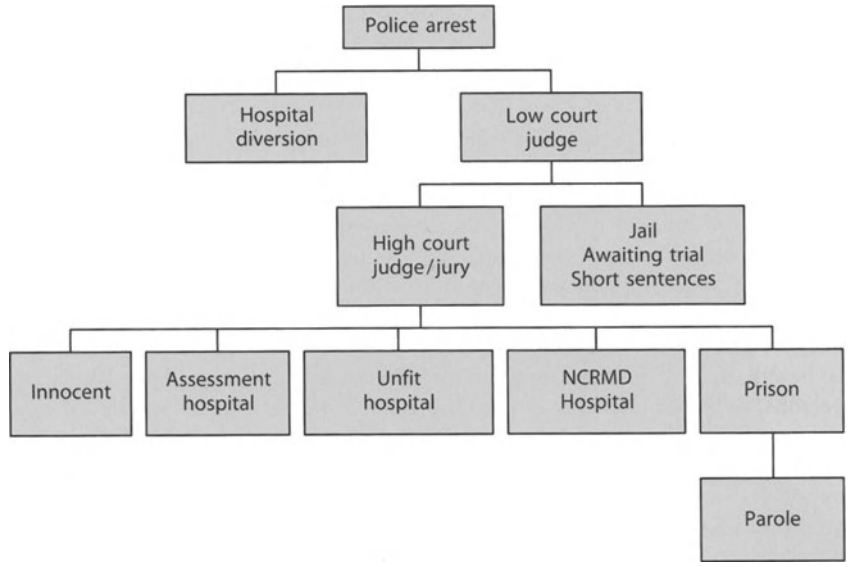

Fig. 1. Legal pathways of arrested individuals. *NCRMD*, not criminally responsible because of mental disorder

makes the correctional system, particularly jails, part and parcel of the mental health system.

2.1 Detention

In many jurisdictions, as a result of minor infractions or when public behaviour is obviously aberrant, police forces have the option to convey mentally abnormal individuals to a mental hospital or to a psychiatric emergency unit for an examination as an alternative to laying criminal charges. For example, in the Province of Alberta in Canada, the Mental Health Act (1992) gives specific powers to a police officer to bring the person for an examination to the emergency unit of a local hospital if the person was acting in a public place in such a manner that, in the opinion of the police officer, the person's behaviour was abnormal. Similar legislation exists in many other jurisdictions in Canada, in the United States (Godschalx 1984; Janus et al. 1980; Matthews 1970) and in other countries. In Jamaica and in the Commonwealth of Dominica, an island state in the Caribbean, the Pan American Health Organization has been involved in the training of policemen as mental health officers in order to extend the reach, the capabilities and the manpower of the mental health system. Policemen in these two countries are given ongoing training on basic mental health concepts, identification of mental problems among detainees, mental health resources and mental health legislation (Arboleda-Flórez and Crisanti 1996).

Powers vested on police officers under these circumstances allow them to circumvent the judicial system and to divert the person directly to the mental health system. Police officers become an extension of the mental health system. Studies have indicated that, given their familiarity with individuals who display abnormal behaviour, police officers can be relied upon to make this type of judgment (Holley and Arboleda-Flórez 1988; Bittner 1967; Teplin 1983).

The failure of de-institutionalization policies in the face of inadequate community resources makes it necessary for the mental health system to utilize other community agencies, such as the police force, to help the mentally ill person in the community. To allow police officers to be part of the mental health system helps prevent further criminalization of the mentally ill and is one of the ways of dealing with the mentally ill offender in the community. The role of the police officer, however, is limited to bringing the person to a hospital; it is the responsibility of clinicians at the hospital to make decisions on further management. The clinical team at the hospital, for example, could make arrangements for outpatient follow-up, the level of community supervision or admission to hospital, either voluntarily or by invoking the commitment powers vested on clinicians within the Mental Health Act or similar legislation.

2.2 Community Disposition

To prevent the revolving door phenomenon and, at the same time, maximize treatment opportunities and provide a modicum of protection to the community, several jurisdictions have implemented outpatient commitment legislation (Hiday and Scheid-Cook 1987, 1989; Scheid-Cook 1987; Miller 1992; Swanson

et al. 1997). Under this type of legislation, the court places an accused on probation on condition of treatment, or a physician discharges the patient to the community on a certificate that enjoins the patient to continue attending treatment and receiving medication for a specified period of time, usually 1–2 years. Case management, where a mental health specialist follows a few number of cases in the community and brokers their social and treatment needs, is usually a strong component of outpatient commitment. Patients are reported back to the court or brought back to the hospital if they fail to comply. Outpatient commitment is based on the premise that seriously mentally ill persons, because of delusions and other symptoms, do not have the ability to make decisions on their need for treatment and do not avail themselves of treatment opportunities. According to some authors, this failure to take advantage of treatment opportunities constitutes a denial of the patient's right to be treated and has negative impacts such as relapses or incarcerations (Bluglass 1993; Royal College of Psychiatrists 1993). Outpatient commitment is, therefore, promoted as an alternative to imprisonment and as a preventative step to avoid relapses or criminalization. This treatment alternative, however, has been criticized on the basis that it presents a threat to civil liberties (Fulop 1995).

2.3 Sentencing

Working arrangements between the police and local hospitals are difficult to implement as they require administrative mechanisms and previously organized payment systems (Borzecki and Wormith 1985; Arboleda-Flórez and Holley 1988). Thus, more frequently, and especially if the charge is of a serious nature, police follow the justice route and bring mental patients to local police lockups, jails or remands centres. Some of these patients may be found not fit to stand trial and sent for assessment and treatment to specialized institutions, from where they are supposed to return to court once their mental conditions stabilize. Later on, during their trial, some of these patients may be found to be not criminally responsible because of mental disorder and sent, according to local laws, for indeterminate periods of time to mental hospitals, special hospitals or special wings in a penitentiary (see Sect. 3). On the other hand, despite the presence of a mental condition, a mental patient may still be found guilty and sentenced to a prison term. These mentally ill offenders tend to suffer from chronic mental problems and are usually found in remand centres or local jails, either because they are detained while awaiting their legal disposition or because they are sentenced to short periods of incarceration. Medium- and maximum-security prisons usually house inmates who have been sentenced to long terms for offences somehow related to abnormal behaviour (antisocial, psychopathic), sexual deviations or addictions that would inevitably bring them into conflict with the law.

Research and the management and treatment of the mentally ill in prisons have a long tradition. For example, considerable research has been conducted in Germany since the 1850s on suicide, the prevalence of mental conditions among prisoners and the influence of the prison environment as a risk factor in psychiatric illness. Ganser syndrome (Ganser 1898) and the term "prison psychosis" originated from this research (Travin 1994).

3 International Perspective

3.1 Canada

In 1992, the Parliament of Canada enacted legislation to amend the dispositions contained in the Criminal Code regarding the management of the mentally abnormal offender. The new law, colloquially known as Bill C-30 (Government of Canada 1991), stipulates that accused individuals who appear to be mentally ill should undergo an assessment as ordered by the judge in no longer than 5 days to determine whether they are mentally ill and, if so, whether they are fit to stand trial. These assessments could be conducted on an in-patient or out-patient basis, depending on the severity of the suspected mental problem and/or the seriousness of the charge. At the request of the psychiatric facility, an assessment could be extended to 1 month and, in special cases, to a maximum of 2 months.

The courts cannot order treatment during the period of assessment, but if treatment is necessary, it is offered on the expectation that the person will consent. If the person refuses and is deemed to be representing a danger to self or others, the psychiatric facility can "commit" the person under the mental health act of the particular province, declare the person incompetent and proceed to forced treatment. The protection of rights is taken into account, and "committed" individuals can appeal their commitment order to an outside hospital tribunal. Following the assessment, the accused could be diverted to the mental health system entirely without any legal encumbrances or sentenced to a probation period on condition of treatment.

If the person is found not fit to stand trial, he or she is sent to a specialized mental hospital for treatment and

is expected to return to court to face the charges once improvement has been achieved. Those found to be not criminally responsible because of mental disorder are also sent to a specialized mental hospital for an indeterminate period of time, but their stay and progress are closely monitored by quasi-judicial tribunals established in each one of the provinces. These tribunals have the power to discharge individuals not criminally responsible because of mental disorder to the community under strict guidelines for treatment. Eventually, it is possible that an individual not criminally responsible because of mental disorder may be set free without any legal restrictions.

A novel disposition in this law is "capping", which means that individuals who are not criminally responsible because of a mental disorder cannot spend more time in a mental institution that the time they would have spent in a prison had they been found guilty of the charge. On the other hand, a controversial section of the law pertains to a finding of "mentally ill and dangerous". Prisoners who fulfill the criteria for this finding are committed to a mental hospital after expiration of their sentences. In Canada, the law does not make any reference to particular types of mental disorders such as psychopathy, alcoholism or drug addictions. Rather it has a general rule, a modification of the McNaghten rule (see Sect. 3.5), to determine the level of incompetence required before an offender can plead not criminally responsible.

Finally, the legislation allows for "hospital orders", but unfortunately, this disposition has not yet been enacted. The health care system and mental health professionals have expressed concerns about the cost and the risk of mixing these patients with "regular psychiatric patients".

3.2 Germany

In Germany, the law of 1975 stipulates that mentally disordered offenders convicted of an imprisonable offence be sentenced by means of a "hospital order" instead of incarceration. According to Article 63 of the Penal Code, the courts have the power to commit an offender to a psychiatric hospital, and under Article 64 to an institution for the treatment of addicts (Konrad 1993). The law does not prescribe the length of stay in the hospital, but the courts retain jurisdiction over these type of offenders and review their progress every year. Commitment of this nature is envisioned when the objective evidence satisfies the definition of the offence, when the condition is of long duration (chronic), when a link can be established between the particulars of the offence and the symptoms, when there is a probability of re-offending, especially if recidivism can be tied to the symptoms, and if the severity of future offences and hence the risk to society are assessed as considerable. These findings will also reduce the level of criminal responsibility ascribed to the accused.

Basically, German legislation requires that, in order to be found not criminally responsible, the offender has to possess a "severe mental abnormality". More specifically, however, criminal responsibility is assessed in two stages. Firstly, it has to be determined whether the accused was suffering from a "severe mental abnormality" at the time of the offence, and secondly, whether the accused had the capacity to judge the wrongfulness of the criminal act or had a capacity to act in accordance to his or her judgment (Rasch 1990). In fact, a third step seems required in that the expert is expected to determine the potential future risk the accused presents to the community. Treatment is provided from large specialized forensic hospitals or from small forensic wards located in general hospitals (Nedopil and Ottermann 1993).

As in Canada, the mental health system and forensic mental health professionals in Germany are concerned with the type and the large number of these patients in mental institutions. For example, it is considered that 27% of judicial committals are "unjustified" and dictated more by legal or social reasons than by clinical needs (Konrad 1993). The effect of hospital orders has been to treat "a heterogeneous population diagnosed with various psychiatric disorders and who have committed different types of criminal behaviour", including "personality-disordered and sexual deviants". This state of affairs has led forensic hospital directors to recommend that treatability and willingness to undertake treatment be made key factors to commit personality-disordered individuals to forensic facilities (Muller-Isberner 1996).

3.3 Italy

The new Italian Penal Code, which replaced the one in existence for 65 years, has kept the old provisions for total and partial insanity. Although it allows for a psychiatric perspective concerning the assessment of criminal responsibility (Ceretti and Merzagora 1994), it does not provide for procedures and factors to be considered in its determination. The Code establishes that a judge should decide whether to commit an offender for custody and treatment to a criminal psychiatric hospital. A very liberal section of the Code would allow for "house detention" if the sentence was less than 3 years of imprisonment and if the offender is suffering from "particularly serious health problems" (De Fazio 1996).

3.4 Japan

The Mental Health and Welfare Law of 1995 makes available to the mentally disordered those services previously available only to the physically disabled and the mentally retarded (Sakuta 1996a). Correctional facilities are staffed with physicians and other medical specialists, and some of these facilities are accredited as hospitals under the Medical Services Law (Sakuta 1996b). Japanese offenders may be found to be "not criminally responsible" and be fully acquitted, "partially criminally responsible" and receive a reduced sentence, or "fully criminally responsible" and punishable. Offenders found "not criminally responsible" on account of a mental condition are admitted to a psychiatric facility. Psychiatrists are usually charged with the responsibility of releasing these patients and setting up the discharge conditions. Unfortunately, these individuals are not required by law to report for treatment and tend to relapse and commit further offences (Sakuta 1996c).

3.5 United Kingdom

As a matter of policy, every effort is made in England and Wales to divert the mentally ill to the mental health system (Home Office 1990). However, most diversion is accomplished after conviction via hospital orders as an alternative to imprisonment. Baker (1996) indicates that The Insanity and Unfitness to Plead Act of 1991 establishes that those defendants who are found not criminally responsible should not be detained for an indeterminate period of time, as was the only possible disposition before, but rather an array of dispositions are now available and left to the decision of hospital authorities subject to consent by the Secretary of State.

The new dispositions still use the McNaghten rule, which states that "to establish a defense on the ground of insanity, it must be clearly proved that, at the time of the committing of the act, the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong" (*R v. McNaghten* 1843).[1] Under this rule, "disease of the mind" has been understood to have been caused by an "internal factor" (*R v. Quick* 1973),[2] and "wrong" means "legally wrong" (*R v. Windle* 1952).[3] The new law "equips the courts with the ability to tailor their response to the particular case before them in terms of treatment needs and the interests of public protection" (Baker 1996).

3.6 United States

The acquittal of John Hinckley by reason of insanity of the shooting of President Ronald Reagan caused a major shift in the population against the insanity defence. This has resulted in a variety of legal tests and sentencing dispositions that change from state to state. Thus, between 1982 and 1985, 34 states revised their insanity defence statutes (Callahan et al. 1987), and by 1995, Montana, Idaho, Utah and Nevada had abolished the special plea of insanity. Nevada, for example, created a "guilty but mentally ill" clause and provided involuntary treatment for these defendants, regardless of their competency, and in Colorado, persons found "not guilty by reason of impaired mental condition" are committed indefinitely to the state forensic hospital (Miller 1996b).

Following legal practice in the United States, management and treatment of the mentally disordered offender are decided not by national legislation, but by legal precedent. As such, legal bases exist that enjoin states to provide mental health services in jails and prisons and that stipulate the required components and standards for these services (O'Leary 1989). A convicted inmate's right to medical and psychiatric treatment in prison is guaranteed by the Eighth Amendment of the United States Constitution, which prohibits cruel and unusual punishment (Dvoskin 1994). In *Estelle v. Gamble* (1976),[4] this prohibition was constructed to mean an obligation to avoid "deliberate indifference" to serious medical needs of inmates. Based on the legal precedent established by *Ruiz v, Estelle* (1980),[5] Cohen listed six essential components for the planning of mental health services in prisons. These include the following: (1) systematic screening and evaluation, (2) treatment that is more than mere seclusion or close supervision, (3) participation of mental health professionals, (4) accurate, complete and confidential records, (5) safeguards and regulations for the use of psychotropic medications and (6) suicide prevention programmes (Cohen 1988). Several national organizations, notably the American Correctional Association, the American Public Health

Association and the Joint Commission on Accreditation of Health Care Organizations, have produced standards that, according to Anno (1994), are not perfect, but tend to complement each other.

4 Relationship Between Mental Illness and Criminality

Mental illness is expressed through behavioural manifestations. Mental conditions affect the cognitive, emotional and volitional aspects and functions of the personality. These are the very functions that the law considers essential to assess in order to adjudicate guilt, label the accused a criminal and proffer a sentence. When a mental condition is suspected in relation to a crime, the unstated assumption is that the condition preceded, and possibly, caused the crime. However, the clinician and the epidemiologist conducting prevalence studies and assessing the relationship between mental conditions and criminality have to keep in mind that mental illness may develop after a crime has been committed. The study of the relationship between mental illness and criminal offences (defined as unlawful acts, by commission or omission, leading to an arrest), therefore, is extremely difficult. This is more so if the researcher or clinician intend to establish a causality link between the two. Much work remains to be done in this area.

4.1 Relationship Between Behavioural Manifestations and Criminality

In general, mental conditions can be related to crime and this is a fact acknowledged by law. The problem, however, is not that the two elements converge, but what the degree of relatedness is between the two and whether a causal connection can be established. In regard to the degree of connectedness, for example, there are mental disorders whose very behavioural manifestations become, ipso facto, a criminal offense. In other words, the semiography of the disorder connotes a criminal act. Such is the case of most of the paraphilias (e.g. exhibitionism, voyeurism, paedophilia), pyromania, kleptomania and others. In these cases, it could be determined that the relationship between mental disorder and criminality is absolute.

Other disorders such as antisocial personality, borderline personality, pathological gambling and impulse control disorders connote a criminological element, but the degree of relatedness is not one to one in that their symptoms could be expressed without necessarily breaking the law. While not all alcoholics end up breaking the law, alcoholism carries a high risk of law-breaking in the form of victimization at the time of intoxication (Pihl and Peterson 1993). Other substance dependencies are known to lead to income-generating crimes in order to finance the habit. Results of the research by Hare and Hart (1993) suggest that psychopathy is strongly associated with a high risk for criminal and violent offences. On the other hand, many mentally ill individuals never commit a criminal offence and many types, perhaps the majority, of mental disorders do not necessarily lead to criminal offences, even despite the high prevalence of mental disorders in the general population.

4.2 Mental Illness and Violence

Lately, the literature seems to provide support for the proposition that there is more than a correlation between mental illness and criminality. For example, Hodgins (1993) followed up a 30-year birth cohort in Sweden and reported that a relationship existed between crime and mental disorder and between crime and intellectual deficiency, with men who had a mental disorder being 2.5 times more likely to have been registered for a criminal offence and four times more likely to have been registered for a violent offense than men not mentally ill or intellectually handicapped.

On the matter of mental illness and violence, Monahan (1992) has reasoned that factors such as socio-economic status and institutionalization should be considered integral components of mental disorders and should not be controlled when studying the association. Previously, these factors had been considered confounders and had been statistically controlled. This type of reasoning and research findings have led some authors to conclude that a strong, and potentially a causal, relationship exists between mental illness and violence (Link and Steuve 1996).

More specifically, on the issue of the degree of causality, studies that have linked mental illness to violence have been criticized on multiple methodological grounds, especially because of selection biases or lack of proper controls for confounding factors. Mental conditions co-morbid with alcohol and substance abuse, however, present a higher risk for violent offences. In a thorough review of the literature on mental illness and violence, Arboleda-Flórez et al. (1998) concluded that "as yet, there is no consistent evidence to support the hypothesis that mental illness, uncomplicated by substance abuse, is a significant risk

factor for violence or criminality, once past history of violence is controlled".

4.3 Potential Impact of a Finding of Causality

A conclusion that more than a statistical correlation exists between mental conditions and criminality, and especially between mental illness and violence, will undoubtedly increase the stigma against mental patients. Under the guise that they are dangerous to be released into the community, such a conclusion will lead to an increase in the number on mental patients sent to prison and in the length of time they remain incarcerated.

5 Systems Issues and Correctional Response

5.1 Burden of the Mentally Ill in Prisons

The proportion of individuals who are seriously mentally ill in prison, although small compared to the general number of prisoners, constitutes, nonetheless, a sizeable number at any given time (Arboleda-Flórez 1994). These individuals have to be housed in an institution that is not typically mandated, or funded, to provide clinical services. Resources for their care have to be placed in the balance with other health priorities and issues in the prison system, such as treatment for acquired immunodeficiency syndrome (AIDS), hepatitis, tuberculosis or sexually transmitted diseases.

Mental patients in prisons represent a burden to the system in that, apart from the need for regular clinical medical and nursing services, they require specialized correctional measures to protect them from suicidal behaviour, from being abused or assaulted by other inmates or from becoming assaultive towards others. Clearly, these patient/inmates require extra services and staff attention, which, given the type of institution, will never be of the quality to be expected from mental hospitals or psychiatric units in general hospitals.

5.2 Organizational Models

These difficulties and problems in the management of the mentally ill in prison have led to the development of several organizational models for the delivery of mental health services in the institutions (Table 1).

Table 1. Models for the delivery of mental health services in prisons

Ambulatory treatment	Mental patients remain with other inmates in the regular cells and tiers of the prison
Special wing within the prison	Mental patients are transferred to this wing, usually for the duration of their incarceration
Specialized security hospitals	Mental patients are transferred out to these hospitals, usually for the duration of their incarceration
Contractual arrangements with outside psychiatric facilities	Mental patients are transferred out to these hospitals or psychiatric units
Forensic community corrections	Every effort is made to prevent mental patients from entering the prison system or, if released from prison, to ensure that they do not go back

The first model opts to keep the patients with the rest of inmates. Ordinarily, this model is prompted by the lack of appropriate facilities in the outside community or the lack of appropriate resources within the system. Under this model, it would be expected that normal inmates will learn to live with the eccentricities and bizarre behaviour of the mentally ill and that the latter will learn to modify and control to some extent their behaviour given the response they receive from the other inmates. Needless to say, this model leads to abuse of the mentally ill and has a negative impact on the guards, who have to be constantly aware of the potential for disruption. In addition, the model presents a potential source of civil liability against the authorities in the prison.

The second model seeks to segregate the mentally ill in special units within the prison. These units are expensive because they have to be staffed, in accordance to their functions, with appropriate number of nurses and correctional officers. These units are often open to abuse of the rights of other inmates, because inmates who are not mentally ill but simply disruptive and unruly could be transferred to the "special unit" for "special handling", meaning being placed under chemical control with medication. These units, therefore, may become the repository of inmates who present disruptive disciplinary problems, whether or not caused by a mental condition. Thus these units can mix treatment needs of the mentally ill with punishment for unruly prisoners. As could be expected, the collusion between the aims of corrections (control and punishment) and the aims of psychiatry (treatment, care and rehabilitation of the mentally ill offender) has brought much criticism and disrepute to psychiatric interventions in prisons.

A third model, special security hospitals, is a variance of the specialized unit within the prison and is subject to the same pressures. These institutions, "maximum-security hospitals", however, offer the advantage that they could be used to house sexual offenders and highly violent individuals who are transferred there to receive specialized treatment or sometimes merely for security reasons. For example, sexual offenders are sent to specialized hospitals not only for treatment but to protect them from other inmates. Similarly, violent offenders are usually sent both for treatment and to keep them away from other inmates who cannot protect themselves from their assaultiveness. Many maximum-security hospitals are, in fact, built for this specific purpose.

Unfortunately, special hospitals tend to develop an affinity for the treatment of serious criminals, sexual offenders or violent individuals and tend to forget the chronic mental patient who also may become a target of abuse at the hands of those in the first group. The confluence between clinical treatment needs and treatment for criminality proper, and the usual lack of autonomy from the prison services, have made these institutions a matter of concern. In fact, several special security hospitals have been involved in controversy because of the use of unorthodox therapeutic modalities, especially behaviour modification techniques or psychosurgery.

Finally, a fourth model seeks to make contractual arrangements with local hospitals or mental hospitals to transfer the patients for the duration of their acute conditions. Arrangements are such that, after improvement has been obtained, the inmate will be returned to prison to conclude the sentence and will receive maintenance treatment for the remaining time. Usually, as they have recovered, these patient/inmates are housed with the rest of the inmates and attend weekly clinics, similar to ambulatory clinics, where they are followed up and provided with medication, usually depot neuroleptics. Apart from the obvious clinical reasons for the use of these medications, depot medications cannot be stolen from the patients and they cannot be used for trafficking by either the patients or the other inmates.

Every system has its flaws and virtues, but any one of them will eventually collapse when the number of patient/inmates outstrips the resources that have been made available within the prison system. In the end, the system is able to provide nothing else than a warehouse service.

This situation has converted prisons, especially the local jails, into modern-day asylums, with all the horrors of abuse and deprivations of the asylums of yesteryears (Torrey 1995). An alternative model would be to prevent imprisonment, especially detention in jails, of those mental patients who are usually charged with minor offences. Such a model is described below (see Sect. 7).

6 Treatment Modalities in the Institutions

In general, although psychological treatments are usually available, reconstructive psychotherapy is not often provided in correctional institutions. However, in specialized maximum-security hospitals a large array of psychotherapeutic and behavioural modification techniques and modalities are found. Some of these techniques have actually been pioneered in prisons. Biological approaches are favoured and include electroconvulsive therapy and even psychosurgery in highly specialized institutions for the criminally insane. Special hospitals provide specific medications for the treatment of sexual offenders, usually anti-androgens such as cyproterone or Depo-Provera (medroxyprogesterone acetate). Some countries allow for castration as a form of treatment for sexual offenders. Sexual offenders are usually also offered other treatment modalities in the form of cognitive therapies, re-socialization or behavioural modification techniques.

Treatment for mental conditions in prisons is largely based on medications. These, however, are usually restricted, especially when resources are limited, to the classic neuroleptics (chlorpromazine) or the classic anti-depressants (tricyclics). The treatment of violent offenders has progressed to include powerful medications including lithium, anti-convulsants such as carbamazepine, and the latest atypical neuroleptics such as risperidone and olanzepine. Because of the potential for trafficking and abuse of medications, as well as reported paradoxical reactions due to disinhibition of violent potential, many correctional facilities stay away from the use of anxiolytics or hypnotics.

It should be kept in mind, however, that treatment in prisons, and especially in maximum-security hospitals, is not only aimed at specific mental conditions, but often at criminality proper. This is a very important distinction in order not to confuse the reasons and aims of treatment and the reasons and aims of corrections. In prisons, it is not often clear what needs treatment or what is being treated, a mental condition or criminal behaviour. Worse, the aims of treatment may also confuse improvement from a mental problem with a push to prevent recidivism. Confusing the reasons for treatment and mixing up the aims of treatment has led to the introduction of ethically dubious "therapies" and abuse of prisoners. Finally, it should be kept in mind that overcrowding, lack of privacy, the overall need for security and the ever-present risk of

assaultiveness among inmates themselves can make the quality of treatment in prison substandard or below the standard expected in hospitals.

7
Forensic Community Corrections

Programmes have been established to divert the mentally abnormal offender from the justice system to the general mental health system. Steadman et al. (1995) reviewed a number of these programmes in the United States and concluded that there are two main types: pre-booking (police) and post-booking (court/jail). The former type is similar to that found in many other places and already described above, where the police have the option of bringing mentally disordered offenders to a psychiatric emergency unit if the offence is a minor one. The second type could be pre-arraignment, post-arraignment or mixed. These programmes usually have workable arrangements at the community level so that services are integrated between several agencies, including correctional institutions, mental health facilities, social services and the judiciary. Regular meetings with members of these different groups guarantee the involvement of each group and their interest in making the programmes successful. Most programmes are based on a "boundary spanner", or case manager, in charge of negotiating with institutions in different systems and of ensuring patient's compliance. The basic ingredient for a successful programme is the ability to integrate with the regular mental health and social systems in the area.

An example of this type of programme exists in Calgary, Canada, where psychiatrists from a major teaching hospital attend regular clinics in the prison system; once the person is released to the community, they provide follow-up from the hospital or by attending a half-way house for the mentally ill offender. This half-way house is operated by the Department of Justice. Community nurses and social workers act as case managers to make sure that patients do not lose their social support entitlements (e.g., welfare, apartments) while they are in prison. The programme also arranges to divert mental patients from the justice to the general mental health system in consultation with the courts.

In Canada, the federal government has just enacted Chapter 22, an act to amend the sentencing provisions of the Criminal Code. This act, already called the Community Corrections Act, stipulates, among other provisions, that the great number of offenders who present no danger to the public should be dealt with in the community rather than incarcerated. It is expected that this act will have a major impact on the management of the mentally ill offender who presents no danger to others (Government of Canada 1996).

8
Research on the Mentally Abnormal Offender

As research subjects, mental patients and prisoners are members of vulnerable populations. These populations are defined as those who, because of mental or physical incapacity, powerlessness induced by institutionalization or status (e.g., minors), need special protection if they are to be engaged as subjects of medical research.

Unfortunately, the record of medical experiments using prisoners is not pristine. Experiments such as those at the Willowbrook State School for the mentally defective, the Alabama Kilby and Draper Prisons or the Vacavillle Medical Facility testify to the blatant abuse of prisoners exposed to medical experimentation. In those instances, no ethical bounds were placed on the investigators and these, on their part, did not know or were oblivious to ethical constraints. For the reader on ethics, a sense of "not being fair", and of injustice, permeates such experiments (Arboleda-Flórez 1991). However, not all abuses of prisoners used as research subjects involve glaring trespasses of ethical boundaries; subtle abuses are also important. For example, confidentiality and informed consent issues, the balancing of risks and benefits and the lack of a clear delineation between therapy and experimental treatments are some of the issues that require much vigilance when treating or conducting research among prisoners.

These issues become magnified if the prisoner happens to also be a mentally ill person. Results from epidemiological studies purporting to substantiate peculiarities of mentally abnormal offenders, as a group, tend to further stigmatize them. Given that these studies may have methodological flaws, the use of their results to implement policies before they have been properly replicated damages the interest of these patients (Weisstub et al. 1995). Prisoners are often used in experiments of new psychoactive substances, clinical trials or experimental treatments. If some of these prisoners are also mentally ill, it would call into question the ethical tenets of such research, as these individuals often may not be completely competent, and hence will be unable to provide proper informed consent to participate.

Although a total ban of medical experiments in prisons is not advocated, given that competent prisoners should be able to exercise their will, Verdun-Jones et al. (1998) suggest mechanisms, such as properly constituted extramural ethical research boards, to make sure that both mentally ill offenders

and regular prisoners are properly protected from potential abuses during medical experiments.

9 Rights of the Mentally Abnormal Offender

Mentally abnormal offenders are in need of further legal protection over those accorded the average prisoner. The reasons why this should be an accepted expectation in any justice and prison system include the fact that mental conditions often lead to legal incompetence, that legal determinations regarding insanity acquittals impose special duties on the state and may represent further restrictions on the mentally ill offender and that findings of dangerousness due to mental illness may lead to indeterminate sentences. Laws stipulating such protection vary from country to country.

Internationally, the plight of prisoners, and in particular mentally ill ones, has been recognized by the United Nations, which has passed resolutions to the effect that prisoners have a right to health services similar to those enjoyed by individuals in the community at large and resolutions for the promotion of the rights of the mentally ill. Similarly, the World Health Organization (1996a) has produced a set of Guidelines for the Protection of Human Rights of Persons with Mental Disorders. A special feature of these guidelines is Principle 20 – Criminal Offenders – which pertains to proper safeguards and treatment needs of prisoners, especially those who are mentally ill. In addition, the World Health Organization (1996b) is preparing a set of Guidelines for Quality Assurance of Forensic Facilities, in which ethical issues are considered in relation to physical environment, security needs, administrative arrangements, staffing and the process of care in these facilities.

Fundamental to this protection are the principles that mentally ill prisoners should not be subjected to cruel or unusual punishment or torture, that proper nursing facilities be provided for treatment and that this be made available within the resources allocated for health needs in the correctional system of any country. Finally, it should be indicated that the Madrid Declaration of the World Psychiatric Association (1996) clearly prohibits as unethical the involvement of psychiatrists in the assessment of mental fitness for torture or death penalty.

10 Conclusions

Mentally ill individuals who suffer from serious and chronic mental conditions may act illegally and come into conflict with the law, which may lead to arrest and possible imprisonment. Other type of individuals may suffer from specific pathologies whose behavioural expression may lead to an automatic claim of criminality. When individuals in either of these groups end up in prisons, they pose a challenge with respect to their management and care, a challenge that prisons are often not able to meet. Several responses have been devised to deal with these inmates within correctional systems. Basically, these responses come down to four organizational models within the system and an extramural model of community corrections.

Mentally abnormal offenders, by virtue of their mental problem and of being in prison, have a dual vulnerability. Administrators, clinicians and researchers should all be vigilant and should err on the side of caution when called to manage these type of offenders.

CHAPTER 18

H. Helmchen, J. Vollmann

Ethical Questions in Psychiatry

Translator: S. Henn

1 Introduction

Present awareness of the ethical implications of dramatic transformations in medicine and psychiatry is growing against the background of upheavals caused by profound changes in social structures resulting from new information technologies, global economic competition, limited social safeguards, the end of the cold war, and, especially in Germany, a renewed review of the past. Likewise, the reanimated discussion of euthanasia has to be seen in the context of the large increase in the number of individuals with severe residual problems following intensive medical treatment in life-threatening circumstances and of very old, dependent, and sick individuals due to longer life expectancies and in the context of patients' increasing desire for self-determination. Similarly, the issue of possible and appropriate care of the mentally ill in the face of current financial restrictions cannot be separated from the question of priorities in resource allocations in health care. In the light of rapid advances in decoding the human genome and in information technology, many are understandably calling for improvements to be made in data protection and for confidentiality to be strictly observed. However, the main question is how, in an increasingly regulated, formalized, and bureaucratic world, psychiatrists and other psychiatric caregivers can maintain and further develop their ability, not only to care adequately for the health and well-being of individual patients using their professional competence, but also to preserve each individual patient's dignity and right of self-determination by perceiving and respecting their wishes and interests.

Ethical questions in medicine and hence also psychiatry have become considerably more important in the last decade. This is shown by an increase in relevant publications (Table 1) and the adoption of a series of declarations by international committees such as the United Nations (UN) and the World Psychiatric Association (WPA) and regional committees such as the Council of Europe or of Latin America – Pan American Health Organization (PAHO)/World Health Organization (WHO) (Table 2); in addition, the law is becoming increasingly complex.

We will begin by presenting aspects of medical ethics that are important as a basis for ethical judgments of psychiatric problems, followed by the relevant declarations, guidelines, and legal norms that serve as a means of orientation and as a framework. These will then be illustrated by current and especially significant problems followed by frequent and typical ethical questions that arise in psychiatric practice.

2 Foundations of Medical Ethics

2.1 Definition of Terms

Whereas there is often no distinction made between the terms "ethics" and "morality" in common usage, a distinction is made in academic discussions. The terms "morality" (L *mores*) and "customs" are understood to refer to the area of moral phenomena, i.e. the essential, normative, and fundamental assumptions for the manner of existence of human beings (e.g. rules for behavior, standards of values, the meaning of ideas). Ethics (Gk *ethos*) as a scholarly discipline of philosophy analyzes, systematizes, and reflects upon these moral phenomena on a theoretical level. In contrast to metaethics, which makes no contents-related statements about the moral value of individual actions, their rules, or criteria for rules, but rather examines such statements in their linguistic form, the

philosophical investigation of practical or applied ethics concentrates on concrete moral problems (Höffe 1992; Patzig and Schöne-Seifert 1995). Depending upon the subject of investigation, we speak of economic ethics, media ethics, animal ethics, and medical ethics, for example, as subdisciplines of applied ethics. It should be emphasized here that we are not dealing with "special ethics" with specific values, rules, criteria, or reasoning strategies, but that generally valid ethical rules simply obtain in particular fields and problem applications (Ach and Gaidt 1993; Beckmann 1996). Whereas in German philosophical usage, the term *Medizinethik* ("medicine ethics") is used, in medicine the terms *medizinische Ethik* ("medical ethics") and *Ethik in der Medizin* ("ethics in medicine") are usual. In English-speaking countries, the term "bioethics" is used (see below). Branches of medical ethics are denoted by terms such as "doctors' ethics," "care ethics," "patients' ethics," etc. Since ethical conflicts in the medical field are increasingly less often able to be solved from the perspective of one professional group, the comprehensive concept of "health ethics" is widely used in the literature. In comparison, suggestions of terms such as "ethics of the healing professions" or "the theory of values" (Seidler 1986) have not gained acceptance.

2.2 Development and Current Discussion of Ethics in Medicine

Problems of medical ethics have long been handled in the medical profession in Germany largely as questions of professional ethics and medical law. Ethical actions were primarily communicated to prospective doctors as medical-collegial behavior on the basis of the Hippocratic tradition (Winau 1994; Wiesemann 1996), which cannot do justice to the many current ethical problems in medicine (Höffe 1987; Beauchamp and Childress 1994). Issues of medical ethics were only of marginal interest and were worked on by medical lawyers, medical historians, and psychiatrists, but above all by doctors who had a personal interest in them alongside or following retirement from their clinical duties. Here, practical experience gained in medical professional practice and moral intuition about the proper behavior of doctors played the decisive role, and traditional ethical principles based on the Hippocratic oath or Christian faith were accepted as a matter of course. However, current ethical dilemmas in modern multicultural societies require a rational, secular foundation for argumentation in medical ethics in order for assumptions to be able to be critically discussed. Here, ethical justification is not developed by a professional group alone or behind closed doors, but rather value decisions must be made transparent and be publicly justified (Steigleder and Mieth 1990; Tugendhat 1994; Schöne-Seifert 1996).

The development of a rational, secular, and liberal discussion of issues concerning medical ethics has become indispensable because of two developments. One is that medical advances have opened up possibilities for diagnosis and therapy for which the traditional principles of medical ethics have proven to be too general, making specific obligations necessary. Second, medical advances have been accompanied by an increasing plurality of value systems and the demand for more patient autonomy in Western societies. Because of varied individual attitudes toward values, problems of medical ethics, which frequently touch upon a person's private sphere, cannot be usefully settled by means of "professional ethics" or by a unified ethical theory.

Since the 1970s, in light of these new ethical questions in medicine, the new, academic discipline of bioethics has developed in the United States, a discipline in which different professional groups (e.g. doctors, philosophers, lawyers, theologians, social workers) work together as equal partners in an interdisciplinary manner (Reich 1994, 1995). In English usage, bioethics is understood as a subdiscipline of applied ethics and concerns itself with questions in medicine and biology (see above). Bioethics constitutes neither a "special ethics," in which only certain ethical rules or theories apply, nor is the term connected to a statement of content relating to concrete questions about the issues. In fact, the Anglo-American bioethics discussion is characterized by a large number of methods, theories, and opinions. While at the beginning of this development approaches of analytic philosophy, liberal contract theory, and value ethics were given priority, since the 1980s philosophical contributions from virtue ethics, feminist ethics, care ethics, communitarian philosophy, and casuistic and narrative models of ethics have gained in significance (Sass 1988). In the international debate, methodical approaches, theoretical models, and the problem of transferring theoretical medical ethics into practice are the subject of much controversy (Siegler et al. 1990; Birnbacher 1993; Bok 1996; Levi 1996), and there is neither a unified theory nor a homogeneous opinion.

Due to lack of knowledge of these developments, the term bioethics in Germany is used mainly as a negatively loaded slogan with which to discredit the opposition in ethical and political controversies. Instead of a discussion based on reasoned argument, it is insinuated that the so-called bioethicists allow themselves to be used to legitimate biomedical research and thereby threaten human rights and dignity. These scholars are accused of a dangerous faith in

progress, which would stand in fatal continuity to that biologistic-reductionistic thought tradition that led medicine to perpetrate the gravest crimes against human rights during the rule of National Socialism. The "anti-bioethics movement" has received wide public attention in Germany, especially with the controversy over the preference-utilitarian theses of the Australian philosopher Peter Singer concerning euthanasia (1984) and in the discussion of the so-called bioethics convention of the Council of Europe (Sass 1995; Schöne-Seifert et al. 1995; Reiter 1996; Vollmann 1996b). The term "bioethics" therefore has such strong negative connotations in Germany that, in contrast to the international academic discussion, it cannot currently be used as a neutral term.

2.3 Theories, Principles, and Rules in Ethical Actions

In considering the medical ethics of moral problems, four levels have to be differentiated: ethical theories, principles, rules, and individual cases.

On the primary level of ethical theories, an attempt is made to determine valid principles and rules which can systematize a great number of individual cases and ideally combine them in a consistent theoretical system. However, this has not yet succeeded, because all the theories proposed in medical ethics have their specific strengths and weaknesses and are invoked by various ethicists for different ways of looking at problems. Fundamental differences among ethical theories concern terminology, classification (which principles and rules?), establishment of methods (which rules in accordance with which principles?), weighting (which norm takes precedence in a case of conflict?), and the interpretation of rules in a concrete individual case. Aside from these differences, all theories that are candidates for a general medical ethics possess three common conditions, requiring (1) the possibility for the generalization of norms (the precept of universalizability), (2) the rejection of egoism as an ethical argument, and (3) the postulation that a rational analysis and foundation is of central significance in the solution of moral conflicts and that only these can be made the basis of generally binding norms (Höffe 1992; Patzig and Schöne-Seifert 1995).

Two main groups of modern ethical theories can be differentiated. Deontological theories (Gk *deon* = duty) judge an action to be moral if a recognized moral principle is followed, regardless of the effects this action has. These include Kantian ethics, which are also important in the debate on medical ethics, the central principle of universality of which states that if I cannot consistently wish that everyone in my situation acts in agreement with the norm by which I intend to be guided, then my way of acting is not morally correct. In practice, this "categorical imperative" can lead to situations that contradict our moral intuition. If, for example, it is generally recognized that we should tell the truth (as a moral duty), well-intended lies are not permissible, regardless of possible consequences in individual cases. Thus, according to the deontological understanding, a physician is obliged in every case to inform a patient completely, even of an unfavorable prognosis. On the other hand, teleological theories (Gk *telos* = end) judge the moral quality of actions on the basis of whether they are appropriate to promote a presupposed goal, such as happiness or well-being. Examples of this are utilitarian ethical theories (L *utilis* = useful), the majority of which are Anglo-Saxon in origin. In utilitarianism, the decisive moral criterion lies in whether the action promotes the welfare of all those affected in an optimal manner. Whereas classical utilitarianism defines hedonism as the maximization of well-being as pleasure and happiness or the absence of pain and unhappiness, in modern preference utilitarianism the degree to which the wishes, needs, and interests of all those affected by an action are taken into consideration is decisive. In practical medical ethics, however, considerable difficulties arise with the necessity to evaluate and weigh up the interests of the various individuals involved. Which "human beings" have relevant interests? How can personal interests be quantified and, if a conflict arises, how can they be weighed up against one another? These problems play an important role in current ethical discussion, e.g. in euthanasia, abortion, research on human embryos, etc.

Principles of medical ethics are derived from ethical theories and define the fundamental norms in the area of health. In spite of differences on the level of theories in the debate on medical ethics, there is much agreement on the so-called middle level of principles. For example, the right of a patient to preservation of life, self-determination, assistance, protection from bodily harm, respect for his or her person, truthfulness, and confidentiality is not disputed. In addition to these patients' rights, there are also certain duties of the physician, e.g. the precept of the well-being of the patient (*salus aegroti suprema lex*) or the medical principle to do no harm (*nil nocere*). Other duties include the duty to help, respect for the dignity and right of self-determination of the patient, the prohibition against killing, the duty to maintain confidentiality, and the principles of fairness, tolerance, and openness (Sass 1988). Various medical ethicists have proposed principles of medical ethics which are relevant to medical practice and which differ in variety, number, and the importance attached to them (Veatch 1981; Engelhardt 1986; Beauchamp and Childress 1994). The latter proposal has received the

most attention, which refers to respect for the patient's right of self-determination (autonomy), the principle of not causing injury ("nonmaleficence"), acting for the well-being of the patient ("beneficence"), and justice (fairness) as basic principles of medical ethics.

From these generally formulated principles, concrete rules are derived by which the physician should be guided.[1] The psychiatrist in clinical practice is generally confronted with ethical questions in individual cases (e.g. should I inform Mr. Smith about his diagnosis at the present time?). In order to act normatively correctly in individual cases, the physician is guided by rules (e.g. patients who are able to make their own decisions should be informed). These rules derive from a higher principle of medical ethics (e.g. everyone's right to self-determination should be respected), for which the ultimate basis is an ethical theory (e.g. Kantian philosophy).

2.4 Weighing Up Conflicting Values

Although there are still differences on the level of theory, the general acceptance of the principles of medical ethics cited here represents a step forward toward achieving a pragmatic consensus on essential norms in medical ethics. Unfortunately, the ethical problems in medicine cannot solved by this pragmatic agreement, however. The major ethical questions always appear when two or more ethical principles come into conflict with one another. In psychiatry, for example, the principle of respect for the patient's right of self-determination (autonomy) and the duty of the physician to act for the well-being of the patient ("beneficence") and to avert harm ("nonmaleficence") can come into conflict with one another if a patient needs to be restrained and treated against his or her expressed will. Other examples are suicide prevention, the benevolent lie, and the just allocation of resources in psychiatry and psychotherapy, which can bring the principle of justice into competition with the well-being of the individual patient.

Agreement in the various ethical theories on the middle level (principles) is therefore only superficially satisfying. In clinical practice, in addition to a knowledge of principles of medical ethics, a physician requires a method by which he or she can judge divergent principles in an individual case. There is no generally recognized approach stipulated by medical ethics for this; instead, each case has to be decided individually by evaluating competing ethical values. Criteria and methods for taking decisions about weighing up values against one another need to be developed, because ethical considerations are necessary not only to take a decision in the individual case but also for subsequent action (Schmidt 1989; Sass and Viefhues 1991; Gillon and Lloyd 1994). In this context, the excessive emphasis of the principle of autonomy coupled with the simultaneous undervaluation of the principles of beneficence and justice has repeatedly been criticized in American ethics. This one-sidedly and short-sightedly concentrates on self-determination, while neglecting the welfare of the patient and the complex consequences for other patients and individuals in a welfare state community (Holm 1994, 1995). Faced with the need to take concrete decisions and actions in an individual case, the physician is dependent upon clinical decision-making, in which not only principles of medical ethics, but also moral intuition and values also play a role. In this context, medical ethics has experienced a revival in the justification of medical actions by virtue ethics on behalf of the well-being of the patient (Pellegrino and Thomasma 1993), as has the casuistry of medical ethics for ethical assessment in individual cases (Jonsen and Toulmin 1988). In view of the fact that a generally binding definitive moral justification is unlikely, Rawls (1975) proposed an interplay between a rational basis and intuitive experience, a reflective balance, in which, in the last resort, a responsible decision needs to be taken in the individual case. Rationally based principles of medical ethics can make an important contribution in the identification, organization, and thoughtful debate of ethical problems. However, not even such a comprehensive ethical system can relieve the treating physician of responsibility for the moral decision in an individual case.

3 Framework: Declarations, Guidelines, Legal Norms

The first statement made by the WPA on ethical questions in the profession was the 1977 Declaration of Hawaii (on the Duties of Psychiatrists; Helmchen and Müller-Oerlinghausen 1978). It was intended to give psychiatrists moral support in conflicts of loyalty in contemporary society and help with decisions. The background, made clear in the first paragraph of the declaration, was the political abuse of psychiatric concepts, knowledge, and techniques that was recognized in the 1970s in countries such as the Soviet

[1] The area of rules concerning medical ethics can be further differentiated. The German Federal Board of Physicians (*Bundesärztekammer*) distinguishes four categories: (1) memorandum, (2) recommendation or opinion, (3) standards, and (4) guidelines (Bachmann and Heerklotz 1997).

Union, Romania, Chile, and South Africa (Helmchen 1986). The declaration specified the fundamental ethical principles of respect for the dignity of patients and their right to self-determination and of action solely in the best interest of the patient. The latter was also supported and promoted in the book *Principles of Biomedical Ethics* by Beauchamp and Childress (1994), a book which later became very influential. Here, they formulate the elements of informed consent, underline the responsibility to maintain confidentiality, comment in particular on forensic examination and involuntary measures, demand the possibility of independent review of such involuntary measures, and require psychiatrists not to abuse the opportunities their profession allows them, and, especially, to refrain from participation in involuntary measures in the absence of psychiatric illness. The emphasis of this last rule, in particular, makes clear the resistance to the political abuse of psychiatry that was necessary at the time. This focus also highlights the fact that other important ethical problems, such as the just allocation of resources in psychiatric care and research, were barely addressed. The Soviet psychiatrists avoided discussion of psychiatric abuse by withdrawing from the WPA before the 1983 World Congress in Vienna (Helmchen 1986). At the same congress, certain binding formulations and the particular emphasis on individual autonomy in the Hawaii Declaration were somewhat moderated by rewording (Hawaii/II; WHO 1996). A series of additional statements by the WPA, prompted not least by an antipsychiatric tendency in the so-called Daes Report (by a working group of the UN Commission on Human Rights), were accepted by the 1989 World Congress in Athens as a Charter for the Rights of the Mentally Ill. The efforts made by psychiatrists and health care politicians in many countries over the last three decades to bring about a fundamental improvement in the care of the mentally ill and a growing awareness of their fundamental rights led in 1991 to UN Resolution 46/119 on the Protection of Persons with Mental Illness and the Improvement of Mental Health Care (*Principles for Policy on Mental Health*; WHO 1996). This is the first UN document drafting human rights for the mentally ill and their right to treatment. They are to be procedurally guaranteed by means of what are in part very detailed regulations. Psychiatrists are to be able to refer to them in their dealings with their administrative bodies and even governments. The governments themselves are to give effect to the principles of this resolution through appropriate legislative, judicial, administrative, educational, and other measures. The first principle stated is the right of every individual to the best available mental health care. It is to be a component of the health and social welfare system. With this and especially with principles 8 and 9 of the formulated standards for care and treatment, which are oriented to the health needs of the patients and to their receiving equal treatment to those who are physically ill, the issues of quality control and the just allocation of resources are gaining more significance.

These central themes of the 1990s also are specifically expressed in the 1996 WPA Declaration of Madrid. At the very beginning, in its first point, it emphasizes that psychiatrists are to be engaged in the just allocation of health care resources if they wish to meet their commitment to the best possible care of their patients in accordance with scientifically proven knowledge and ethical principles. The second guideline explicitly states that psychiatrists must keep themselves informed about scientific developments and that those trained in research should push back the scientific frontiers of psychiatry. The ethical standards to be observed in this context are cited in detail in guideline 7. It is emphasized that the mentally ill are particularly vulnerable as research subjects and that particular care therefore needs to be exercised in order to protect their autonomy and their mental and physical integrity.

Three international declarations that formulate ethical standards for human research, and thus also apply to research with the mentally ill, are particularly significant for psychiatric research. These are the 1947 Nuremberg Code (Sass 1989), which was developed at the time of the trial of the National Socialist physicians and served as a basis for guiding the judgment passed by this international court, the 1964 Helsinki Declaration (on Biomedical Research; most recent amendment made in Somerset West, South Africa, in 1996), which the World Medical Association (WMA) put forward as medical guidelines for biomedical research that are still valid today, and the 1996 Bioethics Convention of the Council of Europe, which is important for international law. The special problem regarding the inclusion of research patients who are not able to give their consent is also addressed in this convention; since this is a very topical and fundamental issue, it will be treated separately in the next section.

The ethical standards formulated in these declarations are in accord with international agreement, but they do have different binding force depending on the national law and cultural context concerned, as a comparison concerning informed consent among various European countries shows (Koch et al. 1996). The laws relevant to psychiatry are treated in earlier chapters (see Chaps. 15, 16, this volume). In Germany, these are above all the *Betreuungsgesetz* (BtG, Law on Care), valid since 1992, and the *Gesetze für psychisch Kranke* (PsychKG, Laws on the Mentally Ill) in each individual *Land*.

4
Special Problems

Medical actions are shaped by medical socialization, based on experience, and stabilized by feelings. They lead to complex intuitions (biases) constituted by implicit pictures of human beings, physicians, and one's self, without which decisive actions in the reality of daily life are scarcely possible. Rational and instructive argumentation can lead to counterintuitive inconsistencies in this context. Nevertheless, the challenges of modern medicine force discussion about these contradictions, even if it is repeatedly endangered by emotional blocks and by intellectual temptations. It should serve to elucidate and justify the various positions and attempt to find permissible, adequate, and practical solutions.

4.1
Psychiatric Research

Psychiatric research is primarily research with human beings. The main reason for this lies in the fact that there are few adequate animal models for most mental disorders. However, in the case of mental disorders, the ability to give consent and the validity of such consent is much more questionable than with other illnesses. Before a patient is included in a research project, his or her ability to give consent must therefore be examined and, if this ability to consent is lacking, it must be considered whether research with this patient is ethically justifiable and legally permissible at all and, if so, under what conditions.

As early as 1900, the Prussian education authority issued a short, but clear instruction to the directors of clinics concerning the principles to be followed in patient research. The supreme court of the German Reich had already given its view on the voluntary nature of patient participation in research projects as early as 1894 and reinforced this view in 1906. In 1931, the German Reich Ministry of the Interior issued rules for clinical research (Vollmann and Winau 1996). In spite of these clear instructions regarding the voluntary nature of patient involvement and weighing up benefits and risks, German physicians carried out criminal experiments under National Socialism which were condemned in Nuremberg in 1947. As a result, explicit rules for the conduct of human experimentation were formulated, and – as the Nuremberg Code – these then became the basis for the adoption of the 1964 Helsinki Declaration by the WMA. Self-determined participation of patients or probands has since been regarded as the fundamental prerequisite for all human research.

The right to self-determination is universally guaranteed in Germany in the constitution (*Grundgesetz*, Basic Law, Art. 1). Only the law governing the manufacture and prescription of medicines deals with this and other conditions for conducting research, however. It is the only German law that is specifically relevant to research. However, it only regulates experiments with medication. Further decrees and guidelines have been issued by the Federal Minister of Health, the Federal Public Health Department and the Federal Institute of Medication and Medical Products (BfArM), and the *Bundesärztekammer* (German Federal Board of Physicians), and court decisions have been made, as a result of which clinical research has become increasingly legally regulated in recent years. Since the revision of the Helsinki Declaration in Tokyo in 1975, ethics commissions have been formed in Germany in nearly every medical faculty and in the boards of physicians of the individual *Länder*. According to German medical law, all physicians must consult such an ethics commission before they begin a research project with patients (Helmchen 1995b).

4.1.1 Informed Consent

The general validity of the principle of self-determination has more than one reason. One source is the European tradition, which is considerably influenced by Kant's philosophy, according to which a person shall never be viewed and treated merely as a means, but always also as an end. Another root of this principle stems from the ethical and political tradition, particularly in the United States, a tradition which is constituted by the self-determination of each citizen and emphasizes the right to freedom of the individual against all forms of authority (state, church, and other institutions). It is the right to decide on matters affecting one's own sickness or health that exemplifies the perception of individual responsibility and self-determination.

The legal theory of informed consent – as developed over the last three decades principally in the United States – can claim general validity as the means to legitimate all medical interventions. The relationship between patient and physician is traditionally understood from the medical point of view primarily as a relationship based on trust and often with only implicit or presumed consent. However, the explicit consent of the patient has acquired a central position in present legislation and court decisions, not least because of physicians' omissions (Vollmann, in press). For that reason, the legal rules concerning the representation of patients who are actually or legally unable to give consent themselves are oriented toward the precept of consent (presumed consent, consent through a care

giver or legal representative; see Chaps. 15, 16, this volume, Part 2).

This development has many and diverse roots. The main focus in modern medicine has increasingly expanded to cover not only acute treatments but also the long-term treatment of chronic illnesses or now even concentrates primarily on the latter. Successful long-term treatments with all their burdens – especially in ambulatory psychiatry – are not possible without the responsible participation of the patient just as in the case of clinical research. In addition, human rights, or rather basic civil rights such as self-determination and patient dignity, are now even more strongly asserted as the patient becomes more dependent upon treatments which cannot be self-determined, something which can happen in modern medicine and its often standardized courses of treatment.

Especially the procedures required by scientific methodologies can limit the individuality of research patients. The nature of gains in scientific knowledge, especially in the testing of hypotheses, goes beyond the individual (and, as a result, at least also uses the individual for the sake of another). Knowledge is gained from more than one patient and exceeds the experience of each single psychiatrist. In order to ensure the scientific comparability of results, observations as well as diagnostic and therapeutic methods must be standardized. In accordance with convictions prevalent today, this is most likely in clinical trials under controlled conditions. Control means the reduction and standardization of context variables, the systematic variation of intervening variables, and repetition. Important techniques for the control of objective influences include randomization. Blind trials, including the use of placebos, control for subjective influence.

Such objectification is compatible with the dignity of the patient only if the patient accepts it, i.e. if the individual patient consents freely and personally following appropriate explanation of the methodologically conditioned dependence. The patient should also be informed about such methodological dependencies precisely because it establishes trust, without which there can be no accepted dependence. The temporary external control must therefore be legitimated by valid consent. Thus the greater the extent to which the individual patient is objectified, i.e. to which he or she is treated as an object, the more certain the validity of the consent must be.

In contrast to the clear validity of ethical and legal standards for consent as a prerequisite to every medical intervention, clear, generally accepted, and practical criteria and methods for determining the ability to give consent are currently still not well known. Grounds for this may lie in the generally accepted subordination of the ability to consent, because the physician as a rule does not question the acceptance or nonrefusal of a proposed intervention that is in the best interest of the patient. Moreover, a mentally ill patient who does not have clear cognitive or behavioral disorders might experience doubt expressed in his or her ability to consent as discrimination and an impairment of the relationship of trust to the physician. Generally, the ability to consent is only called into question in practice if a patient refuses an urgent or life-saving intervention without a recognizable or understandable reasons. In research, however, this question is more important for the very reason that the physician needs to be certain that consent is really valid.

Assessment of the ability to give consent is not easy, requires experience, and is burdened with uncertainty. The key to this assessment is informing the patient, because the ability to give consent is not a universal characteristic, but a relational one, i.e. it can only be assessed in relation to concrete facts in the here and now. Thus the patient must receive sufficient, specific information in a way that is appropriate to his or her ability to understand. "Not everyone is equally capable of understanding the same explanation of a treatment plan. A person is more likely to give valid consent if the explanation is appropriate to the level of his assessed ability" (UK Mental Health Code of Practice, revised in 1993). Analysis of the processing of this information forms the basis of judgment. Criteria for this judgment of the ability to give consent were developed above all in the United States by Appelbaum and Grisso (1995) and in Germany by a working group on "Research Needs and the Problems of Consent in the Mentally Ill" (Helmchen and Lauter 1995).

Two levels of assessment were proposed using the latter (Amelung 1995). First, the psychiatrist must decide whether the affected patient has any psychiatric disorder at all. If this is the case, four functions should then be examined (Helmchen 1995a):

1. The ability to understand a particular fact ("what?"); this is assumed if the patient can repeat in his or her own words what it is about, e.g. trial versus standard treatment, randomization, placebo control, voluntary agreement to participate.
2. The ability to process particular information appropriately ("why?"); this appears given if the patient can substantiate the decision, e.g. with hope for greater chances for healing in spite of certain risks.
3. The ability to assess the information personally without illness-dependent distortion ("why me?"); this should be the case if this assessment is associated with understandable value convictions or concepts of illness that the patient has.

4. The ability of the patient to determine his or her own will on the basis of understanding, processing, and assessment ("if and how?"), i.e. if the patient can clearly express his or her decision.

4.1.2 Informed Consent and the Classification of Research Models

The special importance of consent following information about the research is based on the methodologically required "objectification" of the patient in a research plan that does not exclusively serve the patient, in use for the sake of others, and, finally, in contrast to pure care of the sick, the greater uncertainty, opportunities, and risks of a research project. In such a case, therefore, it is not a matter of an obvious, established standard treatment, but of an innovative diagnostic or therapeutic attempt or even a nontherapeutic experiment. Accordingly, the law raises the standard for informing the patient as the basis for valid consent and limits the possibilities of surrogate consent by a legal representative. Similarly, the threshold of grounds for investigating the ability to give consent should be lowered and the assessment standards raised. The threshold values for these extensive actions depend not only on the type of research intervention and its significance to the well-being of the individual patient, but also on the type and intensity of the potential risks.

If the patient will also be treated by the research intervention, then the project is classified as a therapeutic trial. The individual patient has the opportunity of receiving effective therapy (from which it is expected that it will be more effective and/or safer than the current therapy), and the researcher has the opportunity to improve or increase knowledge. However, if the researcher is pursuing research with a patient solely to win knowledge, then this patient has no personal benefit from it. This is then classified as human experimentation without potential individual benefit or, in the Helsinki Declaration, as nonclinical research. This difference determines the type and extent of consent after the patient has been informed and corresponds to international guidelines for ethical implementation of clinical research.

The therapeutic trials mentioned thus include the "last" trial and innovative "pilot treatment trials" in particular cases, as well as experimentally implemented research treatment with patient groups according to a research plan, i.e. a controlled clinical trial in the strict sense of the term. Consequently, the boundaries between pure therapy and pure experiment can become blurred (Fig. 1). It is therefore the responsibility of the research psychiatrist to recognize these boundaries, because the assignment of a research project to one of various models has different consequences with respect to the information required and the benefit–risk ratio.

Benefits and risks can be quite different in type and intensity. A taxonomy of benefits and risks might therefore be helpful (Table 3).

4.1.3 Research with Patients who Lack Competence

Ethics commissions have increasingly concerned themselves with research projects in which patients are included who are not able to give valid consent after receiving appropriate information. This applies not only to research projects in pediatrics and psychiatry, but also to projects in neurology and neurosurgery, and above all to those in anesthesiology and intensive care medicine. Ethics commissions sometimes appear uncertain if they seek legal advice or if their judgments contradict those of other ethics commissions involved in the same projects, e.g. in multicenter projects. This applies particularly to research projects which do not deal with therapeutic research in the narrow sense. Clearly, therefore, there is a need for clear and binding rules of assessment. In Germany, the working group of the medical ethics commissions has been working intensively for a long time on this theme, and the *Zentrale Kommission zur Wahrung ethischer Grundsätze in der Medizin und ihren Grenzgebieten* ("Central Commission for the Safeguarding of Ethical Principles in Medicine and Adjacent Fields") at the German Federal Board of Physicians, Central Ethics Commission for short, has just published a position on this matter (Zentrale Ethikkommission bei der Bundesärztekammer 1997). The subject has been in the public eye since 1994 in particular as a result of the discussion of the Council of Europe's "Convention for the Protection of Human Rights and Human Dignity in View of Biological and Medical Applications": Bioethics Convention. Above all Art. 17.2 of the Convention of the European Assembly, adopted on September 26, 1996, involving a common legal framework for human biomedical research, was controversial and debated right up to the end. In accordance with a series of preconditions, which are formulated in the preceding Arts. 17.1, 16, and 5, this article attempts to set up criteria for authorized exceptions to research which "does not have the potential to produce results of direct benefit to the health of the person concerned." This position was supported primarily by the Dutch jurist Roscam Abbing (1994) with the following arguments:

- Without nontherapeutic research, the very conditions that make the patient unable to give consent could scarcely be investigated and treated.

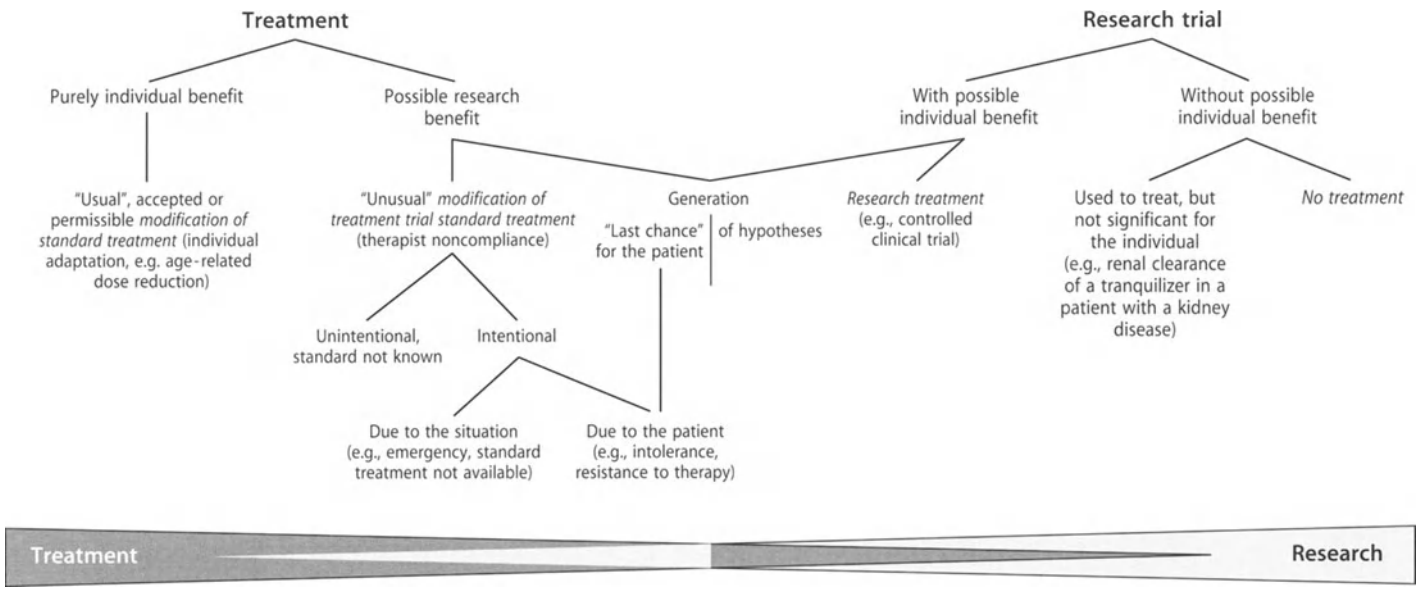

Fig. 1. Types of clinical research. The term "treatment" includes diagnostic, preventive, and therapeutic measurements. According to the *Arzneimittelgesetz* (German Medical Preparations Law, AMG Sect. 40.4), not only therapeutic drug trials, but also diagnostic and preventive ones are permissible, at least with children. Accordingly, these three different research categories can be viewed as being of potential value to the individual. (From Helmchen 1994)

Table 3. Classification of research risks and benefits

Research risks	Research benefits
No risk	No benefit
Minimal risk	Society benefits exclusively (trial *without* possible benefit to individual): - By increasing and validating present knowledge - By discovering qualitatively new knowledge
Slight increase of the minimal risk Clearly greater than minimal risk	The individual and society benefit (trial *with* possible benefit to individual): - By measurably improving existing standards - By discovering new therapeutic (and diagnostic) measures

- The research contributes to the health of other patients groups.
- Society has potentially great interest in the research in view of burdens placed upon the nearest relatives and health care costs.
- Solidarity can be expected from every citizen.

While medical research without direct potential benefit to the person who is incapable of giving consent is viewed in other European countries as permissible according to the exceptions formulated in Art. 17.2, (e.g. the 1988 French research law, Fagot-Largeaut 1996; the proposal by the British Law Commission 1993/1995), under German law (Taupitz et al. 1997) it is questionable or not permissible. It is also criticized or strongly disapproved of by the German public, as became clear in a joint hearing of the Federal Lower House of Parliament's Committees on Law, Health, and Education, Science, and Research on May 17, 1995 and at the Congress of Physicians on "Medicine and Conscience – 50 Years after the Nuremberg Trial Against Doctors," October 25–27, 1996 in Nuremberg (Stein 1996). The main arguments of critics of research without direct benefit to patients incapable of consent are the following:

- There is no real need for this research.
- This research contradicts the constitutionally guaranteed respect for human dignity.
- This kind of research – due at least in part to the criminal human experimentation carried out by Germany under the National Socialists and especially in view of crimes committed against the mentally ill (Klee 1983; Mitscherlich and Mielke 1960) – cannot be controlled and could be the signal of a "dam bursting."

As a consequence of this public debate, Germany was one of three European nations who abstained in the vote over the aforementioned 1996 Convention in the Council of Europe (de Wachter 1997).

The Central Ethics Commission took the following position (Zentrale Ethikkommission bei der Bundesärztekammer 1997) on the problem:

A particular ethical dilemma occurs in research in which the affected persons themselves are not expected to benefit, but other persons in the same age group or affected by the same illness or disorder can at least gain from the discoveries. Here, on the one hand, we have the ban on subjecting a person without his or her consent to measures which benefit another and do not also serve his or her own interests (the ban on using a person as a means to an end). On the other hand, we have the ethical conviction that slight risks may be required of a person if others can thereby be greatly helped.

It is clear that no one – competent or not – can be obliged to help a group of future patients by participation in a scientific investigation, even if the benefit for these patients is great and the risks to the patient minimal. However, inclusion of individuals who are unable to give consent in such an investigation appears to be defensible if, in addition to the observance of further protective criteria, the legal representatives, being familiar with the represented individuals (especially with their earlier lifestyle and views or explicit earlier statements), have sufficient grounds to be able to assume their willingness to take part in the investigation and no contradictory expressions of intent of the affected individuals exist.

A central point of this argument is that this research must be connected to the illness which led to the patient's inability to give consent. This criterion is very important for adults in order to exclude patients who are unable to give consent from ethically unjustifiable research for the exclusive benefit of others, as non-clinical biomedical research is defined in Sect. III of the Helsinski Declaration. Accordingly, individuals with dementia, for example, are excluded from research projects which are not concerned with dementia.

This criterion does not, however, apply to minors, who – independent of a particular illness – are still not able to consent because of their age. The French version of this criterion stipulates that the research project must be valuable to individuals of the same age

or to those suffering from the same illness or similar disabilities (Fagot-Largeaut 1996). An Irish version contains an obviously broader definition, whereby benefit must at least be expected for other patients (Casey 1996).

The Central Ethics Commission has formulated the following protective criteria:

1. "The research project cannot be carried out on a person able to give consent instead." This means that there is no alternative research strategy to answer the research question (Fagot-Largeaut 1996). If, however, the research question can be answered using patients able to give consent, then this research is not permissible with patients unable to give consent. Psychiatric examples of such research questions include the following:
   a) Projects with patients with dementia who are unable to give consent which cannot be conducted with patients with dementia who are still able to give consent as a result of their only slight development of dementia, because the exact diagnosis during the early course of the illness cannot be determined with the necessary certainty or because factors determining the progression of late stages of the illness are different from those in early stages.
   b) Can the assumption of differences in care needs for patients in late stages of dementia between those still living at home on the one hand and those who are institutionalized on the other be verified through epidemiological observation and questioning, which, if confirmed, would have consequences for the specification and improvement of care?
   c) An answer to the question of whether the pattern of psychopathological disorders and the speed of progression of later stages of dementia differs between the "young old" (i.e. up to 85) and "old old" patients (i.e. over 85) would be important in solving the problem of whether, in older patients, dementia is only a matter of accentuated aging or an expression of brain disease (Reischies and Schaub 1997; see also Vol. 2, Part 2, Chap. 10).
   d) In late stages of dementia, does the brain also have a regenerative potential, which could then serve as the basis of a specific therapy, a question which could possibly be answered by a defined pattern of particular neurotrophins, e.g. nerve growth factors, or by metabolites of particular cerebral proteins seen in venous blood or with magnetic resonance imaging.
   e) Particular knowledge of special brain functions, e.g. the basis of verbal skills, which can only be gained by the neuropsychological investigation of aphasic patients, i.e. from patients with speech disorders following brain injuries or strokes. These disorders can impair language understanding and, consequently, the conditions for giving valid consent after being informed.
   f) An investigation into the validation of assumed ability to give consent can only be undertaken if not all patients are actually able to give consent. Thus results with patients in a memory clinic who agree to more precise psychological tests of their ability to consent would show that a proportion of the patients are not in fact able to give consent.
   g) In the report by the Meijers Commission appointed by the Dutch government, a series of additional examples of the necessity for nontherapeutic research with incompetent patients are cited (Meijers et al. 1995).
2. "Fundamental information about the recognition, explanation, prevention, or treatment of an illness can be expected from the research project." Purely replicative ("me too") research or research designed exclusively to devise hypotheses is therefore not defensible. In their assessment, the ethics commission should also take into account the need for the research. For example, the need is urgent in the case of dementia, because dementia which progresses over many years entails continuous suffering for the patient and closest relatives. In addition, the causes of dementia cannot yet be treated and, in the long run, the disease presents an increasing burden on public health services because of its steadily increasing frequency, something highlighted by the continuing discussion about the law governing nursing care insurance and its practical implementation.
3. "Defensible risks in relation to expected benefits can be expected in the research project." This criterion should be used only for research projects which benefit the patients involved themselves, if not at the time of the research, then at least in the later course of their illness or in a later recurrence of it. With research projects in which benefits cannot be expected by the affected patient, but only by those in the same age group or with the same illness, this criterion must be complied with more strongly, "so that in all cases minimal risks

and burdens are expected from the research project."[2]

4. "The legal representative has given effective consent provided that he or she is familiar enough with the person he or she is representing in order to have sufficient grounds to assume that this person is willing to participate in the investigation." A helpful guide to the patient's wishes could therefore be a so-called patient directive, prepared at a time when the patient was able to give consent, or a power of attorney for health affairs. The caregiver should not simply disregard thoughts of the patient in solidarity with other patients simply because the ability to give consent has been lost. Another possibility mentioned in the Dutch legal draft in this context is that the participant included in a research project should be informed according to his or her present level of understanding (Berghmans 1995).
5. "The person concerned does not show rejection in his or her behavior." This means that the investigation must always be discontinued if the patient, particularly a patient unable to give consent, indicates that the investigation is so unpleasant that he or she wishes it to be discontinued. This criterion is specified in the Dutch proposals such that the research investigation shall not be continued if the patient unable to give consent protests and this protest can be judged as different from the usual behavior observed in the affected group of individuals unable to give consent (Berghmans 1995).
6. "The relevant ethics commission has judged that the research project is appropriate." In controversial cases, at least, the ethics commission should substantiate their assenting vote in light of specified criteria and should recommend prompting a judicial decision by their vote, either directly or for the (urgent) appointment of a caregiver.

[2]The Central Ethics Commission explains that the concept of "minimal risk" is difficult to define, "but can be specified by distinguishing degrees of risk and giving a list of examples. Medical specialty associations and ethics commissions can contribute to this. In each case, the objective risk and subjective burden or complaints are distinguished (e.g. magnetic resonance imaging holds no objective risks, but can quite possibly be a subjective burden, which leads to the investigation being interrupted). In particular, there is a great deal of individual variation with respect to subjective suffering and large differences among groups. In the view of the commission, an example of a "minimal" risk would be if small amounts of body fluids or tissue can be obtained during operations that are necessary anyway and thus entail no additional risk for the patient. Certain physical tests (e.g. sonograms, transcutaneous tissue measurements) and particular psychological tests (e.g. questionnaires, tests, behavioral observations) also fall into this group" (Zentrale Ethikkommission bei der Bundesärztekammer 1997).

In summary, extrapolating the corresponding regulations of the *Arzneimittelgesetz* (German Medical Preparations Law) to general medical research, nontherapeutic research with adult patients unable to give consent is not currently regarded as legally permissible in Germany. Nontherapeutic research with potentially immediate benefits, such as diagnostic research in the narrow sense for patients included in such a research project, is seen as ethically justifiable and should also be legally permissible for adult patients unable to give consent, as it is for minors. Nontherapeutic research with only indirect benefits for the patient (group 2 in the statement issued by the Central Ethics Commission) or benefiting only the group of patients with that illness (group 3 in the statement issued by the Central Ethics Commission) appear to be legally defined exceptions under the ethically justifiable prerequisite that strictly defined protective criteria are fulfilled and the patient is exposed to no risk. Finally, research of use to others in the sense of Sect. III of the Helsinki Declaration is not ethically justifiable with patients unable to give consent (Table 4).

Medical research expected to have only questionable or no individual benefit with patients unable to give consent (often incorrectly equated with nontherapeutic research) is and remains a difficult and controversial problem. This is reflected in the fact that such research is legally permissible under certain conditions in some countries such as France and probably also in England, but not in other countries such as Germany. From a medical point of view, such research can only be ethically justified if its necessity is determined according to defined criteria, patient needs for protection are fulfilled, so that the research has no more than minimal risks and negligible unpleasantness for the person participating, and refusal by the patient is accepted. There is a large international consensus on these criteria (Dresser 1996; Helmchen 1998a,b,d; Keyserlingk et al. 1995; Law Commission 1995). In addition, concepts and definitions of benefit and – especially minimal – risks and criteria, rules, and procedures for weighing benefits and risks against one another and, in addition, for the evaluation of individual as opposed to societal benefits need to be developed. Moreover, the question of who should make such evaluations needs a satisfactory answer.

The discussion about so-called nontherapeutic research with individuals unable to give consent strengthens fears of a medical science with inhuman characteristics. Because this research, more than other medical interventions, carries the risk of using a person as an instrument for others, it is highly relevant to the fundamental human right to personal dignity. Public discussion is therefore necessary, not only because respect for human dignity is associated with openness and efforts to understand others, but also

Table 4. Differentiation between case groups according to the position statement of the Zentrale Ethikkommission (Central Ethics Commission)

Case group	Definition	Examples
1	Treatment with present potential benefit to individual	Use of a new antidementia drug which is expected to be more effective and/or have fewer side effects than currently used antidementia medication
2	Intervention with future potential benefit to individual	Diagnostic measures relating to pathogenesis as foundation for development of therapeutic measures which can benefit the patient with a long or relapsing course of illness
3	Research without direct benefit to individual patient, but with potential benefit for the group of patients with the same illness or of the same age	Is the course of late-stage dementia determined by completely different factors than in the early stages? A positive answer would increase the perspective from which to search for treatment possibilities relating to causes in late-stage dementia
4	Nonclinical biomedical research (corresponding to Sect. III of the Helsinki Declaration)	Pharmacokinetic research with a medication which is irrelevant to patients with dementia

because in an open society an understanding of the opinions present in the society is a prerequisite for socially appointed decision-makers to define the basic conditions for such research. In this discussion, for example, philosophers should clarify the relationship between utilitarian and deontological ethics and its practical significance, while medical researchers have the task of representing the individual and societal need for such research, providing specific examples of its consequences and the variety of real benefits, risks, and burdens together with the ethical justification of the research.

To conclude from conceptual errors and the criminal abuse of psychiatry, e.g. "solving the social question" (Dörner 1988) by the "extermination of lives of no human value" (Binding and Hoche 1920), that any deviation from the Nuremberg Code is an inevitable step into the abyss – as, for example, the 1996 Grafenecker Statement (Grafenecker Erklärung 1996; Arbeitskreis zur Erforschung der "Euthanasie"-Geschichte 1996) suggests – does not do justice to the following problems (Helmchen 1998a,b):

1. The medical motivation for this research comes from the immediate experience of the patients' suffering, e.g. from the suffering that dementia causes in patients, their relatives, and caregivers. Physicians wish to treat such conditions more effectively than is presently possible and, therefore, in certain cases also include patients unable to give consent in research investigations, since there is no other way to reach this goal. Thus it is correct that patients unable to give consent are indeed especially weak and vulnerable, because their illness (and not the physician!) robs them of the possibility of being aware of their rights. It is for this very reason that physicians strive to achieve improvements, to heal the illness or at least relieve it to such an extent that the patient recovers the ability to exercise his or her rights. Physicians, however, do not wish – as is implied by some critics – to make these patients "available" for research because they are weak and defenseless, but rather to include them in research under defined protective measures because their illness is so severe and difficult to treat that doctors are called upon to do something about it. This argumentation is also supported by the medical professional directive according to which the physician also has to serve the population (Ärztekammer Berlin 1990) and by the constitutional law guaranteeing freedom of research in Art. 5. Nevertheless, it must be stressed that these duties and rights are secondary to the primary duty of the physician "to serve the health of the individual" (Ärztekammer Berlin 1990).
2. These individual and societal desires for progress in the treatment of serious illnesses have found their expression in the fact that, according to the leading ethical assessment of medical research generally recognized today (the Helsinki Declaration and its revisions), the inclusion of patients unable to give consent in research is viewed as ethically defensible. This appears to be a contradiction to the Nuremberg Code, but can be understood in the historical context in that the Nuremberg Code of 1947 was aimed at condemning "research" with individuals who were not informed, were not voluntary, and were deceived in Germany under the National Socialists and its authors therefore did not mention research with patients unable to give consent

because they did not have them in mind. Furthermore, the necessity for therapeutic research with such patients could not be foreseen from the state of scientific development at that time (see also Meijers et al. 1995).

3. To place a taboo on research with patients unable to give consent hinders the development of criteria and methods which can recognize the special vulnerability of these patients and guarantee their protection and the observance of ethical standards. However, this is exactly what appears to be required. On the one hand, the need for research on serious illnesses is growing, and with it those circumstances which can lead to the inability to give consent (e.g. brain trauma, stroke, dementia, intoxication) or which appear in children who have a developmentally dependent inability to give consent. The example of the broad public conviction of benefit from azidothymidine (AZT) trials in the treatment of acquired immunodeficiency syndrome (AIDS) in the 1980s in the United States, which drove patients and physicians to forge inclusion criteria, makes it clear that precautions to protect vulnerable individuals are evaded if they are not adequate to the problem (Levine 1996). Furthermore, without criteria for the ability to give consent, such consent will be assessed very liberally on the basis of the clinical impression and accepted as given or the threshold determined as an indication for the explicit investigation of the ability to give consent will be placed so high that its absence cannot even be determined (see, e.g. example *f*, p. 327). On the other hand, the globalization of research and the worldwide use of its results carry the danger that a regionally absolute exclusion of all use of a person as an instrument could lead to the continuing use of individuals in this way elsewhere (Rössler 1996). It would then certainly be ethically questionable, but unavoidable due to open borders, to use such results of foreign research in Germany.
4. History has shown that the proclamation of ethical standards alone is not sufficient. In spite of the previously mentioned instructions issued in 1900 and 1931, the crimes committed under National Socialism occurred, and even after the Nuremberg Code of 1947, seriously unethical research projects were carried out and published (e.g. Beecher 1966; Faden 1996). Continuing discussion of the increasing multiplicity of serious ethical problems in both medical research and practice is therefore imperative. Steps in this direction include the establishment of ethics commissions and public discussion. Although there seems to be no alternative for the time being to the institution of expert committees (Rössler 1996), it is still an important step that these experts contribute their arguments in an understandable form to the public discussion and concentrate on significant questions (see statements issued by the Scientific Advisory Board of the German Federal Board of Physicians, the Central Commission for the Safeguarding of Ethical Principles in Medicine and Adjacent Fields, and specialist associations).

4.2 Suicide and Euthanasia

Psychiatrists are confronted with the issue of suicide and euthanasia in a number of ways: (a) in the overwhelming majority of cases, suicide occurs against a background of a mental disorder (see Vol. 6, Chap. 9); (b) a mental illness may also be important in a person's request for help with suicide or in dying; and (c) psychiatrists are increasingly consulted in the assessment of the ability to give consent when a patient asks to die by a life-sustaining treatment being discontinued. The central ethical problem here is that the duty of the physician, the guarantor of life, to act in the best interest of patients (in this case possibly a mentally ill patient unable to give consent) conflicts with respect for the right to self-determination of the patient.

However, as a profession, psychiatrists have had particular experience with the thousandfold abuse of euthanasia in the National Socialist past and therefore have a special obligation to concern themselves with this subject now (Lauter and Meyer 1992), after mentally ill patients have also been affected by physician-assisted suicide (see the comments on the Chabot case below).

Recent developments in the international debate over euthanasia show an increasing acceptance toward forms of directly assisted dying. In the Netherlands, there has been a legal ruling since 1993 (and de facto since 1992) according to which, while retaining the criminal ban on killing on demand and assisted suicide, physicians are assured of exemption from punishment if they follow a formally designated process and actively end the life of a patient whose unbearable suffering has led to their expressing a wish to die (van der Wal et al. 1996). In the state of Oregon (USA), a law was passed by public referendum in 1994 permitting physician-assisted suicide for seriously ill patients who had no chance of recovering. Similar legal reforms were only narrowly defeated in the states of California and Washington. These legal bans on physician-assisted suicide in individual states were upheld as compatible with the Constitution by the U.S. Supreme Court in

June, 1997.[3] In 1996, in the Australian Northern Territory, active euthanasia by a physician was permitted under particular preconditions. However, this ruling was later repealed on constitutional grounds by the Australian House of Representatives.

4.2.1 Definitions

In the controversial medical ethics debate about euthanasia and assisted dying, central terms are used differently. Terms will therefore be defined before their content is discussed. The expression "euthanasia" comes from classical Greek antiquity (Gk *eu* = good, *thanatos* = death), whereby a good, easy, gentle, and honorable death was meant. Euthanasia was a term in philosophy for a long time, and only in the 18th century did it find its way into medicine as related to medical help with dying and to providing support for the dying. Euthanasia was understood positively as a medical task to make the death of the dying person as easy as possible. Euthanasia in the medical literature of the 18th and 19th centuries meant help with dying, providing support for the dying, and relieving and assuaging death. At the same time, it was constantly emphasized that medical measures should never lead to a shortening of life. Such a wish on the part of the dying person was refused by the doctor. Only with the development of Darwinism at the end of the 19th century was euthanasia also discussed as the disposability of human life from the point of view of medical advances, "genuine humanity," and social aspects (Winau 1984; Vollmann and Dörries 1996). In Germany, the term euthanasia was abused by the National Socialists as a code name for the systematic and state-run murder of disabled and mentally ill children and adults (so-called "lives without value"; Winau 1984). Because of this abuse, the term "euthanasia" in Germany has such negative connotations that, in contrast to international usage, it should not be used (von Lutterotti 1992; Winau 1993). Other authors argue against this, saying that the National Socialism abuse of the term cannot be grounds to renounce it (Wassermann 1993), especially since it is common in international discussion.

The international use of the term euthanasia corresponds essentially to that of the German term *Sterbehilfe* ("help in dying"). Especially in the medical literature on *Sterbehilfe* (euthanasia), a distinction is made between an "active" and a "passive" form. According to this distinction, passive euthanasia is understood as the physician reacting passively toward the biological dying process or the fundamental illness and allowing the illness to run its natural course. This includes the omission, discontinuation, and removal of medically possible treatment measures. Whether artificial nutrition is a part of these medical treatment measures or represents an essential component of the care of a dying patient is a matter of controversial discussion.[4] Active euthanasia, on the other hand, is defined as active and intentional medical intervention in order to accelerate the occurrence of death. This includes, for example, deadly injections and administration of medications which intentionally and immediately kill the patient. However, this common distinction is disputed. Since so-called passive euthanasia includes not only a (passive) omission, a nontreatment, but also the (active) removal of therapies, a legal differentiation of indirect and direct euthanasia has been proposed (Wassermann 1993).

Obviously, neither the kind of medical treatment (active/passive) nor its intention and consequences (direct/indirect) are sufficient for a sound, normatively relevant differentiation of euthanasia. In addition to an extensive legal attempt at classification according to type of treatment and success, motivation, condition of the patient, insight and ability to give consent, purposefulness, and potential group of people involved in the deed (Eser 1976), the following classification was suggested from the medical perspective. Euthanasia is divided into two main groups: (1) help in the process of dying and (2) help in order to die. Help in the process of dying means the help and relief which is given to the dying person, i.e. to the patient who already is in the process of dying. This can be subdivided into euthanasia without the shortening of life, by allowing a person to die, by shortening life as a side effect, and by the intentional shortening of life. In comparison, help in order to die means that support is given to a person who is not in the dying process, but who for other reasons no longer wishes to live. Here, a distinction is made between ending a life subjectively felt to be without value through assisted suicide or death on demand, and ending a life which, from the view of a third party, has become without value (Winau 1993). In addition, it must be noted that, according to the Christian religion, there is no objectively worthless life ("the sanctity of God-given life"), and the murder of mental patients under

[3] Vacco, Attorney General of New York, et al. vs. Quill et al., decision of the Supreme Court of the United States, June 26, 1997; Washington et al. vs. Glucksberg et al., decision of the Supreme Court of the United States, June 26, 1997.

[4] This distinction in medical ethics has practical significance in the treatment and care of patients in a persistent vegetative state. In Germany, under the jurisdiction of the Federal Supreme Court (BGH 1 StR 357/94), the room for discretion in decision-making has increased for relatives and physicians of incurable patients lying in comas, and the significance of the presumed will of the patient is emphasized.

National Socialism – referred to as "mercy killing" – was prepared for using this concept, which is why such "killing out of pity" is currently unthinkable in Germany from the physician's point of view (Lauter and Meyer 1992; Winau 1993).

On the other hand, in the Anglo-Saxon discussion of medical ethics, euthanasia is often differentiated not according to the treatment or intention of the physician, but on the basis of the patient's wishes. Voluntary euthanasia occurs through a third party following the express wish of a patient who is capable of self-determination. It can happen either through assisted suicide or through killing at the express request of the affected person, e.g. in cases in which the suffering person is no longer physically able to commit suicide (Singer 1984). Whether the actual act of killing is active or passive, direct or indirect, is less significant in this differentiation. The ethical legitimation emphasizes much more the right to self-determination of the afflicted person, whereas the fundamental distinction from the medical and legal viewpoint between treatment (active) and omission (passive) is seen as ethically insignificant and is therefore the subject of controversy.[5]

Nonvoluntary euthanasia refers to the killing of a person who is not able to understand the decision between life and death, e.g. patients in a persistent vegetative state or severely deformed infants. Euthanasia is always nonvoluntary if the affected person either never had the ability to choose between life and death or, as a self-determining individual, never expressed a wish regarding such a situation. Under certain circumstances, nonvoluntary euthanasia is ethically justified from a preference utilitarian perspective (Singer 1984).[6]

An interdisciplinary, international discussion about euthanasia from the viewpoint of medical ethics therefore cannot draw on a unified terminology. More frequently, the different definitions of terms are used in parallel, and the particular conceptual criteria for definitions must be defined. In the clinical practice of the various specialities of somatic medicine, issues concerning the medical ethics of refraining from or withdrawing treatment at the end of life play the dominant role. Since the majority of mental illnesses, with the exception of organic psychoses, do not lead to a natural death, fewer questions of so-called passive euthanasia arise in psychiatric practice. Psychiatrists are much more increasingly confronted with questions concerning the active ending of a life. According to the new euthanasia laws in the U.S. state of Oregon and in the Australian Northern Territory, a psychiatrist has to be brought in for consultation by a physician before the active ending of a life either generally or in any case of doubt. In the Netherlands, the Supreme Court requires the consultation of at least two psychiatrists before physician-assisted suicide in the case of psychiatric patients. Hence, in the following sections, the problem areas of death on demand and medical assistance with suicide ("physician-assisted suicide") will be addressed in more detail.

4.2.2 Death on Demand

In Germany, any active killing of a seriously ill person with the goal of eliminating unbearable pain is a criminal offense, even if it is done at the express, earnest wish of an autonomous person capable of giving consent (although death on demand fulfills the requirements for mitigation of a sentence, Sect. 216 *Strafgesetzbuch*, StGB[German Penal Code]). Only in extreme exceptions can an emergency be assumed, which may partly justify the act and partly excuse it or may lead the person concerned being exempted from punishment (Eser 1992; Herzberg 1996). In practice, however, this provision of criminal law is extremely rarely used in Germany, and a considerable number of cases presumably go unrecorded (Schreiber 1995).

The overwhelmingly majority of lawyers agree that human life is accorded exceptional legal significance. Demands for legal exemptions from punishment for killing another person, e.g. to make possible a death with human dignity, will come up against the argument of the danger of the "dam bursting" in the protection of life. According to this argument, the protection of life by the state would be overcome and human life would be at the disposal of others. No one, it claims, has both a right to life and a simultaneous claim to end this life as he or she pleases, and if exceptions to the ban on killing were permitted, the protection of the ill, the severely impaired, and those whose lives were coming to an end would be endangered. Elderly and suffering individuals might then be pressurized, directly or indirectly, to request their own death, thus actually serving the interests of a third party (e.g. relatives). Indirectly, the self-determination of the patient would in this way be limited due to the

[5]On the controversy about the moral equivalence of treatment and omission, see Beauchamp (1989), Pellegrino (1989), Rachels (1989), Birnbacher (1990a), Thomas (1993), Bartlett (1995), Cartwright (1996), and Fuchs and Lauter (1997b).

[6]In contrast, involuntary euthanasia is understood as the killing of a person who is able to agree to his or her own death but does not do this because he or she wishes to live or was not asked before the killing. In both cases, involuntary euthanasia is unanimously rejected (Singer 1984). Involuntary euthanasia is a contradiction in terms (*contradictio in adjecto*) and is actually murder. The protest against Singer is probably substantiated even in his own terms, since in Germany this is understood as exactly what the National Socialists did.

unrestricted granting of self-determination for the end of life by another. In addition, advocates of this view point out the practical problems relating to evidence that would arise if death on demand were to be liberalized (Schreiber 1995). In 1986, an alternative outline for a euthanasia law (Baumann et al. 1986) was published, which was worked on by leading lawyers in collaboration with physicians, but it did not lead to any changes in the law. In the draft, the option of not serving the sentence associated with killing on demand in situations of extreme suffering was proposed, in addition to a legal clarification of the mutually agreed discontinuation of treatment and the measures used to lessen suffering with their risk of shortening life (indirect euthanasia). A change in the criminal law can scarcely be expected in the future either, because the abuse of euthanasia in National Socialist Germany has made public discussion of euthanasia in Germany more difficult (Wassermann 1993; Schreiber 1995). In addition, the highest jurisdiction in the Federal Republic (the Federal Supreme Court) has so far been very restrained in extending the discretion that can be exercised by physicians regarding euthanasia.

The German Federal Board of Physicians first published their *Guidelines on Euthanasia* in 1979, and these were revised in 1993. The guidelines refer exclusively to "individuals who are dying," for whom "the irreversible illness or the traumatic injury is taking an unfavorable course and death will occur in a short time." Only in such cases is the physician permitted to refrain from taking further treatment measures. This refers solely to the omission or discontinuation of therapeutic measures, whereas an "intentional shortening of life by artificial interventions in order to accelerate the occurrence of death," even at the request of the patient, is currently rejected (Bundesärztekammer 1979). German medical conferences have repeatedly and decisively rejected the various public demands to legalize so-called mercy killing, most recently in 1996 in the face of developments in Australia and in the Netherlands. In the opinion of the Deutscher Ärztetag (German Medical Society), a physician cannot be obliged to fulfill a person's wish for "mercy killing." Such a demand would destroy the relationship of trust between physician and patient (Bundesärztekammer 1988, 1993). The recently revised guidelines introduced by the Federal Board of Physicians in 1998 for medical support for the dying also changes nothing in the present unambiguous rejection of active euthanasia by the German medical community.[7] In the traditional way in which the medical profession sees itself, any active killing of a patient, even at his or her request, is rejected, since it stands in direct opposition to the medical precept to help and do no harm. Medical participation in active killing would seriously change the inner stance and professional identity of the physician and his or her public image.[8] Death on demand by means of a lethal injection destroys the relationship of trust between physician and patient and is not compatible with the physician's respect for human dignity. Death demanded by a patient should much more be understood as a call for help in coping with death (Lasch 1985; see also Matouschek 1989; Dichgans 1992; von Lutterotti 1993). Petitions and public protests through physician initiatives make clear the overwhelming rejection of active euthanasia in Germany.[9] In view of the decriminalization of death on demand in the Netherlands, the dangers of abuse connected with this are being vigorously pointed out by psychiatrists. Death on demand can be influenced by strong external factors, e.g. interests of other people, or by mental illnesses, which can influence the self-determination of the affected person. In the first case, societal opinions can be cited, as they find

[7]In the new formulation of the euthanasia guidelines, there is a greater consideration of patient directives and the value placed upon the individual, self-determining patients' wishes with respect to dying, and the question of indirect euthanasia, e.g. the cessation of artificial nutrition for patients in a persistent vegetative state (Bundesärztekammer 1998).

[8]The widespread, deeply rooted image which people have of physicians can be illustrated by several quotations. The German psychiatrists Fuchs and Lauter: "The price for the certainty of a quick death is the imposition made on another to carry out the killing. This price shall be paid exclusively by a profession, whose duty it is particularly to maintain life, heal illnesses, and lessen suffering" (Fuchs and Lauter 1997a). The WPA in its Madrid Declaration: "The first and noblest duty of the physician is to promote health, to lessen suffering, and to protect life ... The psychiatrist should realize that the opinions of a patient in a mental illness such as depression could be distorted. In such situations, it is the task of the physician to treat the illness and not to contribute to the death of the patient" (World Psychiatric Association 1998). The American anthropologist Margaret Mead: "The job of the physician, to save life, is of priceless value to humanity and must be protected against the constant attempts to harness the physician into activities of death. The public must be careful that this responsibility of the physician for life is kept. Measures and techniques, such as get discussed under the heading of euthanasia, must remain under the initiative and control of the laity – the medical profession should not be compromised by participation in them" (Mead 1963).

[9]See, e.g. the advertisement in *Die Zeit* on May 5, 1995: "Physicians' Initiative Against Active Euthanasia," the joint action "Europe Against Euthanasia" of the German Hartmann Association and the Dutch Medical Society (NAV) in 1996, or the actions of the German Society for Social Psychiatry and the "in part very emotionally led discussion of different population groups" (Bundesärztekammer 1997). On the Singer debate, see also Vollmann (1989), Hegselmann and Merkel (1991), Schöne-Seifert and Rippe (1991), Singer (1990), Singer and Kuhse (1994), and Vollmann (1996b).

expression in the present euthanasia discussion. Direct or indirect moral pressure can be engendered in expectations made on the affected person, who in light of present economic bottlenecks, e.g. in the medical treatment and care of older people, in effect place the interests of a third party over what are only presumed to be individual wishes. Second, illness-determined influences, particularly mental disorders, e.g. depression, can change the way a patient expresses his or her will, so that there is no real self-determined will of the affected person (Barocka 1992; Helmchen 1992; Lauter and Meyer 1992). With these arguments, as well as reference to the euthanasia debate in the Weimar Republic, in which influential psychiatrists (e.g. Hoche) participated, and haunted by the catastrophic consequences for the mentally ill during National Socialism, psychiatrists in Germany are arguing against any step toward a liberalization of active euthanasia. The demand for euthanasia in the 20th century may spring from the liberal demand for more self-determination, emancipation, freedom, and progress, mixed with an almost religious belief in science and the possibility of abolishing human suffering, and from the fact that death is a taboo. The approach which derives from that – quantifying human suffering and regarding a life as no longer having human dignity or being worth living above a certain level – is a dangerous continuation of earlier demands for euthanasia, which inevitably led down a slippery slope away from the protection of human life and toward a form of medicine which despised and destroyed individuals. It is on the very basis of the murder of mental patients with the cooperation of psychiatrists under the National Socialists that the new euthanasia movement in Germany needs to be opposed firmly and unambiguously, especially by physicians (Dörner 1988; Bastian 1990; Lauter and Meyer 1992; Daub and Wunder 1994). In contrast, Anglo-Saxon psychiatrists are increasingly placing the patient's right to self-determination at the end of his or her life in the foreground and are calling for the legal regulation of active euthanasia. Psychiatrists should participate actively and play an important role in the development of the controls required here (Helme 1993).

4.2.3 Physician-Assisted Suicide

Suicide is legally understood as a conscious and deliberately chosen killing of oneself by means of a definite and purposeful action. Accordingly, a patient who refuses what is probably a life-saving treatment and hence gives free rein to the deadly course of the illness is not considered to be attempting or committing suicide (Kaiser 1992). In German, the expression *Selbstmord* ("self-murder") is frequently used in addition to the word "suicide." However, on the basis of the legal situation in murder, the term is incorrect and normatively prejudicial. Therefore, instead of "self-murder" the term *Selbsttötung* ("self-killing") is more correct (Wassermann 1993). In contrast to other countries,[10] in Germany, neither suicide nor the incitement and assistance to perform suicide are criminal offenses (Wassermann 1993, Schreiber 1995). In medical practice, however, problems frequently arise in defining and drawing distinctions. On the one hand, the seriousness of the death wish needs to be considered. Has the person concerned really openly and autonomously wished for death, or is it much more a case of an attempted suicide, intended as a cry for help? This is frequently a difficult differentiation to make and brings with it the question of the ability for a self-determined will, which can be restricted to a great extent by influences from outside or by mental illness. On the other hand, is the person contemplating suicide faced with a society (or medical profession) that overwhelmingly rejects his or her behavior and views it as socially deviant? Legal questions result for clinical practice as to the measures that are allowed or even medically required for the prevention of suicide, if necessary even against the expressed will of the person. Physicians can thus be caught in an ethical and legal dilemma between euthanasia desired by a terminally ill patient, assistance with suicide desired by someone who is seriously suffering (respect for patient self-determination), and the failure to give assistance (professional duty of the physician). In clinical practice, legal problems frequently exist relating to the distinction between assisted suicide, which is permitted, and the criminal offense of killing on demand (Sect. 216 StGB). According to the highest judicial interpretation of the Federal Supreme Court, the question of who actually controlled the act leading to death is considered to be the crucial factor.[11] In spectacular cases of active

[10] Under Austrian criminal law, anyone involved in suicide, and under Swiss law anyone involved out of selfish motives can be sentenced. In England and Wales, suicide was a criminal offense until 1961 (Kaiser 1992). Since the Suicide Act of 1961, suicide is no longer a criminal offense, although a third party who takes an active part in a suicide is liable for prosecution. In contrast, in Scotland participation in suicide is not a criminal offense (Neeleman 1996; Eser and Koch 1991). According to the Dutch penal code, not only death on demand, but also assisted suicide is a criminal offense (Arts. 293, 294 nlStGB). The wording of the law, valid since 1886, speaks in favor of an unrestricted ban on killing, whereby little room remains for euthanasia. The present liberal practice of euthanasia is made possible by a broad interpretation of general reasons for exemption from punishment and by the decision by criminal prosecution authorities not to prosecute in all cases (Scholten 1991).

[11] See BGHSt 19, 135.

euthanasia on behalf of severely physically disabled patients wishing to die, the public has been very much made aware of how difficult it may be to differentiate between assisted suicide, which is not a criminal offense, and killing on demand, which is (Kaiser 1992).[12]

The criminal assessment of noninterference in a suicide is even more complex. If a person committing suicide becomes unconscious and therefore loses control over the course of events he or she has set in motion, the attending physician, who has a particular obligation toward this person, can be charged with the criminal offense of murder by omission if he or she does not provide the help that is necessary, possible, and reasonable at this stage at the latest (Kaiser 1992). Court decisions generally regard suicide as an accident that needs to be averted, even if the person concerned has acted on his or her own free responsibility. As a result of these decisions passed by the Federal Supreme Court, three constellations arise in the physician's clinical practice:

1. If a patient is under medical or even psychiatric treatment for suicidal tendencies and a suicide attempt is the result of the patient's lack of clear responsibility, the physician has a duty to prevent the suicide. The same applies to minors or patients with an impaired ability to determine their own will.
2. If the physician encounters an emergency situation in which an unconscious patient unknown to him or her has attempted suicide and there is no additional relevant information, the physician must assume that the suicide is "pathological" and take appropriate life-saving medical measures.
3. If, however, an apparently clear desire for suicide is known to the physician, e.g. as a consequence of previous information from the patient or through a patient's directive, according to the decisions taken by the Federal Supreme Court, the physician may not merely comply with the patient's wishes alone. Instead, he or she has "to make a responsible decision on whether or not to intervene, even if such an intervention will not necessarily be successful."[13]

This legal decision is controversial, however, among German criminal lawyers and has come in for sharp criticism in some cases. In differentiating between assisted suicide (not a criminal act) and killing on demand (a criminal act), according to the Federal Supreme Court what matters is that the person attempting suicide does not go to a doctor to tolerate death by the doctor's hand, but that this individual remains in charge of events until the very end. The prevailing legal opinion regards it as decisive whether the event ultimately proves to be an action arranged by the person concerned on his or her responsibility or one arranged by another person (Kaiser 1992; Wassermann 1993). A further point open to criticism in the decision passed by the Federal Supreme Court is the classification of all suicide attempts as accidents, even if the suicide wish was reached autonomously and on the patient's responsibility and the physician has given the patient assistance exempt from punishment beforehand (Schreiber 1995). This decision declares the will of the patient to be irrelevant. However, the decision concedes to the physician an autonomous discretion to appraise the situation, in which the patient's right to self-determination represents only one of several factors (Eser 1985; Gropp 1985). This is even more astonishing, as the Federal Supreme Court rulings in the case of so-called normal patients usually rejects the idea that the physician has a professional duty to prolong life following the onset of unconsciousness if permission to abandon treatment has been granted (Schreiber 1995). This inequality in the way that patient autonomy is treated by the highest court for a self-determining suicidal patient and a so-called normal patient does not appear justified, because the basic law of an ideologically neutral country does not derive from prior assumptions, however well-founded, but from the right to self-determination of the individual citizen (Wassermann 1984, 1993), while in the Federal Supreme Court's decision "the right to self-determination of the person wishing to die ... falls by the wayside" (Gropp 1985).

The Federal Board of Physicians goes beyond these criminal legal requirements by condemning any involvement by a physician in suicide as "nonmedical" (Bundesärztekammer 1993). German medical conferences have repeatedly described interventions to end a life and assisted suicide at the wish of a patient as professionally unethical, without acknowledging the ethical differences between the two acts (Bundesärztekammer 1988). The rejection of any form of

[12] A good example is that of the surgeon Dr. Hackethal, who caused a sensation in Germany the mid-1980s by helping seriously ill patients commit suicide by giving them access to poison. Hackethal was acquitted by the Higher Regional Court of Munich in 1987, because his actions did not exceed assisted suicide and thus did not constitute a criminal offense (OLG Munich NJW 1987, 2940). This decision acquires fundamental significance since, in contrast to the decision by the Federal Supreme Court, it gives priority to the patient's right to self-determination, even for suicide (Schreiber 1995).

[13] BSHSt 32, 367, 387; decision of the Federal Supreme Court of July 4, 1984 in the case of Dr. Wittig (Az. BGH 3 StR 96/84). The physician did not initiate any life-saving measures for an unconscious patient following ingestion of medication in order to commit suicide, since he was aware from conversations and a letter from the patient of her wish to die, respected this wish, and considered medical recovery very unlikely on the basis of the severe intoxication.

physician-assisted suicide is in accordance with the revised Swiss guidelines on euthanasia and with the stance of the WMA.

This rejection is even more understandable in psychiatry, because suicidal potential and mental disorder frequently occur concurrently in practice (see Vol. 3, Part 2, Chaps. 9, 10). Moreover, in Germany, psychiatry is burdened with the experience of the involvement of psychiatrists in the registration, systematic sterilization, and murder of mental patients under National Socialism. On the basis of this historical experience, it is understandable that the overwhelming majority of German psychiatrists reject any form of active euthanasia, including physician-assisted suicide (Helmchen 1986; Dörner 1988). Medical ethos obliges all psychiatrists to attempt to prevent the patient's suicide in the doctor–patient relationship. The one-sided overvaluation of the autonomous freedom of decision could all too easily lead to indifference on the part of the physician. Instead, suicide prevention presents a humane duty incumbent on medicine, especially psychiatry, that should not be questioned by the propagation of the right to commit suicide (Bron 1986). In difficult economic times, in particular, what is presumed to be self-determination on the part of the individual can become the suicide of the sick, disabled, and elderly under the influence of social and economic factors and societal pressure (Heinrich 1992; Lauter and Meyer 1992). With such purposefully weighed and progress-oriented thinking, the danger exists of inhumane elimination of so-called useless and unproductive individuals, as in National Socialist Germany, "the final solution of the social question." Today the danger exists again in Germany that mentally ill and weak individuals will be isolated by the decline of moral and material solidarity. Thus many regard the present euthanasia debate as taking a dangerous, misguided course in social, ethical, and political terms (Dörner 1988).

The mere possibility of abuse is an insufficient argument to counter this rejection of physician-assisted suicide, which stems from the historical experience of abuse. The argument frequently cited in this connection, the "slippery slope,"[14] (Fuchs and Lauter 1997b) claims that making physician-assisted suicide permissible would mean that the active killing of the mentally ill could no longer be controlled at all. If the previous medical taboo against killing falls away, all mentally ill patients are at risk of being killed by their treating psychiatrists. The Dutch development is cited as evidence, according to which the number of deaths on demand in recent years has increased considerably and the concept of "unbearable suffering" has been extended, so that within 1 year 0.8% of all deaths were attributed to nonvoluntary euthanasia. Philosophical authors, in particular, but also physicians in the Netherlands and the United States argue that the danger of the "slippery slope" does not hold on the following grounds: through prevailing legal circumstances, which permit a physician-assisted suicide in a democratic society, it is possible to publicly control the current practice of physician-assisted suicide of severely ill patients. Different social groups, including the medical profession, are in a position to draw up exact guidelines with which to prevent an abuse more effectively than could be done previously (high number of unrecorded cases). Accordingly, American physicians have proposed concrete criteria and regulations for physician-assisted suicide (Quill et al. 1992; Miller et al. 1994). Especially in comparison to active euthanasia, physician-assisted suicide would be less in danger of abuse and could, as the Dutch example shows, be accepted by a large majority of people. Due to the fact that it is "only" a physician-assisted suicide, the patient retains decisive control over the event, which is simply competently supported by the physician. Hence physician-assisted suicide represents a form of voluntary euthanasia (see above) in which the dignity and autonomy of the person is also respected in the last part of life (Birnbacher 1990b; Ach and Gaidt 1994; review in Schöne-Seifert 1996, pp. 604–613). The frequently expressed argument that physician-assisted suicide would damage the integrity of medicine can also be countered by the argument that this form of euthanasia for severely suffering, dying patients represents medical help shaped by a respect for humanity (Momeyer 1995; van der Maas et al. 1996; van der Wal et al. 1996; for reviews, see Fins and Bacchetta 1994, Groenewoud et al. 1997). Of course, it must be considered that, in the special case of psychiatry, physician-assisted suicide by a psychiatrist would fundamentally change the present image of the profession and the way it views itself. Based on their clinical experience as psychiatrists, the authors doubt that medical responsibility to prevent suicide in mentally ill patients is compatible in practice with an active support of patient suicide.

In this context, the case of psychiatrist Dr. Chabot, who helped a depressed patient in the Netherlands to commit physician-assisted suicide, has been critically discussed in psychiatry (Fuchs and Lauter 1997b).

In the autumn of 1991, the psychiatrist Boudewijn E. Chabot helped his 50-year-old patient Netty Boomsma to commit suicide by providing her with a deadly dose of medication, which Mrs. Boomsma took in his presence. The patient, a social worker, no longer

[14]The terms "bursting dam", "stray path," and "inclined plane argument" are used synonymously in German for the English expression "slippery slope argument" (see Guckes 1997).

wanted to live following her divorce and the death of both her sons (her older son committed suicide in 1986 aged 20, and her younger son died of cancer in 1991). Since both her children had been the focus of her life, she saw no hope and meaning for the future whatsoever, viewed her life as hopeless and without any prospects, and repeatedly expressed to her psychiatrist the wish to die. Dr. Chabot had a number of psychiatric conversations with Mrs. Boomsma over a period of about 5 weeks, totaling about 24 h. He diagnosed a pathological grief reaction (adjustment disorder DSM-III-R), which had existed for 5 years, with predominantly depressed mood, but without the presence of a psychiatric illness in the narrow sense, e.g. a severe depression or personality disorder. The mood of the patient was overwhelmingly depressed, although it was capable of change, so that the patient could exhibit self-perspective and humor. Mrs. Boomsma's ability for self-determination was not impaired by her mental state in Dr. Chabot's judgment. She refused both psychopharmacological and psychotherapeutic treatment aimed at making her able to grieve, because she knew from the death of her first son what this entailed and was not prepared to go through it again. Although they had no personal contact with the patient, the four colleagues consulted by Dr. Chabot agreed with him on the basis of the patient's records and his report that no actual psychiatric illness was present, but that the patient suffered persistent and unbearable mental torment. The patient did not suffer from a "hopeless suffering" in the sense of a severe, physical illness leading to death, as euthanasia practice in the Netherlands had required up to that point, nor was she in a physically life-threatening situation.

In June 1994, the Supreme Court of the Netherlands found Dr. Chabot guilty, but refrained from prosecution. In the reasons given for its decision, the court stated that the psychiatrist was not sentenced because of his assistance in his capacity as a physician in the suicide of a mentally ill woman, but because he did not observe the operative rule of a personal consultation by a professional colleague. In this context, the Dutch Supreme Court stated that a physician could also cite an emergency in circumstances in which a patient was not physically suffering and thus not dying. This would justify physician-assisted suicide, since here the extent and prognosis of the suffering and not its cause (physical/mental) were decisive. In the present case, the court recognized for the first time the hopelessness of the situation of a mentally ill patient and explicitly approved physician-assisted suicide. In 1995, a disciplinary court for physicians in Amsterdam reprimanded Dr. Chabot because he had not attempted sufficient psychiatric treatment of the patient. The psychiatrist was permitted to continue to practice. This decision of the disciplinary court, composed of a judge and four physicians, should cause him to "reflect."[15]

Case-related psychiatric comment is difficult, because the facts are known exclusively from Dr. Chabot's point of view and the published court judgment. In spite of the restricted basis for judgment, from a psychiatric viewpoint, both the uncertainty with respect to the assessment of the grief reaction as having the status of an illness (not a real mental illness, but requiring treatment) and the short observation period of only 5 weeks in a depressed patient and the short period of 4–5 months after the death of the second son for the loss determining the abnormal grief reaction are striking. As a rule, this short period is not sufficient for an adequately reliable psychiatric prognosis of outcome. Furthermore, it must be asked whether a (renewed) psychotherapeutic and psychopharmacological treatment trial should not have taken place immediately before the physician-assisted suicide. This requirement seems all the more worthy of consideration since a pathological grief reaction with depressive mood can be successfully psychiatrically treated (Fuchs and Lauter 1997b). On the other hand, it does not appear appropriate in view of the respect demanded for the right to self-determination, since the patient had clearly rejected all forms of treatment. However, the decisive issue of the ability to give consent remains open and is only emphasized by the uncertainty with respect to the evaluation of illness and need for treatment of (as well as the ability to treat) the abnormal condition.

In addition, the case raises fundamental questions about the doctor–patient relationship in mental disorders and in relation to the way in which the psychiatric profession is understood. In clinical practice, a suicidal tendency usually presents as a temporary symptom of a mental illness. With improvement in the state of mental health, the suicidal tendency disappears in the majority of cases. From this psychiatry derives a general treatment and protective role toward each patient wishing to commit suicide. According to Fuchs and Lauter, the psychiatrist must take a clear position against suicide and for the life of the patient in each case. Otherwise, a therapeutic relationship is not possible because communication with the suicidal patient is established from the outset on a contradiction. The psychiatrist, as "the final representative of life and the community" and "the affirmation of life," therefore has to carry out the task "as a person who makes the patient able to experience his or her own

[15]On the judgment in the Dr. Chabot case, see Oglive and Potts (1994), Griffiths (1995), Klotzko (1995), and Fuchs and Lauter (1997b).

value again" and to "find a way back into the community with the patient" (Fuchs and Lauter 1997b). However, it remains to be examined to what extent a teleological mind-set lies at the basis of this assessment of suicide as an illness-dependent action directed against one's own worth, nature, and the community. There are certainly justifiable reasons for this, but in a secular and pluralistic discussion on the medical ethics of values, no universal validity can be claimed. In addition, the value of the patient and of his or her place in society is postulated without addressing the decisive argument to justify suicide, the individual's right to self-determination, in a differentiated way. The fundamental problem of the medical ethics of physician-assisted suicide lies between the patient's right of self-determination (principle of autonomy) on the one hand and the duty of the psychiatrist to foster the well-being of the patient (principle of beneficience) and not to cause harm (principle of nonmaleficence) on the other. Both arguments therefore have to be thoroughly analyzed and carefully considered, which is not possible if suicide is devalued a priori (Momeyer 1995; Diekstra 1996).

From the psychiatric point of view, a real practical problem in the assessment of the medical ethics of physician-assisted suicide lies in establishing as securely and objectively as possible the autonomous will of the patient. The problem for the psychiatrist in terms of medical ethics and the law is less the psychiatric diagnosis (nosological assignment), and more the judgment of the patient's ability for self-determination. The Supreme Court of the Netherlands established in the Chabot case that the ability for self-determination can be destroyed or impaired by both mental and physical disorders, and the differentiation between physical or nonphysical disorders is thus not relevant in assessing whether assisted suicide is permissible (Griffiths 1995). Above all, psychiatric experience and knowledge have shown that the ability to give consent are not necessarily impaired even in patients with mental illnesses. This is confirmed by recent empirical results of psychiatric research on informed consent (for a review, see Vollmann and Helmchen 1997). Consequently, the presence of a mental disorder does not automatically rule out a self-determined and voluntary wish to die.

The evaluation of informed consent in assisted suicide is extraordinarily difficult in depressed patients, because the unambiguous establishment of what the patient "really" wants is, in practice, often hardly possible. Criteria for establishing the presence of self-determination that have a clearly defined content, are differentiated, and are generally recognized are lacking. In addition to the multitude and poor definition of basic criteria (criterion variance), there is also the problem of the determination of these criteria in a particular patient in clinical practice, as different psychiatrists can arrive at different assessments (observation variance; Helmchen 1992). In a mental disorder, the self-determined request for assisted suicide can be impaired by external and internal factors, such that an autonomous decision by the patient is not possible. While human decisions can in general be influenced by a multitude of external factors (e.g. opinions and values of relatives, treating physicians and caregivers, socioeconomic factors, media, the "spirit of the times"), in depressed patients the existential dependence upon the environment can reach such an extent that a request determined by another person can be masked by an expressed suicide wish. (The same naturally applies to the reverse case of a suicide wish that is made taboo by relatives or psychiatrists.) In this context, the ethically paradoxical and dangerous situation arises that, by calling for permissibility, availability, and feasibility of suicide through individual self-determination, the fundamental inviolability of human life would be abandoned and human life would thus become vulnerable not only to one's own, but also to other interests (Helmchen 1992). As an example of the particular impairment of self-determination by external factors, the so-called suicide epidemics can be mentioned, e.g. in religious sects or in the wake of publications such as Goethe's *Die Leiden des jungen Werther* or presentations of suicide in television programs (Schmidke and Häfner 1986; Simkin et al. 1995).

In addition to these external factors, internal ones, such as mental disorders, can impair the ability for self-determination. In a large empirical study, 23.9% of depressed patients were not able to give their consent in therapeutic decisions (Grisso and Appelbaum 1995). Since the threshold for the ability for self-determination in an assisted suicide must be placed higher than with therapeutic measures, it can be assumed that the number of depressed patients unable to give consent is even higher. In addition, a connection between depressive symptoms and the wish for physician-assisted suicide in patients in the final stages of physical illnesses has been proven in empirical studies. In these patient groups, 58.8% of the patients with a desire to die suffered from depression, in contrast to only 7.7% of those not wishing to die, whereby the desire to die fluctuated strongly over time (Chochinov et al. 1995). The inner impairment of a self-determined request to commit suicide correlates with the severity of the depression and is largely independent of its medical genesis (e.g. reaction to serious physical illness or in the framework of a grief reaction, as in the Chabot case, versus "endogenous" or organic brain causes). It is, however, unclear how the degree of depressive psychosis can be established independently of symptoms of physical illness and suicidal tendency,

and it has not been established at what stage of the development of depression the self-determined desire for suicide becomes questionable (Brown et al. 1986; Cassel and Meier 1990; Conwell and Caine 1991; Ganzini et al. 1993; Pohlmeier 1995). These difficult, complex questions require comprehensive, interdisciplinary, psychiatric, ethical, and legal study. Until the unsolved questions of the ability for self-determination of patients with psychiatric disorders desiring suicide have been explored more precisely and empirically, assisted suicide is not ethically defensible from the psychiatric point of view.

5
Common Ethical Problems in Psychiatric Practice

The ethical principles presented at the beginning are essential not only for the assessment of the particularly important problems with which the public is mainly preoccupied, for which two examples were discussed above. Consideration of these principles is also fundamentally significant for medical activity in daily practice. Although the principles are probably usually considered, this is done so more implicitly than consciously. Indeed, this might not always suffice to protect the physician against the pressures of the immediate situation, against personal motivation that is not considered, and above all against dangerous requests resulting from the spirit of the times, ideologically dominated on the one hand and pluralistically noncommittal on the other. In such a context, ethical principles can become unclear or lose their binding character, especially when the physician has to make decisions in a necessarily broad gray zone of individual discretion between the norms of what is unambiguously correct and the what is certainly wrong. The traumatic insights gained in analyses of the practice of the National Socialist euthanasia program, which showed a wide spectrum ranging from active resistance to such murder of the mentally ill to its support, may provide a warning in this context against too much self-assuredness (Schmuhl 1987; Kersting 1996; Helmchen 1998b).

The principle of autonomy as a general human right cannot be accepted without question in a medical context, since it can clearly come into conflict with the original principle in medical ethics of well-being (*salus aegroti*). This significance is not readily apparent in the now diverse practice of the courts either, which imposes an obligation on the physician to inform his or her patient of the nature of any planned treatment, since only an adequately informed patient can make a legally valid decision to consent to a medical procedure. Instead, it only becomes clear if this duty to inform becomes a critical component of medical treatment and facilitates the patient's ability to make an autonomous decision, thereby investing the doctor–patient relationship with trust and pointing out to the patient his or her own individual responsibility.

While the danger arising from laying the sole responsibility ultimately on the patient is now seen more often, paternalism was above all a risk of the previous psychiatric practice. This constitutes the most important problem specific to psychiatry that adherence to the principle of self-determination entails. It is obvious that mental illnesses – more than physical illnesses and even more than the emotional distress caused by the vicissitudes of life – can impair or even destroy a person's ability for self-determination, his or her ability to understand and want something. Since its beginnings, psychiatry has had to devote itself to this illness-related limitation, the loss of self-determination, with its recognition and even more so with its consequences, such as danger to self or others, compulsory admission and treatment, capacity to make a will, legal competence, recognition of guilt, and ability to provide consent (see Chaps. 15–17, this volume). In addition to the relevant legal questions, the physician is always called upon in a particular case to recognize correctly the boundary between the ability for self-determination which is already limited and that which is still retained in order to avoid the harmful consequences of a false assessment. This applies to an even greater extent in the case of patients who are clearly psychiatrically ill, who in many respects can be assumed to have retained the competence to make decisions and who, incidentally, should not be patronized and discriminated against.

5.1
Necessary Treatment Without Patient Consent

If a psychiatric illness leads to loss of the ability to make decisions, i.e. a loss of inner freedom with the consequence of presenting an immediate danger to self or others, then the patient must be prevented from presenting such a danger by withdrawing his or her external freedom, unless less radical measures are able to remove the danger. Such confinement against the will of the patient is legal; from the medical point of view, in addition to averting danger by physically preventing it, it aims primarily at eliminating the causes of the danger by treating the underlying psychiatric illness. Problems usually arise if the danger entailed by the illness is not so clear that the use of force appears to be necessary if the patient rejects the indicated treatment (Helle 1993). The physician is then confronted with the ethical question of how best to undertake the obligation to do everything for the well-

being of the patient without disregarding his or her autonomy, even if this autonomy is reduced on account of the illness. Many psychiatrists now patiently try to convince the patient of the necessity for therapy. However, discharging such a patient without treatment (although certainly not without the offer of resuming treatment at the wish of the patient), a procedure that is now often followed, makes many psychiatrists doubt whether they have correctly assessed the risk of extending the patient's suffering and the danger related to the illness against the risk of destroying by force any opportunity to develop trust on which to base voluntary treatment. Thus the question as to the influence that society-based or other concrete situation-specific conditions connected with the physician's discretionary powers have on his or her appraisal of risks and benefits, e.g. if the patient's motivation for therapy can be described as paternalistic manipulation or if the explanation of alternatives, such as nonvoluntary committal, are experienced by the patient as threats. The same is true if, in so-called psychiatric testaments, the psychiatrist is threatened with punishment, e.g. a lawsuit based on breaking confidentiality, if he or she wants to establish a clear legal basis for the necessary treatment, by submitting an application to a court to issue a mandate for treatment. This also applies to situations in which, in light of the tighter health care budget and the demands for a more just distribution of resources, the length of hospital stays are strictly limited and hospital stays that are not therapeutically useful are not paid for. In each case, the psychiatrist should be clear about the arguments determining the ethical considerations in order to win the trust of the patient through competence and responsibility or to justify the existing trust. Incidentally, the psychiatrist is also well advised to document the arguments comprehensively, since ethical decisions can be queried after the fact or even in court.

5.2 Informing Patients About Tardive Dyskinesias

Tardive dyskinesias are motor disorders that first appear late in the course of long-term treatment with neuroleptic drugs. They are its most serious risk because they are relatively common, only partially reversible, and so far difficult to treat. Reliable predictors of the risk are not known. However, the effectiveness of the long-term use of neuroleptic medication as a prophylaxis against relapse and in symptom suppression is clear. Useful individual response predictors are, however, not known either, with the result that the therapy response to long-term neuroleptic therapy in each patient can fluctuate between complete effectiveness without undesirable side effects and inadequate effectiveness with tardive dyskinesias. In view of the uncertainty of predictions of individual risk in an established therapy whose effectiveness makes it the standard one, a particularly careful appraisal of benefits and risks and informed consent are necessary at the beginning of long-term medication. It is a question of quality assurance not to let an acute neuroleptic drug treatment turn into a long-term one without comment, but rather to establish the indication independently and to explain this new treatment to the patient, including the different goals and risks; in addition, the course of treatment needs to be followed closely, examining therapeutic effectiveness, looking out for undesirable side effects of the medication, especially tardive dyskinesia, and checking that dosage is appropriate. Should tardive dyskinesia then appear, the benefit–risk appraisal needs to be repeated in the continuing course of treatment and alternative therapies considered anew, even if all psychiatrists probably know patients in whom neuroleptics cannot be discontinued despite the appearance of tardive dyskinesia, because the suffering experienced by these patients if their psychosis were to remain untreated (or if atypical neuroleptics were administered that were unable to treat the psychosis adequately) would be incomparably greater than that caused by the tardive dyskinesia (Helmchen 1991).

Fundamental criteria indicating long-term medication with neuroleptics are the persistence of symptoms or a considerable risk of relapse. Understandably, in the former case, the subjective pressure of suffering often motivates the patient to turn to symptom suppression using long-term medication; moreover, relief is usually experienced immediately. However, a patient will usually only decide in favor of long-term medication on the basis of its ability to prevent relapse if he or she has already experienced a traumatizing relapse. As a last resort, if frequent relapses owing to noncompliance put the patient at risk of long-term hospitalization, a neuroleptic depot treatment is indicated in order to compensate somewhat for the fluctuating insight on the part of the patient that the treatment is necessary. Particularly with such patients, as a result of their variable limited ability to give consent, information and self-determination sometimes have limits. Even if the majority of acute psychotic patients who have been treated against their will later consider this treatment to be correct after their symptoms have subsided (Schwartz et al. 1988), the physician will still need to examine closely in each case the particular conditions of an individual patient for indications for a neuroleptic depot treatment based on noncompliance. For example, if noncompliance is caused by a rejection of treatment because the patient is afraid of developing tardive dyskinesia, the physician will be more likely to have to accept this than if

the noncompliance is a result of a delusion of poisoning. In practice, the psychiatrist is often faced with the following dilemma: on the one hand, after carefully assessing the risk of tardive dyskinesia, the motives for depot medication as the best alternative for the patient must be examined without crossing the boundary of paternalistic care for the patient; on the other hand, the psychiatrist may have to initiate a treatment program ordered by a court if a patient's ability to give consent is found to be limited, even if the effectiveness of such treatment is doubtful on an outpatient basis. It is the experience gained with such patients that substantiates the fear of many psychiatrists that too far-reaching an advocacy of the patient's right of self-determination or of a legally indisputable substitute for the decision-making powers which are impaired or destroyed by the illness is actually not in the interest of the patient (Gutheil et al. 1980).

5.3 Information and Justice in the Case of Suboptimal Therapy

The development of so-called atypical neuroleptics that do not carry the risk of tardive dyskinesia entails a further ethical dilemma for the physician: widespread prescription of these neuroleptics for long-term treatment runs counter to the rules imposed on physicians by insurance companies regarding the economic prescription of medication (with consequent threats of recourse), because these drugs are considerably more expensive than standard neuroleptics and therefore place an additional burden on the recently introduced budgeting program, i.e. they limit the possibility of providing other patients with optimal treatment.

Generally formulated utilitarian ethics are gaining in importance in comparison to egalitarian ethics. Compared with the egalitarian precept that all patients should be treated equally, guided exclusively by the needs in an individual case, a precept that has determined medical actions thus far, utilitarian ethics mean, for example, that the available budget is to be used in the best interests of all patients (for whom this budget is valid), even if that means that an individual patient does not receive optimal treatment (Smith and Morrissy 1994). At the same time, it cannot be ignored that, in view of the great need and failing resources in many parts of the world, such utilitarian considerations are inevitable and even triage decisions cannot be avoided. Thus the insufficient aid is only sent to a group that is selected on the basis of certain criteria, such as the best prognosis, as in the allocation of organs in transplantation medicine, for example.

At the same time, physicians face the question of whether to explain to individual patients the suboptimal treatment, allowing the patients themselves to attempt to obtain alternatives, or not to explain it because these alternatives are regarded as not being able to be realized for a particular patient and could therefore merely further weaken the motivation for therapy, which is frequently already limited in psychiatrically ill patients. However, in the assessment of alternatives for the patient, physicians must be conscious of the increasing danger that they may no longer be solely representing the interests of an individual patient, but also other interests (i.e. their own) (Smith and Morissy 1994), e.g. if physicians are given (even partial) control over the use of resources and hence over rationing through the cost controls of budgeting or "managed care," which are now being implemented everywhere (Schlesinger 1995). This can be seen from the example of the introduction of budgeting in 1991 for part of the medical general practice (FHP) in the National Health System (NHS) in England (Smith and Morissy 1994). A further question remains open in this context, i.e. whether the allocation of resources is more just if it is carried out by the physician, who is more familiar with the problems of the individual patient, by the politician determining the regulations governing this allocation, or by insurance company employees, who allocate resources according to the regulations in a more formal manner (Vollmann and Dörries 1996).

These questions have only been addressed in part here and are becoming increasingly important in view of the current reform of our health services into health economies (Tischler and Astrachan 1996). A comprehensive analysis of the resulting influences on ethical principles and foundations of medical care remains to be carried out.

5.4 Medications with Addictive Potential

Methadon has been used for a long time in Germany and is increasingly administered as a heroin substitute treatment for heroin addiction. Recently, heroin itself has also been proposed for these indications (its use as an analgesic has long been permitted in England; Strang and Gossop 1996). Although this has the advantage of lessening the individual's suffering, there is the disadvantage of continued dependency, even if this dependency is medically controlled. The necessary benefit–risk assessment corresponds in principle to that facing the physician for many other treatments (Strang and Gossop 1996). However, this assessment is complicated by two problems: doubt about the ability of the dependent person to give consent and the context of society. The physician cannot simply comply with the patient's desire to suffer less by relieving withdrawal symptoms, since it is not certain

that the patient can meet the requirements for valid consent by correctly assessing benefits and risks. The craving for the addictive substance, which constitutes the dependency, probably limits if not destroys the ability of the dependent person to make decisions. Theoretically, the necessary initiation of compulsory treatment in such a patient might run into considerable practical problems, in particular the threshold of effort required by the dependent person for such a treatment might become considerably higher. As for the second problem, the physician has to verify the degree to which the social objectives associated with substitute treatment come into conflict with the individual well-being of the patient. The welfare of the patient and his or her freedom from suffering is understood much more in the sense of the social goals of decriminalization and resocialization and defined in terms of health policy as serving the common good, so that the unlimited implementation of a substitute treatment, while maintaining public order, cannot aspire to liberate the patient from dependency by achieving abstinence.

However, the social milieu can also tempt the dependent person to abuse substitution therapy, in particular leading him or her to misunderstand total substitution with methadon or even heroin as a "hedonistic signal." The nontherapeutic use of psychotropic substances is certainly widespread in our society, with substances ranging from tobacco, alcohol, hashish, and amphetamines to LSD, heroin, cocaine, and designer drugs such as ecstasy (Gouzoulis-Mayfrank et al. 1996), substances which can be used for relaxation, for pleasure, and for the intensification of mental experiences and achievements, in short to enhance the quality of life. Such psychotropic hedonism as an expression of personal freedom is the opposite pole from a pharmacological calvinism (Klerman 1972), which argues against apparent solutions to complex personal and social problems using psychopharmacological products and urges social control of these substances because of their prevalent and long-term negative consequences, including dependency. The physician therefore has to deal with the question of how to handle people's requests for drug prescriptions, which they seek to combat tiredness, listlessness, bad mood, anxiety, poor ability to concentrate, sleeplessness, a physically poor condition, etc., problems, however, which do not correspond to a diagnosable illness, but are probably connected with a perceptible life stress. Naturally, the question can be raised whether the physician is responsible for eliminating subjective complaints that have only a tenable link with illness just because people seek a doctor's help (Häfner 1997). The situation has become unclear for the physician since 1947, when the WHO proclaimed subjective well-being as a health goal. This effectively pushes everyday distress into the domain of medical diagnoses and has fostered the use of psychiatric treatment in problems of daily living. For this reason, a "social profile" of a drug next to its "biological profile" can be anticipated (Winckelmann 1989).

If a physician affirms his or her responsibility for such treatment, the question regarding appropriate measures must be answered. Naturally, the physician cannot be forced to prescribe a medication against his or her better judgment, no more than a patient can be forced to take it. However, to what extent should physicians be prepared to make compromises on what they regard as the best mode of treatment on the basis of their knowledge and experience, e.g. consultation or psychotherapy, in order to comply with the wishes of the patient? Which criteria should be used to make such decisions? Merely because the patient who is seeking treatment and perhaps also needs help would otherwise receive no treatment? Or because the physician might lose the patient? The duty to inform the patient can be particularly helpful for the physician in this context, as this duty does not merely cover any possible undesirable side effects (including abuse and dependency), but also treatment alternatives, such as psychotherapy or measures involving social therapy. A conversation to inform the patient will then contain elements of consultation and can itself bring significant relief.

5.5 Psychotherapy

Psychotherapy illustrates more subtle restrictions to the self-determination of the patient, but ones which might have greater consequences. Psychiatric therapies in general, especially if they are effective, can have a considerable impact on the patient's life. That is also true of certain forms of pharmacotherapy, as can be shown, for example, by changes in family relationships in the course of successful lithium prophylaxis in preventing relapse in patients with affective psychoses (Rüger 1977). However, this is more likely with psychotherapies, such as dynamically oriented psychotherapies, which not only aim at eliminating symptoms, but also examine the personality structures that produce these symptoms. For a long time, the ethical implications of these concepts seemed to play no role in psychotherapy, and the so-called humanistic therapies, in particular, were implicitly seen as ethically flawless. Only recently were these implications critically discussed (Bloch 1996).

A fundamental question is how much the therapy goals that are defined – not only in psychodynamic therapies, but also in other psychotherapies such as the deconditioning (and sometimes manipulative) techniques of behavior therapy – are influenced by the

therapist's image of the person? "Does it involve conformity, in order to adapt optimally to the social milieu, as if the meaning of human life consists in adaptation and conformity to others? Or is the goal the maximal development of the potential of the patient, so that the criteria for a healthy existence lie only in the individual person?" (Ritschl 1989). At any rate, therapists should continually review their "ethical counter-transference" with respect to their own values (Holmes 1996). This holds especially for psychoanalytic psychotherapies in which dependency on the part of the patient is necessary in the context of his or her "counter-transference neurosis."

In addition to the issue of goal setting, this highlights the asymmetric power relationship between the psychotherapist and the patient in therapy and is cause to reflect on the ethical use of this power, e.g. the balancing act between the desire to give the patient hope and the risk of being thought to be omnipotent (Karasu 1991; Helmchen 1998c). "Yes, the real trouble with psychotherapy lies in its non-explicit nature" (Goldberg 1977, cited in Karasu 1991).

Great demands are made upon the integrity of the therapist, not only because of "the proximity of this field of the healing arts to the sanction-free sphere" (Ritschl 1989), but above all to protect the therapist from abusing the dependency of the patient. This does not primarily mean sexual abuse, which according to psychotherapists themselves is committed by 5%–10% of therapists (Gartrell et al. 1986; Moggie et al. 1992) and is therefore nonetheless alarming, even if they themselves assess it differently. It refers instead to the psychological processes by which the therapist steps onto to this slippery slope (Gabbard 1996). However, the main focus are the many other forms of "emotional exploitation" (Birnbacher and Kottje-Birnbacher 1996), especially narcissistic abuse, under which all those interactions and constellations of relationships between therapist and patient are understood "which primarily serve the narcissistic gratification of the therapist and which hinder or at least make more difficult the development of the 'true self' of the patient" (Reimer 1991). Similar problems were revealed with so-called "recovered memory therapy," i.e. the search for specific suppressed memories (Merskey 1996).

This therapy, in particular, illustrates the need to explain to the patient before the beginning of psychotherapy the variety of possible undesirable effects and negative consequences, such as a psychopathological deterioration, the destruction of familial relationships, financial burdens, or the stress of legal disputes (Merskey 1996). In general, providing the patient with appropriate information before the beginning of a psychotherapy is fraught with difficulties, because it might already be part of the psychotherapeutic process itself, i.e. informing the patient that only a continuous change of personality can lead to an elimination of symptoms and, moreover, that the risk of failure might be associated with long-lasting negative effects as a consequence of unresolved transference or unresolved resistance; the patient's condition might even become worse than at the beginning of therapy. This risk seems especially high in patients with ambivalence, which lies at the core of their illness and might also be connected with a limited ability to give consent.

Some further considerations shall be briefly outlined. The observance of the duty to maintain confidentiality, which is absolutely vital in psychotherapy, can be jeopardized by psychotherapeutic consultative activity, in group therapy, during supervision of a psychotherapeutic training, or by publication of case histories (Vollmann 1996a). The ethical implications of breaking confidentiality if a (suicidal) patient presents a danger to him- or herself or to others were illustrated particularly clearly by the Tarasoff decision (Gurevitz 1977; Roth and Meisel 1977). A new ethical problem stems from the changes in our medical system, which make maintenance of confidentiality more difficult, since direct payment for psychotherapy is generally replaced by third-party (insurance) payment.

In addition to an unethical financial exploitation of patients, a further dilemma of increasing ethical relevance is currently developing as a result of "managed care" structures, since the psychotherapist is caught between the interests of the patient and those of the organization by which he or she is paid. Psychotherapists also increasingly have to answer questions concerning "the implementation of a professionally qualified and competent psychotherapy, the documentation of its effectiveness, the exact indication and scope, in which these conditions fall within the sphere of the medical model and which thereby fulfill the criterion of medical necessity" (Chodoff 1996). Prompted by the questionable effects of the recovered memory movement, the state of New Hampshire (USA) introduced the draft of a Truth and Responsibility in Mental Health Practice Act in 1995, according to which the psychotherapist has to ask for consent following explanation about the prospects of the psychotherapy which is offered. Otherwise, he or she cannot receive reimbursement from a third-party payer. The explanation preceding the consent has to include the following: the condition to be treated, the expected benefits, side effects, and risks of the treatment offered for this condition, the citing of at least two research publications showing adequate safety and effectiveness of the proposed psychotherapy, and accepted alternatives to the therapy. The beginnings of such a quality control in psychotherapy have developed in Germany by means of investigating the indications using an expert review process. The American Psychological Society recognizes in this

sense cognitive and behavioral therapies, interpersonal therapy, psychodynamic short-term therapies, and psychoeducative methods, but not, however, supportive psychotherapy, psychoanalytic long-term therapy, and group therapy (Mersky 1996). In order to avoid extreme regulations such as the legal draft mentioned, psychiatrists and psychotherapists must themselves develop, explicate, and conscientiously maintain high ethical standards. Such standards could be formulated as follows:

In view of the special (personal, nonrational) quality of the therapeutic relationship between the psychotherapist and patient, in consideration of the special difficulties in explaining the therapy appropriately to the patient before it begins in order to obtain the patient's consent, and in addition maintaining confidentiality under all circumstances and, not least, financing the psychotherapy in a changing health care system, the psychotherapist is called upon to develop sensitivity and to preserve it in face of the ethical implications of the view of human beings on which his or her therapy is based and against the use of power in the therapeutic relationship with its dependency of the patient upon the physician, especially with respect to the risk of emotional or narcissistic (and financial) exploitation of the patient.

Further examples could be cited, e.g. the ethical problems of genetic consultation, which is rapidly gaining in importance, e.g. in patients with Huntington's disease and their possibly presymptomatic relatives, in prenatal diagnosis, in genetic research into complex genetic psychiatric diseases such as schizophrenia and depression (see Chaps. 3, 4, this volume, Part 2; Chaps. 3, 18, this volume, Part 1), and the multiplicity of ethical questions which arise in dealing with those with age-related dementia (Berghmans 1997). It may be hoped, however, that the few examples already discussed in detail here have made clear the importance of ethical reflection in daily medical practice and will invite further questions, as the ones already discussed can be helpful.

Problems in medical decision-making have thus been addressed not only by making dogmatic statements – derived from principles of medical ethics – but also by using questions to examine them, in order to give the psychiatrist the ability to find the way which is the most likely to be comply with the principles and rules of medical ethics for each individual patient.

H.J. Walton

Psychiatric Education and Training

1 Introduction

This chapter deals with the training of a psychiatrist from entry to medical school through readiness to become a consultant, and finally to lifelong learning throughout professional life. It presents a paradigm of current good practice pertaining to the continuum of specialist training in psychiatry. The educational programme described is of necessity schematic and general, because of the great variation to be expected among varying countries and different cultures. However, the basic principles set out will apply in any setting.

Psychiatry is a speciality in the field of medicine which is often seen as the archetypal profession. Education in psychiatry is therefore a component of the professionalisation process affecting every doctor. Relevant to it are all the canonical aspects of medical education: access (application to medical school, selection procedures, dropout and wastage), curriculum, teaching methods, educational objectives,assessment (and examinations), evaluation and accreditation. Then follows, in turn, the newly graduated generic doctor, specialist training as a psychiatrist and finally continuing education to maintain professional competence throughout life.

The sequence stated above replaces the earlier medical school paradigm, which was that of vocational training. Instead, a university education in medicine results in a generic doctor, who can then enter postgraduate training appropriate to a particular specialty; followed finally by ongoing continuing medical education (CME). Doctors now trained in developed countries no longer have to rely on their medical school education as the basis for their professional competence.

In developing countries, the paradigm has to be different. The graduate from medical school is required immediately on graduation to start medical practice, under more or less supervision, and – if the numbers of doctors are limited – has to do his or her work through colleagues such as nurses or paramedicals and also traditional healers, whom the doctor instructs and monitors. Medical students need to receive additional training in psychiatry during the medical school period, since psychiatric disorders form such a large part of the work of primary care doctors. This additional psychiatric instruction in developing countries should extend across the curriculum as a whole. It should also continue, after graduation, as part of in-service training and CME (World Psychiatric Association/World Federation for Medical Education 1998).

Medicine, surgery and psychiatry, Reil said in the last century, constitute the three main branches of medicine. Psychiatrists treat only a small portion of any nation's psychiatric morbidity. A great bulk of psychiatric disorder is managed, adequately or otherwise, by doctors whose psychiatric training often is confined to their exposure to psychiatry as medical students.

2 Undergraduate Education: The Medical School Curriculum

Psychiatric teaching is called for throughout the undergraduate curriculum for all medical students, regardless of the branch of medicine they go on to enter (Walton 1986). The broad goals in the teaching of psychiatry to undergraduate medical students, relevant to all future doctors, are the following in order of priority:

1. Communication skills and empathy help medical students become more aware of patients' emotional responses and help students to create the interpersonal relationship between clinician and patient necessary in the medical interview. Both the patient's and the student's subjective responses are involved.
2. The second most important aspect of teaching sets out to make students aware of scientific knowledge about behaviour, so that they can distance themselves appropriately from the personal problems of patients (showing "detached concern"), augmenting their common-sense understanding with empirical knowledge. Behavioural science teaching (notably psychology and sociology) is intended to promote such an objective approach to the patient on the part of the clinician.
3. Medical students frequently experience the same anxieties about mental patients that are customary in their society. Teaching of psychiatry should enable them to overcome prejudices and preconceptions and relate clinically to a wide range of patients with psychiatric illness and disorder. To do so, students need skills in history-taking, in examining the mental state and in psychiatric interviewing of a patient repeatedly over a period of time.
4. Descriptive psychiatry, dealt with in the psychiatric textbooks, cannot be satisfactorily learned unless medical students have proper access to patients *at the same time* as the theoretical teaching is given. This clinical training, for learning clinical skills as well as knowledge, can be extended by videotaped presentation of psychiatric patients, ward rounds,

case conferences, simulated patients and the many other clinical teaching procedures which are available.

5. A great proportion of ill health is psychiatric. The psychiatric instruction given in medical schools has to provide introductory knowledge about the main psychiatric treatment methods and skills, because much the greater part of the mental health needs of the community is met not by psychiatrists, but by general practitioners and specialists in other branches of medicine.

2.1 Psychiatrists as Medical School Teachers

Psychiatrists must of course concern themselves with the total curriculum of the medical school: they must serve on the educational committees planning the curriculum and implementing it, and in their departmental teaching they must naturally promote the institutional objectives of the medical school.

In carrying out these institutional objectives, and in gaining recognition for the teaching of psychiatry itself, psychiatrists have traditional disadvantages. Medical school teachers in general tend to view psychiatry as a backward branch of medicine. They are further dismayed by the ideological differences among psychiatrists (one a biologically oriented doctor favouring the medical model, the other a humanist concerned with psychodynamic processes and practising some or other form of psychotherapy). Medical school teachers are the more disconcerted when these contrasting ideologies tend to be applied to the patients they refer to psychiatrists; it can seem relatively arbitrary how any patient will be diagnosed and treated, appearing to depend too much on the outlook of psychiatrist to whom he or she is referred. Colleagues of the psychiatrist in other branches of medicine find the doctrinal differences among psychiatrists confusing.

The many investigations by sociologists of medical schools, classically those of Merton et al. (1957) at Cornell and Chuval (1980) in Israel, have helped to demonstrate that the status of psychiatry, of teachers of psychiatry and of psychiatric patients in medical schools is not at the level of, say, medicine or surgery. This has a seriously adverse effect on the teaching of psychiatry.

Medical students acquire their professional values and outlook, in large measure, by modelling themselves on leading and respected teachers in the medical school. Students react to teachers in three different ways, by active identification, active rejection or inactive orientation. The third of these responses, bland disregard, is now greatly less discernible in attitudes of contemporary medical students towards psychiatry than it was a generation earlier, when psychiatric instruction was less and poorer.

2.2 Student Attitudes to Psychiatry

It has been found that "psychologically minded" medical students show a greater interest in and a more positive attitude towards psychiatry than organically orientated students. Medical students' preference for psychiatry as a future career is little affected by psychiatric instruction during their training. It has long been known that certain learning experiences in psychiatry, particularly the clinical clerkship when in some types of unit (Eagel et al. 1979), can change attitudes towards psychiatry in a positive way. Despite such favourable responses, very few medical students commit themselves to a future career in psychiatry.

2.3 Psychiatry in the Curriculum

That psychiatry should occupy a major part in the basic medical curriculum is now generally agreed, for three reasons. Firstly, the general approach in contemporary medicine stressing the unity of body and mind is important in the whole of medical practice. Secondly, skills that are learned in psychiatry are important for all doctors, e.g. the ability to form a good relationship with a patient, to assess the mental state and to impart distressing information. Thirdly, psychiatric illness is common among patients seen by specialists in other branches of medicine; for example, among medical outpatients, about 15% of those given a medical diagnosis have an associated psychiatric disorder, and up to 40% of those given no specific diagnosis in fact have a psychiatric disorder (Clare and Lader 1982). Psychiatric disorders are even more frequent among patients seen in general practice. That all future doctors must know about psychiatric disorder is not only because they are common; in addition, their management involves much medical time and resources and gives rise to many serious incidents.

The World Psychiatric Association and the World Federation for Medical Education (1998) have compiled a *Core Curriculum in Psychiatry for Medical Students*. It sets out the minimum psychiatric instruction that will be required by medical students who, after qualification, will enter further training as specialists or general practitioners. Incidentally, in many countries, general practice is now also designated as a specialty, for which a further period of training

is required after graduation and in which future general practitioners extend their psychiatric skills. In countries which have no formal training for general practitioners, the teaching in psychiatry at medical school needs to be supplemented by a module containing the additional material that is essential for management of the psychiatric morbidity encountered in the community.

The psychiatry programme in the basic medical curriculum should be extended through all the years of the undergraduate teaching programme rather than concentrated in isolated separate courses. The sciences related to psychiatry of course include the biological sciences integral to the medical curriculum. That said, science teaching in medicine has been seriously criticised for being concentrated in a so-called preclinical phase instead of being extended throughout the curriculum; in addition, departmental interests have led to the biological sciences being fragmented, at a time when – in place of division according to disciplines – integration of knowledge is the hallmark of advances in the sciences relevant to medicine. *New biology* is an integrated view of whole structures, whether at molecular or macroscopic level. Medical schools have not responded to the paradigm shift in science. Medical schools have imperatively to examine their entire educational programme in order to integrate science teaching properly with clinical instruction. Traditional basic science teaching in the medical schools stands charged with being outmoded, restricted, simplistic and responsible for much of the information overload which mars medical curricula (Marston and Jones 1992).

Reform in this regard is a matter for the medical school as a whole. With respect to the teaching of psychiatry, two main components are to be specified, behavioural science and psychiatry itself.

2.4 Behavioural Science Teaching

Since the 1960s, behavioural sciences (also referred to as psychological medicine, psychology and sociology in relation to medicine) have been included in the undergraduate curriculum, often directed by the department of psychiatry. However, the behavioural sciences remain a problematic area. There has been widespread failure of the teaching of these subjects with considerable criticism from students and from other preclinical and clinical teachers. The following general points are important:

1. Behavioural science teaching should begin early in the curriculum, preferably in the first or second year.
2. Clinically experienced medical (psychiatrists) and non-medical (psychologists, sociologists) teachers should be actively involved in the planning of curricula and teaching.
3. Such teaching should be strictly relevant to medical practice and under no circumstances consist of a condensed general psychology and sociology course.
4. Behavioural science should be a compulsory and not an optional subject.
5. It should be examined along with other preclinical subjects and count towards professional examinations.
6. Separate behavioural science departments are not favoured, and teaching should be inter-departmental with a university department of psychiatry taking an active part in the organising and coordinating of the course.
7. Teachers should be encouraged to introduce clinical cases into their teaching from the start.
8. Teaching should be centred around clearly stated educational objectives.

Behavioural science teaching has often not succeeded in that students sometimes regard it as somewhat irrelevant or discordant with their main concerns as future doctors. The courses have failed at times to be perceived as convincing or a substantial addition to the curriculum.

2.5 Objectives of Behavioural Science Teaching

In each subdiscipline of behavioural science, specific requirements can be formulated.

2.5.1 Psychology

By the end of the course, each student should:

1. Have acquired a basic overall knowledge of the findings, methodologies and theories of psychology which are relevant to the practice of medicine
2. Be aware of how a patient's emotions, attitudes, values and experiences influence his or her response to illness and its treatment
3. Have a knowledge of learning processes and their relevance to medicine
4. Possess normative data of the main aspects of psychological development of humans from birth to old age
5. Possess skills relevant to effective doctor–patient communication and particularly to interviewing

6. Have knowledge of techniques of assessment used to assess the reliability and validity of investigation procedures and therapeutic trials
7. Have attitudes to development that will enable him or her as a doctor to see each patient as a complete human being living in his or her own social environment

2.5.2 Sociology

By the end of the course, each student should be able to:

1. Outline the various attempts to define and measure health and discuss their merits and limitations
2. Describe and discuss the importance of social institutions such as the family, the community, the economy and the law on health and medical practice
3. Describe and discuss the problems of equity and inequality in the provision and utilisation of health services, particularly when classified by age, gender, social class and region
4. Describe some of the more important changes in society and in the practice of medicine which have affected health and disease and the development of social policy
5. Describe the main reasons for the development of the welfare provisions, discuss the advantages and disadvantages of a country's health service and appreciate the problems of planning for change within a health service
6. Describe the social (and sociological) factors that influence the process of becoming ill and the doctor–patient relationship and the effect that ill health and hospitalisation have on the lives of patients and their families
7. Discuss critically the role of preventive medicine and health education and the role of self-help groups
8. Discuss critically the process of medical professionalisation
9. Describe some of the research methods used to evaluate health and medical practice

2.5.3 Biostatistical Sciences

The aims of the course in the probabilistic and information sciences are:

1. To explore ways of making valid deductions from medical data
2. To familiarise students with the basic statistical terminology as found in the medical literature, e.g. *The Lancet* and the *British Medical Journal*
3. To introduce the concepts necessary both for designing and for analysing comparison and experimental studies in medicine
4. To teach methods of accessing and organising medical knowledge and computer literacy

2.6 Clinical Psychiatry

Instruction in clinical psychiatry occurs with the other main clinical subjects. The components are clinical attachment(s), lectures and small-group tutorials.

Lectures are an effective way of promoting factual knowledge if well presented, and an efficient way of teaching large groups of students, but they should not constitute the main form of psychiatric teaching. Lewin (1948) established how experiences created in groups could stimulate learning and modify attitudes. Small-group teaching is expensive and time-consuming (more teachers are of course required than is the case in lectures to large classes), but must continue to be given a high priority by teachers in order to enable students to develop the professional attitudes relevant to psychiatry (Walton 1968). A combination of lectures and small-group teaching is desirable and is most effective.

Small-group tutorials, important in all medical teaching and learning, are especially important whenever *attitudes* are in question, e.g., respect for psychiatric patients or willingness to view mental illness as a valid clinical concern. Teachers who are uninformed about small-group teaching and group processes are of course unqualified, but that has not precluded them from being assigned to provide tutorial teaching, often lamentably. Small-group tutorials are a fundamental component of problem-based learning, a major innovation in contemporary medical education (Tosteson 1994) which medical schools worldwide are eager to introduce.

2.7 Clinical Clerkship

There is evidence that the type of the unit in which medical students do their clerkship in psychiatry influences their attitude to mentally ill patients. The clinical attachment may include experience in general practice, general hospitals and in the community, and at least a proportion of the clinical attachment should be in a general hospital psychiatric unit or in a psychiatric hospital.

The following recommendations may be made:

1. A full-time clerkship of 8–10 weeks' duration should be undertaken.
2. Wherever possible, the clerkship should be on a single general psychiatry unit, and students should not spend their whole clerkship entirely on a highly specialised unit.
3. Students should have both in-patient and out-patient contact.
4. They should have the opportunity to regularly see psychiatrists at work interviewing and treating patients.
5. Students should have the opportunity to interview patients themselves and be involved in the decision-making about clinical management.
6. Students should be encouraged to see the patient in the context of his or her family setting and background. They should have the opportunity to visit a patient's home and assess such a setting.

A prominent aim of psychiatric teaching should be to find instructional approaches fostering positive attitudes to all patients, including psychiatric patients. The consensus is that such attitudes are provided through a clerkship. The indications are that it needs to be 8 weeks at least in duration (World Psychiatric Association/World Federation for Medical Education 1998). Empirical studies demonstrate that attitudinal changes can be achieved and, moreover, are sustained.

2.8 Objectives

In the various areas of clinical psychiatry, different objectives can be formulated. In terms of general objectives, the student should be able to:

1. Conduct a diagnostic interview, including the taking of a psychiatric history and carrying out a mental state examination
2. Relate a patient's symptoms to his or her past experiences, personality and social circumstances
3. Give an account of his or her emotional responses to patients of different kinds and the way in which these can influence his or her judgment and hence the patient's management
4. Give an account of patients' emotional responses to doctors and the way these can influence the presentation of illness
5. Outline the main principles of, and indications for, counselling and psychotherapeutic intervention

In the field of organic psychiatry, the student should be able to:

1. Distinguish between organic and non-organic (functional) psychiatric disturbance
2. Describe and recognise common organic psychoses (acute and chronic), e.g. delirium tremens, senile dementia
3. List the common causes of confusional states and dementia in different age-groups
4. Describe the management of acute confusional states
5. Describe the management of dementia in and out of hospital

With regard to functional syndromes, the student should be able to:

1. Distinguish between a depressed mood and depressive illness and describe in detail the management of the latter
2. Diagnose schizophrenic and related psychoses, outline the management of acute attacks and describe the management of the chronic illnesses in the community
3. Describe and recognise common symptoms of neuroses
4. Define and recognise the signs and symptoms of psychiatric illness important in differentiating the major syndromes, e.g. flight of ideas, passivity experiences
5. Describe and recognise the features of normal and abnormal grief and outline their management
6. Recognise the diverse clinical presentation of alcohol dependence and describe the syndrome
7. Describe the management of alcohol and drug dependence
8. Describe and recognise the common forms of psycho-sexual disorder and outline the principles of their management
9. Discuss the common causes of acute emotional disturbance in different age-ranges and social groups and outline the principles of crisis management, especially in relation to parasuicide
10. Assess the risk of suicide in depressed patients
11. Describe and recognise the common psychological problems of childhood and adolescence
12. Describe and recognise the common psychological problems of old age and outline the social services available for their management

As far as treatment methods and agencies are concerned, the student should be able to:

1. Outline the psychiatric effects of drugs commonly used in medical practice, including corticosteroids, anti-hypertensive agents, opiates, oral contraceptives, barbiturates, sulphonamides and anti-convulsants
2. List the main indications, contraindications and unwanted effects of neuroleptics, anti-depres-

sants, etc. in common use, e.g. phenothiazines, tricyclic anti-depressants, monoamine oxidase inhibitors (MAOIs), benzodiazipines, lithium salts
3. Outline the principles of behaviour modifications and their main clinical applications
4. Discuss some clinically important concepts in psychodynamic approaches, e.g. unconscious conflict and defence mechanisms such as projection and denial
5. List and describe the main agencies for the care and rehabilitation of the psychiatrically ill and mentally handicapped in the community

Further objectives include the student being able to:

1. Describe the main psychiatric disorders found in children and the methods for investigating and treating these conditions
2. Describe the social and psychological problems of the mentally handicapped
3. Describe and recognise the common psychological reactions to physical illness
4. Outline the psychological mechanisms which can produce somatic symptoms and influence the course of physical illness
5. Describe the common associations between crime and mental illness
6. Outline the conditions under which it is legitimate to detain patients in hospital and treat them against their wishes

2.9 Communication Skills

During psychiatry teaching, and ideally also earlier in their preclinical career, students can benefit from the teaching of interview techniques. The effectiveness of such teaching has been amply demonstrated (Sanson-Fisher and Maguire 1980).

The value of allowing the student to watch or listen subsequently to his own interviews has been emphasised. Videotape provides an ideal medium, but listening to simple audio recordings also inculcates skills in perceiving and paying appropriate attention to a multitude of cues which are evident in even a brief interview.

Feedback from a tutor can help the student to understand the interpersonal process; it is as effective when given in a group as when given individually and is much more effective than when students are working on their own. Training in eliciting the history from a patient increases students' ability in essential skills, such as the elementary steps of introducing themselves to the patient and in orienting the patient to the task in hand.

Medical students (as well as postgraduates) can gain from training in interview skills through the use of video recordings, not only of history-taking but also extended to mental state examinations. Attention can be focused on the technique of eliciting the phenomena as well as on analysis of the significance of the signs and symptoms thus detected.

Video recordings of any interview occurring during routine clinical work can form a good basis for teaching (Westberg and Jason 1994). Everyday concerns of psychiatric management, such as the prescription of electroconvulsive therapy (ECT), the decision to permit weekend leave or the review of a weekend at home, all prove a valuable focus for learning and discussion.

Family therapy and individual psychotherapy training can also be augmented greatly by the use of videotape. An experienced therapist can benefit considerably from a regular review of a fragment of one of his or her interviews, and the benefit of such instruction to medical students is correspondingly large. Skills in observing and responding to verbal and non-verbal cues can be sharpened through systematic review of videotapes, particularly of the students' own interactions with patients assigned to them.

2.10 Examinations

The assessment methods used should always be congruent with the objectives of the course. Only too often the methods of assessment are discordant, e.g. multiple choice examinations are given predominant emphasis in some countries, although in theory teachers claim they are *not* concerned with factual knowledge alone. To assess clinical skills and attitudes, the professional examination needs to be composite, e.g. essay questions, short answer questions, an oral examination, continuous assessment during the clinical attachment. In addition, the objective structured clinical examination (OSCE), patient management problems (PMP), simulated patients and role-playing (e.g. the examiner taking the role of a parent enquiring about prognosis in schizophrenia) are all increasingly used.

Psychiatry forms part of the professional examination in many medical schools; it is sometimes part of a composite final examination, when only some students are given a psychiatry clinical examination.

Continuous assessment during the clinical attachments is an important means of evaluation. Colleagues in district hospitals are asked to play a large role in psychiatry teaching and they should of course also be involved in the assessment procedures. There may be

merit in supplementing the clinical examination with the writing up of case histories. Most medical schools now make extensive use of multiple choice questionnaire (MCQ) examinations; a joint MCQ in use among a number of universities in partnership provides resources for more sophisticated construction and makes it possible to draw interesting and informative comparisons between differing patterns of psychiatric teaching.

It is necessary to stress the dominating impact of examinations, because examinations drive the curriculum. Students learn to pass examinations, whatever contrary emphases teachers may seek to convey when specifying learning objectives.

2.11
Conclusions on Basic Education in Psychiatry

The objectives of the psychiatry department must of course be congruent with the overall objectives specified by the faculty of medicine for its medical curriculum. Efforts to reform curricula commonly fail because of failure to change the committee structure of the medical school in keeping with new educational goals. The curriculum cannot be left in the hands of departmental heads. Appropriate governance is essential, namely a curriculum committee answerable to the dean and not to departments, and given its own resources such as budgets and autonomy (Bloom 1988). Departments are then free to pursue their specific non-educational goals, such as research and clinical work, to which in any case they give greater priority (Abrahamson 1996).

Each university hospital must have a psychiatry unit, called upon by the curriculum committee to participate in the educational programme and advise (and provide) its psychiatric component.

Psychiatry, like all branches of medicine, is urgently confronted by the necessity to re-orient the curriculum, so that not only curative medicine is taught, but also prevention of illness and promotion of health. The obstacles to curricular change in medical schools are notorious. Prominent among them is the apathy – as far as education is concerned – of the majority of medical teachers: it seems almost impossible to get a critical mass of teaching staff to become educationally informed, interested and involved in the education of medical students. Medical teachers commonly think they are equipped to teach simply by virtue of their specialist expertise in their research or clinical discipline; they do not respect or know the findings of medical education research and are ignorant of the medical education literature (Miller 1980). They have very often not had personal instruction about how to teach.

When students themselves are studied, they repeatedly convey that they learn best when active student participation is encouraged, when the emphasis is on applied problem-solving (rather than learning of factual materials), when instruction is centred on the students and when teachers are humanistically oriented.

Teaching and learning methods have been revolutionised by electronic information technologies, problem-based learning and simulated (standardised) patients. Curricular time has been freed for special-interest options of students. Above all, the medical school phase in the continuum of medical education has to be disencumbered of information overload and passivity-inducing requirements for the memorisation of facts. Scope must be given for critical thinking, and the development of clinical competence made a priority. Educational leadership is essential, certainly not provided by deans at all commonly, and students have to be valued partners at every level, recognised as able to assist actively in monitoring the quality of their education.

3
The Generic Graduate

Young doctors are not yet equipped for independent practice on graduation. The goal of medical school is to produce a pluripotential doctor, who must then have postgraduate training to acquire the abilities needed for specialist (or generalist) practice. Prior to beginning such postgraduate training, the graduate is in the phase of transition from medical student to doctor.

In Britain, for example, doctors do not become registered practitioners for 1 year after leaving medical school. They are granted provisional registration by the General Medical Council and are required to work as pre-registration house officers receiving "general experience" in general hospitals, under the supervision of the medical school from which they graduated. This mandatory period of graduate clinical training, when the graduate becomes a clinician, is generally acknowledged as the most problematic of all (Richards 1992).

It is variously labelled in different countries: the pre-registration year, senior house officer training, the junior hospital doctor phase, etc. The junior doctor becomes a member of a consultant team in hospital. The notorious defects have been insufficient clinical supervision, insufficient feedback from consultants, excessive hours and poor training standards with inadequate educational provision. In many countries, legal steps have been taken to reduce working hours of junior doctors. By general consent, overwork and low

pay, with junior doctors misused as pairs of hands rather than doctors in pre-specialist training, is no longer acceptable.

Junior hospital doctors, when surveyed, report that the style of teaching on ward rounds and outpatient clinics markedly influence their ability to learn, their self-confidence and their acquisition of clinical competence. They are characteristically sympathetic to patients having psychiatric disorders complicating the organic disease for which they are hospitalised. However, junior doctors do not get into psychiatric hospitals; unless the general hospitals in which they work have psychiatry liaison services or psychiatric units, they receive no psychiatric instruction and no encouragement to consider training as a psychiatrist.

Experience in psychiatry during the pre-registration year would broaden the doctor's education. It could act to counterbalance influences which prejudice recruitment to psychiatry and are hostile to patients with psychiatric disorders. This could be best achieved by an improved liaison psychiatric service in general hospitals.

4
Postgraduate Training

Postgraduate training is in transition at present, not only nationally but worldwide. Indeed, the whole of medical education globally is undergoing massive change (World Federation for Medical Education 1994). In part, this process of re-evaluation and reform results from the altering roles, responsibilities and relationships of doctors: an upheaval so extensive and multifarious that the World Summit on Medical Education at Edinburgh in 1993 was designated: "The Changing Medical Profession".

The Recommendations (World Federation for Medical Education 1994) of the summit gave particular emphasis to the necessity of constant awareness that medical education is now viewed as a continuum. Basic medical education certainly is preparation for postgraduate training; both phases, in turn, are preparation for CME throughout each doctor's entire subsequent medical career.

Emphasis on the continuity of medical education is explicit in Recommendation 15 of the Summit, which calls for a holistic view of postgraduate medical education: "Mission statements of medical schools should specify the types of graduates to be produced, so that the competences assigned to postgraduate education and specialist training programmes are explicit."

The Recommendation continues: "There is need for a holistic view in planning for the broad fields of postgraduate education, with policy-making mechanisms that can support production of balanced numbers of generalists and specialists. The postgraduate training programmes need to be carefully related to the local context in which they will be practised, and linked with undergraduate and continuing educational programmes."

The reference to the local context is crucial. It recognises the importance of culture and history in determining patterns of health care. Appropriately, therefore, each country in Europe is separately engaged in a process of re-orienting postgraduate medical education. Psychiatry is one of the specialties undergoing profound change (Caldicott 1996). Moreover, there are major differences between countries in their organisational frameworks for funding, delivering and assessing postgraduate medical education. This being the phase of specialist training or at least its initiation, postgraduate training is the sector of medical education of particular significance to the specialty organisation in each country, keeping very much in mind that general practice now also has the status of a specialty. The psychiatry component of general practice is of the utmost importance, because of the epidemiological fact that the majority of psychiatric patients are seen not by specialist psychiatrists but by generalists.

4.1
Structure and Implementation of Training

In almost all countries, the Ministry of Health is concerned with postgraduate training, which takes place mainly in the hospitals of the country's health service. Universities are associated with health services in the postgraduate training programmes. For example, 20 psychiatric hospitals in the Netherlands have psychiatric training approval, eight of which are university hospitals.

Speciality organisations customarily set standards and hold examinations in postgraduate education. Their particular role differs considerably between countries. In the United Kingdom, for example, the Royal Colleges and their Higher Training Committees have major responsibilities. Each College, including the Royal College of Psychiatrists, through its Higher Training Committee produces its own assessment standards. The Colleges set formal competitive examinations to regulate entry into higher specialist training. During specialist training, the Higher Training Committee vets the quality of the training posts and the educational progress of each trainee doctor. This is achieved through inspection visits and regular formative assessment of the trainee.

Postgraduate training in psychiatry involves a sequence of posts, providing a wide range of clinical experience and making up a rotational training scheme, usually in one geographical area and often in one approved hospital complex. The rotational training scheme includes a university department or hospital and allows experience in the various branches of psychiatry, including (in addition to adult general psychiatry) child and adolescent psychiatry, mental handicap, geriatric psychiatry, psychotherapy, general hospital (liaison) psychiatry and other special fields.

The academic content should include an introduction to general psychopathology, pharmacology, genetics, interviewing, diagnosis and classification, organic disorders, drug and alcohol dependence, schizophrenia, mood disorders, neurotic disorders, personality disorders, learning disability, psychiatric disorders of childhood and adolescence, old age psychiatry, forensic psychiatry, drug treatments, counselling and interpretative psychotherapies, behavioural and cognitive therapies, rehabilitation and community care.

The specialist examination is taken at differing stages of training in different countries and is also phased differently in the various specialties in each country. In order to sit the U.K. Royal College of Psychiatrists examination, a candidate must have completed 3 years of psychiatric training and must be in a training post. After such general training, trainees may choose to enter additional training for a psychiatric subspecialty; in the Netherlands, for example, an additional 2 years in child psychiatry is required to obtain the Certificate of Completion of Specialist Training (Centraal College 1994).

In addition to the specialist examination, which, as indicated above, may be during the course of training, a number of colleges in the United Kingdom have introduced formal summative assessment at the end of specialist training. Continuous assessment, either as an examination procedure or feedback to trainees about the standard of their clinical performance, or both, is of vital importance. Such formative assessment of each doctor in training includes positive feedback about performance, specific help about any weakness and planning of future training. Summative appraisal, where knowledge, skills and attitudes are evaluated by college-appointed external assessors, will ensure that college-set standards are being met, so that the award of specialist grading may be made. Unlike other specialties in the United Kingdom, the Higher Training Committee for General Practice has statutory authority independent of the Royal College of General Practitioners. This is evidence of more direct involvement of the government in determining the duration and context of training for general practice than is the case for any other specialty.

Educational objectives are as necessary in postgraduate psychiatry are they are in basic medical education and have to be stated in the broad categories of knowledge, clinical skills and attitudes. Customarily, educational programmes are stated in little more than course descriptions. Much more specific educational objectives have to be specified, setting out the knowledge, skills and attitudes expected of trainees in all of the academic courses and aspects of clinical psychiatry included in the psychiatry postgraduate programme (Walton 1986, pp. 77–85).

4.2 Medical Specialities

Countries differ in the designation of separate specialities. Psychiatry is variably recognised; even in the European Union, where medical education and practice is regulated by binding legislation in the form of directives adopted in 1975, the specialty is not uniformly defined in all member states. (The specialties recognised in Europe are set out on pp. 11 and 12 of the European Specialist Medical Qualifications Order 1995). When psychiatry is one the recognised specialties in a country, there are differences in training requirements, including duration. For example, it has been said that psychiatric training in the United Kingdom takes 6–7 years (Caldicott 1996), but only 4 years in Portugal, Greece or Belgium (with no formal examination in Belgium).

4.3 National Differences in Standard Setting

In broad terms, five different patterns of responsibility for standard setting can be identified within Europe:

1. National medical associations, as in Norway and Portugal, take the leading responsibility. In other words, the medical profession itself provides and dispenses the postgraduate training in the country. This is also the case in Germany and in certain Central European countries.
2. Designated professional bodies, distinct from the national medical association, may have major responsibilities, as in the United Kingdom, where the Royal Colleges approve training posts and assess the competence of doctors in training.
3. The government (Ministry of Health), together with the regional medical administration, may take the main role. Sweden is an example of this arrangement.
4. Universities may be the chief responsible bodies, as in Finland and Southern Europe.

5. Postgraduate institutes in some countries are, or were, the chief postgraduate authority, as in Central and Eastern Europe.

In Europe, within each country, there has been steady evolution of postgraduate training over the past 20 years, with formal definition, recognition and support given to the educational programmes (Karle et al. 1993). Postgraduate medical training has secured the confidence of the public on grounds of the medical care provided by accredited specialists.

In the United Kingdom, the statutory basis for the medical education infrastructure has been regarded as a major strength of the national system. The General Medical Council, the body responsible for registering qualified medical practitioners, extended its remit to specify doctors regarded by the General Medical Council as specialists. However, the overriding influence of international law in European Law resulted in a challenge by the European Commission to the system of specialist accreditation in the United Kingdom, as it appeared to discriminate against the recognition of specialist training in other states of the European Economic Area (EEA) and thereby restrict the free movement of doctors. In responding to this challenge, the U.K. government set up the Working Group, whose work culminated in the Calman Report (Department of Health 1993). In meeting the legal requirements, the Working Group availed itself of the opportunity to review not only statutory provisions for specialist registration, but also the entire postgraduate training system in the United Kingdom.

The duration of postgraduate training has been shortened. Planned and structured rotational training programmes have been created to give each trainee an adequate breadth of experience. Doctors will work as specialists in the National Health Service (NHS) sooner than they do at present. The United Kingdom has approximately 30% fewer doctors per head of population compared with other EEA states. For the new arrangements for training to work, many more specialist posts are required. These are drastic changes indeed in the country's medical education system and thus in the structure of its medical services – and all as a result of the European Union's calling into question the country's specialist certification system and thus its medical manpower structure.

The United Kingdom, therefore, is one European country providing an illustration of the rapid, major re-orientation which its postgraduate training system is undergoing. The country has been powerfully influenced by external forces, in this instance the international legislation to which national medical education is subject in the United Kingdom as a member state of the European Union.

4.4 International Context

The European Union is the one region in the world where medical education is controlled by international legislation. The sectoral directives of the European Commission, such as those of 1975 for medical training, promised to be a catalyst for professional improvement and a guarantee of quality. The directives require provision for the free inter-country movement of doctors. The Advisory Committee on Medical Training (ACMT) is the statutory body in Europe for development of common standards and ongoing review of medical education, which in 1978 and 1982 defined and widely publicised criteria for coordinated training to occur in remunerated posts in both university centres and general teaching hospitals; other criteria include a predominance of training over service provision, the existence of a safe system of supervision and instruction in the prescribed curriculum by a range of training techniques. Directive 93/16/EC defines the minimum duration of recognised training demanded in each specialty to achieve specialist status.

So that women, in particular, are not penalised, training arrangements for doctors with domestic or other special responsibilities have to be specified; otherwise, parents who have interrupted their training for family reasons would be precluded from re-entering medical practice. European Union directives on postgraduate medical education now also specify the minimum number of hours of work in part-time training (for general practice, at least 60% of the hours worked by those employed full-time). Similarly, doctors training part-time in hospital specialties will be required to extend their already lengthy training on a pro-rata basis in order to qualify for specialist registration.

Reliance on the duration of educational experience as a guarantee of competence is of course highly questionable. In addition, in every country, professional competence must also be directly assessed by methods of performance appraisal and by formal examinations.

Doctors in postgraduate training have other professional needs which training programmes must cater for. They require, for example, to learn the limits of their own competence, to identify and remedy deficits in their knowledge and skills, to learn when and how to seek the assistance of others and to develop effective working relationships with professional colleagues and others. Structured training programmes are therefore obligatory, incorporating modern educational practice (Borman and O'Grady 1997).

5
Continuing Medical Education

Maintenance of competence throughout professional life is now obligatory and accepted as such by employing authorities, doctors themselves and the general public, who require quality medical care and accountability by doctors for the clinical service they provide. CME consists of those educational activities undertaken by practising doctors to maintain and update their clinical competence.

It is the personal responsibility of every doctor to remain competent. This ultimate obligation of individual doctors calls for proper means to assess constantly the quality of their work and effectiveness of their professional services, such as a system of performance review. Agreed standards are necessary, and computerised medical records greatly enhance audit, the process of examining one's clinical performance in relation to peers.

Being related to performance, CME goes beyond information and knowledge and focuses on the carrying out of actual clinical responsibility and services. The material included in CME, over and above lectures, case presentations, conferences, scientific meetings and conferring among clinical colleagues and their hospital firms or clinical teams, must be based on understanding how adults learn: they are oriented to tasks they undertake themselves and to the personal interests they pursue. Material must be relevant to the practitioner's own daily responsibilities. Old-style courses, in which doctors were brought together to sit through series of lectures haphazardly given by outside experts, are not congruent. Mere attendance at CME courses for which credit is given cannot be assumed to improve professional competence.

There is widespread agreement that the CME system in a country must be closely integrated with the health care system and related to the health needs of the population. Some countries are already imposing sanctions on doctors who do not engage in approved CME activities. Self-evidently, differences in the CME system between countries are to be expected, and indeed greatly varying patterns are compounded by national realities in the health care services, the varying professional bodies with authority for medical education and training, and the forms of statutory regulation of the medical profession.

Medical journals and other medical scientific publications always were and continue to be paramount in disseminating new knowledge and promoting best clinical practice (Vysohlid and Walton 1990). Special continuing education courses were first introduced, in some Central European countries, for doctors practising in state health services in 1878. As increasing numbers of countries introduced social insurance, furthermore, continuing improvement of their employees' professional competence also came to be expected. This direct intervention and involvement of the state, to a lesser or greater extent, in promoting new knowledge and experience for doctors in the public health service is the original model of CME.

Before the Second World War, opportunity was provided for CME in practically all European countries, with great differences in the providers, the organisation and the methods of activities, which – it goes without saying – were not nationally monitored or evaluated. Coordination and cooperation among undergraduate, postgraduate (specialty studies) and CME was non-existent.

5.1
International Cooperation

The World Health Organization (WHO) was founded as a health care agency of the United Nations system in 1948. The regionalised structure of WHO made it possible to deal with comprehensive health problems in terms of specific regional needs, conditions and circumstances.

In Europe, with its many and varied systems of health care, its very different needs, conditions and opportunities, the intentions for unified actions were difficult, if not impossible, to realise. Although some minor problems were recognised, partly solved and innovative approaches initiated, by the end of this period it became recognised that health personnel had not been trained to perform tasks which were essential for providing necessary services and care to the population as a whole. In the absence of long-term planning for training of health care personnel, and of doctors in particular, comprehensive planning, education and management of health personnel remained only partially achieved.

A new impetus for the attainment of greatly improved health for all people by the year 2000 "permitting them to lead a socially and economically productive life" was accepted in 1977 by all member states of the World Health Assembly, the health parliament of the world. In 1978, the Alma Ata Conference on Primary Health Care specified a concept of "primary health care" as the key to achievement of the health goals (World Health Organization 1978).

The European Regional Committee of WHO, within this framework, adopted for the first time a broad health policy for the European region in 1980. In 1984, the same body took the great step of deciding that this regional policy should be strengthened by adopting 38

European regional targets to be attained for resolving identified defects.

5.2 Educational Reform

A decisive initiative was taken by the World Federation for Medical Education, the international body recognised as representative of all stages of medical education, in 1984. The World Federation for Medical Education planned and conducted, for the first time, a world-wide assessment of all stages in medical education and training,. The assessment was based on agreed six main themes (World Federation for Medical Education 1986), which were first discussed at the country level of respective national associations for medical education; the outcomes were then reported to the six Regional Conferences, organised by the World Federation for Medical Education and the Regional Associations. The outcomes of these worldwide actions were used as the basis for the World Conference on Medical Education held in Edinburgh in 1988, with the close cooperation and support of WHO, the United Nations International Children's Emergency Fund (UNICEF), the United Nations Educational, Scientific and Cultural Organization (UNESCO) and the United Nations Development Programme, the U.K. government participating with the World Federation of Medical Education as hosts. The recommendations of the World Conference are summarised in the Edinburgh Declaration (World Federation of Medical Education 1988), translated into all main languages and now widely known and adopted (World Health Assembly 1989). The detailed recommendations of the World Conference are specified in the International Collaborative Programme for Reorientation of Medical Education, now being implemented at global, regional, national and institutional levels.

The reorientation called for by the International Collaborative Programme has many statutory and political implications requiring the active understanding and involvement of the governmental authorities of all countries at the highest level. Principle 8 of the Edinburgh Declaration called for ministerial consultations involving both Ministers of Health and Ministers of Education to be held in all six regions. The European ministerial consultation was held in 1988; the Ministers of Health and of Education of Portugal were the hosts, together with the European Office of WHO and the World Federation for Medical Education; UNESCO was actively associated. This European ministerial consultation, again for the first time, brought together the Ministers of Health and of Education in order to decide how best to implement in close cooperation the recommendations of the World Conference on Medical Education, their report designated by them as the Lisbon Initiative (Government of Portugal, European Office of the World Health Organization and the World Federation for Medical Education 1989).

In 1993, the World Federation for Medical Education called the World Summit on Medical Education, again in Edinburgh. The principles of the Edinburgh Declaration were re-affirmed, and the summit recommendations (World Federation for Medical Education 1994) specifically required CME systems in all countries to ensure professional competence of all medical doctors was updated throughout professional life. Particularly mandatory was the requirement to view the three phases of medical education as a continuum. Moreover, the undergraduate, postgraduate and CME phases had to be interrelated with regard to objectives, content, methods and assessment.

Of greatest moment have been the directives of the European Union which promote the free movement of doctors among the member countries in Western Europe. At the same time, massive, unanticipated and extraordinarily swift political changes have swept across the countries of Eastern Europe, immeasurably complicated by warfare and even genocide of unprecedented ferocity.

5.3 Range of Systems in Europe

The political transformation of the Central and Eastern European countries since the demise of communism has found expression in urgent approaches to other countries for advice and assistance. As these countries change to a market economy, their pressing need is for education and training support, in addition to advice about insurance systems or other methods for financing clinical services, on which training depends.

In all countries of Europe, some systems for CME exist, with the exception of very small countries such as Monaco, which send participants for CME to neighbouring countries. The many national variations are strikingly different in approach, and some of the priority problems can be cited:

1. There is often a lack of any close, working cooperation between the medical education system and the health sector, with neither related to the CME sector, especially with regard to health care needs.
2. A multiplicity of CME providers is the rule, e.g., the Health Service, the State (central, regional and district levels), professional associations, trade unions and private providers, without there being informed cooperation in planning, imple-

menting and evaluating CME programmes and activities.
3. Resources are lacking – both financial allocation and material provision – and planning is fragmented (as follows from the points above).
4. Much discussion over a long period, which is still unresolved, has centred on the conflict between voluntary versus compulsory CME.
5. CME is most commonly considered as merely a means to transmit information, and not recognised as an indispensable agent for change, as the WHO targets and the Edinburgh Declaration insists.
6. CME is now always adapted to identified and actual needs of the health problems of the population and to the health services, particularly in relation to primary health care and ambulatory settings. There has been very slow progress in active, distance and multi-professional learning and teaching activities; very little active involvement occurs by participants in the planning of CME programmes and in the related teaching activities.
7. The assessment of CME which is undertaken is concerned mostly with the teaching and learning process, and not with the outcome in improving the health care provided.

In the following, the variety of CME systems in the health service organisations existing in Europe by the end of the 1980s will be outlined in brief. The World Federation for Medical Education, together with the European Regional Office (EURO) of WHO in Copenhagen and UNESCO, conducted a project exploring and promoting the status in Europe of CME, with the collaboration of the Association for Medical Education in Europe (Walton 1993).

A survey was conducted by obtaining information from each National Association for Medical Education in the European countries. The national profiles have been reported in detail (Walton 1994) and provide a preliminary guide to knowledge about current arrangements in Europe.

There is nearly unanimous agreement among medical educators, practitioners and administrators everywhere that CME is essential in the interests of delivering good medical care. Nevertheless, there is equally clear diversity throughout Europe regarding the current needs, provision, aspirations, planning and legislation of CME.

There are grey areas, in the first place, in the definition of the boundary between CME and postgraduate training. This is most clearly seen in the case of general practice, where the requirement, in many countries, for formal postgraduate training in primary health care has resulted in the better provision of CME. On the other hand, the provision of postgraduate certification for specialists has sometimes led to a view of their being seen to carry an implication of qualification for a lifetime career, with consequent neglect of provision of formal CME. This view is not common, however, and numerous specialties in many countries have given particular emphasis to CME programmes.

Most national governments and the regional government (the European Union), with the support of medical associations and professional societies, are involved in sponsoring and financing CME, setting up mechanisms and providing resources. In about half the countries in Europe, legislation has been passed regarding it. Several national respondents referred to the controversy over the nature and purpose of such legislation. On the one hand, it can be *permissive*, giving every doctor the right and means to participate in CME, but without compulsion. On the other hand, CME can be made *mandatory*. In either option, permissive or mandatory, an optimistic view can be taken that everyone who attends CME activities will learn and practise what they have learned (implied when credits are conferred on the basis of attendance). The alternative licencing approach is to insist that all doctors participating in CME must demonstrate, in addition (usually every 5 or 6 years), that their knowledge and skills have kept pace with advances in modern medical care; otherwise they lose registration.

Naturally, such a re-licensure requirement raises anxieties, and therefore opposition, even among many competent practitioners who fear that they could lose their livelihood through a system that has not been adequately validated. This is probably why some informants considered a valuable role could be taken by the World Federation for Medical Education in encouraging research to evaluate CME programmes before those same programmes become used to evaluate and pass judgement on doctors. It is noteworthy that in countries where there is legislation regarding re-certification for certain groups, there were no worries expressed over such dangers.

At the practical level, the main barriers to CME identified in most countries are lack of finance, lack of other resources and limitation of time.

The provision of clinical information made available by modern information technology is the basis now needed for CME and is already in use in several countries. Many informants pointed out the relative unavailability of CME for doctors working in rural areas and distant from the main teaching areas. There is urgent need to extend awareness about effective techniques of CME and to make generally known why some of the CME practices currently in use are not valid and have to be discarded.

All doctors now have to accept personal responsibility for maintaining professional competence

throughout their working lives through CME. This third, and longest, phase of medical education is the most important, and both basic medical education and postgraduate training must now be planned and implemented as preparatory for lifelong CME.

Lifespan Developmental Psychology

Translator: S. Goss

We would like to acknowledge the many valuable discussions with our colleagues from the Max Planck Institute for Human Development and the Research Network on Successful Midlife Development of the MacArthur Foundation (chair: O. Brim). We also wish to thank Hans Lauter and Hanfried Helmchen for their helpful comments on an earlier version of this contribution.

1 Introduction

Does human development extend across the entire life course or is it completed at early adulthood? Is development completely genetically "preprogrammed"? Is there great variability in the developmental trajectories of different individuals or in different domains of functioning? Can development be both latent and manifest? Is it possible to improve developmental trajectories? Questions such as these are addressed within the field of lifespan developmental psychology. In the following sections, we will try to provide answers to some of these questions.

In order to gain an accurate impression of human development, it is essential to approach it from a systemic perspective. It is not enough, for example, for psychologists to study only psychological development, for physicians and biologists to consider the development of physical functioning alone, or for sociologists and historians to analyze only the social embeddedness of development and how this evolves over time. Physical, psychological, and sociohistorical factors interact and condition each other in the process that we observe as human development.

2 Three Basic Assumptions About the Effects of Biological and Cultural Systems of Influence on Human Development

In lifespan developmental psychology, certain assumptions are made about the effects of biological and sociohistorical or cultural systems of influence on human development (P.B. Baltes 1997; P.B. Baltes et al. 1998). These assumptions are illustrated in Fig. 1 and will be elaborated on briefly below. It should be noted that the specific form of the three functions depicted is not decisive. What is critical is the *overall direction* and the *reciprocal relationship* between the three functions.

2.1 Evolutionary Selection Benefits Decrease Across the Lifespan

The first assumption about the effects of biological and cultural systems of influence on human development is that the selection benefits resulting from biological evolution display a negative age correlation (e.g. Finch 1996). As a consequence, with increasing age the human genome contains more deleterious genes and thus more dysfunctional genetic expressions than in younger years.

The main reason for the "evolutionary neglect of old age" lies in the midlife location of biological selection. The reproductive system, a central component of natural selection, uses fertility and parenthood – events which typically occur in early adulthood – to ensure the selective transmission of the gene. Consequently, over evolutionary history, genetic selection operated *primarily* on the first half of life. Moreover, due to the shorter life expectancy in early human evolution, selection processes could not operate as frequently to begin with when it came to the second half of life. Most people died before possible negative genetic attributes became manifest.

One concrete illustration of the age-related biological weakening of the human organism is the existence of late-life illnesses such as Alzheimer's disease (for further examples, see Martin et al. 1996). This disorder does not typically become manifest before the age of 70. After this age, however, the number of new diagnoses increases markedly (e.g. Helmchen et al. 1999). Following the representation shown in Fig. 1a, Alzheimer's disease is at least in part a late-life disease because reproductive fitness-based selection processes had only a very slim chance, if any, to eliminate it.

Biological aging is, of course, influenced by other factors which individually or conjointly further reduce the biological functioning and plasticity of the organism across the lifespan (e.g. Finch 1996; Martin et al. 1996). Many of these age-related biological losses are associated with the mechanisms of ontogenesis itself, e.g. natural wear and tear, information losses within systems (entropy costs), and the cumulative increase in genetic mutations.

These various considerations about the role of genetic and biological factors in lifespan development result in a converging conclusion which is generally undisputed. Evolutionary selection and the ontogenetic biology of the aging process mean that, with time, the human body becomes increasingly susceptible to dysfunction and marked by symptoms of decline.

2.2 Need for Culture Increases with Age

The second assumption is that cultural development has to be able to compensate for biological processes of decline in order for adaptive development to extend on into advanced old age. With increasing age, the need for supportive cultural resources to help maintain previous levels of functioning becomes more and more pronounced (see Fig. 1b). This view of "culture as compensation" is a main tenet in many evolutionary theories in cultural anthropology (e.g. Elwert 1994).

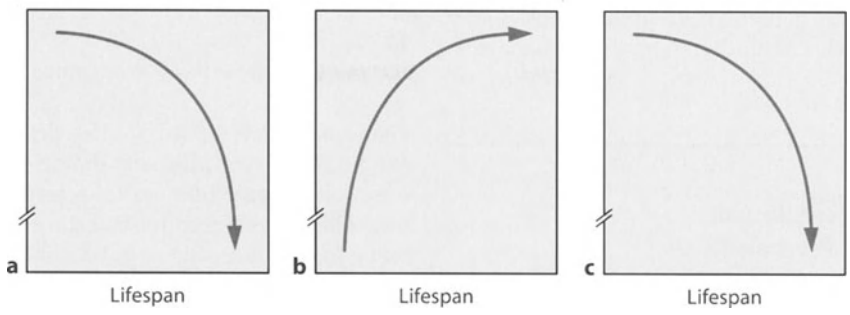

Fig. 1a–c. Three basic assumptions which play a decisive role in regulating the nature of ontogenic development. a Evolutionary selection benefits: decrease with age. b. Need for culture: increases with age. c Efficiency of culture: decreases with age. (After Baltes 1997)

In this context, culture includes all of the psychological, socially interactive, material, technological, institutional, and symbolic (knowledge-based) resources which humans have developed over the millennia. These resources, passed on from generation to generation, have made human development and the life course possible as we know them today (Durham 1991).

Human ontogenesis was therefore only able to achieve increasingly higher levels of functioning (e.g. a longer lifespan and the ability to read and write) because of the concurrent development and dissemination of culture and the associated structures of societal opportunity. If human development is to extend further and further into old age, it will be necessary for additional sociocultural forces and resources to emerge.

Culture and ontogenesis are inextricably intertwined, and the increase in average life expectancy during the twentieth century illustrates the extent of their mutual dependence. Life expectancy rose from an average of approximately 45 years in 1900 to about 75 years in 1995. This marked increase was not caused by changes in the genetic makeup of *Homo sapiens* that occurred over this period of time. On the contrary, it was primarily societal, cultural, and technological progress which contributed to the significant increase in life expectancy.

2.3 Efficiency of Culture Decreases Across the Lifespan

Figure 1c illustrates the third assumption, according to which there is an age-related decrease in the effectiveness or *efficiency* of cultural factors and resources. The human organism is defective from birth onward and thus in need of cultural support in order to survive. However, with age (the age of onset is unclear), the relative efficiency of psychological, social, material, and technical interventions wanes. This is conditioned primarily, but not exclusively, by biological processes of decline.

Cognitive learning potential provides us with an illustrative example of the reduced efficiency of cultural factors over the life course. The older adults are, the more time, practice, and cognitive support it takes them to attain the same level of learning success (e.g. Kliegl and Baltes 1991). Moreover, when it comes to peak levels of performance, older adults are unable to attain the same results as younger adults, even after extensive training. The same can be said for plasticity on the neurobiological level (Magnusson 1996). Neuronal plasticity continues to exist across the entire lifespan, but it becomes impaired with age. The age-related reduction in pharmacologically relevant adaptivity, as shown in pharmacokinetics and pharmacodynamics, is another good example (see Coper and Schulze 1994).

This third assumption might be called into question, or its force diminished, by the following two objections:

1. The notion that culture- and knowledge-based symbolic systems are inherently different from, or even more effective, than biological and physical systems. For instance, fewer lifespan developmental losses in information content (entropy costs) are observed for symbolic systems than for biological processes, which implies that symbolic systems should be able to function longer and more effectively during ontogenesis (P.B. Baltes et al. 1998). However, we should not overlook the fact that the operation of symbolic systems is inalienably tied to a minimum degree of biological functioning (in order to impart knowledge, for example, an individual must first be able to retrieve and formulate that knowledge).
2. The term "efficiency" refers to an evaluation of performance which cannot be applied to certain facets of development, such as the meaning of life and other personal meaning systems (e.g. Dittmann-Kohli 1995; Filipp and Aymanns 1996). This is indeed a serious line of argument. However, it is unlikely that it will alter the ontogenetic *direction* of the efficiency function outlined,

although it will perhaps have implications for the extent to which this third assumption holds.

3 Consequences for Lifespan Developmental Psychology

These three assumptions form a theoretical framework which has certain consequences for the further development of a psychological theory of human ontogeny across the lifespan.

3.1 Three Categories Organize the Two Systems of Lifespan Developmental Influences

The first consequence of this theoretical framework is that development occurs under both facilitating and limiting conditions. According to P.B. Baltes (1987), these systems of opportunities and constraints can be categorized into the following three groups:

1. Age-graded
2. History-graded
3. Non-normative

Some biological and environmental influences have a strong relationship to chronological age and are therefore fairly predictable in their temporal course. For example, the age-related clustering and sequential ordering of biological and cultural challenges has been summarized in the concept of developmental tasks (e.g. Havighurst 1972). The theory of developmental tasks shows that at particular stages of life, we are faced not only with particular biological and cultural opportunities, but also with challenges and constraints (e.g. at the age of 65, symptoms of physical decline, retirement, loss of social contacts, more freedom in planning leisure).

Biological and environmental influences on development may also be history-graded, meaning that they depend on historical time. The influence of pharmacology and nutrition on health and of the education system on cognitive development are examples of such determinants.

Finally, however, there are also non-normative biological and environmental systems of developmental influences. The term "non-normative" is used here in the statistical sense, i.e. these influences do not follow a predictable course, but instead differ from individual to individual. They include idiosyncratic life experiences, such as being involved in an accident or winning a lottery.

3.2 Lifespan Development as a Multifaceted Dynamic System

Figure 1 also allows us to infer that attainments and functions that are primarily biologically based should evince a different lifespan trajectory than those functions that mainly feed on cultural resources. Biology-based functions should reveal decline from early adulthood onward, while culture-based functions should show stability – and under favorable conditions lasting growth – well on into late adulthood. Any theory of ontogenetic development which postulates that developments in later adulthood are "generally positive" or "generally negative" across all domains of functioning must be regarded as false. It would be just as erroneous to assume that child development only consists of gains (see P.B. Baltes 1987). On the contrary, lifespan developmental psychology works on the assumption that development is multidimensional, multidirectional, multicausal, and multifunctional throughout life (M.M. Baltes and Carstensen 1996; P.B. Baltes et al. 1998).

By *multidimensional* we mean that development does not consist of a unitary process, but that it occurs simultaneously in different domains of functioning. For example, an individual's intelligence does not develop independently of his or her personality and social relations. And as we will see below, subfacets of broader domains of functioning, such as intelligence (e.g. reaction speed and knowledge), can develop differently, depending on whether they are primarily based on biology or culture.

Development is *multidirectional*, i.e. not only is variability of development observed in different domains of functioning on the intraindividual level, but there are considerable interindividual differences in developmental trajectories. Development does not consist exclusively of growth or loss on either the intra- or the interindividual level, but involves both components at all points of ontogenesis. Intellectual performance, for example, tends to show losses with time, whereas features of personality and social behavior tend to remain stable. To put it simply, development can also be described as a dynamic balance between gains and losses. However, the balance of developmental gains to losses does become less positive across the lifespan. Thus it is important to differentiate between developmental trajectories specific to particular domains of functioning and the overall balance of developmental gains and losses.

What constitutes a gain in ontogenetic change and what represents a loss is a topic of both theoretical and empirical inquiry (e.g. M.M. Baltes and Carstensen 1996; P.B. Baltes and Baltes 1990). For example, great differences can be observed depending on whether an

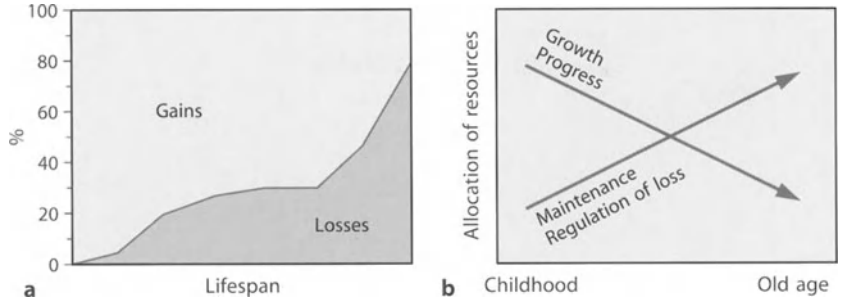

Fig. 2. a With increasing age, losses come to predominate. (After Heckhausen et al. 1989). **b** The relative allocation of resources into three adaptive developmental goals: lifespan changes in the investment of resources into growth, maintenance, and the regulation of losses. (After Staudinger et al. 1995)

external view of the developmental outcome is taken, using objective criteria, or whether the internal view of the developing person is taken, using subjective criteria. Cultural context and age also play a significant role.

The intrinsically relative nature of what is classed as a gain or a loss is encapsulated in the concept of the *multifunctionality* of development. The notion of multifunctionality denotes that there is no single criterion for ontogenetic adaptivity or for what is to be considered a gain or a loss. Investigations on the topic of autonomy versus dependency provide a telling example of such multifunctionality (see M.M. Baltes 1996). It has been shown that the advent of dependent behavior in old age should not always be seen as a loss. Within the everyday ecology of older adults, dependency can also imply gains such as increases in social contact and close relationships to caregivers.

3.3 Developmental Reserves and Their Allocation Across the Lifespan

The third consequence of the assumptions illustrated in Fig. 1 pertains to the latent potential of development. According to the third assumption presented above, the efficiency of culture decreases with age. The aging organism thus displays a reduced plasticity. In other words, there is not only an age-related decrease in biologically based functioning and the level of functioning, but in the potential for adaptivity and repair.

It is important to distinguish between the development of the functional status and the development of adaptivity reserves in lifespan developmental psychology. Only when both of these levels of development are taken into consideration can a comprehensive conception and understanding of lifespan development be arrived at. The performance status attained by an individual at a given point in time cannot be equated with his or her maximum performance potential. Taking developmental reserves into account allows us to consider possibilities for intervention and improvement, i.e. the ways of shaping development.

In lifespan developmental psychology, a distinction is made between three major functions of developmental potential and reserves: growth, maintenance/recovery, and regulation of nonreversible losses (see also Staudinger et al. 1995). In this context, growth means all behaviors involved in reaching higher levels of functioning or adaptive capacity. Maintenance and recovery (resilience) refer to the adaptive goal of maintaining levels of functioning in the face of new challenges or losses. The regulation of loss means adaptive behavior aimed at securing and coming to terms with lower levels of functioning when maintenance of former levels is no longer possible.

Losses in functioning and the conjoint reduction in adaptive capacity, or reserves, suggest that there is a systematic pattern in the *relative* allocation of reserves to these three adaptive functions across the lifespan (see Fig. 2b; P.B. Baltes et al. 1998; Staudinger et al. 1995). In childhood, the major share of resources is invested in growth and the quest for higher levels of functioning; during adulthood, the predominant allocation is toward maintenance and recovery (resilience). In old age, an ever-increasing proportion of the available resources has to be directed toward the regulation of irreversible losses.

3.4 Illustrating Lifespan Theory: Empirical Evidence on Intellectual Development

In the following, intellectual functioning is used as an empirical example to illustrate the tenets of lifespan psychology presented above (see P.B. Baltes et al. 1998; Lindenberger and Baltes 1994). Ever since the early work of Hebb and Cattell, a distinction has been made between two main components of intelligence (compare multidimensionality of development): biology-regulated fluid intelligence and experience-based crystallized intelligence.

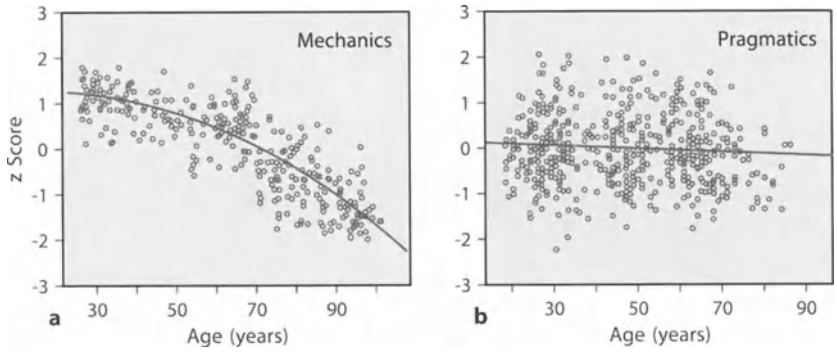

Fig. 3a,b. Pragmatics and mechanics of intelligence: adult age gradients for two exemplary kinds of task. The figure displays empirical data; each *dot* represents the performance of one study participant. (After Lindenberger and Baltes 1995)

In lifespan developmental psychology, this psychometric theory of intelligence has been combined with perspectives from process-oriented cognitive psychology, and a distinction has been made between the fluid *mechanics* and the crystallized *pragmatics* of intelligence (e.g. P.B. Baltes 1987).

By analogy to computer language, the mechanics of intelligence correspond to the "hardware" of the mind, i.e. the brain's neurophysiological information-processing basic operating system (Barkow et al. 1992). The mechanics of intelligence include elementary processes of information processing such as information input, visual and motor memory, and basic perceptual-cognitive processes such as discrimination, comparison, and categorization, as well as the application of these processes in working memory. Because of the close connection between the mechanics of intelligence and neurobiological development, lifespan theory postulates that the life-course trajectory of the mechanics takes the form of an inverted U, with the decline beginning in young adulthood, if not earlier.

Staying with computer language, the pragmatics of intelligence can be understood as the culture- and knowledge-based "software" of the mind. They reflect culturally acquired bodies of declarative and procedural knowledge. Typical examples of the pragmatics of intelligence include reading and writing skills, language, and professional expertise, but also the knowledge about the self and the world which is required in the planning, conducting, and interpretation of life.

Figure 1 suggests that the ontogenetic trajectory of pragmatics can show stability and even growth for longer than that of mechanics, pragmatics being primarily determined by sociocultural factors (compare multidirectionality of development). How far the trajectory can be extended and refined is, in essence, dependent on two conditions. The first is the availability of cultural resources and their translation into programs of cognitive enhancement. The second is the mechanics of intelligence and their development across the lifespan. The mechanics are important because they provide the basic operations on which pragmatic performance is based. For example, if an individual is no longer able to retrieve the relevant knowledge from his or her memory in response to a question, this knowledge is of little further use to him or her.

Most empirical studies of intelligence come to conclusions which are consistent with both this dual-component model and the three basic assumptions of lifespan development. Marked differences are observed in the lifespan trajectories of different aspects of cognitive functioning, depending on whether the task involved is based on biology or culture (Fig. 3).

Thus abilities that involve the mechanics of intelligence, such as working memory, speed of information processing, and attention span, typically show negative age gradients even in early adulthood (Lindenberger and Baltes 1994). However, trajectories for pragmatic components of intelligence, including vocabulary tasks, dimensions of social intelligence, and expert knowledge about life and the world such as wisdom, often remain stable into later stages of life. The lifespan trajectory of pragmatics, which we have studied with reference to the prototypical concept of wisdom (see Fig. 3), profits from certain personality characteristics and experiences, the processing of these, and exchange with other people.

In our wisdom studies, for example, older participants performed as well as younger adults up to at least the age of 75. After this age, however, performance levels seemed to decline in wisdom tasks as well (Staudinger and Baltes 1994). In advanced old age, the biologically determined limitations of the mechanics of intelligence impose increasing constraints on what culture and individuals can accomplish.

Findings on the interdependence between the two components are of particular importance. There is ample evidence that the mechanics and pragmatics of

intelligence interact. For instance, the pragmatics of cognition can be used to offset losses in the mechanics. It has been shown that older office workers who continue to be excellent typists compensate for their reduced reaction time (mechanics: decrease in information-processing speed) by reading further ahead in the text to be typed (pragmatics: experience) than their younger colleagues who have a faster reaction time (Salthouse 1991).

Investigations carried out within the framework of testing-the-limits research show that intellectual developmental reserves also decrease with age (Kliegl and Baltes 1991). The testing-the-limits method is an experimental approach which, not unlike the use of stress tests in medicine, examines the individual at his or her upper limits of functioning, where differences in performance are more pronounced. While older individuals do improve their performance when they undergo training, they are not able to equal the peak performances of younger persons, even after long-term training programs. It should be noted that the age gradient for the mechanics of intelligence remains identical when members of different social classes are compared. Only the level of functioning at the start of the process of decline distinguishes between people from various backgrounds (Lindenberger and Baltes 1995). In other words, culture is not able to guard against cognitive decline.

Further support for the assumption that the mechanics of intelligence are mainly biologically determined is provided by the finding that there is an extremely strong association between sensorimotor functioning and intelligence. All negative age differences in general intellectual functioning disappear when interindividual differences in sensorimotor functioning are controlled for with simple measures of visual and auditory acuity as well as balance. We believe that this powerful connection between sensorimotor functioning and intelligence in old age has a common cause (a so-called third-variable hypothesis), i.e. the age-related changes in neurophysiological brain functioning which concurrently impair the sensory, sensorimotor, and intellectual abilities (P.B. Baltes 1997).

4
A General Model of Development: Selective Optimization with Compensation

Human development across the lifespan is thus characterized by a reduced level of reserves on the one hand and by a combination of growth, stability, and losses in various domains of functioning on the other, with stability and losses coming to predominate with age. In recent years, lifespan developmental psychologists have proposed models describing general developmental processes that make it possible to deal with such conditions in an adaptive way (see, e.g. Brandtstädter and Greve 1994). One of these models is that of selective optimization with compensation (SOC) developed by P.B. Baltes and M.M. Baltes (1990; see also Heckhausen and Schulz 1995).

The precise definition of the terms selection, optimization, and compensation is governed by the theoretical framework and specific domain of functioning in which they are to be applied at any one time. The following general descriptions of these processes hold when an action-theoretical approach is taken:

- Selection refers to the *direction*, the goal, or the outcome of development (e.g. an individual may define himself in the following five phrases: good story-teller, good father, athlete with plenty of stamina, loyal friend, and faithful husband. Should serious physical impairment occur in old age, he can exclude the domain "athlete with plenty of stamina" and concentrate on the remaining domains instead).
- Optimization refers to the *resources* or means which allow developmental goals or developmental outcomes to be realized (e.g. individuals may set themselves the goal of getting a promotion at work and focus their effort on achieving this).
- Compensation involves an adaptive *response to the loss of means* (resources), with the aim of maintaining the functional status (e.g. people may write notes when they realize that their memory is deteriorating).

SOC theory proceeds from the assumption that any process of development involves a unique combination of selection, optimization, and compensation. We further assume that, on account of the biological and cultural factors which condition development, there is a lifespan script for these combinations of selection, optimization, and compensation. For example, as is to be expected on the basis of the assumptions described above, selection and compensation retain more significance than optimization with increasing age (Freund and Baltes 1998).

The use of action-theoretical perspectives in this taxonomy of the SOC model might suggest that SOC is always a process with intention and rationality, but this is not so. Each of the three components can be active or passive, internal or external, conscious or unconscious. Moreover, during ontogenesis, the focus of the components may shift. For instance, forms of behavior which initially emerged as compensatory processes may later be used as strategies of optimization (P.B. Baltes 1997).

5 Adaptive-Productive Functions of Self and Personality

The various empirically identified adaptive-productive functions of self and personality (summarized briefly below) are easily integrated into this general model of development (see Staudinger et al. 1995). Measures of functioning from the domain of self and personality (e.g. subjective well-being, personality characteristics, control beliefs, coping strategies) display a lifespan trajectory that is more akin to the pragmatics than the mechanics of intellectual functioning, i.e. they are primarily characterized by stability. Furthermore, and perhaps contrary to expectations, there is no increase in depressivity and anxiety in old age (e.g. Helmchen et al. 1999). We should not forget that considerable reserves exist in the domain of pragmatics, even in advanced old age (Staudinger et al. 1995). This is illustrated by the fact that older people are able to profit from therapy (e.g. Radebold 1989).

This lifespan trajectory of self and personality functioning lends support to the notion of an "orchestrating" function of self and personality where the activation and management of internal and external developmental resources is concerned. By orchestrating function we mean that certain processes and structures related to self and personality are able to offset losses experienced by the aging person in many domains of functioning, balance out the losses through selection and compensation, and optimize the situation once more. In this context, we speak of the psychological resilience of the self (e.g. Staudinger et al. 1995). Such processes and structures include goal selection, compensatory coping styles, a rich and differentiated self-image, self-efficacy beliefs, conscientiousness, and openness to new experiences (see Staudinger et al. 1995).

6 The Fourth Age: A New Challenge for Science and Society

With increasing age, however, even the processes of selection, optimization, and compensation can no longer completely offset losses. Impairments become increasingly extensive and irreparable. This has recently lead to this stage of life being described as "the fourth age" (P.B. Baltes 1997). The losses and limitations experienced by the very old – those aged over 80 – are far more extensive than those observed in young old age or "the third age" (see P.B. Baltes and Mayer 1999).

In the years and decades to come, the very old will present a formidable challenge for society. Take the prevalence rates of almost 60% for Alzheimer's disease in the over-90 age-group, for example. In a large, representative study carried out in America, Crimmins et al. (1996) studied the percentage of sickly and dysfunctional years of life remaining in old age. They found that for 70-year-olds, 20% of the remaining lifetime is marked by illness and inactivity. For 90-year-olds, this rose to 60%. Hence, the oldest of the old do not survive simply because their functional status is superior to that of their deceased counterparts. The physical functioning of the survivors is also seriously impaired, but not yet to the extent that death ensues.

Moreover, the increase in risk for the fourth age is not observable only where physical variables are concerned, but also when the focus is on psychological variables such as intelligence, the self, personality, and social behavior (Smith and Baltes 1999; Staudinger et al. 1999). With the exception of intelligence, the negative age effects of each individual psychological variable were, in general, relatively small. However, the psychological age gradients for the 70- to 100-year age-group in the Berlin Aging Study all sloped in the same direction, namely downward, in the sense of increasing losses.

When these rather weak age effects for individual variables are aggregated into multivariate profiles, a succinct and rather negative picture of psychological development in old age develops. From the psychological perspective, advanced old age appears to be a period of life which is increasingly characterized by stress and challenge. It appears that advanced old age, the fourth age, represents a kind of boundary situation in which the limits of psychological resilience are frequently overstepped.

7 Concluding Remarks

Although the optimization of human development becomes increasingly difficult in advanced old age, we do not wish to leave the impression that achieving a positive balance of gains and losses in all ages of life is not possible in principle. Neither the biological framework nor the current state of cultural development ought to be viewed as a fixed representation of "the" nature of human aging. States of deficit and limitations, such as those characteristic of the fourth age of life, are powerful catalysts for scientific, cultural, and psychological innovation. Furthermore, despite age-related losses in developmental reserves, there is latent potential for the enhancement

of functioning in advanced old age as well (e.g. training gains, receptiveness to therapy). In this spirit, we need to keep in mind that the future of (our) aging is not something we simply enter, but something that we help create.

CHAPTER

2

H. Remschmidt and E. Fombonne

Developmental Psychopathology

1 Developmental Psychopathology as an Integrative Discipline

There can be no doubt that the developmental perspective is of great importance for the understanding of psychiatric disturbances in children and adolescents. Developmental physiology, developmental neurology, and developmental psychology are basic sciences of child psychiatry. The developmental perspective can be looked upon as a kind of bridge between the different disciplines or as a unifying concept (Eisenberg 1977), integrating different scientific and practical approaches to normality and psychopathology, not only for children, but also for adults. Though there is general agreement about this view, we are far away from a comprehensive and substantial theory of development that would be able to integrate earlier and recent knowledge – and at the same time be open to new hypotheses and results.

Yet the developmental perspective is not a new one. Looking through the history of child psychiatry and psychopathology, we found one of the first hints of the developmental aspect in the German textbook by Emminghaus (1887) entitled *Psychic Disturbances of Childhood*. After complaining that there is no systematic and general symptomatology of childhood psychoses, Emminghaus writes that it is the task of psychopathology to study the anomalies of the mind through all developmental stages and to differentiate normal from pathological psychic processes (Emminghaus 1887, p. 4).

Other textbooks written by Homburger (1926), Kanner (1935), and Tramer (1941) include the developmental perspective, followed by books by Achenbach (1974, 1982), Rutter (1980), Remschmidt and Schmidt (1992), and the *Handbook of Developmental Psychopathology* edited by Cicchetti and Cohen (1995).

Nevertheless, the emergence of developmental psychopathology was characterized by "adultomorphism," i.e. a tendency to understand psychiatric disorders of childhood as predecessors of analogously named disturbances in adults.

According to Sroufe and Rutter (1984, p. 18), the basic perspectives of developmental psychopathology are as follows:

1. The discipline "is concerned with development and is therefore closely wedded to the whole of developmental psychology." Logically, developmental psychopathology thus has to use the methods, theories, and perspectives of developmental psychology.
2. The second topic is the focus on psychopathology, which means looking primarily at developmental deviations.
3. The third element is the integrative perspective, including and combining biological, psychological, and psychosocial approaches with respect to all structures and functions in the growing child.

Taking these elements into consideration, we may define developmental psychopathology as

> ...the study of the origins and course of individual patterns of behavioral maladaptation whatever the age of onset, whatever the causes, whatever the transformations in behavioral manifestation, and however complex the course of the developmental pattern may be (Sroufe and Rutter 1984, p. 18).

Another definition, given by Rolf and Read (1984, p. 9) runs as follows:

> The term 'developmental psychopathology' can be defined as the study of abnormal behavior within a context of measuring the effects of genetic, ontogenetic, biochemical, cognitive, affective, social or any other ongoing developmental influences on behavior.

Both definitions stress the integrative aspect, and from this point of view, developmental psychopathology "is the product of an integration of various disciplines the efforts of which had previously been separated and distinct" (Cicchetti 1984, p. 1).

Bearing these definitions in mind, we can say that the developmental perspective includes processes such as growth, maturation, and learning as well as the interactions between and among these influences. However, one has also to realize that not all influences on children have to do with development; accidental influences also exist, i.e. impairments and unfavorable conditions that are not developmental factors as such, although they do influence development in a profound way. The changes in development are age related and consist of transformations in the structure and the function of an organism, including quantitative and qualitative changes, the latter emerging with the formation of new structures and functions.

The view of development would not be complete without including the role and nature of experience. According to Gottlieb (1976), one may distinguish three distinct roles of experience in the development of behavior:

1. Experience can *maintain* or *preserve* behavioral states.
2. Experience can *facilitate* development by accelerating its rate without changing its course or by increasing the terminal level of proficiency achieved.
3. Experience can *induce* new forms of behavior which will directly reflect the configuration of the stimulus event.

Gottlieb concludes from a review of the literature that there is evidence for the roles of maintaining and facilitating experience, but that at the moment there is no evidence for the role of inducing experience. This issue might have to do with sensitive or critical periods in development, known from research with animals, where new kinds of behavior are induced. The only behavior in children that could be related to this issue is the development of social bonds and attachment in infants.

2 Levels for the Study of Behavior

Behavior can be studied on several levels that represent normal and abnormal behavior of different complexity. In Table 1, eight levels are presented, beginning with very simple ones and ending with very complex ones that take into consideration interactions of individuals, family structures, and also structures that might be influential over several generations.

With respect to a developmental perspective, normal and abnormal behavior on the different levels can show patterns of continuity and discontinuity. Thus it has been shown in several studies that dissocial behavior and conduct disorders that begin early during individual development remain stable over wide age spans and therefore follow a pattern of continuity. In contrast, internalizing disorders such as anxiety states and neurotic disorders show a high tendency of spontaneous remission and therefore represent a pattern of discontinuity.

Table 1. Levels of behavioral organization (from Remschmidt 1992)

Level	Normal behavior	Abnormal behavior
Molecular	Behavior traits	Symptoms
Molar	Patterns of behavior traits	Syndromes
Functions	Levels of functioning	Levels of dysfunction
Adaptation processes	Patterns of adaptation	Patterns of maladaptation
Individual	Personality	Disturbance of personality
Interactional	Personality in context	Personality disturbances in context
Family	Normal family function and structure	Family dysfunction and deviant family structures
Generations	Normal structure of generations	Abnormal structure of generations

From the viewpoint of developmental psychopathology, future research should pay more attention to more complex functions than to symptoms and syndromes. Patterns of adaptation and maladaptation in different age-groups and developmental stages and behavioral reorganization seem to be very important issues for future studies. Behavioral reorganization at different developmental levels, for instance, is a key issue without which certain new abilities or sometimes also a disability cannot be fully understood. Kagan (1981, 1984) has suggested that

> ...many instances of developmental change can be characterized by the replacement of an old structure or process by a new one, with little or no connection between the two hypothetical structures. The suggestion implies that some structures or processes vanish (Kagan 1981, p. 68).

Examples of such reorganization are, according to Piaget (1950, 1983), reaching the level of abstract thinking or the hormonal changes at puberty and their subsequent effects on body and psychological functions. By reaching these levels of functioning, new abilities are acquired that cannot be understood in terms of previous abilities and that represent discontinuity. In the same context, so-called turning points in development may be discussed (Rutter 1996). These are often dependent on individual experiences that are able to restructure past experiences and positively influence the self-concept of children. From these examples, it should be clear that the interaction of biological and psychological influences has to be studied longitudinally, not on the simple levels of behavior traits, symptoms, and syndromes, but rather on higher levels of functioning, including the processes of restructuring and reorganization at different age levels.

3 Milestones of Normal Development: Implications

Several authors have defined the stages of development in relation to different ages. Well-known systems of this kind are the developmental model of Sigmund Freud (1948) and Jean Piaget (1983).

Table 2 describes four developmental models, those of Freud and Piaget and those described by Erikson (1980) and Jersild and Holmes (1935). These models are based upon different perspectives. While the Freudian system is based on the psychosexual stages of development, Erikson concentrates his system on psychosocial stages, Piaget on cognitive ones, and Jersild and Holmes on affective ones. The last column of the table describes different psychopathological

Table 2. Anthony's proposed diagnostic classification for developmental psychopathology (Anthony 1970)

Age (years)	Psychosexual stages (Freud 1948)	Psychosocial stages (Erikson 1980)	Cognitive stages (Piaget 1983)	Affective stages (Jersild and Holmes 1935)	Psychopathology
0–1 1/2	Oral	Basic trust vs. mistrust	Sensorimotor	Fears of: dark, strangers, being alone, sudden noise, loss of support	Autism, anaclitic depression, feeding and sleeping problems
1 1/2–3	Anal	Autonomy vs. doubt, shame	Symbolic	Separation, desertion, sudden movements	Symbiosis, negativism, constipation, shyness and withdrawal, night terrors
3–5	Genital, oedipal	Initiative vs. guilt	Intuition, representational	Animals, imaginary creatures, injury	Phobias, nightmares, speech problems, enuresis, encopresis, anxiety states
6–11	Latency	Industry vs. inferiority	Concrete, operational	School failure, ridicule, loss of possessions, disfigurement, disease, death	School problems, school phobias, obsessions, conversion symptoms, tics
12–17	Adolescent; recapitulation of earlier conflicts	Identity vs. role confusion	Formal, operational	Being different physically, socially, intellectually; sexual fears; loss of face	Identity diffusion, anorexia nervosa, delinquency, schizophrenia

disorders that can be related to the relevant age-groups or developmental stages.

The problem of such a classification is that not all of these stages can be substantiated by empirical studies, e.g. the so-called latency stage in the Freudian system has no empirical evidence. Beyond that, there exists a high variability with regard to age, and finally, the different theories of development do not also correlate with regard to age. For instance, a child could have reached the symbolic stage according to the cognitive theory of Piaget and still be at the oral stage according to the Freudian system. Therefore, modern developmental theories are mainly based on functions (e.g. physical growth, cognitive development, moral development, identity, self-concept) in relation to developmental tasks. A developmental task can be defined according to Havighurst (1972, p. 2) as one

> . . .which arises at or about a certain point of life of the individual, successful achievement of which leads to his happiness and success at later tasks while failure leads to unhappiness in the individual, disapproval by society, and difficulty with later tasks.

Theories of development "attempt to describe, predict, and explain specific changes in behavior over some part of the life-span. To do so, they must generate testable predictions, i.e. ones that can be confirmed or disconfirmed" (Jaffe 1998, p. 47). However, not all theoretical assumptions are and have been subject to empirical testing. Nowadays, there is general agreement that developmental changes depend upon the interaction between hereditary factors and environmental influences, taking into account the fact that the individual is not a passive object of the influences but also shapes and creates his or her own environment.

Current developmental psychopathology has now shifted away from the stage models toward the process models of development that emphasize these interactions between individuals and the large variety of environmental influences and social contexts, at the same time paying attention to the individual as an active participant in his or her own development (Lerner 1996; Wachs 1996; Zahn-Wexler 1996).

These modern trends of developmental sciences also have implications for developmental psychopathology, which still relates psychopathological conditions to the classical stage models instead of the process models that are based on a continuous development of the different functions, paying special attention to the process of interaction.

4 Research Fields and Strategies

In the following section, we would like to refer to some research fields and strategies in developmental psychopathology that seem important to us and promising for the near future.

4.1 Sex Differences and Individual Differences

There is a great amount of knowledge about sex differences in relation to psychopathological disorders

and also of individual differences of general development (for reviews, see Steinhausen 1992; Costello and Angold 1995). The sex differences concern physical state, growth, maturation, development of differential abilities such as speech and language functions, spatial abilities, and most psychopathological disorders (e.g. hyperkinetic syndrome, developmental delays, autism, aggressive and dissocial behavior).

Until puberty, most psychopathological conditions are more frequent in boys than in girls, although the boy–girl relation is very different for the various syndromes. For instance, the hyperkinetic syndrome is up to nine times more frequent in boys than in girls (Cantwell 1977), whereas in autism the relation is 3.7:1 across 20 studies (Fombonne 1998). Tourette's syndrome is more frequent in boys than in girls (3:1; Shapiro et al. 1978). Obsessive–compulsive disorder is also more frequent in boys than in girls (Rapaport 1986).

Although these differences are very clear and well established, we do not really know their cause. This question is therefore open for research, and several hypotheses have been offered:

- Some differences might be connected with a different maturation of the hemispheres in boys and girls. Histological studies of infant brains by Conel (1939–1959) gave evidence for the assumption that selected regions of the cortex are more mature in girls than in boys during the time from birth to the second year of life. A faster maturation may also apply to the left hemisphere and the language functions, which are more advanced in girls than in boys until puberty (Kelly 1985).
- Psychological and psychosocial factors could also be important for some of the above-mentioned sex differences. It is a well-established fact that socialization and education are different in boys and girls. This may explain the proneness of girls toward depression during adolescence in the light of differential socialization patterns (Sroufe and Rutter 1984).
- There could also be an interchange between biological factors such as maturation of the hemispheres and educational and psychosocial influences.
- It might also be possible that some differences between boys and girls are not in fact real differences, but rather caused by a different time pattern of maturation (Kelly 1985). In line with this hypothesis are the results published by Waber (1976, 1977) which demonstrate differences in psychological profiles between early and later maturers. Following this line, it could very well be that early acquired achievement structures could enhance future achievements, finally causing a new or adifferent quality of achievement structure. This hypothesis is connected with another open question, namely, the progressive development from quantitative to qualitative changes during development. Finally, one should mention that the androgenes play an important role in influencing maturation with long-lasting differences in neuropsychological functioning between early maturers and late maturers (Jones 1965; Katchadourian 1977; Rubinow and Schmidt 1996).

A very important issue in both individual and sex differences is aggression. As to childhood aggression, biological factors are as important as psychological ones. Among the biological factors, the relationship between testosterone levels and aggressive behavior in adolescent boys has been studied by Olweus et al. (1988). They found that the circulating levels of testosterone in the blood had a direct influence on provoked aggressive behavior, measured by self-reports. High levels of testosterone intensified impatience and irritability in boys, thus increasing their proneness to aggressive–destructive behavior. On the other hand, psychological factors are also of great importance, e.g. a "deviation from usual attributional processes." According to Bobbitt and Keating (cited in Sroufe and Rutter 1984), "the attributional error is a potentially dysfunctional social cognitive skill that mediates aggressive activity in these boys."

The understanding of sex differences with respect to aggression in boys and girls would also be the key to our understanding of delinquency. This issue also leaves us with the open question of why there is so much continuity in aggression and dissocial behavior in boys.

4.2 Continuity and Change of Behavior

The second research field is that of continuity and discontinuity of behavior in children with respect to the developmental perspective (Rutter 1984, 1995). Although we know the different types of disorders, e.g. a continuous type remaining stable in childhood and diminishing toward adulthood and a type of newly manifested disorder during adolescence, the cause for these different types remains unknown. Further on, the continuity of psychopathological entities from childhood to adulthood depends also (a) on the research strategy (e.g. follow-up, follow-back study), (b) the sources of information (personal investigation, interview, records, questionnaires), (c) the type of sample (clinical populations, general populations), (d) the type of disorder (neurosis, conduct disorder), (e) the outcome variables, and (f) the diagnostic criteria (Garber 1984).

Irrespective of these methodological considerations, the following continuities have been found in several studies: There is a high continuity in pervasive

developmental disorders such as early infantile autism, Asperger's syndrome, and Rett's syndrome (Van Acker 1997; Gillberg and Steffenberg 1987; Gillberg 1991; Klin and Volkmar 1997). There is also a high continuity concerning externalizing behavior patterns (Kazdin 1986; Taylor 1989; Verhulst 1992) and aggressive behavior in boys (Olweus 1979). In addition, a substantial proportion of boys characterized by hyperactivity–impulsivity and attention deficit problems tend to have continuing behavior problems such as antisocial behavior or personality and substance abuse (Gittelman et al. 1985) or aggressive behavior and delinquency (Farrington et al. 1990; McGee et al. 1984a,b).

In a delinquency study, Remschmidt et al. (1984) were able to demonstrate that positive life events (successful professional career, friends, trust in an adult person) were associated with stopping a delinquent career. In relation to this issue, the concept of "turning points during the individual life course" (Rutter 1996) could be useful. Nevertheless, here too it has yet to be demonstrated *why* there is continuity in some children and not in others. With respect to the continuity issue, those children belonging to a certain diagnostic category of the continuity type (e.g. conduct disorders, hyperkinetic syndrome) are especially interesting if they are able to stop the behavior in question on the way to adulthood.

A somewhat neglected issue is that of discontinuity. With the exception of certain developmental disorders that are connected with maturation processes, such as enuresis, encopresis, and some transient speech disturbances, not much is known about discontinuity. It is, for example, unclear why a certain proportion of children with depression do not develop a depressive disorder of the adult type. The same applies to a small proportion of children and adolescents with conduct disorders or substance abuse. It may very well be the case that major life changes induce positive turning points in favor of an undisturbed development of adolescents (Rutter 1995).

4.3 Research on Risk Factors and Protective Factors

Research on risk factors has been one of the most important issues in developmental psychopathology during the last two decades. Using the prospective longitudinal approach, different developmental courses of children at risk were studied and compared with matched control groups. The most interesting question in this context is the development of those subjects at risk who do and do not develop the disorder in question (Garmezy 1974; Garmezy et al. 1984; John et al. 1982; Robins 1978; Robins and Rutter 1990).

This approach gives us not only a better understanding of the effect of risk factors, but also new insights into the process of development as such. Finally, from this study we can draw conclusions for primary prevention, which is an almost completely unsolved problem at the moment. In this context, the following open research questions emerge:

1. What causes are at work in facilitating the manifestation of disorders in children at risk?
2. Which risk factors are most important and how do they interact with each other and with different other influences during the course of development?
3. Which influences stop the continuation of a disorder or a behavior pattern that has been in action for a certain period of time? Examples are dissocial behavior, delinquency, different anxiety states, social phobia, and depression.

The last question can be solved only by longitudinal prospective research in groups with a different set of risk factors and compared with carefully matched control groups. One problem in this context is the natural course of several disorders, which is presently unknown.

Risk factors and protective factors interact with each other during the course of individual development. At the moment, we have by far more knowledge from empirical research on risk factors than on protective factors. The type and nature of protective factors may be very different. We can distinguish protective factors in the child itself (e.g. high self-esteem, favorable temperamental features), within the family (e.g. high family cohesion, good relationship between the parents), and others that have to do with the presence of favorable influences in the external system. As we all know, some protective factors exist and have been studied over the past years, e.g. favorable temperament, good marital relationship of the parents, high self-esteem of the child, and female sex, which is a protective factor against psychiatric disorders, at least until puberty. Nevertheless, many questions remain open for research.

4.3.1 General Mechanisms in the Context of Which Protective Factors Are at Work

There are, of course, hypotheses characterized by the issues of learning, maturation, identification, self-concept, interaction, and attribution. For instance, there is evidence that early secure relationships are favorable influences for the development of high self-esteem. The same applies to successful experiences concerning a high achievement level at early age. High self-esteem and a positive self-concept are in this sense

modified according to the experiences of a child (Rutter 1985; Masten and Garmezy 1985).

As far as the mechanism of action is concerned, two possibilities are likely (Rutter 1995):

1. Children shape and select their environment to some extent, and the capability to do that seems to be connected with certain protective factors.
2. Children also vary in their mode and intensity of response to risk environments, which also seems to be modulated by protective factors such as temperament or favorable experiences in early life.

4.3.2 Coping Mechanisms at the Different Ages and Developmental Stages in Relation to the Developmental Tasks

The issue of coping mechanisms is one of the most promising in all developmental psychopathology. Table 3 gives an overview of the potential relationship between psychopathology and developmental tasks.

The study of coping mechanisms in relation to developmental tasks may lead us to a better understanding of both normal developmental processes and pathological ones. In the clinical field, we can learn a great deal from our patients by asking them questions and observing them while they carry out developmental tasks. Once again, it seems most interesting whether, at certain stages of development, key turning points are at work in changing the course of development and making a child more resistant in the face of adverse factors. This issue, put forward by Rutter, has not yet been investigated, but might be a fruitful idea for our understanding of unexpected developmental changes.

Table 3. Potential relationship between psychopathology and developmental tasks (Garber 1984)

Psychopathological disorder	Developmental task
Separation anxiety	Object permanence, attachment and dependency
Depression	Differentiation of self, self-esteem, social comparison
Suicide	Concept of death, time perspective (future)
Conduct disorder Undersocialized	Moral development
Aggressive	Perspective-taking, empathy
Impulsivity	Delay of gratification
Oppositional disorder	Autonomy, individuation
Schizoid disorder	Peer relations, friendship patterns

4.3.3 Interaction of Risk Factors and Protective Factors

It is too simple an idea that a complementary relationship exists between risk factors and protective factors. Both kinds of influences are not independent of children's personality, their experience, their surroundings, and the development of their self-concept. Thus the study of the interaction of protective and risk factors has to control for many other influences. It may also be dependent on the intensity of risk factors whether protective factors are facilitated or not.

4.4 Research on Prediction

Another important task of developmental psychopathology is to study the predictive power of specific patterns of behavioral or emotional organization within the context of general development. If we look at the large number of influences, issues, and problems present during the course of individual development, we might arrive at the very pessimistic conclusion that prediction will not be possible at all. Several studies (Robins 1978; Bohman 1978; Kohlberg et al. 1972) show that this is not the case.

Why is this so? We think there is a hierarchy of behavioral patterns with a very different predictive power. Successful prediction of later behavior from earlier patterns depends very much on the behavior pattern that was chosen as the predictor.

The following general results can be put forward (Kohlberg et al. 1972; Sroufe and Rutter 1984):

- Early maladaptation predicts later maladaptation (e.g. school failures, poor peer relationships, pronounced antisocial behavior, overdependency in preschool age).
- Early competence and maturity predict later competence.
- Absence of problems and symptoms does *not* predict later competence or maladaptation.
- The "strongest predictors likely will be adaptational failures defined in age-appropriate terms" (Sroufe and Rutter 1984, p. 24).
- There is also evidence that prediction is better when using longitudinal parameters rather than cross-sectional ones.

Important questions for research in prediction may be the following ones:

- Detecting behavior patterns that have a high predictive value in different age and developmental

stages concerning the natural course of behavior and the course of behavior disorders
- Studies on the prediction of therapy success derived from initial variables at the beginning of therapy or from variables characteristic of the individual, the individual's family, and the disorder
- The different predictive value of behavior patterns at different ages and developmental stages.

All of us know that language acquisition and intelligence is of high predictive value in infantile autism, but what are the optimal predictors in these children after they have reached the age of 6? Then other predictors are important, although they are not as efficient as the two mentioned concerning the very early stages of development (for a review, see Gillberg 1991). In the case of psychiatric disorders, other predictors than during normal development are important. Nevertheless, there is a relationship between developmental tasks (as steps in normal development) and symptomatology.

In addition to these considerations and examples, several other predictors of later psychopathology are known:

- Conduct disorders in childhood carry a high risk for depressive symptoms in adult life (Harrington et al. 1990, 1991; Rutter 1991). Further on, adverse parenting in childhood is also associated with depressive disorders in adult life (Rutter 1995).
- Obsessive–compulsive disorders in childhood and adolescence show a high persistence in adulthood. A worse outcome is associated with the presence of tics, parental mental disorders, and an unsuccessful treatment with clomipramine (Leonard et al. 1993).
- Premorbid nonanorexic eating disorders in childhood are associated with a poor prognosis in anorexia nervosa (Remschmidt et al. 1990). Anorexia nervosa in childhood and early adolescence predisposes to nonspecific eating disorders and anxiety states in later life (Herpertz-Dahlmann et al. 1996).
- Hyperkinetic disorders in childhood are associated with an increased rate of antisocial personality disorders, an increased rate of substance abuse, and criminality in adult life (Klein and Mannuzza 1991; Mannuzza et al. 1993).
- Dyslexia in childhood shows a high rate of persistence in adolescence and adulthood and is highly associated with conduct disorders in adolescence with a diminishing tendency in adulthood (Maughan et al. 1994; Rutter 1995).
- Early-onset schizophrenia has a poor prognosis and reveals a high persistence in adulthood (Remschmidt et al. 1994).

4.5 Classification and Categorization of Disorders and Behavior Patterns from the Developmental Perspective

Bearing the above-mentioned research fields and issues in mind, it becomes very clear that a developmental framework for classification is essential (Graham and Skuse 1992; Garber 1984; Sroufe and Rutter 1984). Progress was made when a developmental axis was included in the ICD-9 (World Health Organization 1975) as well as in the ICD-10 multiaxial classification system (World Health Organization 1992) and in DSM-IV (American Psychiatric Association 1994). However, we think we need to go further and include the following research problems (Remschmidt 1989; Graham and Skuse 1992):

1. To further investigate the validity of criteria for use with adults and to develop special criteria that are specific for childhood disorders. It is quite clear that several criteria from adult psychiatry cannot be applied to psychopathological conditions in childhood. For instance, the concept and criteria of personality disorders, of depression, and of anxiety disorders are quite different from what is observed in childhood: age-specific aspects, phase of life orientation, longitudinal course, and interactional aspects are left out (Graham and Skuse 1992). On the other hand, specific criteria for childhood such as hyperkinetic disorders, developmental disabilities, autism, and pervasive developmental disorders that do not have a counterpart in adult psychiatry are still ill-defined and need a further subdivision according to the results of recent investigations and ongoing research (Rutter 1995; Remschmidt et al. 1998; Rispens et al. 1998).
2. To include the issue of continuity and discontinuity of childhood disorders in the classification systems. This issue, discussed earlier in this chapter, raises an important problem with regard to psychiatric nosology. Recent investigations have demonstrated that several psychiatric disorders in childhood and adolescence reveal a high level of comorbidity. Thus the question arises of whether the comorbid disorder is really a separate psychopathological condition or whether it belongs to the core syndrome. A good example is childhood depression, which shows a high comorbidity with conduct disorder and anxiety states (Harrington 1993) and also much continuity as far as depressive symptoms are concerned. In other disorders, e.g. Gilles de la Tourette's syndrome (GTS), the symptomatology changes in relation to age. A quite substantial subgroup shows the following sequence of symptoms from childhood to adulthood: hyperactive

behavior, motor tics, vocal tics, obsessive-compulsive symptoms, and/or obsessive-compulsive disorder (Leckman and Cohen 1988). From this example, it needs to be considered whether GTS is a nosological entity over the entire life span or whether there is a transition into another syndrome in a certain phase of life. This issue has yet to be solved.

3. To change the focus of classification from more limited and isolated behaviors toward patterns of adaptation. These are, of course, different in different developmental stages. A good example (and probably the only one) in this field is the classification presented by Ainsworth concerning the scheme of infant-caregiver attachment during early infancy (Ainsworth et al. 1978): secure attachment, anxious-avoidant attachment, and anxious-resistant attachment. It has been found that these "patterns" are stable for a long time and have predictive value for later emotional behavior. Efforts are now being made to include such patterns of adaptation into classification systems concerning behavior in preschool age (Greenspan and Lourie 1981; Sroufe 1983).
4. Using the idea that not only symptoms or syndromes are important for classification, but also patterns of adaptation, the idea of including the kind and pattern of relationships in a classification system also emerged. This is a very typical and important issue in developmental psychopathology, because relationships are clearly dependent on age and developmental stage. We are still at the beginning of this issue, and from the perspective of the classification of relationships, old problems of psychopathology such as continuity-discontinuity and normality-abnormality have to be seen in a new light.
5. When taking up these new issues, it is also important to further develop empirically derived classification systems and taxonomies. We would like to mention in this context the proposal made by Achenbach (1982, 1995), which uses not only the general categories of "internalizing and externalizing behavior," but also other dimensions and in particular different sources of information (child, parents, and teachers). Thus, finally, in the classification of behavior patterns, the context in which they are observed is very important (e.g. at home, at school, or with peers). A very good example of these different perspectives is provided by the hyperkinetic syndrome. A hyperkinetic child may not be hyperactive in a dyadic communication and situation, but very hyperactive in the classroom together with other children. Thus the issue of "situational context" seems to be very important. Only a few studies exist that focus on these contextual approaches in classification.

4.6 Research on the Nature of the Developmental Process Itself

A comprehensive discussion of research on the nature of the developmental process itself is beyond the scope of this chapter. Nevertheless, we would like to say a few words on this fundamental issue in developmental psychopathology. First, it has to be clear which influences are specifically connected with development and which are not. Second, we have to define very carefully the salient issues of developmental processes in different age-groups. One example is the approach of developmental tasks, but there might be others as well. Third, it is important to differentiate between quantitative and qualitative changes during development and to focus on the relationship between, or the transition from, quantitative to qualitative dimensions. Piaget (1950, 1983) proposed the process of equilibration for the transition from quantitative to qualitative changes. Fourth, we should study the antecedents of psychopathology in close relation to age-defined adaptation processes. This kind of view is not static but dynamic and includes everything discussed before. In doing this, we must be aware of the fact that development is not entirely a progressive phenomenon, but also includes regressive patterns. By this, we do not mean the psychoanalytic concept of regression, but the fact that, at a certain moment in development, both new and progressive tendencies and earlier patterns of adaptation and maladaptation can be observed simultaneously without the necessity of falling back on an earlier developmental stage, as proposed by psychoanalysts.

Finally, the concept of turning points seems to be important and worthy of future study for both normal and abnormal development. In summarizing research on the nature of the developmental process itself, it is necessary to have a relatively universal model or theory of development that is able to include the issues already mentioned and is suitable for theoretically guided longitudinal research.

5 Implications of Developmental Psychopathology for Diagnostics

The influence of the developmental perspective on childhood psychopathology has increased in the successive revisions of the DSM and ICD classifications. This is most obvious for disorders in which age of onset, developmental level, and outcome in adult life are key features of the definition. As an example of the

former, the ICD-10 separation anxiety disorder is defined as "an abnormal continuation of developmentally appropriate separation anxiety" with an onset before the age of 6, which postulates a close link between normal and pathological development. The need to take developmental level into account is exemplified in the diagnosis of autism, where the emphasis is placed on qualitative abnormalities in the definition of communication, social interaction, and play/interests abnormalities and where clinical descriptors for each area of dysfunction have been chosen to illustrate clinical presentations across the life span. Reliance on longitudinal research is shown in the use of diagnostic categories such as depressive conduct disorder (ICD-10) to account for the different prognostic implications for adult adjustment of childhood depression, whether or not it occurs in conjunction with conduct disturbances. However, current nosologies are far from being developmentally sensitive for most disorders. The diagnosis of depression, for instance, is made using adult criteria with little acknowledgment of phenomenological differences in younger, less cognitively mature individuals. Attempts to devise sets of diagnostic criteria specific to childhood depression have so far failed to demonstrate a consistent superiority (Garber 1984). Similarly, the validity of several diagnostic categories used in child psychiatry has not been adequately tested due to the relative scarcity of outcome studies and data on response to treatment.

The assessment of psychopathology needs to be based on a sound knowledge of what constitutes normal development. Thus an important contribution made by child psychiatric epidemiology over the last 30 years was to demonstrate that many symptoms such as fears, phobias, and nervous habits are reported in large numbers of nonreferred children (Rutter et al. 1970; Achenbach and Edelbrock 1981) and cannot be used alone to differentiate between normal from pathological development. In addition, the assessment of psychopathology in children requires complex information-gathering and -processing strategies. In contrast to adult psychiatry, child interviews do not always provide the main source of data needed to assess psychopathology. Rather, children's problems are generally assessed using a variety of procedures and of informants. This reliance on multiple sources of data reflects the situational variations of children's behavior and the cognitive immaturity of young subjects who cannot report on their symptoms accurately. The agreement between informants is, however, far from perfect. In their meta-analysis, Achenbach et al. (1987) showed that the mean correlation was 0.60 between two parents or two teachers, but only 0.28 between two different types of informants (i.e. parent and teacher) and 0.22 between children's self-reports and other informant ratings. These findings clearly illustrate the necessity to rely on multiple sources of data to assess children's behavior and emotions, as no single informant is likely to provide a comprehensive picture of them. Taking this issue one step further, Achenbach (1993) has recently devised an assessment paradigm which is based on cross-informant syndrome constructs, i.e. clusters of symptoms which occurred in the majority of several age and sex groups according to several informants. The eight syndromes thus identified provide an empirical and quantitative system particularly useful to assess current psychopathology and to measure its changes over time.

More generally, it has been recognized that both dimensional and categorical approaches to the measurement of child psychopathology are needed to avoid scientific investigation being stopped prematurely in this field. Even with disorders which represent extreme departures from normal development, the question arises as to where to draw the boundary between indicators of susceptibility to the disorder and expressions of normal development. Thus, to take the example of autism, it is now recognized that genetic susceptibility is indexed in relatives of autistic probands by a broader phenotype, the features of which overlap with expressions of normal variations in development; the measurement of such susceptibility, crucial for etiologic and genetic research, is indeed more amenable to a dimensional model than to a categorical one (Piven et al. 1997; Smalley 1991). Several other areas of psychopathology also illustrate the need to be attentive to subthreshold expressions of psychological dysfunction and of maladaptive behaviors which are not captured by classical, dichotomous, diagnostic approaches and yet have an important psychopathological significance.

For example, with regard to eating disorders, there is a group of adolescents (boys and girls) who meet the weight criteria of anorexia nervosa (BMI below 17.5 according to ICD-10), but are not anorexic in terms of the other criteria. This observation raises the question of whether these individuals are subthreshold anorexics. The same applies to restraint eaters who reveal low blood leptin levels like anorexics, but do not suffer from this disorder according to the ICD-10 or DSM-IV criteria (von Prittwitz et al. 1997).

When assessing psychiatric disorders in children and adolescents, it is now recognized that, in addition to a specific pattern of symptoms, there should be evidence of impairment of functioning (Bird et al. 1990; Weissman et al. 1990). This is consistent with a dynamic view of psychopathology which emphasizes the need to assess several areas of functioning at the same time and to gauge the interference of symptoms with the capacity to perform developmentally appropriate social and cognitive tasks for an individual. Of course, the current measures of impairment are still

too crude, and an important task on the research agenda is to devise subtler, age-referenced, and culturally sensitive measures of impairment.

Current nosologies still rely, however, on a medical and adult-oriented model of "psychiatric disorder" which assumes that dysfunction is entirely defined by its symptom constituents and is based within the individual. To some extent, the emphasis placed on reliability of psychiatric diagnosis, as exemplified by 20 years of use of symptom-orientated interviews and research diagnostic criteria, has contributed to this tendency. While there is no doubt that this emphasis on replicable and rigorous measurement approaches was and will remain necessary, especially when compared to previous theory-driven and unfalsifiable assessment views (A. Freud 1965), it could be argued that there is a danger of reifying psychopathology in uncritically adopting a "disorder" formulation of child psychopathology.

Thus the validity of most of these disorders remains to be firmly established, particularly regarding the identification of distinct etiologic processes at their origin (Jensen and Hoagwood 1997).

In addition, current classifications of child psychiatric disorders do not adequately reflect the fact that disorders, however they are defined, represent complex transactions between an individual and his or her environment and that the historical, cultural, and familial background of the subject is relevant both to the onset, maintenance, and cessation of maladaptive behaviors. Most experienced clinicians weigh the symptom pattern against some form of appreciation of the meaning and background of the individual child; however, these clinical procedures are highly idiosyncratic and remain poorly operationally defined and standardized. Timid attempts to reflect the contextual and transactional nature of child psychopathology can, however, be observed in the multiaxial systems currently in use in which psychosocial situations, life events, and family factors are described, together with a measure of overall impairment. Nevertheless, these contextual variables are mostly treated as accompanying features which need to be covaried out rather than as playing a full role in the etiologic process and current display of dysfunctional behaviors and leading to appropriate intervention. Developmental psychopathology requires models of a higher order of complexity than those currently available in an individual-based approach to disorders. These models will be developed as more data become available from longitudinal studies integrating different domains and contexts of measurement. Perhaps the most important need at this stage is to maintain a critical stance toward our available assessment and diagnostic approaches of psychopathology, in order to avoid their premature closure and to allow for further theory development.

6 Implications of Developmental Psychopathology for Therapy

The consideration that complex transactions exist between different areas of functioning and various social contexts and across developmental stages should ideally lead to fine-tuned multimodal interventions. Indeed, child psychiatry practice has long been characterized by such multifaceted approaches combining community, school-based, family, and individual measures. The particular use of these ingredients certainly reflects the developmental orientation of child psychiatry treatments, as seen, e.g. in the fact that most interventions in preschool children would consist largely in family- or school-based interventions, whereas individual therapies used in isolation are mostly seen among mature, psychologically open-minded adolescents. Similarly, cognitive–behavioral therapy is used with various age-groups, with behavioral techniques used predominantly among the youngest groups and cognitive techniques among the more mature subjects. The fortune of interventions based on family therapy principles or parent–child interactions also reflect the transactional and interactive nature of models used to treat child psychopathology.

Much less is known, however, about the optimal sequences, combinations, and particular timing of these interventions for any given problem. Thus little research has been conducted so far on the relative merits of combinations of interventions in child samples, such as the combination of psychotherapy and drug treatment. In addition, and for obvious reasons, research into the efficacy of intervention has generally followed a paradigm where one variable is manipulated (i.e. the drug or the number of therapy sessions), while other variables are hopefully maintained constant or equal across treatment modalities. These useful randomized interventions allow for a test of the absolute efficacy of one treatment component, but they do little to assess the role of the context in the processes of change. Furthermore, the assessment of intervention has tended so far to focus on symptom reduction as a single measure of outcome, whereas symptom levels as such might be less important to overall outcome than changes in the pattern or direction of symptoms or than parallel increases in social skills, self-esteem, or academic achievement. For example, the Perry preschool project, conducted as part of the assessment of the head-start program, offers a good illustration of the need to adopt an approach to outcome evaluation which includes both a long-term perspective and a wide-ranging strategy to assess change. Thus poor children randomly allocated to an

active preschool program showed improved educational achievement and employment opportunities in their late teens, as well as lower rates of crime, delinquency, and, for females, of teenage pregnancies than controls (Berrueta-Clement et al. 1984). Furthermore, most evaluative research has been centered on the individual, with few studies incorporating measures of change in the broader social context of the intervention, i.e. the family or the school. Recognizing these limitations, Hoagwood et al. (1996) have recently developed a model of outcomes for mental health care in children which, in addition to symptoms and diagnoses, incorporates adaptive functioning, quality of life of the child and his or her family, environmental settings, and broader system functions as elements in outcome measurement. While the empirical value of this model remains to be established, its heuristic value is certain and would appeal to most clinicians and researchers in the field.

7 Conclusions

Though the developmental perspective is not new, developmental psychopathology has only recently become an interdisciplinary and integrative field of research for the understanding of normal and pathological development as well. Progress has been made during the past two decades in several respects: regarding individual and sex differences of certain disorders, continuity and change of behavior, risk factors and protective factors, and turning points in development. Moreover, the current classification systems include the developmental perspective on a special axis devoted to developmental disorders. Nevertheless, there are still huge gaps in our knowledge in nearly all relevant fields that need be filled in the future. On the other hand, the available knowledge has not yet been applied to diagnostic procedures, therapeutic interventions, or preventive measures.

Drawing analogies to adults is still a prevailing trait in many fields of clinical and developmental psychopathology and child and adolescent psychiatry. Developmental psychopathology has to have a broad scope, including biological, psychological, and psychosocial dimensions of development in an integrative view. This view should lead us in the future to the identification of broader patterns of functioning in different environmental settings and to the conceptualization of therapeutic strategies that take into account the multiple influences on children and their active role during normal development and developmental crises.

Finally, more sophisticated methods of evaluation have to be developed that take into account all these influences far beyond the narrow symptom-oriented approach.

Child and Adolescent Psychiatry and Psychotherapy as a Clinical and Scientific Discipline: An Introduction

Translator: S. Henn

1 Development of the Field as an Independent Medical Discipline

According to the currently valid guidelines for specialty training issued in 1984 by the German Federal Chamber of Physicians (Bundesärztekammer), the specialty of child and adolescent psychiatry is defined as follows:

"Child and adolescent psychiatry and psychotherapy comprises the diagnosis, non-surgical treatment, prevention, and rehabilitation of mental, psychosomatic, developmental, and neurological illnesses and disorders, as well as abnormalities of behavior and conduct in children and adolescents."

This definition is generally valid in most European and other countries, although there are variations specific to the different countries.

Table 1 provides a survey of the current status of child and adolescent psychiatry in 31 European countries. The table shows, among other things, that the greatest concentration of specialists (i.e. the largest number of physicians practicing child and adolescent psychiatry per population under 20 years of age) is in Switzerland, followed by Finland, France, Sweden, Iceland, Norway, and Italy. At the same time, the table also reveals variations in population structure (variable percentage of the population under 20 years of age) and gives the year of founding of the specialty society in each country, as well as the number of university and other child and adolescent psychiatric clinics and departments. Further details of the current status of child and adolescent psychiatry in Europe can be found in Remschmidt and van Engeland (1999).

In historical terms, child and adolescent psychiatry has two roots: adult psychiatry and neurology on the one hand, and pediatrics on the other. Important contributions also come from psychology, from various branches of the social sciences and jurisprudence, and from the practical experience of youth and social welfare services.

Child and adolescent psychiatry and psychotherapy have derived important contributions from neurology with respect to the development of the central nervous system, the concept of vulnerability, and considerations of differential diagnosis. "Vulnerability" refers to the heightened susceptibility of children and adolescents with pre-existing brain damage to harmful environmental influences. Special considerations of differential diagnosis arise because many psychogenic illnesses present with somatic manifestations.

Child and adolescent psychiatry, like adult psychiatry, shares objectives and points of contact with psychopathology, which has acquired great importance today in the form of developmental psychopathology (Remschmidt 1989; Remschmidt and Fombonne 1999; see also Chap. 2, Part 1 of this volume). Child and adolescent psychiatry also converges with adult psychiatry in family psychiatry (i.e. the care of mental illness both in children and in adults in a family context), and in the care of adolescent patients, many of whom go on to be treated by adult psychiatrists when they reach adulthood (see Remschmidt and Mattejat 1994). Of special importance for child and adolescent psychiatry are the children of mentally ill parents, especially psychotic parents.

Finally, child and adolescent psychiatry converges with pediatrics in the field of infant psychiatry, which has become very important in recent years; in the care of chronically physically ill and handicapped children; and in the field of psychosomatic disease. In recent years, the collaboration of pediatricians with child and adolescent psychiatrists has led to considerable progress in all three of these areas, with respect to the scientific understanding and treatment of various illnesses.

Also of great significance for child and adolescent psychiatry and psychotherapy is clinical psychology, especially neuropsychology, which may be described as an extension of neurology with psychological techniques. Recently, it has been shown that many disorders can be better understood with the aid of neuropsychological examination techniques and better treated with neuropsychologically based therapies.

The specialty of child and adolescent psychiatry has emerged from the confluence of all of these specialties and has integrated and structured the knowledge gained from each to meet the specific needs of mentally ill children and adolescents and their families. A separate medical specialty has thus arisen, and the American child psychiatrist Leo Kanner, who was the first to describe early childhood autism, has traced its development up to the present as follows:

The first decade of our discipline was characterized by "thinking about children", the second by "doing things to children", the third by "doing things for children" and the fourth decade by "working with children" (Kanner 1957, p. 15).

This historical overview reveals both a gradual process of emancipation not only for the child, but also for the specialty as a whole. Mentally ill and handicapped children now have a right to specialty treatment.

2 Clinical Aspects and Treatment

The majority of studies agree that the incidence of mental disorders and illnesses in children and

adolescents taken together lies between 8% and 15%, and at least 5% of children and adolescents up to age 18 have been reported to require treatment. None of the methodologically sophisticated studies available to date have revealed a lower rate (Remschmidt and Walter 1989, 1990). Various studies also agree, however, that only a small percentage of the children and adolescents in need of treatment are actually treated (Remschmidt and Walter 1990).

With this problem in mind, the German Federal Government's Expert Commission for the Model Program in Psychiatry (Expertenkommission der Bundesregierung 1988) has directed that the following guiding principles for care should be put into practice:

1. Equal footing with other patient groups
2. Integration into medicine
3. Community approach
4. Appropriateness of care

The placement of mentally ill children and adolescents on an equal legal footing with those who are physically ill requires the integration of child and adolescent psychiatry into medicine as both a a clinical and a scientific discipline.

The institutions responsible for the care of mentally disturbed and ill children and adolescents are described in Chap. 6 (Part 1 of this volume).

3 Research and Scientific Societies

Research in child and adolescent psychiatry makes use of the methods of adult psychiatry, neurology, and other disciplines and has also recently developed a certain degree of methodological independence. This is especially true of methods used to assess the dependence of disorders on development, the role of the family, and special features of the forms of therapy that are practiced.

In research, there is common ground with the entire field of developmental medicine and psychology, with various disciplines in the neurosciences, and to a degree with pediatrics, education science, special education, and criminology.

Worldwide trends in research in child and adolescent psychiatry are characterized by three developmental tendencies:

Increasing emphasis on the biological basis of mental illness at all ages (the key words here are molecular biology, genetics, and imaging techniques)

Greater attention to all aspects of development (key words: developmental psychology, developmental psychopathology, developmental neurology, developmental biochemistry, and developmental pharmacology)

The establishment of rationally based, effective, and efficient methods of diagnosis and treatment for use in clinics and practices (key words: standardized diagnosis, development of guidelines, quality assurance, evaluation, and consideration of quality of life)

With regard to therapy, it is internationally accepted that there is no single theory or treatment approach that can be used to characterize or to treat all, or even most, mental and behavioural disorders; rather, disorder-specific approaches to treatment (treatment programs) must be developed which contain multiple components and are specific to the disorder at hand while still being adaptable to the individual features of each case.

We have made the following proposals concerning the further development of research in child and adolescent psychiatry (Schmidt and Remschmidt 1989; Remschmidt 1998):

1. Basic research on the etiology and pathogenesis of mental disorders in children and adolescents: This area includes studies using genetic and molecular biological methods as well as the new imaging techniques. Studies of this type have been performed to date in a number of countries for early childhood autism, Gilles de la Tourette syndrome, eating disorders, dyslexia, enuresis, and a number of other illnesses.
2. Multilevel research on the stability and change of psychiatric illness in children and adolescents: Because the stability and change of disease can only be understood in a network of individual, biological, and social pathogenetic factors and processes and their boundary conditions, they must necessarily be studied with a multilevel approach.
3. Research on externalized disorders (with expansive, aggressive, and disruptive manifestations): This question is particularly important, not least because of the high stability of these disorders and the enormous problems they create for the family, in school, and in society at large.
4. Research on developmental disorders: These are not only frequent, they are also a major risk factor for the development of secondary psychiatric disorders. In the current classification systems (ICD-10, DSM-IV), they are grouped into two categories:
   - Pervasive developmental disorders, which also include early childhood autism, atypical autism, Rett syndrome, and Asperger syndrome, and
   - Specific developmental disorders, which include the disturbed development of speech and language, scholastic skills, motor functions, and combinations of the above.

Important knowledge has been acquired in recent years for both groups of disorders.

5. Research on interventions and care: It is very important for the methods used to treat children, adolescents, and their families to be tested for effectiveness, efficiency, and possible side effects. In this context, effectiveness is understood as the ability to induce remission, while efficiency means a favorable cost–benefit ratio.

Research and development also partly depend on organizational alliances and must always be viewed from an international perspective. The professional societies play an important role here. The three international professional societies for child and adolescent psychiatry and the section of child and adolescent psychiatry of the World Psychiatric Association (WPA) have different emphases: the International Association for Child and Adolescent Psychiatry and Allied Professions (IACAPAP) and the child and adolescent section of the WPA address the whole spectrum of child and adolescent psychiatry, while the International Society for Adolescent Psychiatry (ISAP) focuses on adolescence and the World Association for Infant Mental Health (WAIMH) on the psychiatry of infants.

In addition to these international professional societies, there are other societies covering large regions of the world, such as the European Society for Child and Adolescent Psychiatry (ESCAP), the Asian Society for Child and Adolescent Psychiatry and Allied Disciplines (ASCAPAP), the Federation of Latin American Societies for Child and Adolescent Psychiatry (FLAPIA), the American Academy of Child and Adolescent Psychiatry, which cooperates closely with the Canadian society, and the Australian and New Zealand College of Psychiatrists, which has a section of child and adolescent psychiatry. Many of these societies are umbrella organizations for the national professional societies (e.g. ESCAP, IACAPAP, and ASCAPAP).

4 Undergraduate Medical Education, Specialty Training, and Continuing Medical Education

Child and adolescent psychiatry in Germany is incorporated into undergraduate medical education either in the form of lectures and courses specifically devoted to the subject or as a part of pediatrics and psychiatry. This is not yet the case in all other countries in and outside Europe.

Specialty training takes 5 years in Germany, of which 3 must be in child and adolescent psychiatry and 1 in either psychiatry or pediatrics. There are considerable differences between the European countries and the rest of the world in this regard. In 1993, a child and adolescent psychiatry and psychotherapy section was set up within the European specialty association, the Union Européenne des Médecins Spécialistes (UEMS). This section is dedicated, among other things, to standardizing specialty training in child and adolescent psychiatry and psychotherapy in Europe and has already developed a European specialty curriculum.

Continuing medical education (CME), which has been introduced as a requirement in a number of European countries, is also very important.

5 Ethical Problems

Besides general ethical questions that concern all clinical disciplines, there are a few problems that are quite specific to child and adolescent psychiatry and psychotherapy. One fundamental problem is that all important decisions affecting minor children are made by their parents. Although one can but agree with this arrangement in principle, there will always be cases in which parents do not act in the best interest of their children, especially when questions of custody, of physical, mental, or sexual abuse, or of consent to medical treatment are at issue. Child and adolescent psychiatrists are usually consulted in these cases and asked to apply their expertise toward the determination of a legal decision.

There is no universal rule about whether children and adolescents should be consulted about decisions concerning them; on a case-by-case basis, the child's wishes should be taken into account depending on his or her age. In this connection, the vague legal concept of the child's well-being is taken as a starting point, although it, too, has no universally valid definition, and must be specified individually (Remschmidt and Mattejat 1996).

Important ethical questions in everyday clinical practice relate to the treatment of children and adolescents, to their wishes and those of their parents, to commitment to closed wards in appropriate institutions, and to the use of biological and psychotherapeutic treatment methods. In addition, the use of ineffective or uneconomical treatment methods must be considered not only with regard to quality assurance, but also from an ethical viewpoint.

In the scientific area, controlled clinical studies in children and adolescents present a special problem, both legally and ethically. According to Helmchen and Müller-Oerlinghausen (1978), there are three kinds of clinical studies: (1) therapeutic experiments, (2) therapeutic trials, and (3) studies of established therapies.

The last category causes no problems in child and adolescent psychiatry, but therapeutic experiments, which are designed to increase knowledge about therapeutic interventions but not to help individual patients, create a genuine ethical dilemma, namely that of having to include children who are unable to consent to research that might not benefit them. Doing so may be necessary if we are to avoid the ethically questionable use of therapies that have been tested only in adults and therefore may be ineffective, or even harmful, in children (see also Chap. 18, Vol. 1, Part 2).

6 Outlook

The future of child and adolescent psychiatry cannot be predicted independently of social developments, and prognostication is therefore difficult. Regardless of social trends, however, the following three factors will be very important to the future development of child and adolescent psychiatry (Remschmidt 1988):

1. Lasting support for research: Only through research and development will it be possible to assess patients appropriately and treat them effectively. To achieve these ends, efforts are needed in several areas, ranging from basic and advanced training in methodology for young scientists, to interdisciplinary projects and grant programs, to regional and national research associations. It should be borne in mind that research into mental disorders in children and adolescents is not only a humanitarian task, but also has great economic importance. The development of preventive measures and the establishment of etiological treatment methods would certainly contribute to a major reduction of costs in the health care sector.
2. Improvement of undergraduate medical education, specialty training, and continuing medical education in view of the latest scientific findings: Efforts in this direction begin in the medical schools and must then be integrated into specialty training and then, finally, flow into CME.
3. Further development of interdisciplinary systems of care and establishment of cooperative links to the allied disciplines (pediatrics, psychiatry, education) and to youth services: Of particular importance with respect to cooperation with adult psychiatry is the performance of longitudinal studies, which are best suited to clarifying the developmental psychopathological aspect of mental illnesses and to bridging the gap between adult psychiatry and child and adolescent psychiatry. There is still much to do in this area, although the systems of care are already quite well developed in a number of European countries.

If the constructive work already in progress in these areas can be successfully continued, child and adolescent psychiatry will be able to overcome future challenges.

Diagnosis and Classification

Translator: S. Henn

1 Diagnosis

It is the goal of diagnostic classification in child and adolescent psychiatry to organize information about the problems of a child or adolescent, and his or her family, so that their future course can be predicted and reasonable interventions can be chosen. The underlying conception is that the current state and past history of a disorder may be used to predict its further development.

Both the affected individuals and their families are significant sources of information. Children or adolescents can give information about their own condition and, with increasing age, can inform better than the adults around them about their behavior, their relationship to the environment, the appearance of manifestations in the intermediate term, and their subjective assessment of the situation. Adults who have a significant relationship to the patient are important sources of information about the reason for consulting a child and adolescent psychiatrist at this point, about the patient's behavior in a variety of circumstances, and about the history of the disturbance over the long term, from its first appearance to the present, acute situation.

By gathering information from both sources, the clinician not only becomes aware of differing points of view, but can also recognize the dynamics of relationships within the family system. Interviewing the parents and the child separately gives the parents the chance to tell otherwise unknown facts about their relationship with each other, and to express their own concerns. On the other hand, the child can express his or her perception of the environment, and can discuss aspects of his or her own behavior that the parents do not know about. After the separate interviews have been conducted, a joint discussion serves to establish a definition of the problem, from which the goals of the patient and family are then derived. The alternative practice of conducting only a joint interview, without speaking with the child and parents separately, is forensically unjustifiable. Games, drawings, and dialogue exercises involving the parents and the child, as well as the technique of circular questioning, are useful aids to the diagnostic process.

An interview of the child alone is indispensable. Because children may have difficulty communicating their symptoms or behaviors unless specifically asked about them, the clinician should ask about at least the following list of behavioral areas:

- physical symptoms and sleep disturbances
- separation anxiety and obsessive-compulsive phenomena
- contact disturbances and social anxiety
- relationship disturbances and sexual contacts
- school discipline and attendance
- temper tantrums and aggressive behavior
- disturbances of impulse control and antisocial manifestations
- use of illegal drugs, alcohol, and medications

Protecting the privacy of the child or adolescent is just as important as protecting the parents' privacy, as long as no overriding interests (e.g. risk of progression of the disorder) dictate otherwise. Nevertheless, the child or adolescent must be made to understand his or her obligation to pass on certain information. The ideal of total impartiality is particularly inappropriate in situations in which the child would thereby suffer, be harmed, or be put in danger.

The interview usually provides information about the following:

- the reason for the consultation
- manifestations of the disorder and their history
- previous interventions
- the young person's developmental history
- the family history
- the young person's behavior and affect
- relationships within the (entire or immediate) family
- the young person's present level of functioning, i.e. not only deficits, but also competencies

Information thus gained can be supplemented by the following:

- medical and neurological examination of the child
- neurophysiological studies (when cerebral developmental delay or neurological illness is suspected)
- imaging studies (when malformations, sequelae of trauma, or degenerative illnesses are suspected)
- laboratory studies (when physical manifestations are present, or for the purpose of exclusion in differential diagnosis)
- tests of cognitive performance and neuropsychological testing (for the assessment of scholastic abilities, and when specific developmental delays are suspected)
- diagnostic assessment of the family (if disturbed interactions within the family are suspected)
- projective diagnostic assessment (if perceptual styles, attitudes, prevailing themes and conflicts cannot otherwise be assessed)

The main problem in diagnostic assessment is that of economy, i.e. of collecting only the necessary information. This is evident both in the Practice

Parameters of the American Academy of Child and Adolescent Psychiatry (AACAP 1997, 1998) and in its German equivalent, the Guidelines for the Diagnosis and Treatment of Mental Disorders in Children and Adolescents (Deutsche Gesellschaft für Kinder- und Jugendpsychiatrie und Psychotherapie 2000). The most important source of error is not the failure to perform additional tests, but incompleteness of the information obtained by interview. Complete information is indispensable for accurate diagnosis and must not be compromised by narrowing the focus too early onto a specific suspected diagnosis.

The use of standardized interviews may prevent this error, but they are too time-consuming in practice and are suitable only for diagnostic assessment in the research setting. The available standardized interviews include the Diagnostic Interview Schedule for Children (DISC), the Composite International Diagnostic Interview (CIDI), the Structural Clinical Interview, DSM-IV Version (SCID), and the Schedule for Clinical Assessment in Neuropsychiatry (SCAN) (WHO 1994, 1997).

The German interviews that have been developed for epidemiological studies do not cover all syndromes. These include the Mannheimer Elterninterview ("Mannheim Parents' Interview," MEI; Esser et al. 1989), the Diagnostik-System für Psychische Störungen im Kindes- und Jugendalter nach ICD-10 und DSM-IV ("Diagnostic System for Mental Disorders in Childhood and Adolesence According to ICD-10 and DSM-IV"; Döpfner and Lehmkuhl 1998), and the Diagnostisches Interview bei Psychischen Störungen für Kinder ("Diagnostic Interview for Mental Disorders in Children," Kinder-DIPS; Unnewehr et al. 1995). Döpfner and Lehmkuhl attempt to combine a category-based classification with a dimensional description of the disorders under study, while Unnewehr's interview focuses on integrating clinically relevant information in treatment plans.

Questionnaires such as the Child Behavior Checklist of Achenbach and Edelbrock (1983) do not meet this need because they are based on the use of a large number of equally weighted questions which, when correctly answered without follow-up questioning, can yield information about the child's general symptoms but are inadequate for the provision of a specific diagnosis. Questionnaires have the additional disadvantage that the answers of mentally ill and normal persons may be systematically biased in opposite directions, so that unaffected persons' scores may overestimate the degree of disturbance in a particular dimension, while affected persons' scores may underestimate it (see also the comments on dimensional vs. category-based assessment in Sect. 2).

Once the assessment is complete, information about the following areas is usually available:

- current manifestations and their history
- the problems affecting the child and family, and the reason for the consultation
- competencies, coping behavior and defense mechanisms
- relevant earlier physical and mental illness of the patient and family members
- developmental level attained before onset of the disorder
- quality of relationships
- current or chronic stresses in present life circumstances
- factors maintaining the disorder

Such information is generally used in the final provision of a diagnosis according to a multiaxial diagnostic system (see Sect. 2). In this process, all abnormalities that might be the principal manifestations of a mental disorder must be taken into account, and comorbid disturbances must be listed in order of importance. Individual manifestations should be evaluated according to their significance for developmental psychopathology.

Once one or more diagnoses have been made in this way, a decision follows regarding the need for intervention. This decision is based not only on the nature of the disorders themselves, but also on the wishes of the family. Ethical problems arise when there are fundamental disagreements, e.g. when the parents do not think a serious disorder needs treatment. If a disorder cannot be treated, the parents should be so informed. The most important factor in the decision regarding treatment is the current level of functioning, i.e. the child's ability to perform age-typical developmental tasks.

The hierarchy of necessary interventions is then established: for example, syndromes that fundamentally inhibit development, such as attention disorders, require specific treatment before further interventions demanding the child's cooperation can be initiated. Once the goal of treatment has been agreed upon, information is provided about possible side effects (not only of pharmacotherapy), and the treatment setting is decided upon. A consensus among all involved individuals regarding the goals of therapy is required, except in emergency situations such as suicidal behavior, excited states, intoxications, dangerous conditions in eating disorders, intensification of separation anxiety to the point of a crisis, or physical or sexual abuse.

The next step is further diagnostic assessment with relevance to treatment, i.e. the establishment of a detailed treatment plan specific to the particular disorder (see Chap. 6, Part 1 of this volume).

2 Classification

The goal of classification is the definition of disorders and problem situations in children to facilitate both clinical treatment and scientific exchange. The wide variety of clinical presentations is thereby reduced to a manageable number of symptom complexes. The criteria for the development of such symptom complexes include the symptom profile, the history of the present illness (not necessarily connected to its etiology), its expected course, and its responsiveness to treatment. Developmental psychopathology and research on disease course and therapy incorporating these criteria are a more important element of modern classification systems than are concepts of the etiology and pathogenesis of mental disorders.

It is therefore of prime importance that classification should be oriented toward developmental aspects. It must be reliable, objective, and not overly time-consuming. Logical consistency and validity – above all, predictive validity – are essential. Reliability is not just a matter of providing a correct description, but also of the proper application of prescribed criteria; the latter is achieved not through the accumulation of professional experience but by quality-assurance measures such as consensus conferences, quality management, and the like. Objectivity, too, is enhanced by operationalized criteria. It is diminished by the use of polythetic categories, i.e. the provision of lists of features only some of which must be present, with the result that the same diagnosis may apply to different constellations of symptoms. The problem of economical use of time in classification arises because information that is easy to obtain may not be the information that is essential for predictive validity.

Logical consistency calls for the mutual exclusiveness of diagnostic classes, which should therefore ideally have a comparable degree of differentiation. With reference to predetermined standard diagnoses, Blanz and Schmidt (1994) found a degree of agreement of 50% for three- and four-digit diagnostic codes in child psychiatry, and 58% when alternative diagnoses were also considered. The corresponding figures for three-digit codes alone were 61% and 68%, respectively. With respect to the diagnosis chosen by the largest number of raters (regardless of accuracy), the rate of agreement for four-digit codes rose to 60%, and, for three-digit codes, to 71%. Nearly perfect agreement was achieved with monosymptomatic disorders, and the least agreement was found with those syndromes that are inadequately operationalized for children and adolescents, e.g. somatization disorders or depressive syndromes. This demonstrates the effect of the following on the quality of classification: the level of information in assessment, the current state of nosological research, and the logical consistency of assessment systems. There has been less investigation of the degree to which the assessors' conceptions of developmental pathology affect decisions in classification.

Disorders predominantly requiring dimensional assessment cause greater difficulties in classification (see below). The validity of the construct is more frequently referred to in these cases. However, construct validity may be less relevant to clinical decisions regarding the course of the disorder and its responsiveness to treatment. The importance of classification criteria that provide predictive validity is obvious. In this connection, the reader is referred to the results obtained by Moffitt (1993) on the onset of antisocial symptoms, by Henn et al. (1980) on the role of social ties for the course of antisocial disorders, and by Mandel (1997) on the significance of comorbid antisocial behavior with hyperkinetic disorders; for a summary of work about the course of shyness and social hypersensitivity with regard to its later significance for social phobia, see Beidel and Turner (1998).

Multidimensionality of Classification Systems

The determination of the pathological clinical manifestations, personality traits, and environmental circumstances that are ultimately relevant to therapy in child and adolescent psychiatry has led to the development of multidimensional classification systems. Such systems take also account of the random simultaneous occurrence of features that may not be causally related, and thereby enable statistical correlation between them. Multiaxial classification has significantly influenced research in child and adolescent psychiatry since the late 1970s. Rutter et al. first proposed such systems in 1969.

The two multiaxial systems currently in use are ICD-10 and DSM-IV. The adapted version of the CD-10 (WHO 1996) prescribes six axes:

Axis I: clinical psychiatric syndromes
Axis II: specific disorders of psychological development
Axis III: intellectual level
Axis IV: medical conditions
Axis V: associated abnormal psychosocial situations
Axis VI: global assessment of psychosocial disability

Axis I corresponds to Chap. F, Sect. V of ICD-10, except for codes 80–83, which correspond to Axis II, and Sect. F7, which corresponds to Axis III. Axis IV corresponds to other chapters of the ICD-10. In each case, only current diagnoses are taken into account. Axis V codifies current abnormal psychosocial situations, i.e. those present in the past six months, and does not consider earlier problems. The global assessment of psychosocial disability made on Axis VI refers

to the patients' psychosocial functioning at the time of clinical examination. It should include an assessment of their behavior within the family, with peers, at school, and in their spare time, over the course of the last three months before the examination (for chronic or subacute disorders) or the last few days or weeks (for acute disorders).

The multiaxial classification of adult mental disorders (Janca et al. 1997), which independently surveys clinical diagnoses, impairments, and contextual factors, has a narrower basis. The predictive validity of this method still awaits empirical confirmation in the field. In addition to clinical diagnostic guidelines, ICD-10 has separate research criteria for the disorders described in Chap. F. These are more narrowly operationalized than the clinical guidelines and are intended to increase the homogeneity of the disorders dealt with in the scientific studies. This goal will certainly be achieved, but further attention will have to be paid to the applicability of the results obtained in such studies to everyday clinical practice.

The Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV) provides a system of five axes for children and adults:

Axis I: clinical disorders and other conditions that may be a focus of clinical attention
Axis II: personality disorders and mental retardation
Axis III: general medical conditions
Axis IV: psychosocial and environmental problems
Axis V: global assessment of functioning

The Axis I codes thus also include additional conditions that cannot be attributed to any individual mental illness but nevertheless occasion a need for observation or treatment. Some of these conditions are classified on Axis IV or V of the ICD-10. Axis II of DSM-IV is for personality disorders and mental retardation. While the multiaxial diagnostic system according to ICD-10 (MAS/ICD-10) places personality disorders on Axis I, DSM-IV also allows the classification on Axis II of specific personality traits or defense mechanisms that do not cross the threshold of personality disorders. Hierarchically ordered multiple diagnoses are allowed on Axes I and II. Axis III codes correspond to the Axis IV codes of MAS/ICD-10.

The degree of severity of psychosocial stress factors in the year prior to examination, as coded on Axis IV of DSM-IV, relates only to pathogenetically relevant circumstances and to the predominance of acute events or ongoing life circumstances. The degree of severity is numerically coded in Axis IV of DSM-IV, while Axis V of MAS/ICD-10 assigns abnormal psychosocial situations to nine major categories and 31 subcategories. Axis V assesses the psychosocial functional level – above all, psychosocial and professional capability, both at the time of assessment and before the onset of illness – on a quantitative scale analogous to Axis VI of MAS/ICD-10.

3 Current Problems

Earlier case definitions permitted the use of symptom formation or performance limitation as criteria for the diagnosis of mental disorders. Yet even severe disorders, such as a severe transient tic disorder, need not permanently impair a child's functioning in everyday life, while conversely even a moderately severe social phobia can affect everyday behavior across a broad front. Angold et al. (1999) have shown that 9.4% of children who came to clinical attention but could not be given a category-based diagnosis were significantly impaired in their everyday functioning. Subthreshold manifestations also appear to favor the emergence of more overt, categorically classifiable disorders 5–7 years later (Costello et al. 1999).

The need to consider subdiagnostic symptom constellations and comorbid symptoms has stimulated discussion of the advantages of dimensional diagnosis. ICD-10 differs from DSM-IV (among other ways) in allowing combined diagnoses, e.g. hyperactivity with conduct disorder (F90.1). It is known from clinical observations that the combination of these disorders has a significantly less favorable course than either of them alone (e.g. Mandel 1997). The inclusion of combined diagnoses is based on the fact that certain disorders appear in combination at greater than random frequency. Caron and Rutter (1991) have pointed out a number of mechanisms by which this might occur: two disorders might have exactly the same risk factors; they might share some risk factors and also have other risk factors that are not shared; even if they have no common risk factors at all, the risk factors of one disorder might have a more than random association with the risk factors of the other; or one disorder might be a consequence of the other.

The consistent consideration of comorbid disorders in the additive procedure of the DSM-IV leads to an increase in the number of diagnoses without implications for treatment plans. The use of factor-analytic techniques in dimensional diagnosis, e.g. in the construction of internalized and externalized symptom groups by Achenbach and Edelbrock (1983), has also been used as a search strategy and has led to interesting speculations, such as that of Rasmussen and Eisen (1992) regarding a syndrome group surrounding obsessive–compulsive disorder, including dysmorphophobia, hypochondriasis, paranoid jealousy, Gilles de la Tourette syndrome, trichotillomania, disorders of impulse control, and eating disorders, among others.

Further examples, such as the obsessive-compulsive spectrum described by Hollander (1998) or the bipolar spectrum described by Cassano et al. (1999), are partly the consequence of etiological considerations and partly hypotheses that are useful for research on pathogenesis.

The diagnostic classification of some disorders takes account of their course, as in schizophrenic or bipolar affective disorders, or of the need for various interventions, primarily in chronic, progressive disorders. Consideration of stages of disease is clearly less pronounced for illnesses primarily regarded as psychogenic. The late manifestations of such illnesses – e.g., the severe physical manifestations of anorexia nervosa – are simply seen as complications of the psychogenic process and are expected to regress with successful psychotherapy. Such illnesses are regarded as psychogenic in all stages, and thus reversible. The fact that certain symptom complexes become autonomous is not taken into account. Yet it is precisely with illnesses such as these that stage-specific observation could be important for the planning of interventions. The appearance of specific stages of a disorder during development may also represent a typology of developmental psychopathology, e.g. the appearance of hyperactivity before the emergence of many chronic motor tic disorders, which, with increasing age, may develop into obsessive-compulsive disorders.

The categories of Axis V in the multiaxial classification urgently need to be differentiated and operationalized, so that they may become more reliable (Van Goor-Lambo et al. 1990). The desire to classify protective factors at the same time as risk factors is based on the common misunderstanding that they are merely the positive counterparts of risk factors; this cannot be achieved (Laucht et al 1997, see also Chap. 5, Part 1 of this volume). Protective factors should be regarded as such only if they alter the probability of manifestations of illness when risk factors are present. Similar considerations apply to the inclusion of coping and defense mechanisms in classification.

Because the diagnoses for young children are relatively poorly differentiated, the National Center for Clinical Infant Programs has proposed a classification for 0- to 3-year-olds (Zero-to-three 1990) which simultaneously codes mental disorders, the presence and nature of bonding disorders, disorders of physical development, psychosocial stress factors, and the functional level of emotional development. Unfortunately, this classification differs from the existing multiaxial systems, and is thus unlikely to close the gap between infant psychiatry and child psychiatry. An assessment of bonding might be introduced into the existing diagnostic scheme on Axis V, as long as the coding of psychosocial risk factors were changed so that it could be based less on external circumstances than on underlying mechanisms.

The ICD-10 does not pay due consideration to developmental aspects in the diagnosis of mental disorders of children and adolescents. Not all disorders appearing in childhood and adolescence are listed in the chapters allocated to them in the ICD-10 (Chapters F7–F9); for example, age-typical parasomnias, anorexia nervosa, gender-identity disorders of childhood, and similar disorders are missing. Yet their mere inclusion would still not allow a classification oriented toward developmental psychopathology. Therefore, for these chapters on child and adolescent psychiatry, we have proposed a classification based on the course of these disorders, which distinguishes between behavioral variants and stress reactions, early-onset disorders with persistent course, transient developmentally dependent disorders, disorders with age-typical onset, age-specific interaction disorders, and early-onset adult-type disorders (see Chap. 7, Part 1 of this volume).

Epidemiology and Pathogenesis

Translator: S. Henn

1 Age-Specific Problems of Epidemiological Research

If knowledge of the frequency, causation, and maintaining factors of mental illnesses is to be used as the basis of their treatment and prevention, then incidence and prevalence figures are of significance. The sources of information used to derive these figures are important. Parents give information about psychopathological problems and their minor children's need for treatment. The life circumstances of these children are also relevant to the causation, onset, course, and treatment of these disorders. Because children have an immature central nervous system (i.e. an immature mental apparatus) and are therefore highly dependent on adults, psychiatric disorders in children can often not be conceived of except in relation to the environment.

Sources of information about psychopathological problems in children and adolescents include the young people themselves and their parents and teachers. The younger the child, the more important the information provided by adults. In general, 8-year-olds can already be asked about their feelings, while adults can usually give better information about outwardly observable behavior. Adolescents are also sources of information about their own behavior, because their delinquency, substance abuse, or sexual activity may be unknown to their parents. Thus descriptive epidemiology makes use of information from various sources, not all of which are necessarily in agreement.

Breton et al. (1999), in the Quebec Child Mental Health Survey, studied the degree of agreement of information obtained from different informants. They found that there was agreement between information obtained from parents and that obtained from children with respect to an elevated frequency of hyperactivity in boys and younger children, and also agreement of information derived from parents, children, and teachers with respect to oppositional disorders and conduct disorders, including a higher rate for boys than girls. For anxiety and depressive disorders, however, no such agreement of information across informants could be found.

In studies in which both healthy and ill individuals are investigated, their answers to questions about psychiatric symptoms differ. Healthy individuals consider even mild symptoms to be serious, while ill individuals are likely to mention only their more serious symptoms.

Because a large amount of data must be obtained, epidemiological studies are often carried out in two stages. After a screening process, all abnormal probands and some of the normal probands are tested individually. Prevalence figures are higher when they are based only on reported symptoms, and when their severity and significance are not assessed by interview, than when they are determined from category-based diagnoses.

The rate of refusal to participate in epidemiologic studies of minors is also age-specific, because parents decide whether young children will participate, and the factors motivating adolescents to refuse to participate are also age-dependent. Good epidemiological studies therefore include information about the refusal rate and about the comparability of those refusing with those participating in the study.

Standardized interviews offer good conditions for obtaining precise incidence and prevalence figures. Open interviews are of somewhat lower quality, questionnaires still lower. Observation of behavior can, of course, cover only a limited repertoire of problems, but it is helpful for specific questions, especially the ascertainment of common behavioral problems. The use of videos and computer-assisted video evaluation allows the gathering of epidemiological data about interactive behavior, for example. Video techniques are almost the only way to assess this adequately, because the simultaneous observation of two partners and their interaction in a natural context cannot otherwise be documented quickly enough.

Questionnaires have the special disadvantage that the respondent's understanding of the question cannot be checked. If the number of questions is increased to be on the safe side, overlapping information results, which raises the cost of information processing. Because answers to questionnaires usually cannot be directly encoded as diagnoses, coding is performed through an intermediate step in which symptoms are linked to syndromes by means of factor analysis. Answers to questionnaires are clinically relevant in the transition zone between normal and pathological behavior, but they cannot be used reliably to determine the presence of illness in individual cases.

The assignment of a cutoff value causes difficulties when symptom-based case definitions are used, because monosymptomatic disorders may significantly impair age-typical functioning and thus deserve to be designated as illnesses. Moreover, the number of symptoms does not increase linearly with the degree of pathology, and the transition zone between pathological and non-pathological states has no clearly defined boundaries. Requiring a larger number of symptoms to be present for a diagnosis to be assigned enlarges this transition zone but cannot solve the problem at its boundaries. Cutoff values are often defined with reference to symptom severity in a sample of patients presenting for psychiatric treatment. This is justifiable as long as the presence of major selection effects can be excluded.

Category-based case definitions in epidemiology have the advantage that clinical threshold values can be better defined and operationalization can be stipulated in advance. Prevalence figures then depend on the narrowness or breadth of the category-based definitions, i.e. on whether a classification system allows combined diagnoses, or whether the required listing of comorbid diagnoses leads to higher numbers of symptoms being counted.

Expert-defined disorder entities have no a priori implications regarding the degree of impairment of age-specific functions, even though many category-based definitions include impairment of everyday functioning among the diagnostic criteria. Combining prevalence with degree of impairment offers a way out of this dilemma and is preferable to requiring further information about the need for treatment.

Cross-sectional studies are not highly suitable for the determination of reliable prevalence figures, even if six-month prevalence is determined, as is frequently done. Longitudinal studies in which data are collected at three or more different times yield more reliable information and are useful, above all, for distinguishing normal behavioral variants from clinically relevant deviations. Various questions concerning developmental psychopathology can be answered only in longitudinal studies, including the question of the stability of psychiatric disorders, i.e. whether a decline in symptoms corresponds to a real decrease in psychopathology or only to a change in symptoms; the significance of an expanding spectrum of symptoms, which is a predictor for substance addiction among patients with antisocial disorders, for example (Robins and Price 1991); and the age-specific appearance of certain symptoms.

The random samples used in such studies should be representative and should ideally be investigated in two stages, as described above. Enriched random samples are advisable for the study of rare disorders or for the study of the context of mental disorders. Samples of patients presenting for treatment are suitable, if at all, then only for determining the incidence and prevalence of very rare disorders, on the assumption that most patients with these disorders will present for treatment.

2 Descriptive Epidemiology

Table 1 contains prevalence data for disorders in child and adolescent psychiatry gathered on the basis of ICD-9, DSM-III, or DSM-III-R diagnoses. Mental retardation may overlap with these diagnoses, and pure mental retardation is not considered. The same applies to specific developmental disorders.

Two studies reporting extreme values were excluded from the table. The study of Nylander et al. (1989), involving 4- to 6-year-old urban children in Sweden, found DSM-III diagnoses in 22% of boys and 37% of girls. On the other hand, the French study of Fombonne (1994) found ICD-9 diagnoses in only 6% of 217 children aged 6 to 11. No studies based on questionnaires are mentioned. The data yield a relatively uniform picture with somewhat higher prevalence among adolescents and somewhat lower prevalence among children; the figures generally range from 12% to 18%.

Psychiatric disorders in children and adolescents show comorbidity with one or several other psychiatric disorders in some of those affected, especially in boys. Comorbidity rates can be artificially increased by extensive splitting of disease categories, so that disorders are classified which are actually components of other disorders. An increase in frequency can also result from different disorders having overlapping symptom spectra, or from chance associations. Real (i.e. systematic or greater than chance) comorbidity arises under defined circumstances (Caron and Rutter 1991; see also Chapter 4, Part 1 of this volume).

In a representative sample, Naab (1995) found two psychiatric disorders in 25% of probands and three in 5%. The comorbidity was higher in a sample of patients presenting for psychiatric treatment. Among all patients with psychiatric disorders in the latter sample, 23% were given two diagnoses, and 19% were given three or more. Bird et al. (1988), in the Puerto Rico study, found more than one diagnosis in 51% of those characterized as psychiatrically ill according to DSM-III. This was largely due to the combination of conduct disorders and hyperactivity; comorbidity was thus more frequently seen in boys and male adolescents.

Comorbidities frequently seen clinically and in representative random samples of children and adolescents are: the combination of depressive disorders with conduct disorders (frequency ca. one third); conduct disorders (usually of the oppositional type, or with absent social relationships) with a hyperactive syndrome (ca. 40%); depressive disorders with anorexia nervosa (ca. 40%); and anxiety or other emotional disorders with hyperactivity (ca. 8%). These comorbidities should not be confused with expansion of symptoms or with symptom changes in accordance with the rules of developmental psychopathology.

In children and adolescents as in adults, the symptom spectrum in anxiety disorders or obsessive–compulsive disorders may expand toward depression, anorexia may change into bulimia, and hyperactivity may supervene in cases of tic disorders, whose symptoms may also expand in the direction of

Table 1. Prevalence data for child and adolescent psychiatric disorders

Author(s)	Country	Sample size (*n*)	Age (years)	Prevalence (%)
Anderson et al. (1987)	New Zealand	792	11	17.6
Esser and Schmidt (1987)	Germany/large city	216	8	16.2
Kashani et al. (1987)	USA/Columbia	150	14–16	18.7
Offord et al. (1987)	Canada/large city	1648	4–16	19.6
Offord et al. (1987)	Canada/provincial	1031	4–16	14.9
Bird et al. (1988)	Puerto Rico	386	4–16	18
Costello et al. (1988)	USA/city	300	7–11	22
Jeffers and Fitzgerald (1991)	Ireland/city	190	10–11	25
Fergusson et al. (1993)	New Zealand/ provincial	986	15	27
Döpfner et al. (1996)	Germany/state	1622	4–18	22.3
Lavigne et al. (1996)	USA/city		2–5	11 (m), 7 (f)
Shaffer et al. (1996)	USA/Connecticut/ Georgia/New York/ Puerto Rico	1285	9–17	10.2
Verhulst et al. (1997)	The Netherlands	780	13–18	6 (according to parental data), 5 (according to adolescent data), 8 (according to parent or child data), 2 (according to parent and child data)
Lehmkuhl et al. (1998)	Germany	1030	4–10	13.1–28.3
Breton et al. (1999)	Quebec/city/ provincial	2400	6–14	19.9 (according to child data), 15.8 (according to parent data)

obsessive–compulsive symptoms. Epidemiologic studies have shown that hyperactivity can expand to conduct disorders (independently of the comorbid combination of these two types of disorder), and that conduct disorders can expand to substance abuse (Robins and Price 1991) or become transformed into antisocial personality disorders. In longitudinal epidemiologic studies, symptoms beginning in early school age show a stability of 12%–13% into the middle of the third decade and a five-year stability of approximately 50%.

The less favorable course of the combination of hyperactivity with conduct disorder, as compared to either of the disorders alone, has already been mentioned. Russo and Beidel (1994) found a less pronounced response to stimulants in hyperactive children with comorbid anxiety disorders. According to Henn et al. (1980), children with conduct disorders and without social attachments, i.e. those with earlier relationship disorders, show a course with more delinquency than children with conduct disorders whose relationships are normal for their age.

3 Analytical Epidemiology and Pathogenesis

Psychiatric disorders in school age are at least twice as frequent in boys than in girls. Their overall rates become similar during adolescence, though the rates of individual disorders are still quite different. From the earliest ages onward, boys have more expansive disorders, i.e. disorders with hyperkinetic, oppositional, or aggressive behavior. They also have more developmentally dependent disorders, e.g. speech disorders, specific difficulties of reading and writing, enuresis, and encopresis. Autism is more frequently seen in boys. The incidence of emotional disorders is about the same in children of both genders. Only anxiety and somatization disorders are somewhat more common in girls.

Anxiety-depressive disorders increase in adolescence among girls. In early adolescence, girls temporarily show high rates of aggressive-antisocial behavior, similar to those of boys; the probability that these characteristics will regress is, however, far higher in girls than in boys. Over the course of adolescence, the

rate of substance dependency in boys increases in parallel to antisocial behavior. Clear shifts occur during adolescence in girls toward eating disorders, and in boys toward completed suicides.

Because of the gender differences described, epidemiologic studies of prevalence and incidence without reference to gender are not very helpful. Despite the differences listed, psychiatric disorders are generally more severe in boys and male adolescents than in girls and female adolescents.

Many studies have shown a slight rise in the overall prevalence of psychiatric disorders in children of primary school age, with a second discrete peak seen in many studies at the onset of adolescence. For a long time, the first peak was explained as an expression of increasing levels of activity and interest in daily events at the beginning of school, but the cause of the increase of psychiatric disorders at this age is now considered more likely to be a differentiation of emotional disorders corresponding to the typical, delayed differentiation of the emotions even in the normal context. The second peak is most likely explained by the transient increase in conduct disorders in girls at the onset of adolescence.

Long-term stability of psychiatric disorders is seen primarily in disorders with extroverted manifestations in boys, particularly in connection with earlier hyperactivity. Disorders with introverted manifestations show far less stability but are of long-term importance for the appearance of significant mental disorders in early adulthood, even if the severity of symptoms lies below the diagnostic threshold.

Developmental age mirrors brain maturity. As it increases, the child becomes less dependent on others. Consequently, interaction disorders are more frequent in early childhood and fall off with increasing autonomy. Functions that develop rapidly are particularly susceptible to disturbances. Many physical functions that develop at an early age fall into this category. The higher frequency of physical symptoms at this age may also be an expression of the immaturity of physical systems; stereotypic movements or motor tics, for example, may express an as yet inadequate capability for motor inhibition. As development proceeds, the environment places demands on functions that mature in predictable fashion. Developmental delays affecting such functions, e.g. affect control, easily become manifest as disorders, e.g. the delayed regression of physiological separation anxiety.

As the child reaches school age, there is more reliable differentiation between reality and fantasy and an increase in intrapsychic processing ability. In early adolescence, with its new developmental tasks, new fields are opened for possible mental disorders. The fact that some disorders regularly appear at a later age, e.g. depressive disorders with somatic syndrome from age 16 onward, makes it seem likely that hormonal changes significantly influence the pathogenesis of mental illnesses in adolescence.

According to Rutter (1983), physical illness doubles the risk of appearance of psychiatric disorders, and diseases of the brain triple it. Brain diseases accompanied by seizures present an additional complication. Scar formation in the central nervous system produces the highest risk of cerebral impairment. The significance of organic cerebral impairment in the earliest stages of life is certainly related to the historical period in which it occurred: in previous years, when the care of premature infants was rudimentary compared to today, perinatal brain damage and premature birth were more important risk factors for later behavioral abnormalities (e.g. Pasamanick et al. 1956). The study of increases in motor, cognitive, and behavioral impairment is now focused on premature infants with very low birth weight (Esser et al. 1995; Hall et al. 1995). These organic risks are seen mostly in motor and cognitive functions and become less significant with increasing age.

For a long time, the interaction of biological risks with unfavorable social conditions was overlooked in research, but bivariant research designs now show that psychosocial deficits influence cognitive and, even more, social and emotional development (Laucht et al. 1996, 1997). In addition, the studies carried out by Field et al. (1981) have repeatedly demonstrated that the quality of interaction between parents and children favors or inhibits the pathogenesis of mental disorders.

Models for the pathogenesis of psychiatric disorders are generally hypothetical and imprecise, because the relationship of individual developmental factors to one another cannot be varied experimentally. It was hoped that the increase of knowledge in genetics and molecular biology would allow better predictions to be made, but this has not yet been realized. There are probably genetic contributions to the mental problems of children and adolescents with pronounced mental retardation, reading and writing deficits, autism and hyperactivity, Gilles de la Tourette syndrome, and antisocial disorders. The evidence for this is derived mainly from formal genetic studies (e.g. Edelbrock et al. 1995).

Because most disorders are of multifactorial origin, genetic characteristics mainly assume the role of a predisposition or increased vulnerability to illness. It is unclear under what conditions the corresponding predispositions lead to manifest symptoms. The idea that chronic or acute stress exerts a particular effect on a genetically predisposed individual is certainly too simple. Instead, we must assume that early stressful experiences can change the readiness of an organism to react. Accordingly, research has also gradually

shifted away from very remote risk factors and toward central processing mechanisms.

Urban–rural differences and high urbanization rates (Rahim and Cederblad 1984), migration, social class, and parental level of education are thus regarded as characteristics accounting for only a small part of the variance. Characteristics linked to interactions within the family, such as family disharmony, cramped living conditions, mental illnesses in family members, and criminality of a parent are quantitatively more significant (Blanz et al. 1991). The model of cumulative risk proposed in the classic study of Rutter and Quinton (1977) has been repeatedly confirmed. More of the variance is accounted for when interactions within the family are directly included in the calculations (e.g. Esser et al. 1993).

Since the 1960s, research has been based on the assumption that the concurrence of predispositions, stress factors, and unfavorable interactions does not inevitably lead to psychiatric disorders, and that there is a group of children in critical life circumstances who remain unaffected in spite of such conditions. The size of this group varies, depending on the study cited, from 10% to 25%. Such resilience is attributed to the existence of protective factors, which have been increasingly studied since the 1980s. There are essentially three groups of variables:

1. Personality features such as autonomy, positive social orientation, internal awareness of control, and differentiated linguistic abilities
2. Family characteristics such as a cohesive family, warmth, and absence of quarrels
3. Extrafamilial features such as support systems, significant individuals outside the family to whom the child can relate, and close friends.

The concept is rightly criticized in that protective factors must not be considered the same thing as generally beneficial characteristics or circumstances, or the absence of risk factors. Protective factors are rather those that exert a protective effect where combinations of risk factors exist, i.e. they are required to have been present before the appearance of these risk factors if their effect is to be assessed statistically.

Table 2. Prevalence rates of individual mental disorders in children and adolescents

Kind of disorder	Reference	Probands	Prevalence rates (%)
Hyperkinetic disorder	Costello et al. (1988)	7- to 11-year-olds	2%–10% with a tendency to lower values, maximum in primary school age
	Lavigne et al. (1996)	2- to 5-year-olds	
Behavioral disorders	Lavigne et al. (1996)	2- to 5-year-olds	2%–10%
	Cohen et al. (1993)	10- to 20-year-olds	10%–16% (m), 3.8%–7.1% (f)
Oppositional defiant behavior	Cohen et al. (1993)	10- to 13-year-olds	14.2% (m), 10.4% (f)
Depression	Birmaher et al. (1996)	Children Children of depressed parents Adolescents	0.4%–2.5% 0.4%–8.3% 15%–45% (lifetime)
Anxiety	Lavigne et al. (1996)	2- to 5-year-olds and 10- to 13-year-olds	0.7%–12.5%
Separation anxiety	Cohen et al. (1993)	10- to 13-year-olds	11.4% (m), 13.1% (f)
Tic and stereotypic disorders	Esser and Schmidt (1987)	8-year-olds	4.6% (m), 9.3% (f)
Gilles de la Tourette syndrome	Robertson (1994)	Children	0.3%–1.3%
Enuresis	von Gontard (1998)	7-year-olds	10%
Bulimia nervosa	Ledoux et al. (1991)	Adolescents	0.3%–7%
Autism (Kanner)	Rapin (1997), Steffenburg and Gillberg (1986)	Children up to 10 years	0.04%–0.1%
Autism (Asperger)	Ehlers and Gillberg (1993)	7- to 16-year-olds	0.25%–0.35%
Schizophrenia	Remschmidt (1992)	14- to 20-year-olds	0.09%

m, boys or male adolescents; f, girls or female adolescents.

The discovery of protective factors affords the hope that primary preventive measures can be developed. Yet these factors obviously exert their effects in the context of interpersonal interactions, and the mechanisms by which they do so have not yet been well studied. Observations of mother–child interactions, interactions between friends, the formation of relationships between the child and adults, and similar processes might be worthwhile approaches. Such mechanisms are probably still relatively poorly defined, however, and research continues to focus on the question of early development of neurochemical or neuroendocrine mechanisms for coping with various stresses.

This would open up a field in the epidemiology of biological markers that has been understood to date only in very rough outlines, e.g. with the search for neurological "soft signs," particular features of the electroencephalogram (EEG), and morphological abnormalities of the central nervous system. Biological markers might be a starting point for experimental or quasi-experimental studies and, with the inclusion of functional imaging, might be important for research on pathogenesis. Most of the research in the field is thus moving away from the theory of direct traumatization and toward hypotheses of the long-term effects of congenital or acquired mechanisms on behavior. This trend is also seen in the decreasing importance attached to life events as causes of mental disorders: research in child psychiatry now tends to regard life events as consequences, rather than causes, of abnormalities in children and/or their families. Constructs such as temperament have accordingly acquired new importance.

Table 2 provides information from various sources on the prevalence of individual psychiatric disorders. The different samples used to collect these data, and the possibility that they are based on differing case definitions, must be taken into account in their interpretation.

H. Remschmidt, M.H. Schmidt

Therapy of Children and Adolescents

Translator: S. Henn

1 Introduction

In this chapter, the most important methods of treating mental disorders in children and adolescents are briefly outlined. Their specific application to individual illnesses is described in Chap. 7 (Part 1 of this volume). Current reviews of psychotherapeutic methods can be found in Prout and Brown (1999) and Remschmidt (1997), and current reviews of psychopharmacological therapy can be found in Nissen et al. (1998), Rosenberg et al. (1994), and Kutcher (1997).

The types of treatment used in mental disorders may be classified in several different ways, including the following:

- by method (e.g. psychopharmacological therapy, functional therapy, behavior therapy, psychoanalysis)
- by setting (e.g. individual-centered therapy, family therapy, outpatient treatment, day clinic, or inpatient treatment)
- by the disorders to be treated (e.g. anxiety syndromes, obsessive–compulsive syndromes, hyperkinetic syndrome)

Which method will be used in which setting should ideally be determined on the basis of empirically demonstrated effectiveness.

2 Psychotherapy

Individual-centered treatment methods include all those that are carried out selectively in the individual patient. These include psychotherapeutic methods which are derived from very different theoretical schools of thought, such as psychoanalytically oriented therapy, behavior therapy, functional therapy (e.g. perception training, psychomotor training), creative methods (e.g. catathymic picture experience, music therapy), and cognitive therapy. Individual-centered treatment methods are indicated for practically every patient; the large number of indications cannot be discussed in detail in this brief introduction to the subject.

A *psychodynamic method* is suitable particularly in those cases in which the patient can cooperate adequately and the symptoms are diffuse rather than circumscribed (e.g. crises of individuation, anxiety neuroses). Age is also important. In children of preschool and primary school age, psychoanalytic (more specifically, psychodynamic) treatment must make use of game-playing (Dührssen 1980), while in adolescents the usual verbal method may be used (Seiffge-Krenke 1986), as long as due consideration is taken of the patient's stage of life (Remschmidt and Quaschner 1997).

Behavior therapy is used for habitual symptoms, i.e. those which have arisen on the basis of abnormal habit formation, and for circumscribed disorders. Examples are enuresis, habitual behaviors (e.g. nail biting, hair pulling, excessive restlessness, tics), phobias, some psychosomatic illnesses (e.g. psychogenic eating disorders, including anorexia nervosa), and a large number of disorders in which symptoms can be treated with behavior modification without curing the underlying illness (e.g. autistic syndromes, oligophrenia, schizophrenia) (Steinhausen and von Asten 1993). Behavior therapy has developed considerably in recent years and has incorporated cybernetic models and systemic approaches into its techniques (Margraf 2000). Cognitive behavior therapy now has a special status, as it is readily applicable in children, e.g. for depressive disorders (Graham 1998).

There are also many indications for *functional therapies*. These are mainly used to treat circumscribed deficits (e.g. dyslexia, arithmetical disorder, perceptual and concentration disorders) and to remediate developmental deficits or delays (e.g. in motor and language development).

Creative treatment methods are used whenever a direct approach with verbal psychotherapy is difficult or impossible because of the patient's age and developmental stage, or because of the disorder itself.

Cognitive approaches to treatment (insight therapies) are indicated mainly in neurotic and psychoreactive disorders. They are now being increasingly applied, particularly in depression. In addition, progress has been made in evaluating these approaches (Graham 1998).

In very broad terms, *family-centered treatment* includes family counseling (parent counseling), psychodynamically oriented family therapies, behavior-oriented family therapies, child-centered family therapy, and various "home treatment" methods (treatment in the patient's own environment). The indication for a family-centered method must be carefully established by evaluating both the disorder and the patient's overall situation (Mattejat 1997; Remschmidt and Mattejat 1998).

Group-centered treatment methods include open group psychotherapies (analytic or non-analytic methods), goal-directed group therapies (e.g. assertiveness training, group therapy with children who have contact difficulties or are aggressive), autogenic training in groups, group play therapy, and parent groups with various goals. Group therapies have long been established in our clinical practice. They have proved effective in the following areas: open group therapy for adolescents (with various disorders, particularly with

identity crises) and goal-directed group therapies in adolescents with contact difficulties as well as aggressive and uncontrollable children (Niebergall 1997; Remschmidt 1992).

3 Psychopharmacological Treatment

Psychoses in adults and adolescents are still the domain of psychopharmacological treatment (see also Chap. 6, Part 1 of this volume, and Chaps. 13 and 23, Vol. 3, Part 1). Other important indications are the following: hyperkinetic syndrome, obsessive–compulsive disorders, Gilles de la Tourette syndrome, anxiety disorders, and depression (Kutcher 1997; Nissen et al. 1998). Pharmacodynamic mechanisms in adults do not necessarily apply to children because of differences between children and adults regarding the spontaneous course of mental disorders, developmental stages, and environmental factors.

The use of psychotropic drugs in children is often considered in the treatment of conditions that are not truly medical diagnoses. For example, it is pointless to give medication to a child who is having difficulty at school if diagnostic evaluation (which is, sadly, often not performed) reveals that the problem is due to excessive demands placed on the child by overambitious parents. The guiding principle in the choice of a treatment plan remains that the prescription of medication for the disorders discussed here cannot replace or obviate the need for discussion, psychotherapy, or special education. There is no pharmacological treatment which, when given in a particular dose, can eliminate a mental disorder.

Only general principles can be stated for the dosage and duration of treatment with psychotropic substances. These can be summarized as follows:

- The indication should be substantiated by meticulous assessment leading to the provision of a diagnosis (e.g. hyperkinetic syndrome, schizophrenic psychosis, tic, Gilles de la Tourette syndrome).
- In general, treatment should begin at a low dose, which is then slowly raised.
- Treatment should be given at the optimal dose for at least several weeks, because a treatment that is too short will often fail.
- Abrupt discontinuation is to be avoided.
- Once symptoms improve, a maintenance dose should be given, or not given, depending on the clinical situation.
- The method of administration should be determined by pharmacokinetic and pharmacodynamic considerations and not by rigid preset schemes.
- It is advisable for physicians to use a few psychotropic drugs with which they are highly familiar, rather than prescribe a large number of drugs with which they have insufficient personal experience.

3.1 Neuroleptics

Neuroleptics are a group of chemically and pharmacologically distinct substances which, despite their structural differences, share a number of effects:

- Reduction of physical (CNS) and mental tension
- Psychomotor sedation
- Dampening of excitement and aggression
- Antipsychotic/antischizophrenic effect
- Neurological and autonomic side effects
- Predominantly subcortical mechanism of action

Neuroleptics also alter autonomic function, causing undesired side effects such as hypotension, tachycardia, and dry mouth. Furthermore, most neuroleptics have antiemetic, antipruritic, antipyretic, analgesic, and sometimes appetite-stimulating effects.

The mechanism of action of neuroleptics is now explained mainly as the blockade of dopamine receptors. The effectiveness of the neurotransmitter dopamine is reduced by blockade of the dopamine receptor. It is suspected that blockade of the dopamine receptors leads to a compensatory increase of catecholamine synthesis. Yet dopamine receptor blockade cannot be the sole mechanism of action of neuroleptics, as they also have antiserotonergic, antihistaminic, anticholinergic, and antiadrenergic effects, which are particularly prominent in the new, atypical neuroleptics and determine both their activity profiles and their side effects.

The neuroleptics most frequently used in child and adolescent psychiatry can be classified into six groups:

1. Phenothiazine derivatives: levomepromazine (e.g. Neurocil), promethyzine (e.g. Atosil), thioridazine (e.g. Mellaril), perazine (e.g. Taxilan), trifluoperazine (e.g. Jatroneural), fluphenazine (e.g. Dapotum, Lyogen, Omca), perphenazine (e.g. Decentan).
2 Thioxanthene derivatives: chlorprothixene (e.g. Truxal), flupentixol (e.g. Fluanxol).
3. Butyrophenones: haloperidol (e.g. Haldol), trifluperidol (e.g. Triperidol), benperidol (e.g. Glianimon), bromperidol (e.g. Impromen).
4. Diphenylbutylpiperidines: pimozide (e.g. Orap), fluspirilene (e.g. Imap).
5. Benzamides: sulpiride (e.g. Dogmatil), tiapride (e.g. Tiapridex).
6. Atypical neuroleptics: clozapine (e.g. Leponex), olanzapine (Zyprexa), risperidone (Risperdal).

Indications and Side Effects

The indications for neuroleptic treatment in children and adolescents, as in adults, are based on "target symptoms." In acute psychotic conditions with predominantly productive symptoms, the butyrophenone derivatives (especially haloperidol and benperidol) have been found to be effective, as have the phenothiazine derivatives perazine, fluphenazine, perphenazine, and chlorprothixene. If the psychotic condition is accompanied by marked restlessness, then levomepromazine is indicated for its calming effect.

Clozapine has also proved to be effective in both acute and chronic psychotic conditions. Its advantage, in addition to the general absence of extrapyramidal motor side effects, is its positive effect on psychotic symptoms. Because of side effects on the hematopoietic system (most importantly agranulocytosis), the preparation has been taken off the market. However, it can be used as long as special precautions are taken (regular and repeated determination of the complete blood count, ruling out of epileptiform activity by EEG, and testing of liver and kidney function), and the patients and their parents are informed of possible side effects.

If a lack of drive, negativism, autistic behavior, inhibition, and withdrawal are prominent, then the use of sulpiride is advisable. Success has also been reported with haloperidol and fluphenazine.

Depot neuroleptics are indicated for chronic schizophrenic psychoses. Haloperidol decanoate and fluphenazine decanoate have been used successfully. These medications are given intramuscularly, and their effect lasts from 1 to 4 weeks, depending on the substance. These medications are only rarely used in children and will not be further discussed here.

For psychotic and nonpsychotic restlessness and excitement, neuroleptics with a strong hypnotic effect, such as levomepromazine, are recommended.

A number of neuroleptics have a good or very good effect on tics and Gilles de la Tourette syndrome. Haloperidol, pimozide, and the benzamide derivative tiapride have been used with success.

If hypermotor phenomena are prominent following disorders of brain function in early childhood, thioridazine and the butyrophenone derivative pipamperone can be used successfully. It has been shown that thioridazine in lower doses has a positive effect on concentration and motor ability, which decreases at higher doses.

The side effects of neuroleptic treatment can be summarized as follows:

- Extrapyramidal motor symptoms (EPS): pharmacogenic parkinsonism, acute dyskinesia ("early dyskinesia"), akathisia, tardive dyskinesia ("late dyskinesia")
- Autonomic symptoms: dry mouth, tachycardia, accommodation disorders, constipation, micturition disorders, decreased sweating, increased intraocular pressure (glaucoma)
- Cardiovascular disturbances: hypotension, ECG abnormalities (prolonged QT interval, T-wave abnormalities), arrhythmias
- Mental symptoms: fatigue, pharmacogenic depression
- Endocrine disturbances: galactorrhea, gynecomastia, menstrual disturbances, sexual disturbances
- Neurological side effects: epileptic seizures, delirium
- Hematopoietic effects: transient leukocytosis, eosinophilia, lymphocytosis, agranulocytosis
- Dermatological disturbances: cutaneous allergic reactions, light sensitization
- Hepatic effects: (transient) elevation of transaminases, cholestatic jaundice, liver failure
- Ophthalmologic disturbances: clouding of the lens and cornea, retinal pigmental changes
- Thermoregulatory disturbances: temporary mild fever ("drug fever"), high fever as a component of neuroleptic malignant syndrome
- Metabolic disturbances: decreased glucose tolerance, increased appetite

It should be pointed out that some of the side effects listed are very rare. For example, agranulocytosis appears in only 0.1% of patients and is reversible if diagnosed early enough. This makes it even more important for the physician to be well-informed about side effects.

3.2 Antidepressants

Antidepressants are used more sparingly in children and adolescents than in adults. Their indications have widened recently because of new findings (for a review, see Remschmidt and Schulz 1995).

Antidepressant substances can be divided into five classes:

1. Tricyclic antidepressants
2. Tetracyclic antidepressants
3. Monoamine oxidase inhibitors (MAOI)
4. Selective serotonin reuptake inhibitors
5. Lithium salts

Lithium salts are a group of agents that cannot be designated as antidepressants in the narrower sense. However, they will be discussed here because they have an antidepressant effect.

Antidepressants (thymoleptics) include various substances of different chemical structures that share the

effects of brightening mood, increasing motivation, and relieving anxiety. The effectiveness profiles of individual antidepressants are described in reference to these three components. The following types of effectiveness profile are found (Kielholz 1971):

- Imipramine type: antidepressant and mild psychomotor activating effect
- Amitriptyline type: antidepressant and calming effects
- Desipramine type: antidepressant and marked psychomotor activating effect

Tricyclic antidepressants inhibit the reuptake transport of norepinephrine and other transmitters into neurons. Thus, increased levels of these amines are available at the receptor. Tricyclic antidepressants and MAOI lead to the same end result through different mechanisms of action. Their antidepressant effect is also based on this. The individual tricyclic antidepressants differ in the extent to which they inhibit the synaptic reuptake of norepinephrine and serotonin.

A similar mechanism has been described for tetracyclic antidepressants as for the tricyclics. These, too, inhibit norepinephrine reuptake into neurons.

Tricyclic antidepressants are not effective in childhood depression as demonstrated by controlled studies (Remschmidt and Schulz 1995). Their main indications are other fields of treatment and the period of adolescence and adulthood.

Indications

Although the main indication for antidepressants is endogenous depression, the use of these substances is also indicated as a supportive measure in other forms of depression. The indications for the use of antidepressants are based on so-called target symptoms, which are included in the three-component scheme proposed by Kielholz (1971). The choice of medication is guided by the symptoms and the desired therapeutic effect. If relief of depression and strong psychomotor activation are the objective, desipramine-type antidepressants are given; if relief of depression and mild psychomotor activation are the objective, imipramine-type antidepressants are given; and if relief of depression and a calming action are the objective, amitriptyline-type antidepressants are given.

Antidepressants are generally given orally. The dose is increased gradually so that the full dose is reached in 3 to 5 days. Most antidepressants have relatively long half-lives, and can thus be given twice instead of three times daily. The onset of effectiveness of most antidepressants is within 1 to 2 weeks of the start of treatment. Frequent errors in their administration are inadequate dosing and premature discontinuation. These medications should always be discontinued with a gradual taper.

Drug treatment of obsessive–compulsive syndromes is based essentially on the use of antidepressants. Clomipramine has proved to be especially useful. It is a chlorinated imipramine which preferentially inhibits serotonin reuptake. A dosage of 50–75 mg/day is usually aimed at in children under 14 years of age, and 75–100 mg/day in those over 14 years of age. The therapeutic plasma level has been reported to be 50–140 ng/ml. Fluoxetine, a new selective serotonin reuptake inhibitor, also provides effective treatment, especially in adolescents; this substance has a major activating effect and the dose should therefore be increased cautiously and gradually. As there has been less experience with fluoxetine in children and adolescents, drug treatment of obsessive–compulsive syndromes is based primarily on the use of clomipramine. If the response to tricyclic antidepressants is inadequate, the administration of fluoxetine can be considered.

Antidepressants are also useful in the treatment of school phobia. It should be kept in mind, however, that psychotherapy, rather than drug treatment, is the main component of therapy for this disorder. The administration of tricyclic antidepressants has proved to be useful for patients with this disorder who are depressed.

Numerous observations, as well as meticulous double-blind studies, are available concerning the effectiveness of tricyclic antidepressants (especially imipramine) in enuresis, about which there is no longer any doubt.

Although the pharmacological therapy of hyperactivity consists mainly of the administration of stimulants (e.g. methylphenidate), success has also been achieved with tricyclic and tetracyclic antidepressants. Again, most experience has been with imipramine. Comparative studies show, however, that methylphenidate is superior to imipramine.

In somnambulism (sleepwalking), too, the administration of tri- and tetracyclic antidepressants has proved successful. The greatest amount of data is available for imipramine. The effect is attributed to a reduction of depth of sleep and a shortening of rapid eye movement (REM) sleep. As for enuresis, a one-time evening dose of the antidepressant is administered, e.g. 10–20 mg imipramine.

Contraindications and Side Effects

Previous treatment with MAOI is an absolute contraindication. If tri- or tetracyclic antidepressants are to be used after such treatment, then there should be an interval of at least 14 days in between.

Particular attention should be paid to cardiotoxicity and the reduction of the seizure threshold caused by tricyclic antidepressants. It is advisable to obtain an ECG before initiating their use in order to identify any previously existing arrhythmias, which present a contraindication. An EEG should also be obtained.

The most important undesired side effects of the tri- and tetracyclic antidepressants are the following:

- anticholinergic side effects: dryness of mucous membranes, mydriasis, sweating, tachycardia, accommodation disturbances, fatigue, somnolence
- cardiac arrhythmias and ECG changes: frequent rhythm disturbances (up to absolute arrhythmia), flattened T-waves, hypotension
- Micturition disorders (up to urinary retention)
- Hematopoietic abnormalities: leukopenia, eosinophilia, agranulocytosis
- Hepatic disturbances: jaundice, elevated transaminases and alkaline phosphatase
- Lowering of the seizure threshold, possibly leading to epileptic seizures
- Cutaneous allergic reactions have been seen, as well as gynecomastia, in some cases

These side effects most frequently appear in the first few weeks after treatment is begun, so especially careful observation of patients is required during this period.

MAOI are infrequently used in children and adolescents, although a new generation of these compounds with fewer side effects is currently under development. MAOI interact with various substances, particularly tyramine, which is present in various cheeses and many other foods. The inhibition of tyramine degradation can lead to major fluctuations of blood pressure (usually hypertension). Furthermore, there are interactions with various other foods. Thus the use of MAOI has been restricted. For the new generation of so-called reversible MAOI, the side effects listed here do not apply. Experience with these substances in child and adolescent psychiatry is still limited at present.

3.3 Lithium Salts

The major area of indication for lithium salts is still manic-depressive illnesses. These are very rare in children, but become more common in adolescence. Lithium is given prophylactically. It has been shown that lithium can prevent the reappearance of depressive or manic episodes, or at least postpone them. The effect is documented for both uni- and bipolar endogenous phasic illnesses. Lithium salts have also been used to treat various other mental disorders in children and adolescents, although there have been no large systematic studies. Positive results have also been described in aggressive behavior disorders with a phasic pattern and in impulse control disorders, for example. In such cases, however, an affective component should be also present if lithium salts are to be given.

The dose is gradually increased from 6 to 18 mmol/l. 7 days after the initiation of treatment, the serum lithium level should be determined 12 hours after ingestion of the last tablet. The dose is then increased until the blood level reaches approximately 0.8 mmol/l (maximum tolerated level, 0.8–1.2 mmol/l). Slow-acting preparations which need only be given twice per day are recommended (e.g. Hypnorex retard, Quilinum retard).

In addition to the obligatory provision of information to parents and patients, an ECG and an EEG should be performed in each case and a complete blood count should be obtained before lithium treatment is begun. Thyroid and liver function tests should also be performed. Because of the danger of goiter formation, the neck circumference should be measured and the dermatological examination documented.

Furthermore, tremor, weight gain, polyuria, nausea, vomiting, and diarrhea can occur. Cardiotoxic effects are rare. EEG occasionally reveals paroxysmal dysrhythmic disorders, more rarely seizures. Careful monitoring of medication to ensure that the lithium level remains in the therapeutic range is the best way to prevent these side effects.

3.4 Tranquilizers

Tranquilizers are substances of varying chemical structures that possess a sedating but not hypnotic effect and that have neither antipsychotic nor antidepressant effects at higher doses. They also act specifically against anxiety.

The following classes of tranquilizers are used in child and adolescent psychiatry:

- Meprobamate
- Diazepines (e.g. Valium)
- Lorazepam (e.g. Tavor)

Great care should be taken when prescribing tranquilizers to children and adolescents, not least because of the danger of dependency. Longer-term drug use (over many months) is justified only in exceptional cases.

As for indications, tranquilizers can be used, albeit temporarily, in almost all conditions accompanied by anxiety, tension, contact inhibitions, sleep disturbances, and compulsive symptoms. A particularly important indication is present in certain types of epilepsy, where diazepam and mogadan in particular are used (e.g. for myoclonic seizures).

3.5 Stimulants

Stimulants have a central stimulating effect and can lead to dependency in adults, while they can have a

positive influence on attention and motor functions in children. Recent reviews can be found in Kutcher (1997) and Nissen et al. (1998). The following stimulants are in use:

- Methylphenidate (e.g. Ritalin)
- Dextroamphetamie
- Pemoline

The chemical structure of the amphetamines bears a striking similarity to that of the neurotransmitters dopamine and norepinephrine. Methylphenidate and amphetamine affect catecholamine release through different mechanisms: methylphenidate causes dopamine release from reserpine-sensitive granules, while dextroamphetamine activates the release of newly synthesized cytoplasmic amines (reserpine-resistant). Both mechanisms of increased catecholamine release cause these neurotransmitters to flood the synaptic cleft and interact with postsynaptic receptors and presynaptic autoreceptors. In addition, amphetamines cause a dose-dependent blockade of the reuptake of dopamine, norepinephrine, and serotonin into nerve terminals. This mechanism, similar to the effect of tricyclic antidepressants on norepinephrine and serotonin reuptake, leads to increased concentration of the neurotransmitter in the synaptic cleft.

Stimulants are used in children almost exclusively to treat hyperactivity. The doses used are shown in Table 1.

In recent years, hyperactivity has been treated mainly with methylphenidate (e.g. Ritalin). Because of its short half-life, it must be administered twice daily (optimally in the morning and at midday). Methylphenidate should not be given in the evening, as it can adversely affect falling asleep or the quality of sleep. The medication should be temporarily discontinued on weekends and during vacations. This measure prevents the appearance of growth disorders.

The following side effects are known:

- Loss of appetite
- Sleep disturbances
- Tachycardia
- Lowering of the seizure threshold (methylphenidate is thus contraindicated in the presence of an increased seizure tendency)

Table 1. Range of doses of stimulants in school children

	Total dose (mg/kg body weight)	Individual doses (*n*)
Methylphenidate	0.20–1.0	1–3
Dextroamphetamine	0.15–0.50	1–3
Pemoline	0.50–2.0	1
Deanol	1.0–3.0	1–3

Various studies have shown that treatment with methylphenidate also leads to markedly better mother–child interaction and an improved teacher–pupil relationship. Because the children can concentrate better, they are also better able to meet scholastic demands. They are markedly less disruptive than when they were without medication. It should be pointed out that only about 60% of hyperactive children are responders; responses can be seen within a few days. If there is no response to medication, further administration is pointless. It is not yet clear what determines whether an individual will respond. Stimulants should be used only for clearly defined and unambiguously diagnosed hyperactivity. They are not a suitable remedy for difficulties at school or unspecified behavior problems. The dependency often feared does not occur with hyperactivity.

Stimulants are subject to regulations governing the prescription of narcotics and, in many countries, special prescription forms must be used.

4 Treatment Settings

The treatment setting (modality of treatment) is the framework in which treatment can be most successfully carried out. It must be decided whether to provide outpatient or inpatient treatment, day treatment, or home treatment. All of the methods mentioned above can be carried out in a number of different settings. The choice of setting should take two factors into account:

1. Empirical knowledge of the effectiveness of individual treatment methods in each setting
2. The possibility of establishing an adequate therapeutic relationship with the child and family

Outpatient therapy is most frequently performed, and there are scarcely any individual illnesses in which it is contraindicated. It is indicated both in predominantly organic illnesses and in psychogenic ones.

The usefulness of outpatient treatment is limited under the following circumstances:

- Suicidal behavior or other forms of self-endangerment
- Inability to provide effective treatment for very severe or chronified disorders
- Extreme family pathology, because of which a separation of the parents (or other significant adults) from the child is advisable

Practically all treatment methods that have been confirmed to be effective can be used in an outpatient setting.

The decision to provide inpatient treatment is generally guided by the following considerations:

- Severe and/or chronified illness
- Danger to self or others

Some treatment measures are possible only in specialized institutions. The most important types of institution for treating mental disorders in children and adolescents are the following:

- Outpatient care: child and adolescent psychiatrists and psychotherapists in private practice, institutional ambulatory care centers and outpatient clinics, child and adolescent psychiatric services, mobile child and adolescent psychiatric services with treatment responsibilities, child guidance and family counseling centers, early development centers, pediatric social welfare centers
- Partial hospitalization: day clinics for mentally ill and handicapped children and adolescents, with the option of overnight admission
- Inpatient care: university departments of child and adolescent psychiatry, government hospitals or hospital departments for child and adolescent psychiatry, departments of child and adolescent psychiatry in general or pediatric hospitals
- Complementary rehabilitative care: rehabilitation facilities for special groups of patients (e.g. children with severe traumatic brain injury or refractory epilepsy), halfway houses, group homes, homes of various other types

Not every type of institution listed above is present in every geographic region. Sometimes, the appropriate institution is far from the patient's home. Ideally, the choice of a particular form of therapy should be based on empirical evidence of its effectiveness to treat the disorder in question. Unfortunately, such evidence is still lacking in many cases.

It is often difficult in practice to base the choice of treatment on empirical data. Nonetheless, the therapist must consider whether the prospective treatment method is appropriate for the patient's age and developmental stage.

5 Legal Aspects

According to German law, children have legal capacity "upon completion of birth" (Sect. 1 of the German Civil Code – *Bürgerliches Gesetzbuch,* BGB); for example, they are able to take legal action (obviously represented by their parents or another adult). Until children reach majority, they are legally under the care of their parents (Sect. 1626 BGB). Before the age of 18, children and adolescents acquire partial legal rights in a series of steps, through which they gradually attain legal majority. The most important milestones are at the end of the 6th year (obligation to attend school), the 14th year (criminal responsibility), and the 18th year (full majority). Until age 7, children are legally incompetent (Sect. 104 BGB) and are unable to be delinquent, i.e. they cannot be held responsible for damages inflicted on another person. Between 7 and 14 years of age, they have limited competency (Sect. 106 BGB) and limited (civil, not criminal) delinquency (Sect. 828 (1) BGB). Adolescence begins at age 14, as does criminal responsibility.

In Germany, health insurance companies are responsible for treatment and rehabilitation, and children are usually insured along with their parents. There are a number of therapeutic measures, however, that are covered under other relevant laws. The most important laws are the Juvenile Court Act (*Jugendgerichtsgesetz*, JGG) and the Federal Social Welfare Act (*Bundessozialhilfgesetz*, BSHG). In addition, matters of family law (e.g. laws concerning parental care, divorce law, adoption law) are regulated in the German Civil Code.

The German Child and Adolescent Assistance Act (*Kinder- und Jugendhilfegesetz*, KJHG) lists the following youth services that may be used in addition to therapeutic measures:

- Assistance with child-rearing (Sect. 27 KJHG): The individual(s) having care and custody of the child are entitled to assistance with child-rearing "when a suitable upbringing for the welfare of the child or adolescent is not guaranteed, and assistance is appropriate and necessary for his or her development."
- Child guidance (Sect. 28): "Child guidance clinics and other counseling services and facilities are designed to support children, adolescents, parents, and other guardians in clarifying and coping with individual and family-related problems and the underlying factors that cause them, in the resolution of child-raising issues, and in separation and divorce."
- Social welfare group work (Sect. 29): This is designed to help primarily older children and adolescents "overcome developmental difficulties and behavioral problems."
- Educational supervisors, welfare helpers (Sect. 30): These persons help children and adolescents cope with developmental problems.
- Social and educational family assistance (Sect. 31): These measures serve to support families that are unable to perform their educational tasks adequately.

- Child-rearing in a day group (Sect. 32): This measure is intended to promote the development of children and adolescents through social learning in a group.
- Full-time foster care (Sect. 33): This generally involves the placement of children and adolescents in foster families.
- Care in a children's home, other forms of supervised accommodation (Sect. 34): For children who cannot be adequately helped by the measures already mentioned, care in a children's home or other supervised accommodation can be arranged.
- Intensive, individual socio-educational care (Sect. 35): This measure is essentially for adolescents who need particularly intensive support in order to be able to lead responsible lives.
- Temporary care of children and adolescents (Sect. 42): This is the temporary accommodation of a child or adolescent by an appropriate person, facility, or other supervised living arrangement.
- Options for participation (Sect. 36): Options for participation are addressed in Section 36 of the KJHG, which stipulates that an assistance plan should be drawn up. With regard to participation in the choice of measures, the law states that the guardians and the child or adolescent are to be counseled before youth services are instituted. Such counseling may be within the competence of the physician, particularly when social youth services are to be combined with medical treatment.

The Federal Social Welfare Act (BSHG) concerns "social assistance for living arrangements and support in special situations." The task of social assistance is to provide a wide variety of social services enabling the recipients to lead well-organized lives. In the context of therapy and rehabilitation, assistance with integration for the handicapped (Sect. 39 BSHG) plays a major role. Its objective is "to prevent an impending handicap or to eliminate or alleviate the consequences of an existing handicap, and thereby enable or facilitate the participation of the handicapped person in community life."

The Juvenile Court Act (JGG) applies to adolescents (aged 14–18) being prosecuted under criminal law. Sect. 10 section 2 JGG concerns reformatory treatment, which can be imposed by the court and is not restricted with respect to the measures to be taken. In other words, practically all treatment methods may be recommended, as long as they appear likely succeed. Reformatory treatment may also take the place of punishment. The expert in adolescent psychiatry faces important tasks in this setting.

Matters of family law are regulated by the German Civil Code (BGB). It is beyond the scope of this discussion to deal with these issues individually. Essentially, the following issues are involved:

- Regulation of custody when parents divorce (Sect. 1671, 1672, 1680, 1681 BGB)
- Regulation of visiting rights (Sect. 1634 BGB)
- Procedure when the child's welfare is endangered (Sect. 1666 BGB)
- Adoption issues (Sect. 1741-1772 BGB)

Disorders in Child and Adolescent Psychiatry

Translators: E. Taub, S. Henn

1 Introduction

We use the term "disorders" in this chapter in accordance with the international trend, reflected in both of the current systems of classification (ICD-10 and DSM-IV), toward using this term and avoiding the term "disease." It remains to be seen how long this change will last. The justification for this change in the current classification systems is that the concept of a disorder carries fewer etiological and theoretical implications than that of a disease. The decision not to speak of diseases is not intended to be final; it merely reflects the fact that current knowledge is too limited to allow an etiologically-based classification (Remschmidt 1988).

Until this is possible, there will remain several different ways to describe concepts of diseases or disorders in child and adolescent psychiatry:

1. Definition of different levels on which concepts of disorders can be placed, in the form of constructs. This was the approach of Häfner (1983).
2. Definition of relatively broad areas in which pathological organic changes, behavior, and experience occur. Such a suggestion was made by one of the pioneers of European child and adolescent psychiatry, Moritz Tramer (1942), who classified diseases into 4 groups according to the prevailing state of knowledge at that time: (1) somatic disorders and illnesses, (2) somatopsychic disorders and illnesses, (3) psychosomatic disorders and illnesses, and (4) mental disorders and illnesses. It is of interest that Tramer distinguished between disorders and illnesses, thus anticipating current concepts to some extent, although he defined the concept of disorder less precisely than that of an illness.
3. Orientation toward developmental aspects and considerations of disease course. We have adopted this point of view in our own scheme of classification in this chapter, in that we do not regard "disorder" and "disease" as mutually exclusive entities but rather view disorders as the preliminary stage of diseases. Thus, following Häfner (1983), we define a disorder in child and adolescent psychiatry as "a condition of involuntarily disturbed life functions, which has a temporal dimension in terms of its onset, course, and (sometimes) termination, and which definitively prevents a child or adolescent from actively participating in, and mastering, age-appropriate activities" (Remschmidt 1988, p. 146).

In view of the considerable improvement of our understanding of the development and course of disorders and illnesses in child and adolescent psychiatry over the last two decades, we believe we are justified in using the last-described point of view as the basis of a classification of these disorders and illnesses. In consideration of developmental aspects and of disease course, we classify them into six types:

1. *Behavioral abnormalities* are deviations from normal functioning in various areas over the course of development (e.g. autonomic functions of attachment behavior, language development, social development), which are not yet severe enough to be designated as disorders or illnesses, but whose detection is nonetheless important, so that preventive measures can be taken and parents and significant others can be appropriately counseled.
2. *Early-onset disorders with lasting developmental impairment* include a number of etiologically diverse disorders that begin in the early and middle years of childhood and result in lifelong impairment, or at least have demonstrable effects lasting into the middle years of adulthood (up to approximately age 30).
3. The characteristic feature of *developmental disorders* is their dependence on the developmental and maturational processes of the early and middle years of childhood, approximately until puberty. As maturation progresses, they become significantly less common.
4. *Disorders of age-specific onset* are typified by their onset in a specific age period. The typical course of disorders of this type is different for each disorder.
5. The hallmark of the *developmentally dependent interaction disorders* is that they occur in the context of interpersonal interactions that are specific to certain age periods and levels of development.
6. *Early-onset adult-type disorders* are disorders that are typically found in adults but often begin in adolescence, generally continuing into adulthood.

Four of the six types of course are depicted schematically in Fig. 1. Behavioral abnormalities and developmentally dependent interaction disorders are difficult to depict in this way, and have been left out of the figure.

In what follows, we classify mental disorders in childhood and adolescence according to these 6 types of course. A comprehensive review of the subject is not possible, because of space limitations. Our discussion must, therefore, remain on an illustrative level. We hope that it will serve to orient the reader in the field and provide the key to a deeper understanding.

2
Behavioral Abnormalities and Stress Reactions

Changes in physical and mental function and behavior that occur together at certain times in the life history of the individual constitute a process retrospectively designated as development. Three major types of factors participate in development: maturational processes, adjustment processes, and control by the individual.

Many developmental processes are set in motion by maturation and then come increasingly under the influence of learning and adjustment processes or of individual control. Genetically based processes of maturation are modified by the biological environment, and, in particular, by somatic disorders acquired at an early age; limitations of central nervous function play a major role in these processes.

Adjustment processes are set in motion mainly by social learning: the environment generally places demands on the individual, who must then adjust his or her behavior accordingly. Repeated accommodation results in changes of behavior. The demands of everyday life may be perceived as stressors of variable intensity (physical illness, separation, loss of significant others, scholastic demands).

Thus, even at an early age, children develop coping mechanisms whose biological correlates have as yet been the subject of little research (e.g. Lundberg 1986). There is no doubt that these mechanisms are influenced, in part, by the intensity of the stressful experience. Behavior under the individual's own control is easily observed even in 2-year-olds: children behave differently in different contexts.

Individual developmental factors interact with each other in a manner that is not merely additive. Thus, the relative importance of each will be of lesser concern to us here than the interactions between them and the mechanisms underlying them. Biological processes are heavily involved and determine, among other things, the range of possible reactions in the framework of learning processes. Life experiences make a further contribution to coping styles and to the development of defense mechanisms. The individual creates his or her own personal environment through variable behavior in varying contexts (Bouchard and McGue 1990). The greater importance of the individual environment, which a child does not share with his or her siblings, as compared to the common environment is one of the reasons why genetic influences become increasingly manifest over the course of development. The activity of the individual is a more important cause of diversity in behavior than the variability of the environment. Maximal diversity arises in functions that develop rapidly, because some children develop these functions earlier, and others later.

Genetic predispositions, differing opportunities and demands in the social environment, active behavior, and varying speeds of development create variations in behavior whose extremes lie near, or may overlap with, pathological behavioral abnormalities. The differential diagnosis of such variations from incipient psychiatric disorders may be difficult. The experienced clinician relies more on qualitative than on quantitative abnormalities for diagnostic decision-making.

Typically, however, behavioral variants are characterized by a temporal lead or delay compared with normal behavior, or are extremely deviant in their intensity. They are not, in themselves, a sign that mental disorders are present, but they do constitute a risk factor for them: speech dysfluency of physiological origin, for example, may appear to other persons to be a manifestation of deficient self-control, and an attempt may be made to correct it forcibly, with the

result that overt stuttering develops. Girls whose menses begin early have an elevated risk of contact with older male adolescents, which, in turn, elevates their risk of consuming hashish at a young age (Magnusson et al. 1986).

2.1 Motor Development, Autonomic Functions, and Sexual Development

The assessment of the psychomotor development of prematurely born children must be corrected for gestational age. In the third year of life, the motor overactivity characteristic of that age is so common that it may be confused with the manifestations of a hyperkinetic disorder. Motor coordination is well enough developed in the fourth year of life that the child becomes able to participate in games of skill. Nonetheless, motor function is not yet under complete control: complicated, selective movements are often accompanied by involuntary accessory movements even into early school age. Persistent ambidexterity is considered a sign of late maturation.

Sex differences are apparent in the motor development of school-age children. Strength and skill are important sources of social recognition by peers for children of both sexes – for girl aged 11 years and older, personal appearance is another important source. There is a wide spectrum of motor control of speech: stammering is found in one quarter of all five-year-olds and must be diagnostically differentiated from auditory disturbances and sound agnosia. Speech dysfluency is common in the third and fourth years of life, more so in boys than in girls. Motor development determines the pace of acquisition of drawing and writing skills until age 9; in later school years, the speed of writing is determined mainly by temperamental factors, and, after puberty, by the influence of practice. Stereotyped motor patterns may still reflect immature inhibitory processes in the fourth and fifth years of life.

Young children vary widely not only in the duration of sleep, but also in their behavior while falling asleep. At least one third of four-year-olds display stereotypic movements before falling asleep, need transitional objects, and climb into their parents' beds when they wake up at night (Klackenberg 1987). Resistance to certain foods, or to being fed, are more likely to be an expression of a mother-child conflict than of early eating disorders. Vomiting is not uncommonly a habituated reaction to excitement in irritable infants.

Overweight is found in 13.5% of 5-year-olds, obesity in up to 2.5%. Overweight 5-year-olds are likely to have been overweight babies, although only a small fraction of overweight babies go on to become obese children. Eating behavior does not become stable until school age (Woolston 1991). The only behavioral variants that are considered to occur in the first 6 months of life are excessive crying, disturbances of falling back asleep, and/or isolated feeding disorders. Bladder and bowel control are usually achieved by the age of 3 years, but the range of normal variation is so wide that the diagnosis of enuresis cannot be made before the age of 5 years. A transient reappearance of enuresis under stress may represent an adjustment reaction (see below).

The acceleration of longitudinal growth that marks the onset of puberty occurs in girls aged 10 to 11 and in boys aged 12 to 13. The high point of puberty occurs approximately 2 years later in each sex, with a corresponding time difference between the sexes; the tempo of puberty, however, is subject to variation. Sexual fantasies and masturbation appear in boys at about the age of 13, in girls at the age of 15 on average. By the age of 18, 50% of male and 60% of female adolescents have experienced coitus; this implies a shift toward earlier sexual experience among girls.

2.2 Cognitive Functions and Language

Practice in differential perception is important for the development of intellectual function. The preference for color that prevails until the 6th or 7th year of life is increasingly replaced by a preference for form. In the seventh year, stability of spatial location is achieved, both in perception and in reproduction; mirror-writing still occurs in the first grade, however, especially among left-handers. The concept of number develops in the fourth year, while spatial orientation remains dependent on the child's own position until the early school years, i.e. until reversible cognitive processes come into use. As for the concept of time, an idea of the future develops in the fifth year, before the differentiation of the past; a temporal continuum comes about only in school age. Perceptual illusions are a common symptom of fever until early childhood.

The attention span lengthens between the ages of 5 and 7 years but remains highly dependent on motivation and context. Individual reaction times become shorter until age 13. Simultaneous memory begins in the third and fourth years, while ordered reproduction can be performed only in school age; it is supported by language development. The beginning of school age is accompanied by a massive expansion of short- and long-term memory. Model learning is possible as early as the first year. School education leads to a verbal orientation of learning, at first as multiple discrimination, and later in the form of concept and rule learning, and of problem solving.

Remnants of the magical world view of the preschooler are still recognizable as late as the seventh year; corresponding rituals must sometimes be differentiated from early obsessive-compulsive phenomena. Conceptual thinking is possible after the fourth year, and simple, reversible thought processes are present in the seventh year, while, at the same time, the progressive building up of concepts is a stimulus to causal thinking. The level of intelligence and life experiences exert an important influence on the acquisition of wide-ranging cognitive abilities. A major portion of cognitive variance is already accounted for by the eighth year of life. From the tenth year onward, there is a relative stability of intellectual performance until adolescence; before the tenth year, measurable intellectual performance is more strongly milieu-dependent.

Nonverbal functioning is more suitable than language-bound intelligence for use as a criterion to distinguish a temporary developmental lead from special intellectual talent, because the frequency of vocal expression is correlated with social class even before the sixth year of life. Passive vocabulary develops earlier than active, and language comprehension earlier than language production. Language develops earlier in girls, and with rarer disturbances. Grammatical correctness is largely achieved in the fourth year, and the vocabulary trebles in size while the child is in kindergarten. From the fourth year onward, language serves to communicate thought processes in a manner independent of visual context. Reading may normally be acquired as late as age 8. General intelligence is more closely correlated with language comprehension than with language production. By the end of the primary school years, an understanding of double meanings is acquired, and children can use language to express how they feel.

2.3 Emotions and Motivation

In terms of mental development, displeasure reactions appear earlier than pleasure reactions, and they also become differentiated earlier. The differentiation of the emotions depends at first on autonomic processes, later on imitative processes. Emotional attachment to significant others favors exploration, which occurs independently of significant others in the third and fourth years of life.

From the end of the first year onward, the child reacts sensitively to separation, because the concept of time is still lacking. As perception becomes differentiated, the emergence of anxieties is favored, first by conditioning, and later by model learning. Improvements in cognitive structures also enable the child to have false ideas of danger, which may be reinforced verbally; conversely, the infant's fears can be neutralized by the presence of its mother. Separation requires practice – for example, in the context of going to sleep.

Defiant reactions in the second year of life represent the young child's active attempts to deal with the environment. Because affect regulation is not yet fully developed, these reactions may escalate to the level of temper tantrums. Long, continued crying may turn into respiratory affective convulsions with cyanosis, inspiratory pauses, and ensuing disorientation. By the age of eight at the latest, children can say how they feel more accurately than their parents can. Anxious affect develops earlier than depressive affect, though the former is often inappropriate to the real-life situation, in which no threat is actually present. The greater timidity of girls decreases continuously from the age of 10 onward. As children approach adolescence, they discuss their feelings more readily with their peers, girls more than boys; at later ages, such discussions also take place in groups of mixed sex.

Problems with poor school performance become less common with adolescence, but they may emerge once again in a manner related to social class. Uncertainties about the future and about self-esteem are not the main cause of death wishes and suicidal fantasies, which occur at least once in one fourth to one third of all adolescents. The correlation between such fantasies and suicidal thoughts in the narrower sense is rather low.

Curiosity is one of the child's earliest observable motivations. Motivation to perform, in the sense of competitive behavior, presupposes the cognitive ability to distinguish measurable effects of one's actions. Orientation toward success and avoidance of failure are recognizable as early as the fifth year, and children place demands on themselves from the fourth year onward. The five-year-old is aware of his or her own failure, and also of the different reactions that success and failure generate. The motivation to perform develops in a class- and milieu-dependent fashion, and is optimal when the external expectation always lies just below the limit of what the child can achieve. Even before school age, it becomes unnecessary to reward good performance immediately, but performance-oriented games come to be preferred around this time. When the magical world view disappears, children want to influence their own success. The developmental task of the primary-school child is to replace person-oriented with object-oriented performance motivation. Motivation can be maintained by an attitude that is as demanding as it is supportive. Lasting motivation to perform can protect the individual from the difficulties of orientation typical of adolescence and eases the fulfillment of educational demands.

2.4 Contacts, Conduct, and Self-Image

Shy behavior in school age may reflect either a lack of social competence, or social hypersensitivity (see Sect. 4). Both shy and socially hypersensitive children generally have no difficulty with attachment and therefore want contact with others, even if they want to determine its extent and quality themselves. Normal attachment behavior may be observed in grief reactions to separation (Ainsworth 1978). Securely attached children have an egocentric perspective that recedes only in the sixth or seventh year, in favor of an interactive perspective. When the "difficult" age is past, limits to self-determination are experienced and internalized in this way.

The boundaries separating the self from other persons and things, which are perceived in a merely physical sense in early childhood, come to be perceived mentally during early adolescence. A concept of self arises out of the uniformity and continuity of the individual's own experience, while the adoption of a perspective, something already learned in childhood, now becomes emotionally deepened. Conceptions of self are differentiated to a varying extent; Evans et al. (1994) pointed out the lesser degree of differentiation in adolescents with mental disorders. Self-evaluation begins in the primary school years. A high degree of experienced agreement between self-image and others' image of oneself strengthens self-esteem and leads to self-acceptance (Robson 1988). A high degree of self-esteem enables a more distanced perception and evaluation of the behavior of others, because adolescents with high self-esteem do not have to mobilize defense mechanisms to the same extent.

In a study of defense mechanisms (Perry and Cooper 1989), a distinction was drawn between mature and immature mechanisms. In the context of social development, self-acceptance obviates the need for immature defense mechanisms and thereby permits the establishment of mature moral judgments (Kohlberg 1997), which respect the interests of others and accord with overarching principles of behavior.

The clinically relevant stress reactions described below may be understood as reflecting an overloading of usual coping strategies. The highly affective tone of the acute stress reaction reflects a failure of affect control; the re-experiencing of traumatic situations in post-traumatic stress disorder reflects a failure of reality control; and the temporary inadequacy of coping mechanisms seen in adjustment disorder reflect the excessive stress placed on them.

2.5 Acute Stress Reactions

Even when extraordinary stresses do not lead to the appearance of a disorder corresponding to the particular vulnerability of the individual, they can still have a directly traumatizing effect. Successful coping with the stressful situation does not take place immediately. The child or adolescent is temporarily limited in his or her ability to go about the activities of daily living. The most important factor is the severity of the transient, triggering event, which is generally of a negative character for the involved person, or for another person close to him or her. Such events include natural disasters, accidents, wartime experiences, crimes, and other experiences of loss. Physical exhaustion or chronic illnesses heighten the risk of an acute stress reaction.

The severity of the stress reaction depends both on the stressful event itself and on the individual's coping mechanisms, as becomes clear when one considers the individual nature of these reactions. They generally begin with a diminution of consciousness or attention, which results in stupor or agitation. Because the individual is disoriented, stimulus processing is not possible, or takes the form of hyperactive reactions. Possible affective reactions include anxiety, despair, and depression, as well as anger and withdrawal. The manifestations usually fluctuate, and accompanying autonomic anxiety reactions (flushing, tachycardia) are common. Intervention is necessary only when self-injury or suicidal actions are likely to occur.

2.6 Post-traumatic Stress Disorders

Post-traumatic stress disorders appear after a long delay, or gradually over a long period, with latencies of weeks to months, or rarely even longer. For persons under 18 years of age, the lifetime prevalence of such disorders is said to be as high as 6% (Giaconia et al. 1995). Older children are more severely affected than younger ones, and, from pre-adolescence onward, girls are more commonly affected than boys. Increased autonomic excitability, anxiety disorders, and anxious or obsessive-compulsive personality structures favor the development of post-traumatic stress disorders, as does repeated traumatization (Garrison et al. 1993). Successful coping with earlier trauma does not seem to have a protective effect. Close family ties, however, and other compensatory mechanisms are considered to be protective, as is crisis intervention immediately after the stressful event.

As in adult patients (Yule 1992), this disorder is characterized by repeated recollection of the inciting event, or by a re-experiencing of the stressful emotions associated with it, in response to key stimuli. The situation of recollecting the event, and analogous constellations, are avoided in a phobic manner in order to prevent the occurrence of the accompanying vegetative phenomena, which may include excessive alertness, fearfulness, difficulty concentrating, irritability, hyperactivity, and sleep disturbances. Depressive and dissociative reactions may also occur. The intensity of recollection is independent of the immediate reactions.

Manifestations of the disorder among children, in particular, include fear of the dark and separation anxiety (even when the child sleeps in the parents' bed), failure in school, irritability towards peers and adults, regressive manifestations, difficulty talking about the event with trusted persons (for fear of making them sad), fear of threatening situations for significant others, and, sometimes, feelings of guilt at having survived the event. Information provided by the children themselves is of greater diagnostic relevance than that obtained from their parents. It is typical for the recollections to be experienced as forcing themselves upon the sufferer. The diagnosis is made only if the manifestations of the disorder arise within 6 months of the event. Panic reactions may also occur.

In most persons suffering from post-traumatic stress disorder, the manifestations become milder over time; a transition to a chronic personality change, as occurs after repeated, severe traumatization (for example), is rare. Post-traumatic stress disorder among children is more likely to become chronified if the patient is a girl, if the underlying trauma involved personal threat or experiences of interpersonal violence, or if the coping behavior of significant others is inadequate. Its treatment consists of repeated discussion or reenactment of the stressful event. Resistance preventing psychotherapeutic access to the traumatic event is only transiently operative. A feeling of control over the event, and the anxiety and excitement associated with it, is obtained by talking about it in an anxiety-free atmosphere.

Severely traumatized children are, therefore, treated individually. When the traumatic experience was a shared one, discussion in a group of affected persons is helpful. Treatment in a family-therapeutic setting is reasonable when several members of the family have been traumatized, or when a high degree of family resistance prevents treatment of the child alone. Trauma interviews (Pynoos and Eth 1986) may be helpful in reviving the event. Children are given propranolol in some cases for pharmacological support, while older adolescents may be given fluoxetine, which has been found useful in adults. A purely cognitive approach to the event, without reliving the associated affect, is not an effective form of treatment.

2.7
Adjustment Disorders

Adjustment disorders generally arise not because of dangers inherent in the present situation, but because of lasting, negative changes in life circumstances. Individual predisposition, or the material and social environment, may also be partially responsible. Manifestations of these disorders include depressive behavior, which may be mixed with anxiety, worry, or tension; in children, regressive phenomena such as the reappearance of bedwetting or a reversion to baby talk; and, in adolescents, aggressive or antisocial behavior. One or more of these manifestations generally appear within one month of the event and last as long as six months; depressive reactions may last even longer. In the Puerto Rico Study (Bird et al. 1988), adjustment disorders had a frequency of 4.2% and accounted for one quarter of overall morbidity. Their treatment is based on their most prominent manifestations in the individual patient, with the application of cognitive restructuring. Their prognosis is generally as favorable as that of stress reactions requiring no treatment.

3
Early-Onset Disorders with Lasting Impairment

3.1
Mental Retardation

Mental retardation (ICD codes F70-F79) is a congenital or acquired limitation of cognitive performance. Its nature and intensity are highly variable. The contrasting concept of dementia refers to a deterioration of mental functioning, i.e. it presupposes that a high intellectual level was present until a particular event occurred (e.g. encephalitis or epilepsy).

These disorders are to be distinguished from disorders of impaired intellectual capacity in children resulting from extreme neglect and lack of encouragement, which are designated as mental hospitalism, or deprivation syndrome.

One may assume that mental retardation of varying degrees of severity is present in ca. 9–10% of the general population. The more severe the retardation, the more rarely it is found. Severe and very severe mental retardation are generally caused by diseases or injuries of the brain, malformation syndromes, inherited metabolic anomalies or chromosomal aberrations. In the statistical distribution of the intelligence quo-

tient (IQ), the prevalence rates at the lower end of the distribution do not correspond to the values that would be expected on a Gaussian curve; the lower grades of intelligence are significantly over-represented. This is explained by the fact that mental retardation may be the result of a combination of genetic and organic causes (Zigler 1967). The mean IQ of patients with organic mental retardation is approximately 35.

The most important classifications of mental retardation and dementia are based on severity, the causes of the intellectual impairment, and the opportunity for improvement (reviewed in King et al. 1997; Neuhäuser and Steinhausen 1998; State et al. 1997).

Varying levels of intellectual capacity can be measured with the intelligence quotient, which deals with the entire spectrum of intellectual capacity, and not just with retardation. These varying levels are listed in Table 1 according to the multiaxial classification scheme (MAS) for mental disorders of children and adolescents according to the ICD-10 (Remschmidt and Schmidt 1994). Brief descriptions of the most important types of mental retardation are provided.

In the MAS, mental retardation is assigned to a separate, third axis of classification independent of psychiatric illnesses and specific developmental deficiencies. The DSM-IV also allows a multiaxial classification, in which intellectual impairments are assigned to the second axis.

Because classification by IQ is inadequately descriptive, mental retardation is also broken down into two types that are distinguished by differing ability to learn in school:

- learning difficulty (IQ ca. 50–80), and
- mental handicap (IQ ca. 30–55).

The classification of mental retardation by etiology is problematic, in that the etiology can be determined in fewer than 30% of cases. Furthermore, the elucidation of the etiology depends on the severity of the mental retardation. More severe cases tend to be associated with organic insults, malformations, metabolic disorders, and other somatic abnormalities. An extensive review is found in Neuhäuser and Steinhausen (1998).

The diagnostic evaluation of mental retardation and dementia has the following objectives:

- Discovery of the cause of the disorder. A precise determination of the etiology can lead to specific treatment recommendations.
- A differentiated description of the pattern of the disorder, which is helpful in the formulation of an individual treatment plan and in predicting the prognosis. A thorough psychological assessment is used to meet this objective. Treatment measures are accordingly based, not just on global IQ scores, but on the individual patient's profile of abilities and skills.
- Acquisition of important information for genetic family counseling. Genetic counseling is provided to the children themselves when they reach reproductive age, and to their parents and siblings.

Mental retardation must initially be differentiated from dementia. The most important distinguishing feature of dementia is a measurable decline in the level of intellectual functioning, which may have very diverse causes. Its origin may lie in the progression of an underlying illness, such as Rett syndrome or Heller's infantile dementia, the etiology of which is still unknown. Mental retardation must also be differentiated from autistic disorders, epilepsy, and Landau-Kleffner syndrome (acquired aphasia with epilepsy).

Because the treatment in most cases must remain at the symptomatic, rather than the causal, level, the treatment plan must be directed toward the areas that have the greatest potential for improvement and are associated with the greatest impairment in the patients' everyday lives. Therapeutic interventions generally cover the following areas:

- *Functional therapy* is indicated when there are motor disturbances or special deficits.
- *Behavioral therapy* is performed to reduce or eliminate accompanying behavioral abnormalities (e.g. self-destructive behavior). It is also used successfully to further the goal of personal independence (e.g. in dressing, eating, shopping, self-assertion).
- *Pharmacotherapy* may be used to treat transient, severe behavioral abnormalities, or to treat marked hyperactivity and the associated attention disorders.
- *Counseling of parents and the social environment* is beneficial for children and adolescents in many ways. Its most important objective is to help persons in the social environment achieve a realistic attitude toward the intellectually handicapped child or adolescent and learn how to deal with him or her appropriately.
- *Support* in school, in vocational training, and in obtaining a job is of central importance.

With respect to the components of the rehabilitation of the mentally retarded, it is useful to retain the distinction drawn in the international classification scheme of the WHO between "impairment" (the mental and physical problems themselves), "disability" (the resulting functional limitations), and "handicap" (the negative social consequences). As the impairment is usually fixed, rehabilitation measures are generally oriented toward the remediation of disability and handicap. A series of graded interventions are provided by institutions specializing in the rehabilitation of

Table 1. Variations in intellectual capacity (MAS – ICD-10; Remschmidt and Schmidt 1994; WHO 1996)

Level of intelligence (IQ)	Verbal Classification	Brief Characterization
Very high intelligence (IQ > 129)	Intelligence far above average	
High intelligence (IQ 115–129)	Intelligence above average	
Normal range (IQ 85–114)	Average intelligence	
Low intelligence (IQ 70–84)	Below average intelligence, borderline mental subnormality	These children have mildly impaired intellectual capacity but are able to function independently in everyday life and often complete primary and secondary school.
Mild mental retardation (F70) (IQ 50–69) (in adults, intellectual age of 9 to <12 years)	Mild mental subnormality	Children with intellectual capacity in this range generally attend a special school for the learning-impaired. Their practical intelligence is usually better than their theoretical intelligence. They can carry out concrete cognitive operations and acquire the basic elements of scholastic skills.
Moderate mental retardation (F71) (IQ 35–49) (in adults, intellectual age of 6 to <9 years)	Imbecility	Children with intellectual capacity in this range can usually be taught appropriately only in special schools for the practically educable mentally handicapped. Their mental/emotional development is far behind that of non-handicapped children. They cannot acquire scholastic skills.
Severe mental retardation (F72) (IQ 20–34) (in adults, intellectual age of 3 to <6 years)	Severe oligophrenia	Some of these children can still be taught in special schools for the practically educable, but this presents considerable difficulties for many children, not least because of additional impairments that are often present (e.g. paralysis, deformities).
Profound mental retardation (F73) (IQ < 20) (in adults, intellectual age of <3 years)	Idiocy	These children usually have an extremely limited learning ability. In many cases, they cannot walk, eat independently, or speak. They tend to display stereotypic movements and primitive reactions. The developmental age they can achieve corresponds approximately to that of 18-month-old infants. Their intellectual functions are restricted to the sensorimotor level. They cannot make their learning more efficient by means of language.

the severely retarded with the goal of integrating them in the workplace and in society. Further information (in German) is found in the guide *Rehabilitation Behinderter* ("Rehabilitation of the Handicapped") published in 1994 by the German Federal Task Force on Rehabilitation.

Prenatal diagnosis and genetic counseling are means of primary prevention of mental retardation, as are dietary measures for the prevention of severe metabolic disturbances (e.g. in phenylketonuria or hypothyroidism). Continuous and meticulous prenatal care is also of obvious importance, both to prevent injury to the developing fetus and to provide early warning of possible complications, so that suitable plans can be made for the remainder of pregnancy and delivery.

The course and prognosis of mental retardation depend on its type and severity, on possible progression of the underlying disorder, and on the kind of support provided. Recent years have witnessed a change of attitude favoring greater integration of the mentally retarded into the community. This change and the increased availability of workshops for the handicapped and other "protected" work environments has led to a major improvement in the quality of life of mentally retarded young people.

3.2 Autism

3.2.1 Early Childhood Autism

The most prominent manifestation of early childhood autism (ICD-10 classification, F84.0) is a major disturbance of interpersonal contact whose first signs appear in the first months of life, although they are still difficult to recognize at this time. The children are delayed in their emotional and motor development, fail to make eye contact, and treat significant others with resistance and rejection whenever they try to make

contact. Further manifestations include an anxious clinging to the familiar (fear of change), various language abnormalities (delayed language development, echolalia, pronoun reversal, ungrammatical speech), and often abnormalities of the voice and of speech melody, as well as a number of other behavioral abnormalities, commonly including obsessive–compulsive behavior, self-destructiveness, aggressive and impulsive behavior, and a lack of fear in the presence of real danger. A comprehensive review is given by Cohen and Volkmar (1997).

Studies of unselected samples have revealed that the prevalence of early childhood autism is approximately 4–5 per 10,000 children and adolescents, and that boys are more commonly affected than girls. The sex ratio is in the range of 2:1 to 3:1.

Over the course of development, the manifestations of the disorder change in a somewhat predictable fashion. The predominant manifestations in early childhood, such as sensitivity to noise, paroxysms of fear, psychomotor unrest, sleep disturbances and a tendency to touch people or objects, steadily decline in intensity (Weber 1970, 1985).

Factors thought to play a role in the pathogenesis of early childhood autism include the following:

1. The findings of family studies and twin studies imply that *genetic factors* play an important role. Family studies on the frequency of early childhood autism among the siblings of autistic probands have revealed that they have an approximately 3% risk of developing the disorder, which is 60 to 100 times higher than the risk in the general population. Twin studies have shown that the concordance rate for monozygotic twins is far higher than that for dizygotic twins.
2. There have been many observations of *structural and functional abnormalities of the brain* in children with early childhood autism. These include a number of neurobiological abnormalities (e.g. disturbances of the sleep rhythm, eating disorders, abnormal crying, elimination disorders, excessive excitability) that are not found in normal children. Moreover, approximately 30% of all children with early childhood autism later develop epileptic seizures. Early childhood autism is associated with a number of other neurological syndromes more often than would be predicted by chance. Structural anomalies of the brain and abnormalities of cerebral metabolism have also been reported in a fairly large number of cases.
3. The hypothesis of a *disturbance of cognitive and emotional development* is based on the observation of Leo Kanner (1943) that children with early childhood autism have an "innate inability to form the usual, biologically provided affective contact with other people" (ibid., p. 250). This basal deficit makes such children unable to achieve further normal progress in development. They thus fail to learn at an early age, as normal children do, that other persons, too, have affective relationships, ideas and thoughts that one can sometimes infer from their behavior, and into which one can even, at times, project oneself.

The diagnosis of early childhood autism is made on the basis of the history and clinical observation. Aids to diagnosis exist in the form of scales with diagnostic criteria.

The differential diagnosis of early childhood autism from childhood schizophrenia is of great practical and clinical importance. The disorder must first be differentiated from autistic personality disorder (Asperger syndrome). It must then be differentiated from Rett syndrome, which is characterized by a progressive decline resulting in dementia. The possibility of sensory deficits and oligophrenia must also be considered. When speech peculiarities are present, audimutism (developmental dysphasia or aphasia) must also be ruled out.

The guiding principle of therapy, intervention, and rehabilitation in children with early childhood autism, as experience has amply confirmed, is that strongly behaviorally oriented, direct and structured treatment methods are more likely to succeed than "laissez-faire" methods that leave the patients to their own devices.

Every treatment plan must be based on a consideration of the developmental profile of the individual autistic child and be "custom-tailored" to it, to a certain extent. From this point of view, the following measures have been found useful and productive:

1. *Early intervention* is indicated in all autistic syndromes. Autistic syndromes should be diagnosed early, and development-promoting measures should then be instituted, with the aim of positively influencing the development of autistic children, in the sense of making their behavior more like that of healthy children.
2. Many *behavior-therapeutic methods* are used, ranging from operant conditioning and the use of reinforcements and aversive stimuli to "prompting" (the provision of specific help), "shaping" (i.e. of behavior) and "fading" (a gradual withdrawal of prompting).
3. A number of different *body-based treatments* may be used; these are a very heterogeneous group of methods whose theoretical justification and empirical confirmation remain controversial (for a review, see Weber and Remschmidt 1997):
   - *Developmental stimulation (after Delacato)* is intended to bring the children up to pace with missed developmental steps and bears the danger that the extent and intensity of the treatment will

overtax the children, their parents, and other family members.
- *Integrative physical therapy* is intended to promote the child's overall personality through the use of the body. It emphasizes the importance of emotional experience (communication of warmth, security, and understanding).
- *Holding therapy* is based on the idea that autistic children lack primal trust and tries to reestablish it by body contact (holding), even when the children resist (Tinbergen and Tinbergen 1984). Despite several encouraging case reports, the effectiveness of the method cannot yet be regarded as proved.
- *Facilitated communication* is a therapeutic measure that is designed to help people with severe disturbances of communication express themselves without speaking. This is done with the aid of letter tables or computers. The therapist can support the writing hand, or the arm. Most studies performed to date have failed to demonstrate the efficacy of facilitated communication (Howlin 1997).

4. We may use the term crisis to designate a situation that lies outside the range of the experience and behavior of the individual up to that point in time and that cannot be resolved by any available strategy. *Crisis intervention* is the combined use of all suitable measures to end the crisis, or at least eliminate the acute danger. Crisis intervention measures must be applied quickly and specifically and are distinct from long-term methods of treatment and rehabilitation (Weber and Remschmidt 1997).

The most important indicators of prognosis are the state of language development and the level of intelligence in the fifth and sixth years of life. Autistic children who have developed language relatively well up to this point and are of relatively high intelligence (IQ > 80) have a more favorable prognosis, as long as further complications, such as epileptic seizures or other neurological problems, do not arise.

3.2.2 Atypical Autism

In children with atypical autism (ICD-10 classification: F84.1), some, but not all, of the characteristic features of early childhood autism are observed. The disorder is frequently not present from birth, but rather develops after an organic illness in the first few years of life (e.g. encephalitis). Most of these children are mentally retarded and display so-called autistic features, i.e. features also found in early childhood autism. These include: delayed language development, echolalia, delayed motor development, stereotypic movements, (often) attention disorders, and, to a variable extent, disturbances of social communication. Many of these children also have neurological abnormalities, which are often attributable to a concurrent neurological illness or to the residua of a past neurological illness. This subject is reviewed by Cohen and Volkmar (1997).

The treatment consists of two components: treatment of the underlying illness, when there is one, and modification of autistic behavior. If the underlying illness is progressive, as in tuberous sclerosis or other chronic progressive illnesses, effective treatment is scarcely possible. The behavioral-therapeutic approach to the autistic manifestations must also take the underlying illness into account. If additional behavioral abnormalities are present, neuroleptic medication may be required.

The prognosis is a function of the underlying illness, the severity of the intellectual impairment, and the severity of the autistic manifestations. If a progressive organic disease of the brain is present, the prognosis is unfavorable; in cases where a disease of the brain has reached a stable state (e.g. in the aftermath of encephalitis), the prognosis depends on the severity of the intellectual impairment.

3.2.3 Asperger Syndrome

Asperger syndrome (ICD-10 classification F84.5) can be regarded as an extreme variant of the schizoid personality structure. Children with Asperger syndrome have a less pronounced disturbance of interpersonal relationships than children with early childhood autism, and they are often of normal or above average intelligence. They come to attention later than children with Kanner syndrome, typically only when special demands are placed on their ability to integrate themselves into social groups, e.g. when beginning kindergarten or (at latest) primary school. The severity of the disorder is highly variable. A review is provided by Weber and Remschmidt (1997).

Language development occurs early. The children often begin to speak before they can walk freely and acquire a versatile language with a large vocabulary and neologisms. Their language is disturbed in its communicative function in a different way from that of children with Kanner syndrome; they talk whenever they want without adapting to their audience (spontaneous talk), and they often talk to themselves. They never show the characteristic disturbances of preverbal and verbal communication found in children with early childhood autism, but they do have comparable abnormalities of the speaking voice.

They are capable of original thinking and have good logical and abstracting abilities. They often have excessively intense, narrowly defined, and unusual

special interests. They sometimes have good lexical knowledge of specific areas, but they mostly just store up knowledge without organizing it into larger contexts. Despite their high intelligence, they often do badly at school, because (like children with early childhood autism) they have a marked disturbance of attention arising not from external, but from internal distraction, i.e. they are preoccupied with themselves. Their physical clumsiness is evident from an early age, and dyspraxic disturbances are also frequently observed.

Children with Asperger syndrome can cope with other people or social situations only to a limited extent. They are inconsiderate in the furthering of their own desires, they are often happy about others' distress, they have no feeling for personal distance, and they lack a sense of humor.

The diagnosis is made on the basis of history-taking, examination, and observation of behavior. Personal observations made outside the examining room are especially helpful. A meticulous psychological examination with consideration of neuropsychological aspects, cognitive functions and personality is very important for diagnostic classification. Problems of differential diagnosis arise with respect to the following disorders: early childhood autism, personality disorders secondary to organic brain insults, and specific personality disorders.

In the broader genetic circle of children of Asperger syndrome, some investigators have found an increased number of persons with similar or identical abnormalities of personality. An inherited factor is thus thought to be involved in the etiology of autistic psychopathy. Autistic personality disorder is explained as a disintegration of the intellectual and emotional areas of the personality, or as a disturbance of intuitive ability. Harmful substances in the environment and early organic brain insults are further (co-)factors in etiology.

The presumption that Asperger syndrome has a genetic basis does not preclude the possibility that it might be treated effectively. The most important persons in the lives of these children (parents and others) should be counseled as early as possible, so that further progression can be prevented to the greatest possible extent. Adequate counseling requires a thorough acquaintance with the personalities of children in general and of the specific child (patient) in particular, including his or her overall state of maturity. If secondary neuroses are present, psychotherapy with involvement of the parents may be necessary. Sensorimotor exercise therapy should be performed early to treat motor disturbances.

The prognosis is usually favorable. The older these children become, the better their social integration proceeds, because of their increasing intellectual maturity, their rational adjustment to people and situations, and the fact that communication on a rational level is easier among adults; some of these children also achieve an improvement in social maturity, after a delay. Most adults with this personality disorder become well integrated in an occupation, often a demanding one in which they perform at an above average level. Their interpersonal relationships remain difficult, however, particularly with their closest relatives. Many adults with severe Asperger syndrome remain aloof loners and adopt "outsider"-type occupations, which they change frequently.

3.3 Rett Syndrome

This syndrome has the ICD-10 classification F84.2, in the broader category of profound developmental disorders. It is classified analogously in DSM-IV.

This syndrome was originally described by the Austrian child psychiatrist Andreas Rett (1966). It occurs predominantly in girls and first appears between the 7th and 24th months of life, after previously normal (or nearly normal) development. Its characteristic manifestations are:

- total loss of goal-oriented use of the hands, accompanied by frequent episodes of hyperventilation;
- total or partial loss of language;
- regressive social development and play development in the first years of life;
- slowing of head growth, with severe and progressive intellectual impairment;
- peculiar, stereotypic "winding" movements of the hands;
- neurological manifestations such as truncal ataxia and apraxia, often in association with scoliosis and kyphoscoliosis;
- tooth-grinding; and
- in approximately 50% of patients, epileptic seizures after the 18th year of life.

The full clinical picture of the disorder has been observed to date only in girls. Its prevalence in the female population up to age 17 is approximately 1 in 10,000.

The cause of this syndrome is not yet known. Family studies and observations of a small number of twin pairs have led to the conclusion that the cause is, at least in part, genetic. Cases of this syndrome in combination with other disorders suggest that what is inherited is not the classical phenotype of Rett syndrome itself, but rather a particular pattern of neuropsychiatric impairment that progresses until adolescence. Morphological and histological studies have shown that the cerebral development of patients with Rett syndrome is abnormal in a way that suggests a genetically transmitted neurodegenerative disorder.

The diagnosis is made on the basis of the clinical manifestations and can be assigned fairly securely in the first 3 to 5 years of life, as long as the diagnostician is acquainted with the syndrome. Its diagnostic differentiation from other neurodegenerative disorders requires a meticulous neurological examination, EEG, and computed tomography of the brain, as well as laboratory studies to rule out disorders of amino acid, lipid, and polysaccharide metabolism. The EEG during stage II sleep often reveals spike-discharges in the central and centroparietal regions.

The differential diagnosis of Rett syndrome first requires its differentiation from early childhood autism. A number of metabolic disorders must also be ruled out, as well as epilepsy as an independent disorder.

Treatment directed at the cause of the disorder does not yet exist, nor is there any way of arresting its progression. Emphasis is thus placed on symptomatic measures intended to achieve the following goals:

1. Education of parents and other involved persons about the nature of the illness.
2. Facilitation of nonverbal communication.
3. Medical treatment of epileptic seizures (Uldall et al. 1993).
4. Medical treatment of behavioral abnormalities (Zappella et al. 1990).

The prognosis is unfavorable, as the disorder is characterized by a steady intellectual decline and progression of the neurological abnormalities until puberty. It seems to remain relatively stable thereafter.

3.4 Disintegrative Disorders

The disintegrative disorders are also classified among the profound developmental disorders, both in ICD-10 (F48.3) and in DSM-IV.

The prototype of childhood disintegrative disorders is Heller's infantile dementia, described by Theodor Heller in 1908. All of these disorders are characterized by a loss of previously acquired abilities and skills after a period of normal development. Their most conspicuous manifestations are the loss, or progressive decline, of language and of intellectual, social, and communicative skills.

The age at which manifestations usually appear is between the 2nd and 4th years of life. The disorder usually begins insidiously. The children become mildly irritable and withdrawn, can no longer make themselves understood through speech, have disturbances of memory and perception, are anxious or aggressive, can no longer cope with social situations, often lose already acquired bladder and bowel control, and develop stereotypic movements, until the fully developed picture of a dementia emerges. The behavioral withdrawal and impaired communication skills sometimes create the impression of autism. It is noteworthy that the facial features of these patients do not become coarsened, despite their often severe dementia; this phenomenon is known among German-speaking child psychiatrists as the *Prinzengesicht* ("princely face").

This is a very rare disorder affecting an estimated 10 per million children. According to Gilberg (1995), children with disintegrative psychoses (Heller syndrome) make up about 1% of all patients in the spectrum of autistic disorders. The sex ratio of affected boys to girls is 8:1.

The etiology of this disorder remains unknown. An organic cause in the brain is presumed because of the characteristic course (onset of the dementing process between the 2nd and 4th years of life). A study of 76 cases by Volkmar (1992) revealed that the illness begins between the 2nd and 3rd year in 40% of cases, and between the 2nd and 4th year in 80%. Further evidence for an organic etiology is provided by the frequently observed EEG abnormalities and the presence of seizures in just over 50% of patients.

The diagnosis is usually made on the basis of the characteristic clinical manifestations. This disorder must be distinguished from early childhood autism and Rett syndrome.

There is no etiologically directed treatment to date. The treatment consists of measures that make it easier for the patient's family and others to deal with the disorder, and that protect the patient from further injury.

The prognosis of this disorder is unfavorable. Its inexorable downward course cannot be influenced by any currently available therapy.

3.5 Expressive Language Disorder

In ICD-10, expressive language disorder (F80.1) is listed among the specific developmental disorders of speech and language (F80), as is receptive language disorder. In DSM-IV, both disorders are subsumed under the designation "communication disorder."

Children with expressive language disorder display a discrepancy between their impaired ability to use spoken language and their otherwise normal, or nearly normal, intellectual ability. Language comprehension is normal in this disorder (unlike receptive language disorder). The disorder becomes apparent during language acquisition when the children remain unable to produce individual words or sounds, which results not only in a temporal delay, but also in a qualitative abnormality of language development. This qualitative abnormality is already manifest in the first and second

years of life when the child's first words are unintelligible, and continues as an inability to produce simple two-word sentences at the age of 3, marked uncertainty over the choice of words used to designate an object or to describe a situation, poverty of vocabulary, and abnormalities of sentence length, syntax, and grammar (Bishop 1994; Remschmidt, in press).

The following criteria are obligatory for the diagnosis:

1. The expressive speech disturbance must be significantly worse than the child's overall cognitive level.
2. Language comprehension must be within the normal range for age.
3. Nonverbal communication by means of facial expression and gestures must not be disturbed, as reflected above all by the child's attempts to compensate for his limited linguistic ability through nonverbal communicative gestures.

As in receptive language disorder, the language abnormalities of expressive language disorder are often accompanied by additional emotional and behavioral disturbances that are not specific to the disorder, but rather belong to the individual child's repertoire of reaction patterns. Aggressive and defiant behavior, depressive reactions and social withdrawal, attention disorders and hyperactivity are often seen.

These disorders must be distinguished from other disorders that are associated with expressive language disorder at a rate higher than chance would predict, including dyslexia and early-onset disorders of articulation.

3.6 Receptive Language Disorder

Receptive language disorder (ICD-10 classification: F80.2) is classified in both major systems in a manner analogous to expressive language disorder.

Children with receptive language disorder are characterized by a significant discrepancy between their language comprehension and their cognitive level. Parents become aware of the disorder when the child fails to react to simple vocal expressions or to commands expressed in language, despite normal, or nearly normal, overall development. The deficient comprehension of language naturally results in a failure of normal language development, so that expressive language is nearly always impaired as well. This manifests itself in disturbances of word and sound production.

As early as the first year of life, it becomes apparent that these children, once they emerge from the normal babbling phase, produce only more or less unarticulated sounds and cannot understand their parents' onomatopoeic expressions or simple verbal commands. In the second year, they are unable to name objects or follow simple commands, unless these are underscored by gestures or by corresponding eye contact. In the third and fourth years, they cannot adequately understand the grammatical structures of language (questions, negations, comparisons), nor can they understand the facial and gestural expressions accompanying speech (Bishop 1994; Remschmidt, in press).

Because these children nearly inevitably have difficulty in understanding and being understood, a number of behavioral abnormalities arise, including hyperactivity, attention disturbances, aggressive behavior, fearfulness, isolation, and rejection by peers.

The cause of this disorder usually lies in an organic brain disturbance that must be presumed in most cases and can only rarely be identified. In many cases, a number of other organic abnormalities accompany the disorder.

The diagnosis and differential diagnosis of receptive language disorder are made by means of a meticulous history and a comprehensive neurological and neuropsychological examination. Hearing must be tested next, as well as language comprehension and, where applicable, the auditory discriminating capacity for speech-related sounds. The performance of an EEG serves either to rule out epilepsy or to give evidence for hypersynchronous activity, and neuroimaging techniques (computed tomography, magnetic resonance imaging) can be used to detect structural brain anomalies. Particular attention is paid to a careful assessment of language comprehension and of language production, which is usually poorly differentiated. The prognosis depends largely on the level of language development.

The differential diagnosis of receptive language disorder includes early childhood autism, which can be excluded relatively easily if its other characteristic symptoms are absent. A further entity to be excluded is Landau-Kleffner syndrome (acquired aphasia with epilepsy).

Because no treatment directed at the etiology of the disorder is currently available, therapy consists of the following symptomatic measures:

1. Parents and other persons in the child's environment should be thoroughly informed about the nature of the disorder and the fact that secondary behavioral abnormalities often arise as a result of the impairment of verbal communicating ability.
2. If the child is cooperative or can be taught to cooperate, exercises can be used to extend his or her repertoire of sounds and words, in small increments.

3. Opportunities should be created for the stimulation of speech and the promotion of nonverbal communication, if verbal communication is massively impaired.
4. In speech therapy, the emphasis is no longer placed on highly structured exercises and rigidly applied treatment programs based on imitation, because it has been found that children do not remain motivated to continue with such exercises in the intermediate term, and that the patterns of communication acquired and practiced during the exercises are difficult to transfer to everyday, real-life situations. Thus, attempts are increasingly being made to incorporate elements of verbal communication, and practice of these elements, into normal play situations.
5. The introduction of sign language is recommended only if the child has a severe hearing impairment and can therefore not be expected to achieve adequate speech comprehension and production.

In half of all cases, the outcome is unfavorable, with persistent disturbance of language comprehension and inadequate acquisition of expressive language. The secondary consequences for the affected persons are a lack of satisfactory friendships and partnerships, and increasing social non-integration and isolation.

3.7 Landau-Kleffner Syndrome

Landau-Kleffner syndrome is listed in the ICD-10 among the specific developmental disorders of speech and language (classification: F80.3).

This illness consists of a predominantly receptive disturbance of language that first manifests itself at the age of 3 to 6 years along with the simultaneous appearance of epileptic seizures or of hypersynchronous EEG activity (Aicardi 1992). It may begin suddenly or insidiously and is at first characterized by a marked disturbance of language comprehension, which is usually followed by a disturbance of verbal expression.

It is understandable that children suddenly or gradually confronted with a deterioration of their comprehension of language and of their ability to speak react with emotional and behavioral abnormalities. These may appear in the form of depressive reactions, extreme fearfulness, or aggressive or defiant behavior, and create further problems for treatment.

The prognosis of this illness is unfavorable and its major manifestations persist despite the occurrence of repeated, but transient, episodes of improvement. The earlier the disorder arises, the less favorable its course (Bishop 1985). Thus, children in whom Landau-Kleffner syndrome becomes apparent before the fifth year of life have considerable problems with language comprehension lasting into adulthood, despite intensive efforts to improve the situation through therapy. It has also been found that anticonvulsive drug therapy, though it may prevent seizures and improve the EEG pattern, does not lead to a significant improvement of language functioning (Deonna et al. 1995).

The cause of the disorder is currently unknown. An organic etiology is assumed because of the characteristic pattern of manifestations and the accompanying abnormal EEG activity. The disorder has no known genetic basis.

The diagnosis is usually made on the basis of the typical history, the clinical manifestations, and the EEG findings. History-taking often reveals that the decline of language expression was preceded by a phase of abnormal behavior reflecting a disturbance of language comprehension. Many children with Landau-Kleffner syndrome may be thought to be deaf once the full clinical picture develops; for this reason, a hearing examination is urgently indicated.

It may be difficult to distinguish Landau-Kleffner syndrome from the disintegrative disorders of childhood, because a phase of normal development precedes the onset of both disorders. The differential diagnosis is established on the basis of the epileptic seizures and the characteristic bitemporal EEG abnormalities seen in Landau-Kleffner syndrome. Early childhood autism differs from Landau-Kleffner syndrome in that it is present from the earliest stages onward and has characteristic manifestations that are not found in Landau-Kleffner syndrome.

This illness, too, has no etiologically directed treatment, though the epileptic seizures may be alleviated by appropriate medication. Parents and other persons in the child's environment must be educated about the nature of the disorder so that they may better understand not just the underlying disease, but also the secondary behavioral abnormalities that result from it.

The epileptic seizures require treatment; carbamazepine in age-appropriate doses has been found to be useful. Such treatment generally does not improve language function, nor does it eliminate abnormal EEG activity. There is as yet no conclusive evidence in favor of corticosteroid treatment, but a trial of such treatment seems to be indicated in the early stage of the disease (Lerman et al. 1991).

3.8 Specific Disorders of Reading and Spelling (Dyslexia)

The specific disorders of reading and spelling (dyslexia) are classified in the ICD-10 among the specific developmental disorders of scholastic skills (F81). This heading covers the following disorders: specific reading disorder (F81.0), specific spelling disorder (F81.1), specific disorder of arithmetical skills (F81.2), mixed disorder of scholastic skills (F81.3), other developmental disorders of scholastic skills (F81.8) and unspecified developmental disorder of scholastic skills (F81.9).

The hallmark of specific reading disorder is a major, specific impairment of the development of reading ability that cannot be attributed to mental retardation, a sensory deficit, or the consequences of an illness. Reading difficulties are often the result of developmental disorders of speech and language. Reading disorder is often accompanied by spelling disorder, which is why the two disorders are commonly designated together as reading/spelling disorder (dyslexia). At later ages (e.g. in adolescence and adulthood), the spelling deficits are generally more severe than the reading deficits. Specific diagnostic criteria include the following:

- reading performance significantly below the norm for age (e.g. 1.5 to 2 standard deviations below the norm), which cannot be attributed to mental retardation,
- spelling performance that is below the norm to a comparable degree,
- the occurrence of developmental speech disorders in preschool age,
- an IQ over 70 and
- normal school experience.

The impairment in the development of reading skills manifests itself mainly in the following ways: the omission, substitution, or jumbling of words, low reading speed, difficulty starting to read aloud (long pauses or losing one's place in the text), incorrect parsing, exchanging of words and deficient reading comprehension, and an inability to reproduce verbally what has been read, or to draw conclusions or instructions for action from it.

The clinical picture of spelling disorder involves various types of errors that are not specific to this disorder, e.g.: the turning around and omission of letters, introduction of letters in the wrong place, and incorrect ordering of letters. The errors are inconstant, i.e. the same word is written with different mistakes at different times (Maughan and Yule 1994; Remschmidt, in press; Warnke and Roth 2000).

Children with reading/spelling disorder characteristically have a number of other disturbances: abnormal language development can be demonstrated in roughly 60%, one third have attention deficits and hyperactivity, and 5% to 10% have visual or visuomotor abnormalities. Secondary problems resulting from reading/spelling disorder include disturbances of learning and performance behavior, emotional disturbances, impaired concentration and hyperactivity, psychosomatic symptoms (headache, stomachache, and nausea, particularly before tests in school), depressive mood abnormalities and conduct disorders. The disorder is significantly more common in boys than in girls (sex ratio approximately 2:1). Its prevalence is approximately 6% to 7% in the second and third grades and 8% in a representative population of schoolchildren up to 18 years of age (Remschmidt and Walter 1990a,b).

Although many studies have been performed on the question, the etiology of reading/spelling disorder remains unknown. A number of hypotheses have been advanced (cf. Warnke and Roth 2000) that are not mutually exclusive, each of which can be supported by a certain amount of evidence:

1. The hypothesis of a genetic etiology is based on the increased frequency of reading/spelling disorder in certain families, and on the findings of twin studies. Both types of findings imply the existence of an important genetic factor. The results of more recent studies suggest that reading/spelling disorder and its component disorders may be traced to abnormalities in a single gene. There is already a replicated finding that reading/spelling disorder may be linked to a particular chromosome.
2. The hypothesis of a disturbance of information processing is based on findings concerning the processing of both verbal and visual information. As for the former, it is known that as many as 60% of children with reading/spelling disorder suffer from disturbances of language development that involve various aspects of language acquisition (deficient phonological awareness, impaired auditory discrimination, difficulty in the storage and reproduction of verbal material). As for the latter, children with reading/spelling disorder cannot process visual information adequately, as normal children can. They need more time to perform the same tasks, and their performance often differs qualitatively as well, as can be demonstrated by differences in evoked potentials. These findings may be interpreted as implying a disturbance of the temporal dimension of information processing.
3. Hypotheses of abnormalities in brain structure and function are based on the following arguments: A number of studies have shown that the planum temporale, an important structure in human language development, is of comparable size in the two

hemispheres in persons with reading/spelling disorder, though it is larger on the left side in the great majority of normal persons. One may, therefore, conclude that the normal cerebral asymmetry fails to develop to an adequate extent in persons with dyslexia. Furthermore, autopsy studies have revealed histological abnormalities and abnormalities of vascular supply in the brains of patients with dyslexia. Studies employing evoked potentials have revealed both temporal and qualitative abnormalities of information processing in the brain of dyslexics. Finally, some children with reading/spelling disorder also have significant disturbances of attention, which mainly relate to selective, i.e. directed, attention, rather than to long-range attention.

The disorder is diagnosed on the basis of meticulous history-taking, clinical examination, and psychological testing. During history-taking, particular attention must be paid to language development in the preschool years and to the possible occurrence of reading or spelling difficulties in other members of the family. The clinical psychiatric and neurological examination is directed toward additional manifestations and neurological findings. Clinical examination should also include auditory and visual testing, and testing of other sensory modalities. Finally, psychological testing is performed in order to assess reading and spelling ability in a standardized fashion, as well as calculating ability (important for differential diagnosis).

Reading/spelling disorder must be differentiated from the following other disorders: a disturbance of reading and spelling secondary to low intelligence; acquired dyslexia or alexia; an acquired disturbance or reading and spelling resulting from an emotional disorder; and specific spelling disorder without impairment of reading (F81.1).

The treatment of reading/spelling disorder consists of three types of intervention (Warnke 1987; Warnke and Niebergall 1997):

- functional therapy of reading and spelling,
- helping the child cope with the disorder mentally and emotionally, and
- treatment of secondary mental manifestations with inclusion of family members and other persons in the child's environment, possibly with support from the child's school.

The individual German federal states formulated specific guidelines and directives for assistance to children with reading and spelling disorders in response to a recommendation issued on 20 April 1978 by the conference of German ministers of education and cultural affairs. These guidelines and directives differ in detail, but all share the following elements (Warnke and Roth 2000):

- All children with reading/spelling disorder have a right to scholastic assistance, e.g. through special classes or individual attention.
- Spelling performance must not play a decisive role in promotion or non-promotion to the next grade, in transfer to a special school, or in the transition from primary to secondary school.
- Spelling mistakes must not be considered in the grading of written assignments, such as essays, that are not specifically intended as spelling tests.

Most of the German states also allow the option of not grading spelling performance.

There is no medication that has a specific influence on reading/spelling disorder, but medications are occasionally useful for the treatment of additional and secondary disturbances. Antidepressants, for example, have been found useful for the treatment of accompanying depressive manifestations. The use of stimulants can be considered when dyslexia is coupled with a hyperkinetic syndrome. Treatment with nootropic agents is controversial. A number of findings suggest that children treated with these substances read more rapidly and accurately and have a better verbal memory performance (Wilsher 1986).

An uncompensated reading/spelling disorder is a major risk factor for additional mental disturbances, antisocial behavior, and possible failure of vocational development. Various studies have found that 25% to 75% of juvenile delinquents suffer from specific learning disorders, most commonly dyslexia. Approximately 30% of children with reading/spelling disorder manifest behavioral abnormalities (Rutter et al. 1970, 1976); the corresponding figure for adolescents is 50% (Korhonen 1984). The prevalence of reading/spelling disorder among prison inmates is also notably high (Weinschenk 1965).

Only 20% to 25% of children with reading/spelling disorder achieve age-appropriate spelling performance during the primary school years, and only 4% of children with severe dyslexia achieve normal spelling performance (Watson et al. 1982).

3.9 Specific Disorder of Arithmetical Skills

This disorder, too, is classified in ICD-10 under the specific developmental disorders of scholastic skills (ICD classification: F81.2).

The specific disorder of arithmetical skills – which we will refer to here as arithmetical disorder – is characterized by a marked impairment of arithmetical ability lying well below the child's general intelligence level. A discrepancy of at least 1 or 1.5 standard deviations, or of 12 *t*-value points, is generally required for the diagnosis. The disorder becomes

apparent in the early school years (no later than the fifth school year) and is often found in association with developmental disorders of speech or language, of motor function, or of visuomotor function. These children can read and spell normally, and their inability to calculate is a more or less isolated weakness within the overall performance profile. These children manifest additional social or emotional behavioral abnormalities, which may often be secondary consequences of the arithmetical disorder. The ICD-10 diagnostic guidelines require that impairment of arithmetical skills should not be attributable to lack of training, visual or auditory deficits, or neurological illnesses.

The manifestations of arithmetical disorder are variable, because different components of calculating ability can be affected to differing extents. There may be disturbances of spatial representation and spatial thinking, a lack of understanding of mathematical terms or signs, difficulty in arranging numbers in the right order, a diminished capacity for abstraction, etc. (Remschmidt, in press). In everyday life at school, the disorder manifests itself in deficient or unsatisfactory performance on arithmetical tasks, while performance in other areas is at a normal level.

The prevalence of arithmetical disorder not associated with other developmental and learning disorders is estimated at 1% among children. If one includes cases that are associated with disorders of these types, its prevalence lies between 4% and 6%. From the educational point of view, approximately 15% of schoolchildren require special help with arithmetic (Warnke, in press). The disorder seems to be more common in girls. These epidemiologic data should be used with caution, however, because studies of unselected population samples are not yet available.

The etiology of arithmetical disorder (not related to lack of training or to neurological disease) remains essentially unknown. Its common association with other developmental disorders implies that various cerebral processes become impaired in the course of development. It is still unclear to what extent genetic factors may be involved.

The diagnosis is made on the basis of the history, clinical examination, psychological testing and, where appropriate, neuropsychological assessment. Intelligence testing is mandatory, as is the application of age-specific tests of arithmetic and spelling. Furthermore, language development, motor development, visuomotor function and attention should be specifically tested in every case. Finally, emotional and other problems should be explored, and the family background should be evaluated, as part of the diagnostic process.

As for differential diagnosis, arithmetical disorder must be distinguished from difficulty with arithmetic in the context of mental retardation, neurological disease, lack of training, neglect, and other psychiatric disorders (e.g. obsessive-compulsive disorder, depression, anxiety disorders). Difficulty with arithmetic may occur as a reaction to experiences of failure in arithmetic that then engender severe performance anxiety, so that the difficulty perpetuates itself.

The appropriate treatment consists of functional therapies performed on an outpatient basis and based on a meticulous analysis of the deficient components of the calculating process. Three specific areas are addressed:

- preconditions for adequate performance of arithmetical tasks: spatial representational ability, the concept of quantity, the capacity for abstraction and other basic underlying abilities;
- the type of error made while calculating (e.g. reading errors, orthographic errors, errors when writing numbers); and
- calculating strategies, i.e. the systematic application of basic abilities so that the correct answer is obtained. More complex problems can be solved in various different ways, which should first be illustrated individually with concrete examples, and then practiced in abstract form.

The child's motivation to undergo functional therapy is extremely important, as success is achieved slowly and in small steps.

3.10 Hyperkinetic Conduct Disorder

Hyperkinetic conduct disorder (ICD-10 classification: F90.1) is coded in ICD-10 as a subcategory of the hyperkinetic disorders (F90). In DSM-IV, various subcategories of hyperkinetic disorder are coded under 314.xx (attention deficit hyperactivity disorder), and – in contrast to ICD-10 – there is no mixed category for the combination of hyperkinetic disorder with a conduct disorder.

Hyperkinetic conduct disorder is characterized by the cardinal manifestations of hyperkinetic disorder – attention deficit, motor hyperactivity and, in some cases, marked impulsiveness – and additionally by the antisocial, aggressive, and rebellious behavior typical of conduct disorders.

The attention deficit manifests itself in the premature termination of tasks and activities. The children appear to lose interest in tasks easily because they are distracted by other stimuli. Motor hyperactivity involves not only a compelling inner drive toward movement, but also an excessive restlessness that is particularly evident in situations demanding relative tranquillity. This feature is found above all in structured situations requiring a large measure of self-control.

Impulsiveness, i.e. an inclination toward excessively rapid and poorly thought out activity, appears in everyday life and particularly in situations in which performance is demanded. In school and other performance situations, these children have an "impulsive working style," i.e. they have trouble waiting their turn, and they interrupt others and shout out their responses without fully answering the question asked. Impulsiveness is not only the manifestation that appears regularly in the greatest number of situations, but also the one that persists for the longest time over the course of development (as these children grow older). Not least, the impulsive behavior of these children, in combination with their antisocial, aggressive, and rebellious behavior, often leads to difficulties and rejection in the social sphere.

The available epidemiological data concerning the frequency of the overall group of the hyperkinetic disorders are highly divergent. All in all, it is thought that some 3% of school-age children suffer from a disorder of this type. Boys are significantly overrepresented; the ratio of affected boys to girls is approximately 3:1, in clinical studies as high as 6:1 or 9:1.

No single cause of hyperkinetic disorder has been discovered, though many possible etiological factors have been discussed. Constitutional factors, i.e. genetic predispositions, seem to play a decisive role. On the other hand, the severity and long-term course of the disorder and the nature of the accompanying manifestations seem to depend very strongly on environmental influences. This is particularly true of hyperkinetic children with conduct disorder.

The task of diagnosis presents considerable difficulties. The main reason for this is that the manifestations of the disorder are many and varied; a further reason is that they are situation-dependent and thus subject to fluctuation. The developmental dimension must also be taken into account in the diagnostic process, because the normal degree of motor activity varies in close relation to a child's age and stage of development. Not least, normative conceptions also play a role in the labeling of a child as "abnormal." Because of all of these problems, the diagnostic process should be carried out as thoroughly and comprehensively as possible, with attention to all of the relevant dimensions.

As far as differential diagnosis is concerned, it must be borne in mind that abnormalities on the basis of comorbid disorders may be found. In particular, the differentiation of hyperkinetic conduct disorder from the conduct disorders proper presents major difficulties. The creation of a special category for the area of overlap between hyperkinetic disorders and conduct disorders is a product of this state of affairs. Aside from conduct disorders, other possible comorbid disorders include affective disorders, anxiety disorders and specific learning disorders.

The many and diverse therapeutic approaches that have been tried are an indication that the treatment of this disorder must be multidimensional and multimodal. There is no single therapeutic measure that is effective by itself in the treatment of hyperkinetic disorders. This fact has led to the formulation of treatment programs that contain a variety of different elements and are flexible enough to be tailored to the individual needs of each patient.

Pharmacotherapy may play an important role, depending on the severity of the disorder. The use of stimulants (methylphenhydate, dextroamphetamine) is the major form of drug treatment. Antidepressants (e.g. imipramine) and neuroleptics have also been tried. It has been demonstrated that treatment with stimulants can alleviate the specific hyperkinetic manifestations (e.g. the attention deficit) but cannot eliminate the conduct disturbance. Stimulants are ineffective in 10% to 15% of hyperkinetic children and lose their effect after 6 months in a further 20%. In approximately 40% of children, the treatment can be discontinued after 1 or 2 years without return of manifestations to any marked degree. Pharmacotherapy can never be used as the sole form of treatment. It meets the objective of enabling these children to cope with an important stage of their development, but does not eliminate the disorder or affect its underlying causes.

Pharmacotherapy is often combined with behavior therapy. Operant techniques have proved useful not only in the form of programs and written instructions, but also as aids to orientation in everyday activities and in parent counseling. Self-instruction training is an attempt to improve the capacity for self-control by systematic verbalization and practice of instructions for dealing with problem situations. Social competency training is intended to make the child behave toward others in a better adapted and more socially acceptable way, and thereby stabilize the child's emotional well-being.

Emotional stabilization is further promoted by functional therapies that alleviate deficits of learning and performance and thereby increase self-esteem.

Finally, working together with the child's parents is an important part of treatment. This is not merely a matter of educating the parents thoroughly about the disorder. The parents' perception of the child, which is usually very strongly fixated on his or her inappropriate behavior, must also be changed.

Contrary to the previously widespread notion that children "grow out of" hyperkinetic disorders when they reach puberty, it is now known that at least three quarters of affected persons go on to have further difficulties in school and vocational training, in the family, and in general social adjustment. This state of affairs continues even into adulthood. At least 60% of affected young adults still have manifestations of the

disorder. Particularly at risk are those with low intelligence, low socioeconomic status, and a high degree of aggressiveness. Limited social contact with peers, emotional instability and, above all, psychopathological abnormalities in parents also confer a poor prognosis. The affected individuals are especially at risk for addiction and delinquency and show higher rates of these problems than other persons in comparable age groups.

4 Developmental Disorders

As explained above in Sect. 2, behavioral changes occurring over the course of time, including developmental processes, are partly under biological control and are thus normally subject to wide variation. Observation is indicated when a child's developmental progress is at the border of the normal range. Conditions lying outside this range are considered pathological. This remains true even when it is certain that such partial developmental delays will be fully compensated in the intermediate term without external support. Such delays can transiently impair the interplay of the affected function with other developmentally relevant functions, or they can cause other persons to perceive the child or adolescent so differently that they no longer place age-appropriate demands on him or her.

Developmental disorders are quantitative or qualitative deviations from behavior that is expected in normal development. They most often resolve spontaneously in the intermediate term, but they may nevertheless permanently affect the overall development of an individual, either directly or indirectly (i.e. through the behavior of other persons).

The pathogenetic basis of developmental disorders is usually biological. Familial clustering of certain developmental disorders and their more common occurrence in boys lead one to suspect a genetic component. Delays of cerebral maturity are also a possible pathogenetic mechanism and are mainly attributable to impairments or illnesses of the immature central nervous system. Developmental disorders cannot manifest themselves before the expected developmental appearance of the function in question; thus, their onset is usually tightly coupled to the time of appearance of rapidly developing functions.

Functions of this type are especially susceptible to outside influence and also especially dependent on support from the environment. Their development also depends on the individual's motivation to learn. Lack of support, disturbing external influences, or conflicting motivation can promote the emergence of a developmental disorder. The determination of pathogenesis is generally difficult in the individual case. Medicolegal questions about the origin of bedwetting or of an attention disorder, for example, cannot be definitively answered; often, one can only say that there is no single underlying cause.

The course of developmental disorders is usually favorable. Some, however, persist because a partial developmental delay becomes fixed and autonomous, while others are prolonged because the disorder creates a gain of some type for the individual. The risk that the disorder will become fixed is higher if it includes behavior that deviates from the norm not just quantitatively, but also qualitatively. In a small number of cases, persistence of a "developmental" disorder is actually due to misdiagnosis of a condition more correctly interpreted as an age-specific disorder with an open prognosis or a tendency to persist (see Sect. 5).

4.1 Disorders of Motor Development and Articulation

In the specific developmental disorder of motor function and in specific speech articulation disorder (ICD-10 classifications: F82 and F80.0, respectively), the developmental level of coarse and fine motor function, or of articulation, deviates from the attained developmental level of cognitive function. The corresponding perceptual functions are always involved as well, e.g. kinesthetic sense or auditory discrimination. The major manifestation of the motor disorder is a slowed performance of complex tasks requiring a high degree of coordination, such as climbing stairs with one foot after the other, tying knots, balancing, riding a bicycle, eating with knife and fork, writing and drawing. Often, too much or too little force is applied for the proper performance of the task. In the articulation disorder, sounds are not acquired at the usual times or in the usual order. Omissions, distortions, and substitutions occur which may make the patient's speech difficult to understand. The two disorders frequently occur together.

Boys are affected more often than girls. The six-month prevalence of these disorders in primary-school age has been reported as 1.5% for the motor disorder and 5% for the articulation disorder; the prevalence is higher in younger age groups.

The fact that these disorders occur with familial clustering implies that they have a genetic component, while the fact that they improve with increasing age implies the involvement of maturational processes. Organic brain disorders seem to make these disorders more likely to occur. Practice seems to play no role in the motor deficit, as practice can speed up motor function only slightly. Articulation disorders are more likely to occur when the child learns to speak from bad models in the environment, or when there are distur-

bances of auditory discrimination and sequential stimulus processing.

Neurological illnesses, sensory deficits, mental retardation and lack of external support must be excluded in the differential diagnosis. The diagnosis of disorders of motor development and articulation requires that they manifest themselves at the time of the expected appearance of the function in question. "Soft" neurological signs and delayed maturation of background EEG activity are common, but not obligatory for the diagnosis. The diagnosis is supported by the occurrence of other cases in the family. Articulation disorders are not diagnosed as an independent entity when they occur as accompanying manifestations of expressive or receptive language disorders. The diagnosis is based on a major discrepancy between motor function or articulation and the child's intellectual level.

Functional therapy is the usual form of treatment; its effectiveness is better documented for articulation disorders than for disorders of motor development. The prognosis for spontaneous improvement is much better than that of the specific developmental disorders of speech or written language (Esser 1991). Comparative longitudinal studies of the effect of treatment are lacking; indeed, even the "spontaneous" remissions seen in cohort studies mostly took place after functional therapy.

4.2 Stereotyped Movement Disorders and Transient Tic Disorders

Stereotyped movements (ICD-10 classification: F98.4) are nonfunctional, voluntary, repetitive, often rhythmic movements of a single type. Tics (ICD-10 classification: F95.0) are repetitive, sudden, quick, nonrhythmic movements of specific muscle groups; the most common transient tics are blinking and grimacing. Tic disorders are of age-specific onset and are accordingly discussed in Sect. 5.2. Both types of disorder usually appear in preschool age and affect approximately 3% of this age group. Children who are mentally abnormal in other ways often develop stereotyped movements with self-injurious behavior. Stereotyped movements not involving self-injurious behavior generally remit when the children reach school age (Werry et al. 1983).

Stereotyped movements occur under conditions of either decreased or increased stimulation; transient tics occur spontaneously, although they may be reinforced by stress. The most common stereotyped movements are head-tossing and body-rocking (often before falling asleep); nail-biting and thumb-sucking are also common. Pulling out hair and eyelashes is a disorder of impulse control. Stereotyped movements are often components of other illnesses (e.g. autistic syndromes) and, in such cases, are not diagnosed as a separate entity.

4.3 Pica and Rumination

Pica and rumination (ICD-10 classifications: F98.3 and F98.2) are rare eating disorders of childhood consisting of the regular eating of inedible substances (pica) or the regurgitation of swallowed food (rumination). Rumination is closely related to the stereotyped movement disorders. Pica is more common in mentally retarded or neglected children, and also in those with iron-deficiency anemia (Parry-Jones and Parry-Jones 1992).

4.4 Sleep Terrors, Sleepwalking, and Nightmares

Sleep terrors (ICD-10 classification: F51.4, also called "pavor nocturnus") are found in approximately 4% of preschool children. These children awaken during the first third of the night (sleep stage III or IV) with signs of panic, increased motor activity, high levels of autonomic discharge, and disorientation that may last several minutes. They have no recollection of the event afterwards. Lack of recollection of the event also characterizes sleepwalking (ICD-10 classification: F51.3), a disorder whose prevalence reaches a peak in the 12th year of life. Children with this disorder arise from bed in the first third of the night (sleep stage III or IV), occasionally several times per night. While they are walking around, they are poorly responsive and their behavior is difficult to influence, and they have a fixed facial expression and an empty gaze. They are briefly disoriented afterwards. In nightmares (ICD-10 classification: F51.5), vivid dreams occurring during REM-sleep in the last third of the night – or even during daytime sleep – lead to anxiety and a feeling of danger. Recollections of nightmares are vivid and plastic and arouse the fear that they will return, possibly leading to difficulty falling asleep (Clore and Hibel 1993).

Disturbances of maturation of the central nervous system are thought to be responsible for sleep terrors and sleepwalking, and special features of emotional development are thought to be responsible for nightmares. Traumatic experiences are thought to cause nightmares in only a small minority of cases.

Disturbances of maturation are characteristic and easily diagnosed from parents' descriptions. As for differential diagnosis, nocturnal seizures can be ruled out by sleep EEG, and, in case of doubt, by investigation in a sleep laboratory.

These childhood parasomnias have a favorable prognosis. Sleep terrors frequently become transformed into sleepwalking as the child enters school age. Sleepwalking rarely persists and, when it does, usually in combination with major psychopathology. Parent education is mandatory in sleepwalking to prevent injury to the children. The rare persistent forms of sleepwalking may be treated with tricyclic antidepressants. In children with nightmares, the child's fear that the bad dreams will return may require treatment.

4.5 Enuresis and Functional Urinary Incontinence

These disorders, subsumed under the heading of nonorganic enuresis (ICD-10 classification: F98.0), require further differentiation. Two forms of primary enuresis (failure of bladder control) may be distinguished: an isolated and a combined form.

In the isolated (monosymptomatic) form, large volumes of urine are voided during non-REM sleep in the first few hours after falling asleep. The affected children are not awakened by the elevated intravesical pressure and are also difficult to awaken by other means. This isolated, primary nocturnal enuresis tends to occur in families. In the combined form of the disorder, diurnal enuresis often occurs in parallel with symptoms of functional urinary incontinence, encopresis, and other mental abnormalities, and in contrast to the isolated form, bedwetting may occur several times per night. Bedwetting is a stimulus that awakens the child (von Gontard 1998). The primary form accounts for almost one third of patients seen in clinical practice, and secondary nocturnal enuresis for a little more than one quarter.

In secondary enuresis, bedwetting returns after an interval of good bladder control lasting more than 6 months. It is often associated with daytime urge incontinence, and with mental abnormalities of a mainly extroverted type; familial occurrence of enuresis is common. The six-month prevalence of nocturnal enuresis is 15% among 5-year-olds, 8% among 8-year-olds, and 3% among 13- to 15-year-olds. After puberty, boys are affected nearly exclusively; until puberty, the ratio of boys to girls is 2:1.

Pure diurnal enuresis is rare and is almost exclusively due to functional urinary incontinence (Hjälmas 1992), which occurs somewhat more commonly in boys than in girls, at a rate of 5% among 7-year-olds and 1% among adolescents. Pure urge incontinence predominantly affects girls (van Gool 1989). The frequent bladder emptyings in this disorder are of only about 60% of the total bladder capacity, yet no delay can be tolerated. Fatigue exacerbates the symptoms. Bladder-holding cannot prevent the release of small quantities of urine. Urge incontinence often occurs in combination with secondary nocturnal enuresis. A large fraction of children with functional urinary incontinence are incontinent during the day because of deliberate postponement of urination; the urinary volume is elevated, and bladder-holding is common. This disorder is more common in boys than in girls, often combined with encopresis and constipation, with incomplete bladder emptying, and with psychiatric comorbidity (also with extroverted manifestations) (von Gontard et al. 1998).

A small subgroup of children with functional urinary incontinence suffer from incoordination of the detrusor and sphincter musculature. Inadequate sphincter tone prolongs the time needed for bladder emptying and makes it incomplete. Detrusor hypertrophy and obstruction of the urinary pathway result (Hinman 1986; Olbing 1993).

A major genetic component of primary nocturnal enuresis has been identified and traced to loci on chromosomes 8, 12, 13 and 22 (Eiberg et al. 1995; von Gontard 1998; von Gontard et al. 1998). In other forms of enuresis, too, familial occurrence points to a genetic predisposition. Pathogenetic factors include a reduction of antidiuretic hormone, increased depth of sleep, and, in some cases, inconsistent toilet-training. Secondary nocturnal enuresis often begins in the context of external stress and in the framework of defiant or regressive behavior (e.g. after the birth of siblings), but it often persists after the triggering factor has been removed. Secondary mental phenomena may complicate the treatment of primary nocturnal enuresis as well as its secondary psychopathology. An important contributing factor in daytime incontinence is the activation of the detrusor muscle during the vesical filling phase, a sign of incomplete maturation. The cause of detrusor-sphincter incoordination is unknown. Voluntary postponement of urination acts in opposition to physiological bladder emptying. Recurrent urinary tract infections or asymptomatic bacteriuria are commonly associated with functional urinary incontinence.

The subtypes of the disorder are diagnosed on the basis of the family history, onset and frequency of manifestations, length of asymptomatic intervals, quality of toilet-training, other developmental disorders, current stressors, and other psychiatric manifestations. The information to be obtained includes the amount of urine voided and whether bedwetting awakens the patient at night, as well as the frequency and volume of urination by day and the possible occurrence of urge symptoms and holding maneuvers.

The physical examination is directed toward external signs of malformation of the urinary tract, while laboratory testing is performed to detect bacteria and

other signs of urinary tract infection (Hansson 1992) and sonography is performed to detect detrusor hypertrophy and residual urinary volume (Olbing 1993). Sphincter-detrusor incoordination can be detected only by a urination program and is not diagnosed in children below 5 years of age. The asymptomatic interval in secondary enuresis must be at least 6 months long. Other entities to be ruled out include dysuria, polyuria, hematuria, incomplete voiding, mechanical problems (outflow obstruction, reflux, cystitis), neurological problems (nighttime epilepsy), and, rarely, the onset of type I diabetes. If there is urinary dripping, anomalies of the urinary tract must be ruled out.

The annual rate of spontaneous remission is approximately 15% of the age-specific prevalence until late adolescence and is somewhat higher in preschool children. The course is more favorable in girls. Functional urinary incontinence has the best prognosis; the prognosis of secondary nocturnal enuresis is relatively favorable, that of the isolated and combined primary forms less so. These disorders require treatment even when the spontaneous prognosis is good, because their manifestations lead to social disadvantage and to impairment of the patients' self-esteem.

Before the proposed treatment is begun, it should be established that the child and the parents will be able to comply with it. Measures that tend to reinforce the manifestations of the disorder (fluid restriction, diapers) should be avoided. Hyperkinetic disorders should always be treated first, as should oppositional defiant disorders, while conduct disorders should be treated at least in parallel. Self-control and reinforcement techniques are adequate to control manifestations in 30% of primarily and secondarily incontinent children; these techniques require a consistent transfer of responsibility to the child and can succeed only if behavior-therapeutic rules are meticulously followed. If this form of treatment remains ineffective for 6 weeks, treatment with enuresis alarms is recommended, which, when meticulously applied, leads to improvement in 75% of patients within 8 weeks. Because the rate of nighttime urination is 40%, overlearning by means of fluid loading is advisable. If this should fail, alarm training is coupled with intensive bladder training; this has been reported to yield a success rate of at least 75% in 4 weeks, with a 30% relapse rate. A high degree of parental cooperation is required.

The administration of tricyclic antidepressants carries the risk of cardiac side effects, is associated with a relapse rate of 50%, and is thus not a treatment of first choice. Desmopressin treatment has a success rate of approximately 50%, but its relapse rate is on the same order of magnitude and there is a risk of side effects from fluid restriction. Pharmacological intervention is indicated only if there is a short-term need for successful treatment, or as a supportive measure accompanying behavior-therapeutic methods.

The various forms of functional urinary incontinence generally require treatment. Daytime incontinence due to voluntary postponement of urination can be treated successfully by consistent, controlled voiding according to a behavior-therapeutic treatment program. Detrusor-sphincter coordination can be achieved through biofeedback training; the success rate is 50%, and the rate of partial success 20%. The treatment of urge incontinence begins with the elimination of urinary tract infections, which leads to a full remission in some patients. In the second step, if needed, behavior-therapeutic principles are applied to make the patient aware of the pressure of a full bladder and to train him or her to empty the bladder completely. The third step consists of additional treatment with oxibutinin or, in older children, bladder capacity training. The success rate of this form of treatment has been reported to be 70%.

4.6 Encopresis

Encopresis (ICD-10 classification: F98.1) usually occurs by day, more rarely by night, and usually secondarily, i.e. after the acquisition of sphincter control. Repeated, voluntary or involuntary deposition of stool in varying quantities in inappropriate places occurs in 2% of 8-year-olds and 0.6% of 13-year-olds and is approximately four times more common in boys than in girls. Encopresis is isolated in 80% of cases and is due to constipation or fecal retention as a result of genetic predisposition, nutritional habits or avoidance of defecation, and sometimes as a result of depression (Christophersen and Rapoff 1983; Levine 1975).

When constipation is the underlying mechanism of encopresis, it is not perceived by the child, and its pathogenetic mechanism is unclear. In such cases, soft stool generally travels past more solid stool already located in the rectum. 15% of cases of encopresis are due to an irritable colon reacting in this way to stress or anxiety. This form of the disorder is often associated with emotional disorders. Deliberate, manipulative encopresis accounts for 5% of cases and is usually associated with oppositional defiant disorders or antisocial manifestations. The age at which toilet-training is given is irrelevant, but its quality is crucial. The secondary form of encopresis is more common than the primary form. Secondary combinations with other mental disorders are frequent, as is a secondary combination with enuresis.

Diagnostically relevant considerations include the nature and history of the manifestations, accompanying psychiatric disorders, personal maturity, and

current or chronic family stresses, as well as physical manifestations of constipation. The diagnosis is not made in children under 5 years of age.

The need for treatment arises from the social consequences of the disorder and the danger of chronic constipation. In secondary forms, the emotional or defiant-antisocial manifestations are treated at least in parallel with the behavior-therapeutic regularization of bowel function. In primary forms, the treatment of constipation is the next most important objective after the achievement of bowel control and is carried out with behavior-therapeutic measures.

4.7 Age-Specific Somatoform and Conversion Disorders

Recurrent headaches and stomachaches in childhood are often precursors of somatoform functional disturbances of autonomically controlled organ systems. Such disturbances have been reported to occur in 10% to 30% of school-age children but are found in only 1.5% of children presenting for treatment. They include dysphagia, globus hystericus, abdominal symptoms, vertigo and palpitations, and, less frequently, nausea, dysuria and hyperventilation. 40% of affected children also have dissociative symptoms such as motor or sensory disturbances, visual disturbances, and aphonia. In adolescence, non-specific pains become less common and psychogenic seizures become more common. Girls are more commonly affected than boys, and conflict-associated unconscious affects can usually be discerned. Suffering and a need for sympathy are found in place of the "belle indifférence" typical of somatoform disorders in adulthood.

The behavior of adult role models seems to play a role in pathogenesis. Sexual abuse is often said to contribute to the generation of these disorders.

The diagnostic assessment of these disorders requires both an elucidation of the patient's past history and behavioral models, and the early and thorough exclusion of somatic disorders. It is typical for patients to reject an interpretation of their symptoms as psychogenic, even though they seem to be relatively unconcerned about them. Depending on the triggering situation, the symptoms may subside in weeks or months, but they may recur in situations of chronic stress.

Younger children are treated indirectly through the influence of their parents, while school-age children are treated directly, particularly when the symptoms are acute. The somatic manifestations are accepted as such, and therapeutic use is made of their regression under placebo treatment and suggestion. Attention is paid to minimizing the patient's gain from illness and to building up an inner conviction of being able to control the symptoms. The psychogenic interpretation is brought into play gradually as cognitive maturity develops.

4.8 Attention Deficit Hyperactivity Disorder

Longitudinal studies show that remission eventually occurs in approximately 50% of cases of pure attention deficit disorder or of simple attention deficit hyperactivity disorder. The most important positive prognostic factor is the absence of concurrent oppositional defiant or aggressive-antisocial disorders, as the combination of a hyperkinetic disorder with a conduct disorder is considered to have a negative prognosis.

It is currently believed that the combined disorder is more strongly genetically determined (Silberg et al. 1996), while simple attention deficit hyperactivity disorder is associated with faulty maturation of the central nervous system. The prevalence of these disorders in the primary-school age group is approximately 3%; they occur predominantly in boys.

The diagnosis and treatment of the prognostically less favorable combined hyperkinetic disorders, which confer a significant degree of handicap, are discussed in Sect. 3.10. It is unclear whether hyperkinetic disorders have a greater tendency to overlap with tics, stuttering and specific developmental disorders when they are associated with conduct disorders.

4.9 Age-Specific Phobias

Monosymptomatic (specific) phobias are related to particular objects and situations. The commoner kinds include animal phobias (e.g. of spiders or dogs) as well as fear of enclosed spaces (claustrophobia), of large public places (agoraphobia), of the dark, and of specific situations. Monosymptomatic phobias may arise in childhood, adolescence, or early adulthood.

Phobic disorders of childhood are usually abnormally intense versions of normal age-specific anxieties, e.g. fear of animals, of the dark, or of storms; panic symptoms accompany them only rarely. Between 7% and 10% of children entering school age suffer from such disorders; boys and girls are approximately equally affected. It is unclear whether a genetic component plays a role in the process of abnormal intensification of anxieties (Beidel and Turner 1998) Avoidance behavior on the parents' part in dealing with these symptoms appears to be significant. It is of importance for the diagnosis that the phobic manifestations are no longer appropriate to the child's age or developmental stage. Their spontaneous course is

favorable, and treatment is necessary only in some cases, when the child's ability to function in everyday life is impaired. Behavior-therapeutic techniques such as prolonged exposure, systematic desensitization and model learning require that both the child and the parents are motivated to cooperate.

Social phobias are common in adolescence and early adulthood. As certain social situations – e.g. scholastic tests, eating or speaking in public, getting together with the opposite sex, and public appearance of any kind – become increasingly important in the lives of adolescents, fear and anxiety become directed toward them. Affected adolescents may fear that such critical situations will cause them to feel faint or vomit, or that they will be exposed to ridicule. Such fears are associated with the usual physiological manifestations of anxiety. In contrast to other phobias, social phobias are approximately equally common in boys and girls.

The etiology and pathogenesis of monosymptomatic (specific) phobias and social phobias are similar. There are three arguments favoring the hypothesis that constitutional and genetic factors play a major role:

1. Twin studies show that anxiety syndromes generally manifest a higher concordance in mono- than in dizygotic twins; the same is true of social anxieties (Torgersen 1979).
2. Phobic patients are more excitable in general, and less capable of habituation, than normal control subjects (Lader and Wing 1966).
3. Anxiety disorders (not only phobias) tend to occur in families, and the children of anxious parents are more likely to be anxious.

Predisposing psychological and psychosocial factors include premorbid personality traits (contact avoidance, depressive tendency, social withdrawal), family dynamics (similar behavior among family members) and conditioning processes. According to the concept of "preparedness," phobic content can be explained as the product of evolution. Phobia is always directed toward objects that were associated with danger during the evolutionary development of the species (e.g. dangerous animals, heights, sharp objects), never toward modern technological appliances (e.g. washing machines, cars, radios, or television sets). Cognitive theories of emotion (Lazarus 1966, 1981) rest on the assumption that anxiety arises from the cognitive assessment of a situation as dangerous.

The diagnosis is made on the basis of the history and clinical manifestations, which can, in part, be directly observed. To be excluded in the differential diagnosis are other anxiety syndromes and disorders of other types in which anxiety plays a major role (e.g. schizophrenic psychoses, depressive disorders).

Various behavior-therapeutic strategies are the treatment methods of first choice for both monosymptomatic and social phobias. Success has been reported with systematic desensitization and, in particular, with "flooding" (exposure and prevention of reaction). Very recently, cognitive strategies, with or without relaxation exercises, have come to the fore. Among these are various forms of training in problem-solving and self-instruction, combined with self-confidence training. Cognitive strategies seem to be inferior to the method of exposure and reaction prevention (Reinecker 1990).

Drug treatment is also available. Two substance groups are most commonly used, the antidepressants and the benzodiazepines. Patients with generalized anxiety disorders respond better to antidepressants than do patients with monosymptomatic anxiety (Zitrin et al. 1983). The appropriateness of antidepressant administration depends largely on whether depression is present as an accompanying manifestation. The use of benzodiazepines in adolescents is only recommended in severe cases because of their potential for addiction, and only in the short term (for no more than 6 weeks).

As for the course of these disorders, the phylogenetically explicable fears (animal phobias, claustrophobia, fear of heights) seem to persist longer. Social phobias, if untreated, also tend toward chronification (Agras et al. 1969). Favorable prognostic factors include the absence of a depressive mood disturbance, consistent avoidance of the anxiety-producing situation, motivation to undergo treatment, and satisfactory progress in the initial treatment sessions (Marks 1987).

4.10 Social Hypersensitivity

This disorder consists of a pathological exaggeration of age-typical worries and anxieties relating to contact with strangers or social situations that seem threatening. Its prevalence is 2.5% (although a study of adolescents alone revealed a higher value), and boys are more commonly affected than girls.

The pathogenesis of the disorder seems to lie in the intensification of age-typical avoidance of strangers by temperamental traits. The major factor is the use of ineffective social strategies by the sufferer, rather than rejection by others. Role models suffering from social anxiety, and reinforcement of avoidance behavior in the affected person's upbringing, are further contributing factors. Traumatic experiences are rare as triggering factors. Hypersensitivity may be directed toward peers, older individuals, adults, or strangers in general. Attachment behavior is undisturbed, but the social circle is frequently small because of avoidance. The lack of social experience favors accompanying symptoms of anxiety and a feeling of incompetence. In

older children and adolescents, social status is negatively affected.

The differential diagnosis requires the separation of this disorder from social phobias consisting of specific fears related to the other individual – these usually begin in late childhood – and from acute reactive disorders (see Sect. 2). The need for treatment is a function of the degree of social impairment. Unfavorable prognostic signs include the (rare) occurrence of panic symptoms, familial loading with anxiety disorders, worsening of symptoms over time, and their failure to improve with social support. A transition from social hypersensitivity to social phobia is rare, but this possibility should be borne in mind (Beidel and Turner 1998). The goals of treatment are the acquisition of competence through model learning, the correction of distorted social perceptions and the strengthening of the inner conviction of self-control. The treatment is supplemented, if necessary, with exposure and reaction prevention.

4.11 Oppositional Defiant Disorder and Socialized Conduct Disorder

The significance of oppositional disorders is unclear. Persistently disobedient and rebellious behavior with a hostile component but without aggressive or antisocial acts is often considered to be a possible preliminary phase of a conduct disorder. Oppositional disorders appear mainly in the early school years and affect boys more often than girls. Severe accompanying emotional abnormalities are rare, chronic stress and deficient education are common, and temperamental factors are considered to predispose to these disorders. A disturbance of this type can be classified among the transient age-specific disorders only if there is no accompanying hyperkinetic disorder. There are no reliable epidemiologic data for oppositional defiant disorder. The oppositional behavior is directed mainly toward authority figures in the near environment, whose demands are passively or actively disregarded. The anger of others is deliberately aroused, and others are blamed for the resulting difficulties. Provocations are frequent, and a low frustration threshold leads to frequent temper tantrums.

The emergence of conduct disorders in early adolescence is of prognostic significance; according to Moffitt (1993), approximately 85% of conduct disorders appear at age 10 or above. The affected adolescents, despite their persistently antisocial behavior, are able to make social attachments and often have good relations with their peers. Conversely, the lack of social attachments to peers, physical aggression, and the combination of an early-onset conduct disorder with a hyperkinetic disorder are frequently seen features that, when present, confer an unfavorable prognosis (Biederman et al. 1996). The prevalence of these disorders rises from 1–2% in the primary school years to approximately 6% in adolescence. Boys are more commonly and more severely affected than girls. There is a risk of substance abuse and delinquency. Lack of social correction promotes the persistence of the behavioral disturbance. Its manifestations range from fighting, bullying, vandalism, lying, stealing, outbursts of rage, and truancy to running away from home, setting fires, physical assault, and other criminal offenses. Mild accompanying emotional disorders are common; transient, severe depressive disorders also occur as comorbidity.

Unfavorable temperamental traits and faulty upbringing, usually consisting of a lack of sufficient parental control despite adequate affection, favor the development of oppositional behavior in childhood. Antisocial role models in the child's own family or (more commonly) among peers, failure at school and social rejection are clearly major predisposing factors for the development of age-specific antisocial behavior, which only manifests itself in specific contexts (e.g. not at school or in the workplace; Matt 1995). Less is known about the origin of this disorder than about its course.

The diagnosis is made on the basis of the patient's history and the exclusion of primary disturbances of cognitive performance (e.g. deficient verbal differentiation of affective experience) and hyperkinetic syndromes. The context in which the abnormal behavior arises requires careful attention, as do the extent and quality of social attachments and possible membership in groups engaging in deviant behavior. Persistence of the abnormal behavior is another important factor for the diagnosis; a single incident of delinquency does not suffice. The abnormal behavior must not be a component or consequence of another psychiatric disorder.

The oppositional defiant disorders are considered to require treatment because of the risk that they will be transformed into conduct disorders (which has not been adequately quantified to date). Conduct disorders beginning on the threshold of adolescence, accompanied by good social contact and the ability to form attachments, are considered to have a good prognosis. Such disorders generally remit during adolescence in girls, but may not remit in boys until the mid-twenties. They require treatment because of the risk of substance abuse, which increases as a function of the number of antisocial manifestations. As stated by Patterson et al. (1989), the measures that have proved effective in the treatment of oppositional defiant disorders are generally directed toward the parents' child-rearing behavior. Important factors for successful treatment include

the involvement of significant persons in the child's upbringing, the analysis of misperceptions, the development of alternative behaviors in both the child and the parents, the acquisition by the parents of effective means of control and discipline, and the maintenance of success by continuous repetition. Other measures directed toward the child's problem-solving ability are more appropriate for older children and adolescents. The treatment of substance abuse has priority. The treatment of adolescents may be focussed on specific manifestations such as truancy, stealing, and setting fires. If everyday behavior is impaired in multiple ways, therapy involving multiple systems is necessary. Field interventions improve the prospects for success (for a discussion of the current state of research on treatment effectiveness, cf. Kazdin 1997).

4.12
Crises of Sexual Maturation

This term covers emotional – often, anxious or depressive – reactions to the individual's own sexual orientation. The reaction is usually to a deviant sexual orientation, identity, or preference. These disorders occur in adolescence, when the individual first becomes aware of such deviations, and become significant because the establishment of sexual identity is a developmental task in this phase of life. The adoption of such deviant sexual roles may be more difficult than the establishment of heterosexual identity, and is often associated with subjective suffering. There are no reliable epidemiological data on the frequency of such crises.

The diagnostic difficulty lies in the differentiation of transient disturbances in the course of sexual development from permanent sexual attitudes. The former may be perceived as transitional manifestations requiring no treatment; while the latter may require counseling or psychotherapy, of which the main objective is the development of self-acceptance. These tasks can be accomplished only on the basis of meticulous history-taking with respect to psychosexual development. The therapist must also possess a thorough knowledge of the relevant aspects of developmental psychology, including behavioral variants, as well as experience in dealing with adolescents with complex problems (Rekers 1982).

5
Disorders of Age-Specific Onset

The following sections deal with various disorders whose common feature is that they begin in childhood or adolescence and continue into adulthood. Their manifestations may remain constant or may change over the course of the transition into adulthood. The latter is the case for some of the tic disorders, for example, which may continue into adulthood as obsessive–compulsive disorders, or for those eating disorders that begin as anorexia nervosa and then become transformed, as the patient grows older, either into a subclinical form of anorexia nervosa, or into bulimia nervosa.

5.1
Disorders of Speech Fluency

5.1.1 Stuttering

Stuttering is a usually situation-dependent disturbance of speech fluency. Its ICD-10 classification is F98.5.

Stuttering is found in approximately 5% of 5-year-old boys and 2% of 5-year-old girls. It may begin during the phase of language development (between the third and the sixth years), in the early school years (sixth and seventh years), or during puberty (twelfth through fourteenth years).

Three forms of stuttering are distinguished:

1. *clonic* stuttering, i.e. repetition during the initiation of speech;
2. *tonic* stuttering, i.e. blockage in the course of speaking; and
3. *tonic-clonic* or combined stuttering, in which both of the above are present.

The most important manifestation for the diagnosis is the patient's tonically or clonically distorted speech. Tonic stuttering is distinguished by clearly evident straining at the beginning of words or sentences, clonic stuttering by the repetition of sounds, syllables, or words. Often, both components are found. The disorder is easily identified as a disorder of speech fluency. Moreover, there are usually difficulties in the coordination of other functions coupled to the process of speaking (breathing, facial expression, gestures, vocalization). Finally, nearly all patients have major autonomic reactions while speaking (sweating, blushing, irregular breathing). It is an important observation that stuttering does not occur during singing in the great majority of cases; this can also be put to therapeutic use. In the differential diagnosis, stuttering must be distinguished from cluttering. Stammering, a disturbance of sound formation, is easily distinguished from stuttering, in which sound formation is normal.

There are many hypotheses concerning the origin of stuttering, which can be summarized under the following four headings:

1. Recent studies have shown that the influence of *heredity* in the stuttering syndrome is less than previously thought. A genetic component is thought to be probable in approximately 8% of cases.
2. *Organic brain abnormalities* are present in a considerable percentage of patients who stutter. These are revealed by abnormal EEG findings, which may be found in a relatively high percentage of stutterers. The hypothesis of an organic etiology is also supported by the fact that stuttering occurs in as many as 20% of patients with brain damage.
3. *Psychogenic influences* certainly play a major role in the appearance of this disorder. According to Schilling (1963), most stutterers (68%) suffer from neurotic disorders, and psychogenic influences cannot be definitively ruled out in 12%, while psychogenic influences can be definitively ruled out in only 20%.
4. According to the *multifactorial hypothesis*, several factors acting together cause the disorder. For example, a mild cerebral dysfunction may act in concert with aggravating environmental influences to produce stuttering.

Just as the hypotheses as to the etiology of stuttering are diverse, so, too, are the approaches to its treatment. These may be summarized under the following five headings. Often, several different treatment methods are used in combination:

1. *General measures* primarily concern parents and other persons interacting with the child. The basic principles include: disregard of stuttering, attentive and patient listening when the child speaks, and elimination or moderation of the circumstances that are presumed to have led to stuttering or to maintain it.
2. Many *functional treatment methods* have been used for stuttering, with variable degrees of success, including: breathing exercises, speech therapy, the use of rhythm, relaxation exercises (e.g. autogenic training), and application of the principle of delayed speech feedback.
3. *Psychoanalytic treatment* is based on the assumption that stuttering is an expression of a neurotic disorder resulting from experiences of conflict. Resolution of conflict is the goal of analytically oriented play therapy.
4. From the *behavior-therapeutic* point of view, stuttering is regarded as a learned mode of behavior that may be eliminated by treatment based on learning principles.
5. *Drug treatment* generally cannot eliminate the manifestations of stuttering in the etiological sense, but it can definitely reduce the associated anxiety and tension. The most frequently used agents are chlordiazepoxide (Librium) and butyrophenone derivatives such as haloperidol (Haldol).

As for prognosis, one third of patients become asymptomatic after prompt and intensive treatment; one third are considerably improved; and one third remain unchanged.

5.1.2 Cluttering

Cluttering is a disorder of speech fluency characterized by rushed speech, swallowing of sounds, syllables, or words, and garbling of various components of speech. It has been given the ICD-10 classification F98.6.

The process of speaking is accelerated and hurried, and the flow of speech is chaotic. The patient's speech is sometimes difficult to understand because of slurred articulation or distortion of words. In contrast to stuttering, speech improves when the clutterer pays attention to it. The disorder occurs in approximately 1–1.5% of 7-year-olds; prevalence declines with increasing age.

The disorder is mainly attributed to hereditary influences or organic brain abnormalities. The frequent familial occurrence of the disorder is evidence for the former. Evidence for the latter is provided by a high frequency of electroencephalographically detectable, though unspecific abnormalities in children and adolescents who clutter.

The manner of treatment depends on the predominant component. In pure cluttering, speech therapy is indicated, with particular emphasis on speaking slowly, directing attention to the speaking process, and beating time along with the syllables. The therapist should also make the family aware of the importance of speaking slowly.

5.2 Tic Disorders and Gilles de la Tourette Syndrome

Tics are involuntary, recurrent, circumscribed movements or vocal productions of sudden onset that are experienced by patients as irresistible but may nevertheless be suppressed at times. Gilles de la Tourette syndrome is a special form of tic disorder involving multiple motor tics and at least one vocal tic; the motor and vocal tics need not occur simultaneously. The vocal tics may involve a variety of sounds (e.g. throat clearing, coughing, grunting, or uttering obscene words or phrases).

In what follows, we will maintain the distinction between transient tics, chronic motor or vocal tics, and Gilles de la Tourette syndrome. Transient tic disorders

are very common in childhood and adolescence and are discussed in Sect. 4.

In chronic motor or vocal tic disorder, motor or vocal tics occur, not simultaneously, though possibly in temporal succession. In contrast to transient tic disorder, the manifestations persist for more than one year and usually involve multiple tics.

The syndrome originally described by Gilles de la Tourette in 1885 is characterized by multiple motor tics and phonation tics (i.e. the uttering of unarticulated sounds, or coprolalia). The disorder always begins in childhood and often continues into adulthood. Like other tic disorders, Gilles de la Tourette syndrome is 2 to 3 times more common in male children and adolescents than in females. The average age of onset is approximately 7 years. The motor tics most frequently involve the head and face, less frequently the trunk or the upper or lower limbs. The vocal tics that are always associated with the disorder may involve sounds of various types, words, coprolalia, or palilalia.

The illness usually begins as an isolated motor tic (in 50% of patients), which is most often localized to the face. Other possible initial manifestations include sticking out the tongue, sniffling, hopping, throat-clearing, stuttering, explosive production of sounds or words, and coprolalia (Shapiro and Huebner 1985). It is typical of the disorder for the initial manifestations to be replaced by others over the course of time (Hebebrand et al. 1997a,b). The severity of the disorder (i.e. the intensity of its manifestations) is highly variable over time.

Current hypotheses of the etiology of Gilles de la Tourette syndrome (for review see Leckman and Cohen 1999) are based on genetic and neurobiological findings, while environmental factors seem to play a role in determining the severity of the disorder. As for genetic causes, family studies have revealed that first-degree relatives of index patients with Gilles de la Tourette syndrome have a 5% probability of having it themselves, and a 10% probability of having a chronic tic disorder. Twin studies have revealed concordance rates of approximately 50% for monozygotic twins. An autosomal dominant inheritance pattern was postulated on the basis of family studies, but has not been confirmed to date; the disorder seems to be polygenic (Tourette Syndr. Assoc. 1999). Neurobiological hypotheses, based on the clinical features of the disorder, invoke possible functional disturbances in the basal ganglia; tics are thought to result from disturbed neural activity in subcortical regulatory circuits. The biochemical findings to date are not uniform. Recently, there has been interest in the immunological findings of Sydenham's chorea, a disorder in which children develop tics after a rheumatic infection, which may be considered a model for Gilles de la Tourette syndrome.

Items to be excluded in the differential diagnosis include other disorders producing choreiform movements (including Sydenham's chorea, whose relation to Gilles de la Tourette syndrome has recently attracted interest, as just mentioned). Myoclonus, which sometimes occurs continuously, must also be excluded; when present, it is usually due to another neurological illness, whose other manifestations simplify the differential diagnosis. A special variety of myoclonus is the type that normally occurs while the child is falling asleep. Finally, epileptic seizures and, not least, obsessive-compulsive manifestations should be excluded. The latter may be difficult to distinguish from Gilles de la Tourette syndrome, for two reasons: Obsessive-compulsive phenomena may occur as part of the syndrome (e.g. continuously repeated words, sentences, or melodies); moreover, in some 30% of cases of the syndrome, its manifestations change in the direction of an obsessive-compulsive disorder, or else an obsessive-compulsive disorder arises in addition to the already present Gilles de la Tourette syndrome (Leckman and Cohen 1999).

Tic disorders, because they are highly visible, often lead to considerable social impairment. Patients and their parents are thus highly motivated to undergo treatment. The type of treatment recommended depends on the severity of the manifestations and of the associated social impairment. Treatment usually consists of three components: thorough education as to the nature of the illness, drug therapy, and individually tailored psychotherapy.

D_2-receptor antagonists such as tiapride, haloperidol, and pimozide are the mainstays of drug therapy, while α_2-adrenergic agonists such as clonidine are used as agents of second choice. Clonidine probably affects the dopaminergic system indirectly through an alteration of norepinephrine metabolism. Drug therapy should be initiated and terminated gradually. Its goal should not necessarily be the complete elimination of tics, but rather a reduction of manifestations so that the patient can get along in everyday life (Remschmidt and Hebebrand 1993). If obsessive-compulsive features are also present, antidepressants such as clomipramine or selective serotonin reuptake inhibitors such as fluoxetine and fluvoxamine can be tried, perhaps in combination with neuroleptics. As far as psychotherapeutic treatment is concerned, behavior therapy has proved useful.

The prognosis of tic disorders is favorable, with the exception of Gilles de la Tourette syndrome. Transient tics tend to regress spontaneously: after a follow-up interval of three years, 70% of patients have major improvement or even disappearance of the tics. The manifestations persist in approximately 30% (Remschmidt and Remschmidt 1974). In Gilles de la Tourette syndrome, approximately 30% of cases have a transi-

tion to obsessive-compulsive manifestations. In the great majority of cases, the syndrome persists, with a fluctuating tendency toward improvement.

5.3 Conduct Disorders, Antisocial Disorders, and Delinquency

Conduct disorders are characterized by antisocial, aggressive, and rebellious behavior that appears repeatedly and displays a tendency to persist. In the ICD-10, four types of conduct disorders are defined:

- conduct disorder confined to the family context (F91),
- unsocialized conduct disorder (F91.1),
- socialized conduct disorder (F91.2), and
- oppositional defiant disorder (F91.3).

The first three types of conduct disorder are defined in relation to the social sphere and the relationship structure in which each occurs, while the last is a characteristic pattern of manifestations that can appear in practically any social sphere and is not bound to a specific type of relationship. Socialized conduct disorder and oppositional defiant disorder are strongly developmentally dependent and are accordingly described more extensively in Sect. 4. Conduct disorders almost always begin in childhood and early adolescence and, when severe, often undergo a transition to personality disorders in the adult.

The question must be raised whether it is truly a clinical entity that is being discussed here, because conduct disorders often must be regarded, not as psychiatric illnesses, but rather as a social failure caused by faulty education, and should accordingly be treated by educational means. In any case, the manifestations of these disorders are extremely diverse. The ICD-10 research criteria (Dilling et al. 1994) list no fewer than 23 manifestations and modes of behavior that can be found in these disorders, ranging from frequent arguing, lying, physical conflicts, persistent violation of rules set by parents, cruelty to animals, stealing, truancy, running away, and bullying to actual criminal offenses such as burglary, arson, and the use of dangerous weapons (e.g. sticks, knives, guns).

Two types of conduct disorders are traditionally distinguished: those beginning in childhood (usually before the 10th year) and those beginning in adolescence (from the 13th and 14th years onward). Conduct disorders may be classified as one of the four types listed above only if the general criteria for a conduct disorder (F91) are fulfilled. It can then be decided, on the basis of the more specific criteria for each disorder, whether the conduct disorder is confined to the family context (F91.0), whether it is associated with a lack of social relationships (F91.1) or with existing social relationships (F91.2), or whether it manifests itself primarily in oppositional and defiant behavior (F91.3).

The ICD-10 research criteria also provide a scale of severity for conduct disorders, including the three levels mild, moderate, and severe. It is difficult, and sometimes problematical, to determine the boundaries between these disorders and variations of normal behavior, which cover a wide range in childhood and adolescence. The division of conduct disorders into socialized and unsocialized, introduced by Jenkins (1968), has been found to be worth retaining, as it yields a certain degree of insight into the dynamics of these disorders; socialized conduct disorder has a better chance for improvement, and thus a more favorable prognosis, than unsocialized conduct disorder.

As in most mental disorders and illnesses, as well as most behavioral deviations, the causation of conduct disorders is thought to involve an interaction of biological and environmental factors, in which the number and type of risk factors in both areas influences both the probability that these disorders will arise, and their severity. The interrelatedness of the individual risk factors must be borne in mind, of course, as well as the individual's active attempt to deal with his or her social environment. The following etiological hypotheses have been proposed:

- *Biological hypotheses* emphasize on disorders of cerebral function, neuropsychological abnormalities, chromosomal aberrations, genetic factors, and constitutional variables. The last category also includes personality, whose precursors in childhood are summarized under the term "temperament." Twin studies and adoption studies indicate the presence of a genetic factor. Neuropsychological and neurophysiological studies have revealed that children and adolescents with severe conduct disorders have both neuropsychological deficits and a diminished arousal response. The more common occurrence of antisocial behavior in male children and adolescents is attributed to hormonal factors, as it is known that androgens not only influence brain development, but also may be responsible for aggressive behavior in male adolescents. Furthermore, the autonomic nervous system has been found to be less reactive in adolescents with conduct disorders, as revealed by a diminished reactivity of the pulse and of skin conductivity.
- *Psychogenic hypotheses* lay emphasis on the influence of early childhood development. Deprivation and unfavorable family circumstances and, in adolescents, peer influence (antisocial cliques), drug abuse, and depictions of violence in the media are considered to be important factors. Several studies have shown that the moral development of delinquents is delayed.

- *Sociological hypotheses* focus attention on the influence of unfavorable social circumstances, bad role models and family desolation.

None of the approaches listed above have yet been able to provide an adequate explanation for conduct disorder, antisocial behavior, and delinquency.

The diagnosis is made on the basis of the past history, clinical manifestations, and, for a number of disorders, direct observation. Particular attention must be paid to developmental conditions. Conduct disorders must be distinguished form personality disorders and antisocial and delinquent behavior in the context of other psychiatric illnesses (e.g. psychoses).

In accordance with the presumed multifactorial origin of conduct disorders, their treatment must be based on a number of different factors. Treatment methods are divided into three types, after Kazdin (1995), according to the major focus of the intervention: child-focused, family-focused, and community-based (see Table 2).

- *Child-focused methods* are currently based mainly on behavior-therapeutic techniques; training in problem-solving has been found to be effective. In this approach, social situations are acted out with the child and constructive outcomes of conflicts are anticipated, so that the child will behave in the actual situation as previously practiced during problem-solving training.
- *Family-focused methods* are most often used in younger children with conduct disorders. Parental training is intended to improve the parents' ability to bring up their child, while family therapy, which is less commonly performed, is intended to improve family relationships.
- *Community-based methods* include the participation of the affected child or adolescent in group activities in and out of school and the workplace, so that social behavior in peer groups can be practiced under supervision, and the implementation of youth service measures by the responsible government offices. The German Law on Child and Youth Service (*Kinder- und Jugendhilfegesetz, KJHG*) provides for various measures, ranging from assistance with child-rearing (Sect. 27), parental counseling (Sect. 28), supervision of parents (Sect. 30), socioeducational family assistance (Sect. 31), and day care (Sect. 32) to full-time care (Sect. 33), care in a children's home (Sect. 34), and intensive individual socioeducational care (Sect. 35 KJHG).

Longitudinal studies of children with conduct disorders have shown that about half of all cases remit, and half persist into adulthood. Conduct disorders beginning in the pre-school years have an unfavorable prognosis and are associated with a lack of social relationships and with impulsive and hyperactive behavior. The prognosis is further worsened by the frequent comorbidity of these disorders with alcohol and drug abuse. Some cases of severe conduct disorder are evident in adulthood as personality disorders, mostly of the dissocial type.

5.4 Eating Disorders: Anorexia Nervosa and Bulimia Nervosa

Anorexia nervosa and bulimia nervosa are common eating disorders in childhood and adolescence. The age-specific incidence of anorexia nervosa is highest at 14 years, that of bulimia nervosa at 17 to 18 years. The prevalence of anorexia nervosa has been reported to be 1%, while bulimia nervosa is more common, occurring in approximately 2% to 3% of all boys and girls. Both illnesses predominantly affect females.

As seen in Table 3, the most important feature distinguishing bulimia nervosa from anorexia nervosa is the occurrence of hunger attacks. Longitudinal studies have shown that a transition from anorexia nervosa to bulimia nervosa is common, while the reverse is extremely rare. Reviews are found in Garner and Garfinkel (1997) and in Vandereycken and Beumont (1998).

The major components of the clinical picture of anorexia nervosa are marked weight loss and refusal of food, abnormal eating behavior, constipation, and absence of menstruation. These patients try at all costs to achieve progressive weight loss or to maintain an extremely low weight. They do so not only by refusing to eat, but often also by self-induced vomiting or laxative abuse. Many patients also try to maintain a low weight by keeping the body in motion at all times (constantly pacing back and forth, extreme gymnastics). Fasting may be the exclusive means of attaining the desired weight loss (so-called restrictive form of anorexia nervosa), or additional means of reducing nutritional intake may be used, such as vomiting and laxative or diuretic abuse.

The mental abnormalities characteristic of these girls include an asthenic personality, an inclination to depressive mood disturbances, marked ambition to succeed, and, frequently, hysterical or schizoid personality traits, along with usually normal intelligence. The depressive mood disturbances are mainly a function of weight (Herpertz-Dahlmann and Remschmidt 1989). Extreme weight loss is associated with a massive change of attitude and an often entirely unrealistic body image.

The physical manifestations are all a function of weight and mostly regress after the patient's weight is normalized. These include acrocyanosis, hair loss, hematopoietic abnormalities (leukopenia, anemia), electrolyte disorders, low levels of all hormones except cortisol, osteoporosis, and cerebral pseudoatrophy,

Table 2. Antisocial behavior: therapeutic focus and processes of major classes of treatment. (After Kazdin 1987)

Treatment type	Focus	Key processes
Child focused		
Individual psychotherapy	Focus on intrapsychic bases of antisocial behavior, especially conflicts and psychological processes that were adversely affected over the course of development.	Relationship with the therapist is the primary medium through which change is achieved. Treatment provides a corrective emotional experience by providing insight and exploring new ways of behaving.
Group therapy	Processes of individual therapy, as noted above. Additional processes are reassurance, feedback, and vicarious gains by peers. Group processes, such as cohesion and leader.	Relationship with the therapist and peers as part of the group. Group processes emerge to provide children with experiences of others and opportunities to test their own views and behaviors.
Behavior therapy	Problematic behaviors presented as target symptoms. Prosocial behaviors are trained directly.	Learning new behaviors through direct training, modeling, reinforcement, practice, and role playing. Training in the situations (e.g. at home and in the Community) in which the problematic behaviors occur.
Problem-solving skills training	Cognitive processes and interpersonal cognitive problem-solving skills that underlie social behavior.	Teach problem-solving skills to children by engaging in a step-by-step approach to interpersonal situations. Use of modeling, practice, rehearsal, and role playing to develop problem-solving skills. Development of an internal dialogue or private speech that uses the processes of identifying prosocial solutions to problems.
Pharmacotherapy	Designed to affect the biological substrates of behavior, especially in the light of laboratory-based findings on neurohumors, biological cycles, and other physiological correlates of aggressive and emotional behavior.	Administration of psychotropic agents to control antisocial behavior. Lithium carbonate and haloperidol have been used because of their antiaggressive effects.
Residential treatments	Means of administering other techniques in day treatment of residential setting. Foci of other techniques apply.	Processes of other techniques apply. Also, separation of the child from parents or removal from the home situation my help reduce untoward processes or crises that contribute to the clinical problem.
Family focused		
Family therapy	Family as a functioning system rather than the identified patient serves as focus. Interpersonal relationships, organization, and roles and dynamics of family.	Communication, relationships, and structure within the family and processes as autonomy, problem solving, and negotiation.
Parent management training	Interactions in the home, especially those involving coercive exchanges.	Direct training of parents to develop prosocial behavior in their children. Explicit use of social-learning techniques to influence the child.
Community based		
Community-wide interventions	Focus on activities and community programs to foster competence and prosocial peer relations.	Develop prosocial behavior and connections with peers. Activities are seen to promote prosocial behavior and to be incompatible with antisocial behavior.

demonstrable by both computer tomography and magnetic resonance imaging.

The essential feature of bulimia nervosa is the episodic occurrence of hunger attacks in which large amounts of food of high caloric content are consumed and then usually expelled by means of self-induced vomiting. The patients are aware that their eating behavior is abnormal. They are afraid of not being able to stop eating, often suffer from depressive mood disturbances and self-reproach, worry about their

Table 3. ICD-10 criteria for anorexia nervosa and bulimia nervosa

Anorexia nervosa	Bulimia nervosa
1. Body weight at least 15% under norm, and body mass index ≤ 17.5.[a]	1. Constant preoccupation with eating and hunger attacks in which large quantities of food are consumed in a short time.
2. Weight loss is intentional.	2. Attempts to counteract the fattening effect of eating by various means such as self-induced vomiting, laxative abuse, restrictive diet, etc.
3. Disturbed body image and excessively stressed idea of being too fat.	3. Morbid fear of becoming too fat.
4. Endocrine disorder of the hypothalamic–pituitary–gonadal axis.	4. Often, a past history of anorexia nervosa.
5. In cases beginning before puberty, disturbance of pubertal development, including growth, which is often reversible after remission	

[a]Body mass index = body weight (kg)/[height (m)]^2.

weight, and often have abdominal pain and panic-like anxiety attacks, in addition to guilt feelings after eating. Their eating behavior also often leads to fluctuations of weight, although the average weight is higher than that of patients with anorexia nervosa. Many patients are, in fact, overweight.

Both of these varieties of eating disorder are currently thought to be of multifactorial origin. Twin studies and family studies reveal the importance of genetic factors, although it remains unclear whether the two disorders have a common genetic basis. The psychological and psychosocial influences favoring the occurrence of these disorders include: the esthetic ideal, current in Western countries today, of thinness, which comes into conflict with the increase in body fat that occurs during puberty and is more marked in girls than in boys; the often self-imposed pressure to succeed that is common among girls in our society; premorbid eating disorders in childhood; and family influences, which are now considered to be less important than previously thought. The importance of sociocultural factors is demonstrated by the higher prevalence of anorexia nervosa and bulimia nervosa among immigrants to Western countries and by the increased prevalence of the disorder in groups at special risk because of an exaggerated ideal of thinness (e.g. ballet dancers, gymnasts, actresses and models).

Sexual abuse is often considered to be a factor contributing to the occurrence of anorexia nervosa and may indeed be so in some cases, but it is no more common in girls suffering from anorexia nervosa than in girls with other psychiatric disorders. Thus, sexual abuse cannot be regarded as a specific etiological factor.

Excessive vulnerability of the serotonergic system has been postulated as a common underlying mechanism for both disorders. This assumption is based on the observation that patients with anorexia nervosa who have regained normal weight have elevated central serotonin activity, while patients with bulimia nervosa have diminished central serotonin activity. The hypothesis of faulty serotonergic regulation is also compatible with observations on comorbidity in the eating disorders, which are associated with depressive mood disturbances and with anxiety disorders.

There are both similarities and differences between the modes of treatment of the two disorders. The major initial objective of treatment is weight normalization in the case of anorexia nervosa, normalization of eating behavior in the case of bulimia nervosa. Treatment with antidepressants is not effective in anorexia nervosa (despite the frequent comorbidity with depressive disorders), but it has been found useful in bulimia nervosa, for which selective serotonin reuptake inhibitors (e.g. fluoxetine, fluvoxamine) have been used with success. The most important aspect of the treatment of both disorders is the integration of all treatment measures in an overall plan, which usually consists of several phases. The severity of the disorder and the patient's willingness to cooperate, and that of her family, determine whether treatment is best provided in an ambulatory or inpatient setting.

A multiphase treatment plan has proved useful in the treatment of anorexia nervosa (Remschmidt and Herpertz-Dahlmann 1988; Remschmidt 1992). The first four phases of clinical treatment generally take place over four to six months:

1st phase: Elevation of body weight.
2nd phase: Introduction of an eating plan agreed to by the patient, with monitoring of compliance by treating personnel.
3rd phase: "Self-determination of food intake": in this phase, the patient learns to control her own food intake and eating behavior.
4th phase: In this phase, the emphasis is placed on joint family effort for younger patients, and on the development of independence in all areas of life for older patients. At the same time, preparations are made for discharge.
5th phase: Oupatient follow-up and continuation of treatment measures, as needed, for a further 2 years.

The treatment of bulimia nervosa consists mainly of psychotherapy with cognitive behavior-therapeutic methods. A meticulous problem analysis should be

performed in every case, and the individual problems should be addressed with suitable specific measures. As in anorexia nervosa, a multiphase treatment plan is recommended (Fichter 1989):

1st phase: At first, the major emphasis is on the cessation of pathological eating behavior. This goal is served by the development of a stable relationship with the therapist, the introduction of a structured eating plan with regular meals, thorough education of the patient about the illness and the damage it may cause, the involvement of significant others, and the establishment of alternative modes of behavior, particularly for the times at which the bulimic attacks occur.

2nd phase: This phase is devoted to the discovery of the factors that enabled the disturbed eating behavior to become chronic. A careful causal analysis is performed of all maintaining factors, e.g. inadequate conflict resolution strategies, distortions of body image, and depressive mood disturbances.

3rd phase: Finally, the achieved therapeutic progress is maintained, and future problem situations are anticipated and dealt with constructively through the use of appropriate strategies.

The many longitudinal studies of anorexia nervosa currently available reveal that two thirds of patients no longer suffer from the eating disorder after six to eight years of follow-up, while chronification or, at least, persistence occurs in one third; in the latter patients, the disorder still causes impairment, even though it may no longer fulfill the diagnostic criteria for anorexia nervosa. Remission of the disorder is, in many cases, not synonymous with a return of mental health: even six to eight years after diagnosis, 20% to 30% of patients still suffer from anxiety disorders, drug or alcohol abuse, and personality disorders.

In bulimia nervosa, rates of cure of up to 50% have been reported after follow-up intervals of 2 to 3 years. In the remaining half of all patients, the disorder becomes chronified, or additional mental disorders occur, such as depressive syndromes, alcohol and drug abuse, and personality disorders.

5.5 Mutism

In ICD-10, mutistic behavior is classified under the overall heading of "disorders of social functioning with onset specific to childhood and adolescence" (F94).

The term "mutism" refers to the absence of speech despite the ability to speak. Mutistic behavior occurs mainly in children and adolescents but may also be observed in adults. Absence of speech has a wide variety of causes: diminished drive to speak, fear, reaction to conflict, and defiant refusal to communicate, or, on the other hand, organic disorders and psychoses. *Elective mutism* is distinguished from *total mutism:* in the former, the affected person speaks only with selected persons, in the latter with no one.

Elective mutism is a rare disorder that most commonly arises in childhood between the ages of 5 and 9 years, and rarely in adolescence. The syndrome, narrowly defined, has a prevalence of 0.8 per 1000 children in this age group.

The diagnosis is made on the basis of the clinical history and direct observation. Loss of speech because of organic brain damage, intrinsic mutism, schizophrenic psychoses, and partial or total deafness must be excluded in the differential diagnosis.

Recent discoveries belie the previous assumption that mutism is an exclusively psychogenic disorder. The findings of empirical studies suggest that developmental delay, premorbid abnormalities of personality, and family pathology establish the preconditions for mutistic behavior, which may then be triggered by additional external stress.

There is currently a consensus that the treatment of mutism must always be multidimensional, i.e. it must consist of diverse elements, including treatment of the patient as an individual combined with measures involving his or her environment. In accordance with these general principles, the following treatment elements and methods have been applied successfully:

- *Behavior therapy:* The principle of this form of treatment is the operant reinforcement of speaking with adults and therapists, which may subsequently become generalized. Treatment begins with the promotion of nonverbal communication (eye contact, writing and drawing, facial expression and gestures). In the next step, verbal behavior is systematically promoted and rewarded. In recent years, cognitive behavior therapy has been increasingly used.
- *Family therapy:* The involvement of the family in treatment is very important, because family influences play a major role in the causation and release of mutistic behavior. In the family-therapeutic approach, an effort is made to discern the factors and conditions that have brought about the disorder and continue to maintain it. Admittedly, family therapy cannot be the major form of treatment for mutism, because the patient usually refuses to speak in this setting.

- *Psychosocial interventions:* This heading covers all measures involving the child's living environment, including not only the family but also the kindergarten or school environments, extracurricular activities, and peer groups. In the clinical setting, the patient is involved in creative individual and group activities, physical activity and sport. The establishment of normal communicative behavior is thus promoted on all age-appropriate social levels.
- *Psychotropic drugs:* Many clinicians view mutistic behavior as the result of a causal triad of anxiety (social phobia), obsession, and depression. Psychotropic drugs have been used to treat these putative etiologic factors; the currently available data on such treatment are derived mainly from case reports. The medications given include the MAO inhibitor phenelzine (which is not available in Germany) and the selective serotonin reuptake inhibitor fluoxetine, for which positive results have been reported in both case reports and controlled studies. Fluoxetine may thus be regarded as an effective component in a program of treatment for mutistic behavior, though not as the single or most important treatment measure.

The available data on the prognosis of mutism are inconsistent. While a favorable course has been reported for most patients, in others the manifestations may be extremely tenacious and refractory to treatment.

6 Developmentally Dependent Interaction Disorders

The developmentally dependent interaction disorders include induced sleep disorders and feeding disorders (usually at younger ages), sibling rivalry, separation anxiety disorders, Münchhausen's syndrome, and induced delusional disorder. Some authors also include conduct disorders limited to the family context within this group of disorders.

All mental disorders in children and adolescents have a reactive component, i.e. they are related in some way to the social environment, which plays a major role in their causation, their further course, or both. In the interaction disorders, the contribution of the environment is of another type. It consists of transaction mechanisms by which the disorder, once set on its course, is continually maintained by the behavior of an adult in the child's circle, because the signals emitted by the adult are perceived, interpreted, and internalized by the child in such a way that they go on to exert their effects independently. The primary releaser is relatively unimportant; the decisive factor is that another person is required for the maintenance of the disorder. That which becomes autonomous is thus not, as in other disorders, a particular pattern of behavior of the child alone, but rather a pattern of behavior of the child activated by key stimuli coming from the adult, or else a pattern of behavior of the adult activated by key stimuli coming from the child.

The relationship of the child to the adult is properly emphasized by schemes of classification for mental disorders in infancy that provide a second axis to describe the quality of the relationship. A mother who fears that something might happen to her child during sleep, or that the child might have trouble falling asleep or staying asleep, can induce a sleep disorder in the child (in ICD-10, sleep disorders are classified under the category F51). Frequently asking the child whether it has fallen asleep, frequent checking in the night to see whether the child is still asleep, or nighttime feeding because of the idea that the child has been awakened by hunger systematically maintain the sleep disorder. It is characteristic of induced sleep disorders that the child awakens at specific intervals, namely those at which the mother checks after or feeds the child. These disorders thus maintain the periodicity of early infancy, in which the mother–child or child–mother relationship was still symbiotic.

The treatment of this disorder is directed toward the mother, not the child. She must become more secure in the knowledge that nothing will happen to her child at night, that it is not hungry, that it can fall asleep even without her checking, and so forth. Indeed, many prolonged crying episodes of 2- and 3-month-old infants are induced by mothers who believe they must continually carry, move, and be near the child, and thus prevent the children form learning to be alone (Skuse 1984).

The feeding disorders – encoded in ICD-10 as F98.2 – are a second example of induced disorders which generally result from a conflict between mother and child. These disorders are not induced by the child; they are, at most, supported in their initial phase by the child's behavior. The most important causative factor is that the mother wishes to force her idea of proper eating on the child, i.e. that she feeds the child without consideration of its needs. If the child is fed too often, it becomes accustomed to the frequent interruptions of its daily rhythm and nighttime sleep by feedings, which it comes to expect. If the child is fed in excessive quantities, it develops resistance, and eating turns into a negatively charged experience.

Treatment must accordingly begin with the mother's coming to understand her feelings toward the child and the reasons why she feeds it in this manner. Either she has incorrect notions of the child's needs, or she cannot allow the child to regulate its own feeding behavior. It is no accident that the classic examples of age-specific interaction disorders come from the early childhood years, in which the symbiotic relationship is

still very close. We also see cases in which this symbiotic relationship is maintained beyond infancy and early childhood (Skuse 1994).

An example of the latter is furnished by separation anxiety, classified under category F93.0 in ICD-10. The mother induces the child's anxiety when it becomes separated from her and is alone. As a reaction to separation, the child develops the notion that something might befall the mother, that she might go away or never come back. The child's fears, thus aroused, are overvalued by the mother, possibly to such an extent that separation anxiety disorder is produced in its classical form as school phobia, for which the groundwork may be laid at a very early age. This pattern may be carried on as the child grows older and is generally associated with a lack of independence. The child is happy only when its mother is near.

In milder forms, the mechanism of separation anxiety appears when children who have been raised in part by their grandmothers, or fatherless children, become highly dependent on their mothers and thereby fail to develop independence and have difficulty with separation.

A number of authors draw a parallel between separation anxiety disorder and conduct disorders restricted to the family context. They view the latter not as a preliminary phase of a conduct disorder that goes on to spread outside the family context, but rather as a particular type of parent–child interaction in which the parents persist in applying certain notions of child-rearing at the price of becoming victims of their own children, are hit by them, and so forth, as is well known in the "battered parent syndrome." This pattern seems to be more common with adopted children.

Sibling rivalry (ICD-10 classification: F93.3) is a further example relating not to parents, but to siblings. The presence of the sibling, or the mother's paying attention to the sibling, arouses or maintains abnormal behavior in the child, either regressive or aggressive. The child affected by sibling rivalry cannot give in, or get over its unhappiness, until it is made to realize that its predicament is not really so bad.

Münchhausen's syndrome (ICD-10 classification: F68.1) is a factitious disorder in which the individual intentionally produces or feigns manifestations of illness or disabilities, either physical or psychological. In contrast, Münchhausen-by-proxy syndrome is a rare form of abuse in which a caregiver, usually a parent, produces manifestations of illness in the child or another dependent person. The deception is usually repeated on many occasions, with resulting hospitalizations, morbidity, and sometimes death. The victims include not only unknowing infants, but also older children, who are surprisingly tolerant of their parents' actions, presumably because of fears of loss. A false accusation of sexual abuse directed at a divorced father may constitute a variant of Münchhausen-by-proxy syndrome if the child is led to adopt this idea as its own.

The causative chain in induced delusional disorder (ICD-10 classification: F24) is easily understood. The illness of the mother (or other caregiver) frightens the child and makes it susceptible to her pathological desires for interaction.

The treatment of all of these disorders, diverse as they are, requires an intensive diagnostic assessment of the patterns of interaction within the family. In very young children, a disturbed mother-child relationship is especially likely to produce somatic manifestations, for which organic causes must first be ruled out.

Once the mother-child interaction has been carefully analyzed, measures can be chosen to alter it. Behavior-therapeutic principles have been found particularly useful both in parent counseling and in the treatment of the affected children. Family-therapeutic techniques may also be used (joint family conversation, "behavior tasks," etc.).

7
Early-Onset Adult-Type Disorders

The disorders listed under this heading are illnesses typically occurring in adulthood that may arise in late childhood and early adolescence. They are significantly more common in adolescence.

7.1
Anxiety Disorders

Anxiety disorders are characterized by two features: the development of unusually strong and situationally inappropriate anxiety, and equally marked avoidance behavior.

In ICD-10, phobic disorders are classified separately from other anxiety disorders, and two variants of agoraphobia (with and without panic disorder; F40.0) are distinguished. In DSM-IV, panic disorder occupies a dominant position, and is divided into forms with and without agoraphobia. Both classification schemes have a category for anxiety not related to specific objects or situations, i.e. anxiety neurosis or generalized anxiety disorder (F41.1).

In childhood and adolescence, three kinds of anxiety may be distinguished:

- phobic anxieties related to specific objects and situations,
- fluctuating anxieties (anxiety attacks) that are not related to specific objects or situations, and

- generalized anxieties that do not occur episodically, but rather are persistently present and are not related to specific objects or situations.

The latter form of anxiety is also referred to as free-floating anxiety; it is rare in childhood and becomes significantly more common in adolescence.

Among children and adolescents suffering these disorders, there are significantly more girls than boys (the sex ratio is approximately 3:2). As for the age of onset of illness, monosymptomatic (specific) phobias generally arise in childhood (especially animal phobias); social phobias generally arise around the time of puberty and in early adolescence, in which the themes of childhood anxieties undergo a marked, developmentally typical change toward social situations. In what follows, two groups of anxiety syndromes will be discussed: (1) panic attacks and agoraphobia and (2) generalized anxiety disorder (previously known as anxiety neurosis). Reviews of the anxiety disorders can be found in Klein (1984) and Bernstein et al. (1996) (for a discussion of phobic anxiety disorders, see Sect. 4).

7.1.1 Panic Attacks and Agoraphobia

Panic attacks (anxiety attacks) are severe, recurrent episodes of anxiety that begin suddenly, are not associated with specific situations or circumstances, and therefore cannot be predicted. Their manifestations vary widely from case to case but always include a number of physical symptoms, some of which appear dangerous, such as shortness of breath or a feeling of suffocation, dazedness, worry, a feeling of being about to faint, tachycardia, diaphoresis, trembling, etc. The attacks last only a few minutes and are highly variable in their frequency (a few per month to several per day). Although it is not characteristic for the attacks to be associated with specific situations or circumstances, there are a few patients in which they are. These situations and circumstances are then anxiously avoided (e.g. riding the bus, being in a crowd).

The term "agoraphobia" was originally applied only to fear of open spaces. It is currently a collective designation for fears of the public and of gatherings of people in a wide variety of locations. Thus, the alternative term "multiple situational phobia" has also been suggested for the disorder.

Agoraphobia is among the more common anxiety syndromes. Its longitudinal prevalence lies between 3.4% and 9%. The lifetime prevalence of panic attacks in the general population has been determined to be between 1.4% and 2.4% (Angst and Dobler-Mikola, 1985a,b; Wittchen 1986).

In contrast to the phobic syndromes, there is no clear evidence for the presence of a strong premorbid disposition to anxiety among patients with panic attacks.

It is also questionable whether there is a specific genetic risk factor for panic attacks, which are etiologically more closely related to generalized anxiety disorder (earlier called anxiety neurosis) than to the phobias. Psychophysiological explanatory approaches are based on the observation that panic attacks are often described by patients as beginning with physical symptoms. This has led some to conclude that the physical symptoms are primary and the emotional state of anxiety secondary.

It has been known for some time that agoraphobia, unlike panic attacks, can be induced by stressful life events (Marks 1987), although the patients often cannot remember the acute situation that induced it.

The diagnosis of both types of disorder (panic attacks and agoraphobia) is made on the basis of the clinical history and the symptoms described by the patients. The differential diagnosis must exclude other anxiety syndromes and organic illnesses, particularly those involving the cardiovascular system.

In accordance with current conceptions of the etiology and pathogenesis of panic attacks, in which the auto-observation of physical symptoms precedes the development of anxiety, current methods of treatment are very strongly oriented toward confrontation with physical stimuli. The following approaches have proved useful:

1. confrontational treatment employing strategies for coping with anxiety;
2. the provision of coping strategies;
3. cognitive strategies;
4. drug therapy with tricyclic antidepressants or monoamine oxidase inhibitors. (Benzodiazepines have also been found helpful, but should be used as little as possible because of their potential for abuse.)

Agoraphobia is treated according to the same principles as other phobic syndromes. When it is coupled with panic attacks, the treatments listed above for panic attacks are specifically modified in order to address the agoraphobic component. Confrontation has proved to be the most effective method for treating agoraphobia, as well as panic attacks. It should be carried out in a natural setting whenever possible. For agoraphobia, too, drug therapy with tricyclic antidepressants and benzodiazepines has proved useful, but it should only be applied in combination with behavior therapy (Remschmidt 1997a).

The highest age-specific prevalence of panic attacks and agoraphobia lies between the ages of 20 and 30. Approximately 10% of cases appear before the 16th

year. Both disorders have a strong tendency to become chronified if they are not treated or if they have persisted for a long period of time (e.g. more than one year).

7.1.2 Generalized Anxiety Disorder

The most prominent manifestation of this disorder is generalized, free-floating anxiety that is not associated with any particular situation and does not arise suddenly and episodically, as in panic attacks, but rather persists as a kind of permanent background state and is accompanied by many somatic manifestations such as muscle tension, diaphoresis, trembling, continuous nervousness, palpitations, vertigo, and sometimes upper abdominal symptoms. Fears and worries about the future are often expressed, for example a fear that the patient or a near relative may become ill or have an accident.

Three groups of manifestations of generalized anxiety disorder (ICD-10 classification: F41.1) are listed in the diagnostic guidelines of the ICD-10:

1. worries such as fear of future misfortune, a feeling of being at one's limit, difficulty concentrating;
2. motor tension in the form of physical agitation, tension headache, trembling, and inability to relax;
3. autonomic overexcitability, expressed as diaphoresis, tachycardia, tachypnea, vertigo, and dry mouth, or as dazedness and upper abdominal symptoms.

The DSM-IV diagnostic guidelines emphasize the unrealistic or exaggerated nature of the anxiety and worry about two or more areas of life, which last for at least six months in most patients.

A marked premorbid disposition to anxiety, which occurs on a familial basis, is thought to underlie generalized anxiety disorder. There is often also an accompanying depression, or at least a tendency toward depression. The illness usually begins between the ages of 20 and 30, frequently subsequent to a depressive mood disturbance. It is slightly more common in women.

Because the disorder has no specific situational association, there is no corresponding situational treatment (e.g. by the method of exposure and confrontation). Thus, the aim of treatment is to reduce anxiety in general and to promote the development of coping strategies (Remschmidt 1997a). The following treatment measures have proved useful:

1. relaxation training (e.g. autogenic training or progressive muscle relaxation, after Jacobson);
2. direction of treatment toward physical symptoms (e.g. through biofeedback);
3. drug treatment (with antidepressants, as the disorder often begins after a depressive mood disturbance).

The course of generalized anxiety disorder is variable. In many cases, periods of relative freedom from anxiety alternate with periods in which anxiety is often present. Unlike many phobias, the disorder usually begins in late adolescence or in adulthood, and tends to become chronified. The prognosis with respect to cure is increasingly unfavorable the longer the disorder has been present.

7.2 Obsessive–Compulsive Disorders

Three types of obsessive–compulsive disorders are distinguished in ICD-10: those with predominantly obsessional thoughts or ruminations (F42.0), those with predominantly compulsive acts or obsessional rituals (F42.1), and those with mixed obsessional thoughts and acts (F42.2). The lifetime prevalence of obsessive–compulsive disorders is approximately 2% to 3% in adults. The point prevalence among adolescents is approximately 2%. Obsessive–compulsive disorder usually begins in late childhood and early adolescence. In later adolescence and adulthood, the sex ratio is fairly even, while there is a mild excess of boys in childhood. The clinical picture of these disorders is characterized by a broad spectrum of severity, situational dependence of manifestations (most pronounced in unfamiliar environments), marked comorbidity with other disorders (most commonly anxiety disorders and depressive disorders), abnormal premorbid personality and similar traits in relatives, and, in many cases, a specific provocative factor. Reviews may be found in March and Leonard (1996) and Rapoport et al. (1994).

Family studies have shown that approximately 20% to 25% of children with obsessive–compulsive illnesses have at least one parent who suffers from an obsessive–compulsive illness. First-degree relatives of patients with tic disorders also have an elevated frequency of obsessive–compulsive disorders. These findings imply that genetic factors play an important role. Infections and immunological factors have also been discussed recently among possible etiologic factors for obsessive–compulsive disorders (Swedo and Rapoport 1990). On the neurotransmitter level, these disorders have been attributed to dysfunction of the serotonergic and dopaminergic systems. This hypothesis is supported by the therapeutic effectiveness of selective serotonin reuptake inhibitors and by the high degree of comorbidity of these disorders with tic disorders, for which there is also thought to be an underlying dysfunction of the dopaminergic system.

The treatment is multidimensional in practice; behavior-therapeutic methods are used in combination with drug therapy. The former include desensitization

techniques, particularly in cases with a strong component of anxiety. Moreover, cognitive strategies are combined with action-oriented measures (e.g. thought stopping and saturation methods) (Remschmidt and Niebergall 1997). Among drug therapies, serotonin-specific antidepressants such as clomipramine and selective serotonin reuptake inhibitors such as fluoxetine, fluvoxamine, and paroxetine have been found effective. The therapeutic benefit usually sets in after a delay of three to four weeks from the start of treatment.

The prognosis of obsessive–compulsive disorders in children and adolescents, as in adults, is rather unfavorable. Follow-up studies have revealed that chronification takes place in 30% to 40% of cases of obsessive–compulsive disorders with onset in childhood and adolescence. The further course and prognosis also depend on comorbidity; common comorbid disorders include anxiety disorders, depressive disorders, and personality disorders (Neudörfl and Herpertz-Dahlmann 1996).

7.3 Dissociative Disorders (Conversion Disorders)

In ICD-10, the terms "dissociative disorders" and "conversion disorders" are used synonymously (F44); in DSM-IV, a distinction is drawn between the two. The term "dissociation" designates an interruption of the normal integration of mental functions such as consciousness, perception, memory, identity, personality, and (sometimes) motor control (Blanz et al. 1987; Michelson and Ray 1996).

The discussion in this section is based on a tripartite division of these syndromes:

- conversion disorders (with predominantly physical manifestations),
- dissociative disorder (with predominantly mental manifestations), and
- histrionic personality.

In view of the lack of representative studies on the frequency of these disorders in field samples, one must rely on data from clinical and non-representative reports. Among the patient population of clinics for child and adolescent psychiatry, the prevalence of conversion syndromes and dissociative disorders has been reported as lying between 1.5% and 5%. In most studies, girls predominate, with a sex ratio of 3:1 to 4:1.

Conversion Disorders (Predominantly Physical Manifestations)

Approximately 40% of all conversion syndromes in childhood and adolescence take the form of seizures or movement disorders, while approximately 13% take the form of psychogenic paralysis or sensory deficits.

Psychogenic seizures are the most common type of conversion syndrome in childhood and adolescence, followed by psychogenic gait disturbances and twilight states. Nevertheless, one can often observe patients who suffer both from genuine epilepsy and from psychogenic seizures. The most important features of these disorders are:

1. *Psychogenic seizures* are characterized by their sudden occurrence, their occurrence in the presence of others and tendency to go on longer than epileptic seizures, and the fact that they can be provoked by an experience or stress reaction. Further typical features include bizarre and uncoordinated movements that do not resemble those of known patterns of epileptic seizures, the lack of EEG abnormalities, and the rarity of self-injury.
2. *Psychogenic paralyses and movement disorders* usually involve complex, goal-directed motor processes such as walking, standing, and other voluntary movements. The severity and localization of the movement disorder does not conform to known anatomic patterns of innervation, but rather to lay notions of how the body is constructed. The following psychopathological observations can be made:
   - The manifestations appear to be purposeful and have an ordered content that may be related to the provoking situation.
   - They often have a demonstrative character.
   - Despite the severity of the manifestations, the patient seems remarkably unconcerned about them ("la belle indifférence").
   - The relationship of the manifestations to the provoking situation can often be recognized by outsiders, but not by the patient.
3. *Psychogenic sensory deficits* are found in the form of psychogenic visual disturbances, including abnormal visual perceptions such as micropsia or macropsia, and partial or total psychogenic deafness.

Dissociative Disorders (Predominantly Mental Manifestations)

Dissociation most often affects memory (amnesia), personal integrity (depersonalization, multiple personality) and consciousness (trance states). These disorders are rare in childhood but more common in adolescence. They are characterized by sudden onset (psychogenic amnesia, psychogenic fugue), disturbances of identity (depersonalization), and a disturbed connection to reality, in the absence of psychosis. The individual disorders may be described as follows:

- *Psychogenic amnesia* is characterized by a sudden inability to remember important current and personal events. The loss of memory is so all-encom-

passing that it cannot be explained as ordinary forgetfulness. Exclusion criteria for the diagnosis include the presence of organic brain damage, intoxication, or multiple personality disorder.

- *Depersonalization and derealization* are characterized by a partial loss of reality without an overall disturbance of the patient's connection to reality (as in the schizophrenic psychoses, for example). Depersonalization is a feeling of foreignness in relation to one's own self, often accompanied by the feeling that certain parts of the body no longer belong to one's own body. Derealization is an experience of the environment (persons, objects) as foreign and unreal. When depersonalization occurs in the framework of dissociative disorders, neither hallucinations nor delusions are found. These patients are aware of their experiences of alienation and highly disturbed by them, but they are able to remain rooted in reality.
- *Multiple personality disorder* (dissociative identity disorder) is characterized by the coexistence of two or more "persons" in a single individual. Affected patients perceive the various personalities as discrete units with specific modes of behavior, memories and relationships, and, often, individual names. They often say that one or more of the personalities belong to the opposite sex or are younger than they themselves are. The disorder is extraordinarily rare in childhood and more common in adolescence and young adulthood.

Histrionic Personality Disorder

Histrionic personality disorder can also be mentioned here because it shares certain general features with conversion and dissociation disorders, although it manifests itself not in the form of specific physical or mental symptoms, but rather in abnormal attitudes of the personality as a whole (see Sect. 7.6).

According to Berblinger (1960), hypotheses concerning the etiology and pathogenesis of the conversion syndromes and dissociative disorders can be classified according to three types of postulated underlying mechanism:

1. inactivation of organs and organ systems (e.g. in paralyses, movement disorders, or sensory deficits);
2. increased functional autonomy of the mental apparatus (functional augmentation; e.g. in psychogenic seizures and exaggerated movements); and
3. decreased functional autonomy of the mental apparatus (e.g. in twilight states and amnesia).

A number of etiologic factors have been discussed but have not yet been integrated into a definitive theory. These include familial factors (whether genetic or in the sense of a family tradition), predisposing aspects of personality structure, exposure to role models, conflict-laden or overly demanding situations, and previous medical illnesses, which may influence the "choice of symptoms." The patient's gain from illness has also been emphasized, at least as a factor that may help maintain the disorder, as has the increased frequency of conversion disorders in brain-damaged patients.

The diagnosis is based on meticulous history-taking, negative findings of a thorough neurological examination including ancillary testing, and an extensive psychiatric and psychological examination. The latter must take the patient's cognitive functional level, individual emotional features, and personality structure into account, and must concentrate especially on the possible relationship of the manifestations to typical provoking situations and conflicts.

The differential diagnosis of conversion syndromes and dissociative disorders includes the following illnesses:

1. psychosomatic illnesses (as already described, in all essential features, by Alexander in 1943);
2. paralysis, epileptic seizures, and other movement disorders (video-EEG is useful here);
3. schizophrenic psychoses, which not uncommonly manifest themselves in childhood and adolescents as dissociative disturbances.

If the underlying conflict or the often typical, excessively demanding situation can be identified, then the goal of treatment should be its elimination or neutralization. Thus, treatment always involves a change in the patient's general living conditions. Functional therapy is often required on the level of symptoms as well, e.g. by gradual practice of walking in patients with psychogenic paralysis. One may explain to the patient that he or she has forgotten how to walk because of the illness and must now slowly relearn it.

Treatment is usually provided on an individual basis, because group therapy fulfills the pathological need of many patients for domination and is therefore not indicated, at least in the initial stage of treatment. If additional manifestations are present, such as seizures, treatment is provided according to the same principles, but the role of medications in the overall treatment plan is particularly important. The most significant factors for the success of psychotherapy are the following: the therapist must adapt the therapeutic relationship as precisely as possible to the patient's abilities, and he or she should be cautious about making possibly premature symbolic interpretations. The patient must be provided with alternative coping strategies so that the illness manifestations are no longer necessary.

Conversion syndromes arising for the first time are usually easily treatable and rapidly eliminated.

Treatment is more difficult when the disorder has been present for a longer period and the patient has repeatedly drawn considerable gain from it (Remschmidt 1997b).

7.4 Affective Disorders

The term "affective disorders" encompasses several disorders that differ from one another in etiology, manifestations and course but are similar in the following respects:

1. They are characterized by marked abnormalities of mood and drive, with or without accompanying anxiety. The patient's mood may be altered in the direction of either depression or mania.
2. Furthermore, they are regularly accompanied by cognitive and somatic manifestations.
3. They tend to recur and often become chronified.

The classification of these disorders is still unsatisfactory at present and is based on pragmatic clinical considerations. ICD-10 distinguishes the following types of disorder: depressive episodes (F32), recurrent depressive disorder (F33), manic episodes (F30), bipolar affective disorder (F31), and two types of persistent mood [affective] disorders (F34), namely cyclothymia (F34.0) and dysthymia (F34.1). The DSM-IV essentially follows the same basic scheme; under the designation "depressive disorder," it includes two subtypes – major depressive disorder as a single episode (296.2) and recurrent major depressive disorder (296.3). In both systems, depressive reactions may also be classified as adjustment disorders.

Affective disorders may begin as early as the childhood years but become significantly more frequent in adolescence and then undergo a transition to the adult illness pattern; they are thus discussed in this chapter among other adult-type disorders of early onset. Current reviews are found in Goodyer (1995), Harrington (1993) and Rutter et al. (1986).

The manifestations of depressive conditions can be quite varied. Emotional manifestations other than the sad background mood include marked inhibition of drive, loss of interest, increased anxiety and irritability, sometimes mood fluctuations over the course of the day, and, often, feelings of guilt. Cognitive manifestations include inhibited thinking, brooding, disturbances of concentration, a feeling of helplessness and powerlessness, negative expectations for the future, and suicidal ideation. Finally, there may be somatic manifestations such as sleep disturbances, lack of appetite, weight loss, fatigue, psychomotor slowing or agitation, loss of libido, hypochondriacal symptoms, and other somatic-vegetative complaints such as headache, stomachache, and digestive disturbances.

An understanding of depressive disorders in adolescence requires knowledge of the following special aspects of developmental psychopathology (Rutter et al. 1986):

- Both depressive mood disturbances and well-defined depressive illnesses can occur in childhood but become much more common in adolescence, more in relation to the process of puberty than to chronological age.
- Boys predominate among sufferers from affective disorders in childhood, but the sex ratio shifts in favor of girls over the course of puberty.
- Both suicidal ideation and suicide attempts (within and outside the context of depressive disorders) become considerably more frequent during adolescence, and are more common among girls. Completed suicide is extremely rare before puberty and rises in frequency from adolescence until adulthood.

The single depressive episode is regarded as constituting a disorder in itself, because it is often unclear whether it is a component of a larger disorder. Its characteristic features include the cardinal manifestations of depressive disorders, such as a sad and oppressed basic mood, loss of drive, loss of interest, and sleep disturbances, as well as increased fatigability. Further common manifestations, according to the ICD-10, include difficulties of concentration, diminished self-esteem and self-confidence, guilt feelings, pessimistic perspectives on the future, suicidal ideation or behavior, sleep disturbances, lack of appetite, weight loss, diffuse anxieties, and motor unrest.

The manifestations of recurrent depressive disorders are the same as those of the single depressive episode. The episodes occur repeatedly, and the duration of each is highly variable (weeks or months). The first episode may occur at any age between childhood and old age. In the recurrent depressive disorders, too, various degrees of severity are distinguished (mild, moderate, and severe recurrent episodes; the last may be with or without psychotic manifestations).

The severe forms of recurrent depressive disorders have a great deal in common with the depressive episodes that occur in bipolar illness; thus, the latter must be excluded in the differential diagnosis. The occurrence of hypomanic or manic episodes is regarded as a criterion of exclusion for the diagnosis of a recurrent depressive disorder.

As for manic episodes, these are characterized by excessive drive, lack of distance, aimless activity and hyperactivity, elevated self-esteem and exaggerated conception of oneself, and further by ideas of grandeur or thoroughly unrealistic plans for the future. In these

phases, patients require almost no sleep and are constantly in motion. Mania in children can "flip over" into depression within a few days. In adolescence, mania often displays manifestations that are otherwise typical of schizophrenia, including delusions and hallucinations, and may thus easily be misdiagnosed as a schizophrenic or schizoaffective psychosis. A reliable differential diagnosis is usually feasible only through observation of the patient's further course.

Bipolar disorder is characterized by an alternation of depressive and manic episodes, interspersed with phases of normal mental health (remissions) lasting for variable periods of time. Disorders with exclusively manic or hypomanic manifestations are extremely rare in childhood and adolescence and are also classified among the bipolar disorders. In both classification systems (ICD-10 and DSM-IV), the type and severity of the current episode are classified in individual categories—for example, "bipolar affective disorders, current episode manic without psychotic symptoms" (F31.1). Common precursors of bipolar disorders include conduct disorders and hyperkinetic disorders; this fact makes their diagnosis in childhood more difficult (Remschmidt 1998). Bipolar disorders are extraordinarily rare in childhood and have a prevalence of less than 0.1% in adolescence as well. Their lifetime prevalence is 0.4% to 1%.

The ICD-10 designation "persistent mood [affective] disorders" refers to "persistent and usually fluctuating disorders of mood in which individual episodes are rarely if ever sufficiently severe to warrant being described as hypomanic or even mild depressive episodes. Because they last for years at a time, and sometimes for the greater part of the individual's adult life, they involve considerable subjective distress and disability. In some instances, however, recurrent or single episodes of manic disorder, or mild or severe depressive disorder, may become superimposed on a persistent affective disorder. The persistent affective disorders are classified here rather than with the personality disorders because of evidence from family studies that they are genetically related to the mood disorders, and because they are sometimes amenable to the same treatments as mood disorders" (WHO 1992, p. 128). Cyclothymia and dysthymia are included among these disorders.

Cyclothymia is a persistent instability of mood characterized both by mild depressive episodes and by episodes of elevated mood. The definition of cyclothymia states that it develops in early adulthood, but it may also arise in childhood and adolescence, although the diagnosis is extraordinarily difficult to make in this phase of life. The family history is useful, as cyclothymia is more common in relatives of patients with bipolar affective disorders. Moreover, persons with cyclothymia are more likely to develop bipolar affective disorder. Thus, a preliminary phase of a bipolar affective disorder may be recognized in childhood and adolescence in the form of cyclothymic mood fluctuations.

Dysthymia is a chronic depressive mood disturbance that usually lasts for months but is repeatedly interrupted by periods of good mental health. It is characterized by marked depressive manifestations, generally in the aftermath of a traumatic experience. The traumatic experience may also be a persistent conflict with which the child or adolescent has been preoccupied continuously and for a long period of time, often without being aware of it. Furthermore, marked manifestations of anxiety are often present, or a mixed state of anxiety and depression. Delusions, hallucinations, and daily fluctuations are absent. The general state of chronic depression alternates with periods of good mental health lasting days or weeks. The diagnostic guidelines of the ICD-10 emphasize the chronification of the depressive manifestations, which nevertheless are not severe enough to reach the level of a mild or moderately severe recurrent depressive disorder.

Depressive conditions are diagnosed on the basis of the history and clinical manifestations. Supplementary techniques are available in the form of interviews, checklists, and scales. The differential diagnosis involves both the differentiation of depressive disorders from other psychiatric disorders that may have depressive manifestations (e.g. schizophrenia or organic illnesses) and their differentiation from one another. This is done mainly in reference to the diagnostic criteria of the two classification systems; from the point of view of child and adolescent psychiatry, it should be observed that these systems are not always directly applicable, in unmodified form, to our patient population.

A number of etiologic factors for the affective disorders have been postulated. Family studies have shown that the highest rate of recurrence is among relatives of bipolar index cases (ca. 18%), while that among relatives of unipolar index cases is lower (ca. 7%; Propping 1991). Twin studies have revealed concordance rates among monozygotic twins of 73% for bipolar disorders and 42% for unipolar disorders, and concordance rates among dizygotic twins of 14% for both disorders. Personality traits such as introversion, tendency to anxiety, and neuroticism are positively associated with depressive disorders.

Many models of depression postulate important roles for negative early experiences and current psychosocial stress. The best known is Seligman's (1975) model of learned helplessness, according to which a person unable to control his or her own subjective experiences eventually learns helpless behavior. Such a person feels that he or she is powerless

with respect to self-control and therefore expects to be helplessly exposed to other situations in the future.

According to the current, generally accepted model, all etiologic and pathogenetic factors for depression lead to the end result of an impairment of the biochemical neurotransmitter systems affecting mood, and to neuroendocrine alterations, which finally become manifest as the emotional, cognitive, and somatic features of depression.

Children and adolescents with severe affective disorders should be hospitalized because of the risk of suicide, which is often present in the form of a presuicidal syndrome even before the depressive disorder appears. The presuicidal syndrome of childhood and adolescence consists of marked withdrawal, neglect of interests, and suicidal thoughts, sometimes accompanied by an announcement of suicidal actions.

The use of tricyclic antidepressants to treat depressive children and adolescents remains controversial because the currently available double-blind, placebo-controlled studies have failed to show any therapeutic benefit of antidepressants in this population. They are nevertheless commonly used in clinical practice, and many clinicians are convinced that they are quite useful in individual cases. Their side effects have been very thoroughly studied; the most severe ones are tachycardia and slowing of intracardiac conduction. Thus, an EKG is mandatory both before and during the administration of these drugs, as are follow-up EEG studies, because of their possible influence on cerebral activity. The value of selective serotonin reuptake inhibitors in the treatment of depressive children and adolescents is currently being investigated; no conclusive statement can yet be made about it.

Lithium preparations are used to treat bipolar disorders. They have a prophylactic effect with respect to manic and depressive phases of endogenous, phasic illness. Thus, they can be used to treat acute mania and for prophylaxis in uni- or bipolar affective disorders. Carbamazepine, too, has been found useful in the treatment of certain kinds of affective disorders (prophylaxis against the recurrence of bipolar and unipolar psychotic phases) and for the prevention of recurrence in the schizoaffective psychoses (often in combination with neuroleptics or antidepressants). Finally, there has also been favorable experience with a combination of lithium and carbamazepine for the treatment of affective disorders with psychotic manifestations in adolescence. When such a combination is used, the dose of lithium can be lower than when lithium is given alone. The side effects of lithium, and the feared complication of lithium toxicity, can be avoided by meticulous checking of the serum lithium level, which should lie between 0.8 and 1.2 mmol/l, preferably toward the lower end of this range. Reviews of drug therapy are provided by Kutcher (1997), Nissen et al. (1998), and Remschmidt and Schulz (1995).

The modern forms of behavior therapy, which incorporate cognitive aspects as well, have gained acceptance in recent years for the treatment of depressive disorders in childhood and adolescence and have been found to have a high chance of success. Therapy of this type involves the following elements: establishment of a sturdy therapeutic relationship, reduction of stressful cognitions (thoughts and ideas), establishment and promotion of positive ties and social contacts. For bipolar disorders, however, the cognitive behavioral therapy of depression is indicated only in special circumstances, and only as an auxiliary measure (Harrington et al. 1998).

Additional measures to be considered include all those that take the patient's life circumstances and living environment into account. Two aspects are particularly important in childhood and adolescence: involvement of the parents and involvement of the environment at school or in the workplace.

Severe depressive disorders (i.e. major depression) in children and adolescents are associated with a mean duration of episodes of ca. 7–9 months and are thus considerably more protracted than previously supposed. The currently available studies of disease course all document relapse rates of 40% within 2 years of disease onset and 70% within 5 years. Children and adolescents exposed to a conflict-laden family environment have even higher relapse rates. Furthermore, 20–40% of adolescents who suffer a severe depressive episode develop a bipolar disorder within 5 years (Harrington et al. 1990, 1991).

7.5 Schizophrenia

In the two current classification systems (ICD-10 and DSM-IV), the schizophrenic, schizotypal and delusional disorders are classified in essentially the same way. Schizophrenia is divided into several subtypes. Both systems further provide separate classifications for the schizoaffective disorders (F25) and for schizotypal disorder (F21), which DSM-IV calls schizophreniform disorder. A major difference between the two systems is that DSM-IV includes a temporal requirement (duration of illness at least 6 months). The result of this is that many patients who would be diagnosed as schizophrenic according to the ICD-10 criteria are said to suffer from schizophreniform psychoses according to the DSM-IV criteria. The diagnosis of schizophrenia in DSM-IV is thus more restrictive.

Approximately 4% of all cases of schizophrenia arise before age 15, and 1% before age 10. Among the patients of clinics for child and adolescent psychiatry,

schizophrenic illnesses are present in 1%–2% of children and 2%–5% of adolescents. Boys predominate by a small margin. Studies of clinical samples have revealed that approximately 10% of schizophrenic psychoses appear between the ages of 14 and 20, and 42% between 21 and 30. Approximately three quarters of all schizophrenic patients are between 20 and 40 years old.

In recent years, the findings of empirical studies have cast doubt on the classical subdivision of schizophrenia into hebephrenia, catatonic schizophrenia, paranoid schizophrenia and schizophrenia simplex. Karl Leonhard formulated such doubts years ago and explained his reasons for them in detail in the last edition of his book, *Die Aufteilung der endogenen Psychosen* ("The Classification of the Endogenous Psychoses"). According to Leonhard, the retention of this scheme is partly responsible for the stagnation of research on schizophrenia.

While Leonhard proposes a highly detailed subclassification of the schizophrenic psychoses according to their psychopathological features and course, the simpler concept of positive (Type I) and negative (Type II) schizophrenia – a dichotomous classification of schizophrenia by psychopathological features – has received support from the findings of experimental and clinical studies. The most important features of both types of schizophrenia are listed in Table 4. They differ not only with regard to their clinical manifestations and premorbid personalities, but also with regard to other, experimentally testable functions.

This classification scheme is not entirely free of overlap; manifestations of both types may be present in a single patient.

Despite their relatively vague boundaries, the classical subtypes of schizophrenia mentioned above can be diagnosed in adolescence. In childhood, however, they are difficult to differentiate from one another and rarely appear as "pure cultures." With advancing age, their manifestations become increasingly similar to those seen in adulthood.

The general manifestations of schizophrenic disorders affect the areas of cognition and perception, emotion, language, motor function, and drive (see also the ICD-10 and DSM-IV diagnostic guidelines):

- *Cognition and perception* are frequently disturbed by formal thought disorders, delusions and hallucinations. Delusions become systematized during adolescence, extremely rarely before age 10. Adolescents relatively frequently have somatic hypochondriacal experiences and ideas of interpretation as well as delusions of persecution, of being influenced, and of being poisoned. The hallucinations are most commonly auditory, while visual hallucinations are more common among children. The latter must raise the suspicion of a possible organic etiology.
- *The emotional area, social contact, and conduct* are often disturbed, in adolescent patients, by marked manifestations of withdrawal and isolation. Not uncommonly, the patient's relationship to the outside world is qualitatively restructured, and substitute relationships are established, sometimes with personification of inanimate objects. Affect disturbances, particularly a suspicious and anxious mood, affect lability, negativism, and regression to infantile behavior, are common.
- *Language* disturbances may include changes in the manner of speaking, in logorrhea, a tendency toward perseveration, verbal stereotypies, echolalia, or phonographism. The abnormal speech of childhood schizophrenia may be difficult to tell apart from autistic speech. Neologisms are produced, and the meanings of words may be altered.
- *Spontaneous motor function:* there is often a general lack of coordination (stiffness, jerkiness) and

Table 4. Major features characterizing Type I and Type II schizophrenia

	Type I schizophrenia (positive symptoms, productive manifestations, acute schizophrenia)	Type II schizophrenia (negative symptoms, withdrawal manifestations)
Clinical features	Hallucinations, delusions, positive thought disorders, increased drive, aggression, excitement, bizarre behavior, logorrhea, neologisms	Flat affect, lack of drive, social and emotional withdrawal, apathy, paucity of speech, diminished drive to speak, anhedonia, negative thought disorders (thought inhibition, disconnected thoughts, entangled thoughts)
Attention and sensorium	Increased distractibility	Diminished information-processing capacity
	Broadened attention	Narrowed attention
Hemispheric function	Left hemispheric hypofunction	Frontal dysfunction, bilateral functional disturbance
Premorbid personality	No major cognitive or motor impairment	Cognitive and motor impairment

a reduction of spontaneous movement. Catatonic and cataleptic phenomena are occasionally seen. Stereotyped movements are relatively common (e.g. stereotypic postures or bizarre finger games). Obsessive-compulsive phenomena, which commonly occur as prodromal manifestations of schizophrenia, are often first manifested in the area of motor function.

- *Disturbances of drive* in affected patients include a loss of their earlier spontaneity and initiative. They sit listlessly in their rooms for hours and have no interest at all in pursuing a conversation, reading, or otherwise occupying themselves. The lack of initiative may be so extreme that they sit motionlessly without speaking or eating and no longer even voluntarily urinate or defecate.

The various subtypes of schizophrenia are characterized as follows:

- *Paranoid schizophrenia*, the commonest type, can arise as early as adolescence, but it is most common in adulthood. Delusions and auditory hallucinations predominate. There are also disturbances of cognition and affect. This form of the illness usually does not lead to a change of personality or affect the patient's intelligence. It is the prototype of "positive schizophrenia."
- *Hebephrenia* usually begins after puberty with lack of drive, chaotic thinking, flatness of affect, and a cheerful, silly mood. As the illness progresses, it generally leads to a decline of cognitive and emotional functioning. These patients often already manifest premorbid personality traits (being a "loner," shyness, timidity). The diagnosis of hebephrenia should be made only after several months of observation. The rapid development of negative manifestations places this disorder in the class of the "negative schizophrenias."
- In *catatonic schizophrenia*, the most prominent manifestations are motor phenomena, acute excitement and blocked states (stupor), and mutistic behavior. Command automatism may alternate with negativism. Many other manifestations may also be present, most commonly delusions and hallucinations, which may also be associated with a dreamlike (oneiroid) state.
- *Schizophrenia simplex* leads slowly and inisidiously, without particularly noticeable manifestations, to a condition of permanent mental impairment. The illness usually begins in adolescence; the patients lack drive and have a dull affect, they have no energy or initiative, they are depressed or ill-humored, and they fail in school or at work. They often abandon their usual activities or change jobs, drift along and let themselves go. Schizophrenic illnesses of this type can be very difficult to recognize because the usual diagnostic categories often do not apply to their extremely bland clinical manifestations.
- *Schizoaffective psychoses* are characterized by the simultaneous presence of manic or depressive manifestations and schizophrenic manifestations. These disorders cannot be diagnosed either as schizophrenia or as an affective psychosis. The most important factor for the diagnosis is the *simultaneity* of the schizophrenic and affective manifestations. If these always appear in separate episodes, a schizoaffective psychosis cannot be diagnosed. ICD-10 provides a further level of detail in the classification of these disorders, according to the type of affective manifestations present – thus, schizomanic, schizodepressive, and mixed schizoaffective disorders are distinguished. DSM-IV provides a comparable subdivision (bipolar vs. depressive type). Recurrences are frequent in this form of psychosis, but there is no residual state or lasting mental impairment.

Even though research on schizophrenia is being carried out intensively all over the world, we are still far away from a comprehensive understanding of its etiology. In view of this situation, we can do no more than list the causative factors whose importance has been confirmed by empirical studies, even if we cannot yet integrate them into a unified theory: genetic factors, brain damage, disturbances of cerebral function, and psychogenic factors. For reasons of space, these factors cannot be discussed here in detail. A mere look at this brief list leads one to conclude that the ultimate explanation of the etiology of schizophrenia will be multifactorial.

The currently available empirical data appear to permit the following statements. The functional substrate for the schizophrenic illnesses seems to be a regulatory system for information processing, which is susceptible to disturbances produced by factors of different kinds. These include organic factors (infection, hypoxia), intrapsychic factors (personality, ego structure), genetic factors, and familial and psychosocial factors (deviant communication, "expressed emotions," social stratum, "life events"). One may hypothesize that this system for the selection and processing of information is anatomically located in the limbic system. Evidence in favor of this hypothesis comes from the fact that the limbic system is particularly susceptible to hypoxic damage (including in the pre- and perinatal period). It is also the case that certain viruses, such as cytomegalovirus, have a special affinity for the limbic system, as has been pointed out by the proponents of the "infectious theory of schizo-

phrenia." When the limbic system has been weakened through a combination of influences, the affected persons may develop a schizophrenic psychosis, particularly when they have a genetic predisposition to schizophrenia and have also been exposed to stressful events in their family lives.

The diagnosis of schizophrenia is made on the basis of the clinical manifestations according to the guidelines of ICD-10 and/or DSM-IV. Ancillary scales and interviews are often applied, e.g. Andreasen's scales for the assessment of positive and negative manifestations (Andreasen 1984a,b), or other checklists. Entities to be excluded in the differential diagnosis include psychoses of somatic origin, drug-induced psychoses, and schizoaffective psychoses. Once schizophrenia has been diagnosed, an attempt is made to distinguish between forms with predominantly positive manifestations and those with predominantly negative manifestations, because this distinction is relevant to treatment.

Neuroleptic treatment is necessary in the acute phase of schizophrenia and has been repeatedly shown to be effective. Neuroleptics have the following therapeutically beneficial properties: psychomotor calming, damping of excitement and aggression, and an antipsychotic-antischizophrenic effect (review by Remschmidt et al. 2000).

In the treatment of acute psychotic states with predominantly productive manifestations, the butyrophenone derivatives (particularly haloperidol and benperidol) have proved very useful, as have the phenothiazines perazine, fluphenazine, perphenazine, and chlorproxithene. If the acute psychotic state is accompanied by pronounced agitation, levopromazine is recommended as a means of damping it. The foregoing "classical" concept of the medical treatment of schizophrenia is now beginning to change, however, as so-called atypical neuroleptics are being developed. These substances have a broader receptor binding profile than the typical neuroleptics (most of which are dopamine D_2-receptor antagonists), hardly any extrapyramidal side effects, and a better therapeutic effect on negative manifestations. The most important substances of this type are clozapine, olanzapine, and risperidone.

The greatest amount of experience to date with drug therapy in schizophrenic children and adolescence has been gained with clozapine, which should, however, be used with special caution because of its known adverse effect on the hematopoietic system (risk of agranulocytosis). Thus, complete blood counts must be obtained weekly during the first 18 weeks of treatment, and monthly thereafter. The treatment guidelines further require that clozapine be given only after two other neuroleptics have been tried without success. Under these conditions, and after thorough education of the patients and their parents, the use of clozapine is permissible, and usually very effective. The two other atypical neuroleptics have also been found to be effective. They have no adverse effects on the hematopoietic system and are therefore not subject to the special precautions and conditions for administration that apply to clozapine, but they do not have an equivalent antipsychotic effect. (Table 5 provides an overview of the most important typical and atypical neuroleptics, and corresponding dosages.)

Sulpiride is recommended for the treatment of psychotic states with non-productive manifestations, in which lack of drive, negativism, autistic behavior, inhibition and withdrawal are prominent. Success has also been reported with haloperidol and fluphenazine. Here, too, there is a current movement toward treatment with atypical neuroleptics, not least because of their total or near-total absence of extrapyramidal side effects.

Chronic schizophrenic psychoses are an indication for the use of depot neuroleptics. These have the same effectiveness profile as short-acting neuroleptics and, like them, influence not only the productive manifestations (hallucinations, delusions, thought disorders) but also autistic behavior, withdrawal, and psychomotor inhibition. Haloperidol decanoate, fluphenazine decanoate, fluspirilene, and penfluridol are used as depot neuroleptics. They are given intramuscularly, and their effect lasts for 1 to 4 weeks, depending on the substance. Depot neuroleptics are given in relatively low doses in comparison to short-acting neuroleptics. They have the same side effects. Recently, the atypical neuroleptics have been increasingly used instead of depot neuroleptics.

The common undesired effects of the typical neuroleptics include vegetative effects (hypersalivation, disturbances of accommodation, urinary disturbances, hyperhidrosis), cardiovascular effects, hematological effects, hepatic effects, endocrine effects (e.g. galactorrhea, gynecomastia, amenorrhea), and extrapyramidal effects. Epileptic seizures may occur as a consequence of a lowered seizure threshold, and non-specific mental effects may also occur.

The common undesired effects of clozapine include hypersalivation, weight gain, seizure tendency, and possible hematopoietic effects, which can be avoided by regularly checking the complete blood count. Olanzapine also causes hypersalivation and weight gain but has no effect on the hematopoietic system. Risperidone, unlike clozapine and olanzapine, causes extrapyramidal side effects in a dose-dependent manner and thus occupies an intermediate position between the typical and atypical neuroleptics. Epileptic seizures have also been observed in association with risperidone use.

Supportive psychotherapy is a valuable complement to drug therapy and consists of the following measures:

Table 5. Effectiveness profile of selected neuroleptics

	Sedation	Positive symptoms	Negative symptoms	Neuroleptic potency	Usual oral dose or usual i.m. depot dose
Typical neuroleptics of high potency					
Benperidol	+	++	++	100	1–6 mg/d
Flupenthixol (decanoate)	+	++	++	50	2–10 mg/d (20–100 mg/ 2–4 wk)
Fluphenazine (decanoate)	+(+)	+++	++	30	5–20 mg/d (12.5–100 mg/ 2–4 wk)
Fluspirilene	+	+++	++	300	(2–10 mg/wk)[a]
Haloperidol (decanoate)	+	+++	++	60	2–20 mg/d (50–300 mg/ 2 wk)
Perphenazine (enanthate)	++	+++	++	8	12–64 mg/d (50–200 mg/ 2 wk)
Pimozide	+	+++	++	50	4–20 mg/d
Typical neuroleptics of intermediate to low potency					
Chlorpromazine	+++	+++	++	1	150–600 mg/d
Chlorprothixene	+++	++	++	0.8	150–600 mg/d
Levomepromazine	+++	++	++	0.8	75–600 mg/d
Perazine	++	++	++	0.5	75–600 mg/d
Pipamperone	++			0.2	120–360 mg/d
Promethazine	+++				50–400 mg/d
Sulpiride	+	++	+++	0.5	100–800 mg/d
Thioridazine	+++	++	++	0.7	200–700 mg/d
Tiapride	+				300–600 mg/d
Atypical neuroleptics					
Clozapine	+++	+++	+++	(0.5–2)	25–600 mg/d
Olanzapine	++	+++	+++	(8–20)	10–20 mg/d
Quetiapine	+	+++	+++		150–750 mg/d
Risperidone	+	+++	+++	(50)	1–12 mg/d
Zotepine	++	+++	+++	(2)	75–300 mg/d

+, little or no effect; ++, intermediate effect; +++, strong effect.
[a]Only available in depot form.
Neuroleptic potency is given in relation to chlorpromazine (=1). The neuroleptic potency of the atypical neuroleptics was determined from the mean clinically effective dose rather than the threshold for extrapyramidal symptoms.

psychological guidance of the patient, encouragement, addressing everyday problems and worries, improvement of self-esteem and the ability to make contact and communicate. It has been found to be important not to let the patients regress excessively during supportive psychotherapy, and not to give in to their tendency to withdraw. Psychotherapy with the aim of uncovering putative underlying conflicts is contraindicated in the acute phase of schizophrenic illnesses and, even in the chronic phase, carries the danger of promoting a relapse of psychosis. The reason is that an excessively intense probing of emotional and instinctual impulses may overwhelm the patient's processing abilities.

A further approach in the psychotherapy of schizophrenic patients is directed toward the so-called basic cognitive disturbances, which the patient must first be made to understand and which can then be dealt with by means of a special training program. Cognitive disturbances of thinking, perception, and behavior manifest themselves as blockages, oppressive and racing thoughts, absence of thought, and compulsive ideation, as diffuse, scattered, and easily distracted thinking, or as highly associative thinking lacking direction. The patient's concentration is impaired, as are memory and immediate retention. Perceptions may be distorted both quantitatively and qualitatively. There may be hypersensitivity to light and sound, sensory hypervigilance, blurred, distorted or deformed vision, or similar disturbances. Motor activities may be impeded or even blocked. The ability to carry out automatic or semiautomatic processes is lost; finally, there are coenesthesiae and vegetative disturbances.

Such disorders must be dealt with actively by the therapist, because the patients often fail to complain of them. Making the patient understand the disorder means, in the present context, that the child or adolescent should understand that these disturbances, which he or she can describe quite competently in a

subjective way, are due to the underlying illness and that they can be improved or eliminated by functional therapy and by a treatment of the underlying illness. The integrated psychological therapy program for schizophrenic patients (IPT) of Roder et al. (1992) may serve as an example of a structured therapy programs. Such programs, of which several are available, provide a graduated sequence of training in cognitive differentiation, social perception, and communication, and exercises through which problem-solving techniques may be practiced.

The goal of occupational therapy is to help these frequently introverted and aloof patients become mentally more relaxed and enable them to live in the community again. Through artistic activities (painting, drawing, working with clay), many patients can become less reserved and can, indeed, develop a more optimistic self-image through the often surprisingly good results of their creative efforts. Work therapy is usually used in adolescent patients to adapt them better to their environment through the imposition of progressively more difficult physical demands. It is thus a component of rehabilitation, which is an important goal for all psychiatric patients.

The younger the patient, the more important it is to involve the family in the treatment process. The emphasis is no longer placed on highly ambitious family therapy in which intrafamilial roles are reconstructed, but rather on educating the family about the illness, family counseling, practicing ways of dealing with critical situations, and promoting family strategies for coping with stresses within and outside the family. Only a few such programs have been systematically studied with respect to their use among adolescent schizophrenics.

For adult schizophrenics, treatment programs combining adequately dosed depot medication with structured supportive family programs have been found to be effective. The combination of these two measures has two major effects:

- The structured therapy program with the family may result in the patient's being exposed to fewer inappropriate and hostile emotions on the part of other family members.
- Neuroleptic medication, by its prophylactic effect, helps prevent the patient from being impaired by the emotions that are present.
- 40% of schizophrenic adolescents cannot resume their scholastic or occupational activities, or even return to their home environment, immediately after their discharge from inpatient psychiatric care, either because their illness has become chronified, or because of severe disturbances in their families. This group of patients requires a rehabilitation program designed to enable them, after one to two years of treatment, to become reintegrated into their familiar environment, or to develop a new perspective on advancement in school and at work.

A program of this type was developed at the Marburg Clinic in cooperation with the Leppermühle home for special educational needs. It was shown that this rehabilitation program meets the patients' needs and enables their gradual reintegration into school, the workplace, and the family. The four phases of this program of treatment and rehabilitation are shown in Table 6. The first two phases take place in the psychiatric clinic, the last two in the rehabilitation center.

The course of schizophrenic psychoses beginning in adolescence has been less well studied that that of schizophrenic psychoses beginning in childhood or adulthood. This may be because the psychoses of adolescence have already been grouped together with those of adulthood, as there is not expected to be any great difference between them. Yet this assumption is false, as the few studies published to date have shown: schizophrenic psychoses beginning in the prepubertal period and during adolescence have a less favorable course than those beginning in adulthood. Among cases beginning in adulthood, complete remission was observed in 25%, partial remission in 50%, and a chronic course in 25%; but, among cases beginning in adolescents, complete remission was observed in 23%, partial remission in 25%, and a chronic course in 52%.

7.6 Personality Disorders

The concept of personality disorders has always been problematical in child and adolescent psychiatry (cf. Remschmidt 1978). A historical look at the development of this concept reveals that arguments for and against this type of diagnosis (then termed psychopathy) were advanced decades ago, and the problem is just as real today. In ICD-10, the corresponding chapter is entitled "Disorders of Adult Personality and Behaviour." This title reflects that view that certain particularly marked behavioral abnormalities and disorders of reactive origin are related to the personality disorders. DSM-IV proceeds along similar lines. The most important personality disorders, according to ICD-10, are listed in Table 7.

The frequency of personality disorders in the general population has been estimated as lying between 3% and 8%. Among patients in psychiatric clinics, the rate is about 40%; the disorders most commonly diagnosed are borderline personality disorder, emotionally unstable personality disorder, and anxious personality disorders.

Both biological and psychological factors contribute to the etiology and pathogenesis of the personality

Table 6. The four phases of a treatment and rehabilitation program for adolescents with schizophrenic psychoses, and the objectives of each phase (After Martin and Remschmidt 1983)

Acute phase (clinical treatment)	Remission phase (clinical treatment)	Rehabilitation phase I (care in a home)	Rehabilitation phase II (supervised living group)
Inpatient admission	Further inpatient care	Depot medication, group therapy	Depot medication, becoming independent in the group
Neuroleptic medication	Neuroleptic medication	Individual therapy	
Rapid mobilization	Integration in the group	Practice of daily activities	Self-sufficiency
Individual therapy and care	Participation in a working group	School attendance	Vocational training or apprenticeship
Occupational therapy	School attendance or individual instruction	Finding a vocation	
Maintaining contact with the family	Reality training	Reality training	
Group activities (where possible)	Concentration training Activities in town, becoming independent, leaves of absence, family discussions	Creative support, family contact	
Objective: Improvement of acute manifestations, prevention of withdrawal and chronification	*Objective:* Reintegration in the clinical setting	*Objective:* Reintegration in the larger community, adjustment to reality, finding and preparing for a vocation	*Objective:* Self-sufficiency, vocational development

disorders. As for biological factors, twin and adoption studies have shown that genetic influences are very important in determining personality. Because many personality disorders are characterized by impulsive behavior, lack of self-control, and aggressive impulses, there has been a search for biological markers that might explain these behavioral abnormalities. It is now regarded as scientifically established that they are related to a diminished activity of the serotonergic system. Moreover, neuropsychological deficits corresponding to diffuse or localized disturbances of brain function have been found to be more common in persons with personality disorders than in normal individuals. Finally, persons with personality disorders also have been found to suffer more frequently from attention disorders, and to have a diminished capacity for habituation.

Psychosocial factors such as stressful conditions in early childhood, being raised outside the family, experiences of separation and loss, and physical and sexual abuse – thus, generally speaking, highly unstable developmental conditions – are thought to promote the development of personality disorders in individuals with an underlying (genetic) predisposition. From the point of view of developmental psychology, personality disorders are due to a lack of development of processes of structuring and differentiation.

In the path-breaking conception of August Aichhorn (1925), psychopathy and demoralization were considered to result from ego dysfunction and ego weakness. The therapist's task is accordingly to make up for these developmental deficits. This can be a lengthy process. The concept of pedagogical guidance is most commonly applied in the treatment of personality disorders. Patients, particularly adolescents, with personality disorders can be brought to a relatively good level of adjustment through a suitable configuration of the treatment milieu and environmental influences. Short-term treatment programs are of no use in the treatment of such severe disorders.

There are major differences among personality disorders with respect to their course. The personality disorders that are associated with impulsiveness and antisocial and delinquent behavior have the least favorable prognosis, as was revealed by follow-up studies as early as the 1960's (Robins 1966, Sundby and Kreyberg 1968). On the other hand, many pathological features become milder as patients grow older, as found by Tölle (1966) on long-term follow-up of "psychopathic adults." Approximately two thirds of his sample group ($n = 115$) had achieved a satisfactory mode of living, though sometimes with restrictions. It must be mentioned that the risk of suicide in persons with personality disorders is approximately three times higher than that of the general population; the highest suicide rates are found among patients with borderline or narcissistic personality disorder.

Table 7. Overview of the different types of personality disorders, according to the ICD-10 (WHO 1992)

Specific personality disorder	ICD-10 category	Principal features
Paranoid	F60.0	Suspiciousness and a pervasive tendency to distort experience by misconstruing the neutral or friendly actions of others as hostile or contemptuous
Schizoid	F60.1	Limited capacity to experience and express emotion, anhedonia, emotional coldness, aloofness, social indifference and isolation, shyness and reserve in interpersonal contacts
Dissocial	F60.2	Habitual tendency to deviancy and delinquency, which begins in childhood in many cases; characteristic features such as lack of empathy, callousness, egocentrism, and underdeveloped conscience; also impulsiveness, persistent irritability, unreliability, weakness of attachments, and disregard or violation of social norms
Emotionally unstable	F60.3	*Impulsive type:* lack of impulse control and affect guidance, easy excitability, and, particularly in frustrating situations, a tendency toward outbursts of violent and threatening behavior
		Borderline type: instability of mood and of interpersonal relationships, identity crises, aggressive outbursts under emotional stress, autoaggressive tendencies ranging to drastic self-destructive and parasuicidal acts
Histrionic	F60.4	Dependence on attention from others, confirmation and recognition; labile and superficial affect, tendency toward dramatization, artificiality, and flirting; overconcern with physical attractiveness and inappropriately seductive behavior; suggestibility; lack of consistently maintained goals and values, leading to instability in interpersonal relationships and partnerships
Anankastic	F60.5	Conscientiousness, perfectionism, orderliness, conformity to rules, rigidity, indecisiveness, insecurity; difficult interpersonal relationships
Anxious (avoidant)	F60.6	Insecurity, feelings of inferiority, timidity; shyness, tension, clumsiness in interpersonal contacts; extreme fear of disapproval and rejection
Dependent	F60.7	Inability to lead one's own life independently; inability to assume responsibility for oneself; in close relationships, constant fear of loss and abandonment, accompanied by efforts to adapt to others and comply with their wishes

7.7 Sexual Disorders

The adult-type disorders of early onset include disorders of sexual identity, which may be seen even in childhood and becomes more common in preadolescence (atypical sex-role behavior, transvestitism, transsexualism), and disorders of sexual preference (exhibitionism and fetishism) (Green 1994; Martin and Remschmidt 1997).

In disorders of sexual identity in childhood and preadolescence, there is a discrepancy between the child's anatomical sex and its role behavior. The terms "atypical sex-role behavior" and "atypical psychosexual development" apply to these disorders, and are synonymous. In clothing, habits, and relationships with the opposite sex, affected children adopt modes of behavior that are inconsistent with their own sex. The ICD-10 speaks of a "gender identity disorder of childhood" with the major characteristic that the child wishes to belong to the opposite sex, without desiring to be anatomically transformed, as in transsexualism. The DSM-IV also provides an independent category for this disorder (gender identity disorder), which is very rare. No epidemiologic data are available.

Transvestitism is a deviant sexual behavior in which wearing clothes belonging to the opposite sex generates sexual pleasure, but there is no desire to assume another sexual identity. This disorder is designated by the same term in ICD-10 and DSM-IV. Transvestitism occurs in both male and female children and adolescents. Its prevalence in adults is one per 100,000 males and one per 400,000 females.

Transsexualism is a disorder of sexual identity characterized by an unshakeable desire to belong to the opposite sex, and to achieve this goal by means of a sex-change operation. This desire is a continuation of the mental constellation of the affected individuals as children and adolescents; they view themselves as unlucky individuals who think and feel as women, while being trapped in the body of a man (or vice versa).

The ICD-10 diagnostic guidelines stress that, in addition to the desire to be anatomically transformed,

the transsexual identity must persist for at least 2 years and must not be a manifestation of another disorder, such as schizophrenia or genetic or sex-chromosome abnormalities. DSM-IV provides no independent category for transsexualism and instead subsumes it under the category of gender identity disorder.

Transsexualism occurs in both sexes and is more common in women than in men (sex ratio, 3:2). It is a rare disorder and is thus only rarely seen in child and adolescent psychiatry. When such young people come for an office visit or are brought to the clinic by their parents, the problem is usually very serious, and is often accompanied by further mental disturbances (e.g. suicidal tendencies, depression, aggressive behavior).

The indication for treatment depends on whether the affected young person wishes to develop a sexual identity in accordance with his or her anatomical sex; only then is the patient motivated to undergo treatment. In the absence of such motivation, treatment, in the proper sense of the word, is not possible; the intervention must be limited to educating the young person about the nature of the disorder. At the same time, the parents are a second focus of treatment. They, too, must be educated about the nature of the disorder, and they must learn to accept their child's lack of motivation to undergo treatment. The therapist can best achieve these goals through joint conversations with the parents and the affected young person, in which all open questions can be discussed from both sides.

Some of these cases will pass over into genuine transsexualism, in which there is a desire for a surgical sex change. The prognosis is considerably more favorable when the patient is motivated to acquire a sexual identity in accordance with his or her anatomical sex. In such cases, the frequency of secondary mental disorders is also lower than in cases that progress to genuine transsexualism.

7.8 Substance Abuse and Drug Dependency

Mental and behavioral disorders due to psychoactive substance use are classified in ICD-10 under the category F1. By international agreement, these disorders are classified according to the substance used. They are discussed in detail in Vol. 3, Part 2, and we will therefore not describe them more extensively in this chapter on child and adolescent psychiatry. We will restrict the discussion here to the question of comorbidity with other types of developmental psychopathology (Schulz and Remschmidt 1999). Knowledge of the relationship between substance abuse and dependency and comorbid psychiatric disorders in childhood and adolescence opens new possibilities for the understanding and early recognition of risk factors for addiction. A complex interaction takes place between personality traits, increased vulnerability for mental disorders, and familial and psychosocial stress.

The problem of comorbidity of drug abuse in adolescence may be described as follows:

- Many psychopathological manifestations may be consequences of drug abuse (e.g. amotivational syndrome in cannabis abuse, drug-induced psychoses).
- A number of psychiatric illnesses in childhood and adolescence make drug abuse more likely and influence its course (e.g. hyperkinetic syndrome, conduct disorder, dissocial personality disorder).
- Drug abuse, in turn, influences the course of various psychiatric disorders (e.g. depressive syndromes, bulimia nervosa).
- Familial and psychosocial risk factors favor the development and maintenance of a drug problem (e.g. a broken home, addiction and dissocial personality disorders in other family members, deprivation syndromes, etc.).

Currently available longitudinal studies of the period from kindergarten to adolescence show that children at risk of developing drug addiction can be identified at an early age. As early as kindergarten, these children manifest aggressive-expansive behavior, lack of self-control, and a high degree of impulsiveness. They are easily excited and blind to danger; their behavior is characterized by hasty action, an intense search for immediate reinforcement, and an elevated sensitivity to external stimuli, and they often behave inconsiderately toward others. These findings should be used to develop preventive measures that can then be put into practice.

Diagnostic Problems in Geriatric Psychiatry

Translator: E. Taub

1 Introduction

There are three main areas of difficulty in the diagnosis of mental illness in elderly patients: (1) the differentiation of mental disorders from the mental changes of nonpathological aging, (2) the differentiation of mental disorders from the signs and symptoms of physical illness and impairment, and (3) the differentiation of mental illnesses from one another.

2 Differentiation of Mental Disorders from the Mental Changes of Nonpathological Aging

There are a number of methodological and factual problems complicating this area of differential diagnosis. The first methodological problem is that there is no accepted definition of "normal aging." If we were to define the norm as a statistical average, i.e. the mean values of quantitative indices of mental function across the entire population of individuals in a certain age category, then we would find that an impairment of cognitive ability satisfying the definition of dementia is "normal" for individuals over 100 years old, for example. To avoid such paradoxes, we may prefer to define the norm as the mean value of age-associated changes in healthy elderly individuals only. The distinction between health and illness is often blurred in old age, however, because nearly all individuals over 70 years old carry several medical diagnoses (Borchelt et al. 1996; Linden et al. 1996a). It is difficult to tell whether relatively mild and slowly progressive mental and intellectual changes in old age are products of the normal aging process or of disease, because many diseases of old age begin insidiously. Categorical diagnoses are therefore often based on threshold values of severity along one or more dimensions. The setting of these threshold values and the choice of the dimensions themselves are conventions that are admittedly influenced by contemporary trends and by other uncontrolled factors, such as subjective assessment of the state of health (Borchelt et al. 1996) or the recognition of social roles in the assessment of everyday activities.

Thus the recent trend toward increased life expectancy and better health in old age have led to the splitting of the "third life phase," i.e. age 70 and beyond, into two phases: a new "third life phase" from age 70 to approximately age 85, typified by an active life style (e.g. travel, sport, clothing), and then a "fourth life phase" of increasing physical frailty (P.B. Baltes 1997). In the multicultural context of a society that includes immigrants from many different parts of the world, specific cultural expectations for the behavior of older people may affect the way normal and diseased aging are distinguished from each other. The threshold for a diagnosis of dementia may be affected, for example, by the (still) high degree of respect for the elderly in Asian cultures or by culturally determined degrees of social support for the elderly, which may be sufficient to compensate for impaired performance of everyday activities (one of the dimensions of the diagnostic scheme).

In any case, psychiatric norms for old age are generally based on the second type of model discussed above, i.e. on the notion of "average mental health," however defined – even in the absence of adequate empirical evidence for many such parameters. Such evidence is vitally important, because parameters in different areas change in different ways over the course of aging (see Chap. 1, Vol. 2, Part 1), or some parameters (e.g. many laboratory values) may indeed remain quite stable from young adulthood to extreme old age (Kage et al. 1996).

The first concept of the norm seems to be the dominant one in the popular understanding, in which dementia is seen as a "normal," inevitable component of aging, and depression as a "normal" reaction to the common experiences of loss in old age; neither is considered a sign of disease. The many consequences of this assessment of aging, which does not effectively distinguish health from disease and thus amounts to a negative stereotype, are discussed at length in the Anglo-American literature under the heading of "ageism" (Butler 1990; Illhardt 1993). Even scientifically trained physicians are influenced by such prejudices, when they fail to recognize the mental illnesses of old age as illnesses (Helmchen et al. 1999), or when they wrongly consider present impairments to be irreversible and fail to treat them (Linden et al. 1996b). In contrast to this negative stereotype of aging, which is still widespread in the medical community, a very different positive stereotype of "the golden autumn of life" has come about in the context of psychological research on aging (Thomae and Maddox 1982; Lehr and Thomae 1987). This equally erroneous stereotype probably arose because these studies were performed largely on people who were healthy enough to respond to the advertisements for study volunteers and mobile enough to visit the research sites without external help.

Thus stereotypes of aging might affect the investigator's diagnostic threshold values, i.e. the diagnosis of mental illness in old age is susceptible not only to variations in diagnostic criteria, resulting from lack of scientific knowledge, but also to subjectively colored, method-dependent variations in observation.

A further methodological problem is posed by the cohort-specific appropriateness of instruments (Israel et al. 1984). Satzger et al. (1996) showed that the reference values of the Hamburg-Wechsler intelligence test (HAWIE), which are set in accordance with a sampling of the population at large, have risen by a full standard deviation in the last 50 years; in other words, the population has become "more intelligent" in terms of the HAWIE, and the reference values have therefore been corrected upward. The use of the new, corrected instrument in very old individuals will therefore yield an underestimate of their intelligence, because the altered reference values were derived from a different age cohort. On the other hand, Knäuper and Wittchen (1994) showed that depression in individuals over 80 years old is inadequately detected by the Diagnostic Interview Schedule (DIS), because the linguistic usage of the test instrument no longer corresponds to that of the elderly test-takers. Moreover, the considerable amount of psychiatric morbidity that falls below the threshold values set by the current systems for operational diagnosis (ICD-10, DSM-IV) – so-called subthreshold morbidity – leads us to ask whether these systems give an accurate picture of the extent of psychiatric morbidity in the elderly. According to the Berlin Old Age Study (*Berliner Altersstudie*, BASE; Helmchen et al. 1999), 17% of a random age- and sex-stratified sample of the 70- to 100-year-old population of West Berlin had subthreshold psychiatric morbidity. Even if this prevalence figure is not significantly higher than that of younger age-groups (Maier et al. 1994), it is still remarkably high. Above all, further studies are needed to better define the border between subthreshold psychiatric morbidity and lesser degrees of impaired well-being that are not the product of illness (Häfner 1997; Helmchen and Linden 2000), as well as to confirm or refute the hypothesis that there are age-specific difficulties in diagnosis, not only because of the increased prevalence of somatic illness and co- and multimorbidity in old age (see below), but also because of variable changes in affect, motivation, and cognitive performance.

Jacob (1986) vividly described the experiential change of the elderly, which takes place on the background of the generalized multimorbidity of old age. He stressed the need to complement the usual clinical and psychological tests of disease manifestations and impaired performance with the exploration and analysis of internal perceptions and experiences. Certain features of inner experience are common to normal and pathological aging, according to Jacob; the structure of inner experience in the elderly is typified by "the progressive infiltration of the past into the present, leading to the increasing availability of long-remembered information, and the decreasing relative availability of information that is currently being acquired." He drew particular attention to the "bland indifference, unshakeable passivity, and aloof attitude" of patients with certain diseases of the brain, and to their "selective inattention or semi-attention, non-perception, and unawareness of central nervous impairments."

Subthreshold morbidity in old age most often falls into the category of the affective disorders. Subthreshold affective abnormalities differ from the operationally defined affective disorders not only quantitatively, in the lesser severity of disease manifestations (such as feelings of guilt, feelings of worthlessness, and suicidal ideation) and in their shorter duration (more fluctuating course of depression), but probably also quantitatively, in the psychopathological pattern of worry, lack of well-being, and suffering (Geiselmann and Bauer 2000; Linden et al. 1998). Such abnormalities are difficult to label as pathological. Depressed affect in old age, often referred to as "body-centered complaints," "mild resignation," or "unhappiness," may be considered an appropriate reaction to the patient's changing life circumstances and finite life prospects (Palmore 1988), while elevated affect, perceived as "friendly remoteness," or a perhaps remarkable cheerfulness, despite physical or socioeconomic hardship, may be interpreted as a "wise" adaptive mechanism, as an expression of the protective effects of self-perception, self-esteem, and individual personality traits in the elderly, or as a "protective illusion" (Staudinger et al. 1996). An apparently unreasonable cheerfulness may, in fact, be pathological euphoria accompanying an organic brain disease (Alsen 1960); in the elderly, it is not always easy to distinguish cheerful imperturbability from uncritical indifference (see Chaps. 11 and 12, Vol. 2, Part 2). Above all, dejection, or loss of the will to live, should not simply be taken as an appropriate reaction to the patient's life situation, for depression in the elderly is known to be too rarely recognized and treated (Helmchen et al. 1999). Linden and Barnow (1998), authors of the BASE, concluded that expressions of being "tired of life," or of thoughts about death, are relatively uncommon even in the elderly and should always be followed up by an exploration of possible death wishes or suicidality, which may be symptoms of depression requiring treatment.

The relation between age-specific and dementia-induced changes in cognitive performance has also been inadequately studied to date, particularly in the extremely aged (Helmchen and Reischies 1998). Because both old age and dementia give rise to cognitive deficits, a problem of differential diagnosis arises. In the diagnostic process, it is important to bear in mind the concept of cognitive aging and the distinction between the clinical dementia syndrome on one hand and cerebral dementing disease on the other, as well as empirical findings regarding (a) the patient's current

neuropsychological state, (b) his or her premorbid intelligence, and (c) the rate of progression of the deficit.

Aging alone considerably reduces the speed of cognitive processes in healthy individuals (Lindenberger et al. 1993; Salthouse 1985). Salthouse found that the maximum speed of a 70-year-old was only about 40% of that of a 20-year-old (Salthouse 1982). A 60% reduction of speed, however, by no means implies a 60% reduction of other aspects of cognitive performance; these were essentially unchanged (Reischies and Lindenberger 1996). It would not be considered a significant cognitive impairment if a 60-year-old could converse freely just as well as 20-year-old, while taking twice as much time (though perhaps the 20-year-old might think so). On the other hand, qualitative intellectual impairment, e.g. reduction of the cognitive reserve capacity, as revealed by the "testing the limits" method (M.M. Baltes et al. 1992), and impairments of such functions as orientation, the use of tools, the recognition of known faces, the use of language, and word-finding, are signs of dementia.

Baseline adult intelligence is obviously important. A very old individual of low baseline intelligence might be assigned the diagnosis of a dementia syndrome in the absence of any causative dementing illness. A low level of education or vocational training is thus considered a risk factor for dementia (Fratiglioni et al. 1991; Kay et al. 1964; O'Connor et al. 1991; Parsons 1965), although there is some controversy on this point (Moritz and Petitti 1993). It remains unclear whether education simply alters the threshold for clinical manifestations, because highly educated individuals can (perhaps) compensate for an impairment of cognitive functioning longer than others, or whether there is also an effect of education on the disease process itself: a high educational level might be associated with a larger amount of neuronal stimulation, or with a more healthful lifestyle, and thus perhaps lead to a lesser risk of the chronic illnesses or deficits that give rise to dementia (Berkman et al. 1986; Mortimer 1990; Helmchen et al. 1999).

As for the processes that lead to impairment of cognitive performance, and ultimately to the diagnosis of the dementia syndrome, an important new piece of evidence was provided by the recent study by Davidson et al. (1995). Dementia is significantly more common in elderly schizophrenics than in the elderly population in general. Davidson and colleagues found, and others subsequently confirmed, that the neuropathological findings in demented elderly schizophrenics have no features in common with those of patients with neurodegenerative dementing illnesses. It was concluded that the dementia of elderly schizophrenics is the product of a different pathophysiological mechanism (Arnold et al. 1998; Purohit et al. 1998; Rajkowska et al. 1998). The important consequence of this fact for nosologic diagnosis is that the differential diagnosis of dementia must take factors other than neurodegenerative illness into account.

The normal aging process leads to a deterioration of cognitive performance over the eighth, ninth, and tenth decades of life by approximately one to two standard deviations below the normal values for retirement age (Reischies and Lindenberger 1996). It therefore follows that the cognitive performance of a less gifted person, or one suffering from a persistent, mild cognitive disturbance because of schizophrenia or prior brain injury (Harvey et al. 1995), may deteriorate to a very low level over the course of normal aging, with the result that the affected person may be unable, or barely able, to adapt to the changing demands of everyday life (see Chap. 10, Vol. 2, Part 2). Such individuals will become increasingly dependent on the help of others, and some diagnosticians might consider them to have a mild dementia syndrome, in accordance with the accepted diagnostic criteria for dementia, even though no dementing illness per se is present. Conversely, the development of a dementia syndrome in a person of high baseline adult intelligence may be undiagnosable by standard diagnostic criteria until the dementing illness has reached a relatively advanced stage. In both of the cases just discussed, an assessment of the patient's present cognitive state alone, without taking its temporal course into account, would lead to an erroneous diagnosis.

It thus becomes necessary to consider the rate of deterioration of cognitive performance. Longitudinal studies have shown that the test performance of many elderly individuals is essentially constant, i.e. does not decline to any psychometrically detectable degree after an interval of 1 year (Brayne et al. 1995; Reischies and Geiselmann 1997; Schmand et al. 1995). This state of affairs is clearly distinguishable from the rapid deterioration of patients with Alzheimer's dementia, whose score on the Mini-Mental Status Examination (MMSE) declines by 3 to 4 points per year (Berg et al. 1990; Reischies and Schaub 1997).

This rate-of-change criterion for the early diagnosis of dementia would be more useful if tests were available that were more sensitive to small changes, and if empirically determined threshold values for the rate of deterioration could be applied. The MMSE cannot adequately assess the cognitive performance of highly capable individuals, who have to suffer considerable deterioration before any change in the MMSE score is noticeable; it also remains to be demonstrated that a rate of change in MMSE scores of 1 point or less per year, or of 3 or more points per year (say), is indeed a valid criterion for the diagnosis of normal or pathological cognitive aging, respectively.

Despite the methodological difficulties of using a rate-of-change criterion, including its high variability and its susceptibility to learning effects, and despite its lesser applicability to patients with a fluctuating course, or to those, such as stroke patients, who remain stable at a low level of function, it is nevertheless clear that consideration of the rate of progression may be very useful in the diagnosis of dementia, particularly when the cognitive deficit is still relatively mild.

3 Differentiation of Mental Disorders from the Symptoms and Signs of Physical Illness and Impairment

A further problem complicating the psychiatric assessment of the elderly arises from the fact that older individuals often suffer from one or more somatic illnesses, whose effects are not always easily distinguished from the somatic and psychic consequences of mental illness, and the resulting performance impairment and disability. Participants in the BASE underwent a comprehensive physical examination by medical specialists in several disciplines and received an average of eight medical diagnoses, of which an average of two were considered severe (Linden et al. 1995); 30% of patients 70 years and older suffered from five or more moderately severe or severe illnesses (Steinhagen-Thiessen and Borchelt 1996). It had already been found in a previous study that depressed patients have more somatic illnesses than mentally healthy individuals (Stevens et al. 1995), and this finding was confirmed in the BASE (Helmchen et al. 1999). Along with this somatic comorbidity, elderly depressed patients also have a higher mortality rate (Ernst and Angst 1995), which is attributable to the poorer somatic health of this group and, more specifically, to an elevated cardiovascular morbidity (see Chap. 14, Vol. 2, Part 2). In the BASE, demented patients had worse results than individuals without a psychiatric diagnosis on renal, pulmonary, and thyroid function tests, as well as on the complete blood count and parameters of functional impairment, but the mean number of chronic illnesses of demented patients was not significantly higher than that of control subjects (Helmchen et al. 1999).

The somatic comorbidity of the elderly is accompanied by the further problem of polypharmacy: 87% of BASE participants aged 70 and older took at least one medication daily, and 24% took five or more medically prescribed drugs (Steinhagen-Thiessen and Borchelt 1996). These included drugs with relatively frequent adverse effects, including depressive manifestations (methyldopa, beta blockers, corticosteroids, levodopa) or cognitive impairment (benzodiazepines, haloperidol, phenothiazine, barbiturates, meprobamate, propranolol, methyldopa, reserpine) (Borchelt and Geiselmann 1995). Participants diagnosed as having depression took significantly more medications daily than those without a psychiatric diagnosis; in these depressed patients, too, the risk of depressive manifestations or cognitive impairment as an adverse effect of medication was significantly higher than in the controls (Helmchen et al. 1999).

In view of the frequency of somatic comorbidity and polypharmacy among the elderly, it may be asked whether the individual items used to establish the presence of a depressive syndrome in scales such as the Hamilton Depression Scale, or to aid in the differential diagnosis of depressive illness according to the ICD-10 or DSM-IV criteria, are indeed valid diagnostic indicators of depression. Certain somatic and vegetative disturbances among these items – such as sleep disturbance, weight loss, loss of libido, somatic complaints, and loss of motivation – may well be the direct results of simultaneously present somatic illnesses or else adverse effects of the medications used to treat them.

The multidisciplinary approach of the BASE offered a good opportunity for closer study of the problem of somatic comorbidity in elderly depressed patients. For all patients who had both depressive manifestations and a somatic illness, an internist was asked to judge whether the positive items of the Hamilton Depression Scale (out of a total of 21 scale items) were "possibly," "probably," or "probably not" the result of a somatic illness or of adverse effects of medications (Linden et al. 1995).

As expected, the results differed for different items of the Hamilton Depression Scale. Nine of the 21 items on the scale were judged by the internist to be a "possible" or "probable" direct effect of somatic illness or medication in more than 50% of patients. This was true to a marked degree for the item "general physical symptoms," which was judged as a purely psychopathological phenomenon in a mere 7% of patients. The same was also true, albeit to a lesser extent, of typical features of depression such as agitation or loss of interest. Even the two cardinal manifestations of depression, "depressive mood" and "[impairment of] work and other activities," were relatively frequently thought to be possible direct results of somatic illness or medication. Items least frequently thought to be due to somatic causes included "guilt feelings," "suicidal ideation," "daily fluctuations," and "hypochondria." The mean overall score on the Hamilton Depression Scale dropped from 5.3 to 4.4 when all items that were "probably" the result of somatic illness or medication

were removed from the calculation, and to 2.4 when "possible" items were also removed.

The question remains unanswered, of course, whether the participants' disease manifestations were actually caused by somatic illnesses or by medications, rather than by depression itself. As for the medications, the possibility cannot be ruled out that some of them were prescribed to treat depressive symptoms that were not recognized as such, but were instead attributed to somatic illness, as is often the case when depression and somatic illness coexist (Lobo and Campos 1997). In such patients, the prescription of medication would not be the cause, but rather the effect of depression. Furthermore, this study reveals that the diagnosis of depression in old age is susceptible not only to the "false-negative" misattribution of subthreshold and otherwise unclassifiable depressive manifestations to other causes, but also, in many patients with somatic comorbidity, to the "false-positive" misattribution of symptoms of other origins to depression. Such errors, and the misguided therapeutic efforts that they produce, can only be avoided by basing the diagnosis of depression in patients with somatic comorbidity exclusively on those disease manifestations that have been found to be specific, reliable criteria for depression and which are, at most, very rarely caused by somatic illness or by medication use. These include guilt feelings, daily fluctuations, hopelessness, anhedonia, and lack of emotional responsiveness.

4 Differentiation of Mental Disorders from One Another

The earliest attempts at a systematic differential diagnosis of mental illness in the elderly were made in the 1950s (Madden et al. 1952; Roth 1955). Since then, considerable progress has been made, initially in the clinical sphere and, in the last decade, in the area of standardized neuropsychological testing.

The most important diagnostic distinction between mental illnesses in old age is that between depression and dementia, not only because they are by far the most common mental illnesses, but also because these two diagnoses carry substantially different prognostic and therapeutic implications. The differential diagnosis of these two entities is complicated mainly by the frequent simultaneous occurrence of depressive manifestations and cognitive disturbances in the elderly. Many manifestations, especially those affecting behavior, such as lack of motivation, social withdrawal, and loss of communication and motivation, are nonspecific (Helmchen and Linden 1993; Lishman 1987) or may be signs of depression occurring in the context of subcortical dementia (Folstein and McHugh 1978). Hierarchical stratification rules ("dementia before depression") and negative stereotypes ("advanced age equals dementia") confer a high risk of overlooking the diagnosis of a treatable dementia or of wrongly considering it untreatable.

If the frequency and intensity of depressive and cognitive symptoms are such as to fulfill the diagnostic criteria for both depression and dementia, then one speaks, in the current terminology, of comorbidity. This phenomenological designation, however, leaves open the question of whether two independent diseases are truly present. This can only be concluded with a degree of confidence when there is a long-standing prior history of depressive episodes without cognitive disturbance, or of the development of cognitive impairment independent of depression. When only the patient's present state is considered, there is generally no way to determine whether the problem is dementia with depressive manifestations, or depression with dementia-like manifestations. Reifler et al. (1982) suggested naming these two possibilities "type 1" and "type 2." Emery and Oxman (1992) introduced the concept of a dementia spectrum of depression, consisting of interlocking continua of depression, cognitive impairment, and degenerative dementia, on the basis of which they defined five prototypes:

1. Major depression without depressive dementia
2. Depressive dementia
3. Degenerative dementia without depression
4. Depression in the presence of degenerative dementia
5. Independent, simultaneous occurrence of dementia and depression

In this scheme, the second category, "depressive dementia," corresponds to the particularly interesting syndrome considered by other authors under the name "dementia syndrome of depression" (Folstein and McHugh 1978) or "depressive pseudodementia."

The concept of "depressive pseudodementia" (Bulbena and Berrios 1986; Kiloh 1961; Post 1962; Wells 1979) arose from the observation that cognitive disturbances sometimes improve after the remission of depressive manifestations. The term has, however, largely been abandoned in recent years (Zimmer and Lauter 1984), because its definition was too broad, too vague, and too variable to be of use, because the cognitive disturbances mostly do persist after remission of the depressive manifestations (see Chap. 10, Vol. 2, Part 2; Reifler et al. 1989), and because depressive disturbances commonly occur both prodromally and at the onset of dementing illnesses (Devanand et al. 1996; Helmchen et al. 1999; Henderson 1990; Kral

1983; Kral and Emery 1989; Liston 1977; Shraberg 1978). A quantitative meta-analysis of 16 studies of "reversible dementia" published between 1972 and 1994 revealed that the disease states so designated are predominantly the result of depression or of drug intoxications, and more rarely of other mental illnesses such as dissociative disorders, and that they are quite rare – when strict criteria are applied, "reversible dementia" accounts for less than 1% of the mental illness seen in outpatients (Weitingh et al. 1995). Depressive disturbances with significant cognitive impairment are, accordingly, now usually designated as dementia with depressive mood disturbance (DSM-IV: 290.13; ICD-10: F00.13).

There have been several reports of complete remission of cognitive disturbances after the disappearance of depression, but approximately half of such patients nonetheless turn out to have persistent cognitive disturbances after a follow-up of 2–3 years (Reischies et al. 1997), and as many as 90% are demented after a longer follow-up averaging 8 years (Rabins and Pearlson 1994). In these cases of "depression-induced cognitive impairment (DICI)" (Rabins et al. 1994), it remains unclear whether depression leads to functional or structural changes in the brain, or whether depression is itself the result of other, as yet unknown processes. A further possibility is a combination of these two mechanisms: perhaps depression lowers the level of cognitive functioning below a critical threshold in individuals with an already low cognitive reserve capacity (Lishman 1987).

Tests of cognitive performance can be used to distinguish between dementia and depression when they are not narrowly restricted to memory, but also include assessment of language, attention, motivation, speed, and psychomotor variables (Christensen et al. 1997). According to a recent meta-analysis (Christensen et al. 1997), the number of errors made by depressed patients on such tests is more than half a standard deviation higher than that of mentally normal control subjects, while patients with Alzheimer's disease make approximately twice as many. Tests such as the Inglis Paired Associate Learning Task, the Anomalous Sentences Repetition Test, the Boston Naming Test, and the Wechsler Adult Intelligence Scale (WAIS) Block Design Test can be used to distinguish depressed patients from demented patients, but not from normal subjects, while the Halstead Category Test and Halstead-Reitan Finger Tapping, Wechsler Memory Scale (WMS), Animal Naming, and Number-Symbol Tests can be used to distinguish depressed patients from normal subjects, but not from demented patients. The assessment of memory deficits with the aid of verbal or visual memory and recognition tasks does not, in general, distinguish depressed from demented patients, but some differentiation is nonetheless possible by means of tasks that are relatively undemanding (requiring little motivation or attention), relatively unpleasant, and temporally unconstrained. The differentiation of depression from dementia was more difficult in very old and very depressed patients and in those who had undergone electroconvulsive therapy.

In conclusion, after decades of effort, there is still no neuropsychological testing procedure that is practical for clinical use and yields a sharp differentiation between dementia and depression. The clinician must bear in mind that depression can both lead to cognitive disturbances and be masked by them, particularly when complaints of memory loss, intellectual slowing, and lack of spontaneity dominate the clinical picture. In addition, depression is commonly overlooked in elderly patients because it may be mild and of long standing, and somatic complaints may be most prominent. The clinical criteria shown in Table 1 for the recognition of depression in the presence of cognitive impairment therefore retain their usefulness (Lauter and Dame 1991).

In summary, this discussion of "depressive pseudodementia" has drawn attention to the fact that cognitive disturbances in old age need not be symptoms of a dementing illness, but may rather be an expression of any of several reversible mental disorders, and must therefore be differentiated in terms of their different etiologies and pathophysiologies. In the clinical field, the important fact to remember is that depressive manifestations in patients with cognitive disturbances may be treatable, whether they are primary or secondary (Reifler et al. 1989). In addition, all other treatable causes of reversible dementia must be excluded (see Chap. 2, Vol. 2, Part 2).

Diagnostic difficulties also occasionally arise from the different manifestations and course of certain mental illnesses in patients of advanced age (see Chap. 9, Vol. 2, Part 1), either because the "gestalt" of a long-present chronic illness may change as the patient ages, or because the first signs of a newly appearing disease in an elderly patient may be quite different from those more commonly seen in younger patients.

Thus 25%–50% of patients with Down's syndrome over the age of 50 develop dementia (Johannsen et al. 1996), while individuals with mental retardation of other causes develop dementia approximately four times as frequently as the normal population (Cooper 1997a). Retarded patients also have a larger number of additional somatic illnesses and a lesser capacity for adaptive behavior (Cooper 1997a; Moss and Patel 1997). Behavioral disorders, eating disorders, and the appearance or intensification of aggression, as well as a high rate (27.6%) of psychotic complications (delusions of being robbed or persecuted, visual hallucinations of strangers in the house), are quite common among mentally retarded individuals who have become

Table 1. Differentiation of the cognitive disturbances accompanying depression and dementia

	Depression	Dementia
Complaints Patient's description	Rather extensive and detailed; "I don't know"-type answers	Rather trivializing, circumstantial
Content	Difficulty thinking, impairment of memory	"Perhaps a bit more forgetful"
Findings behavior	Plaintive but also lacking initiative, diminished language output, social withdrawal, not unkempt, discrepancy between complaints of cognitive dysfunction and objective neuropsychological test findings	Loss of initiative, language disturbances (paraphasias etc.), unkempt, neglect of personal hygiene, marked cognitive disturbance but relatively mild disturbance of affective communication (maintained facade)
Psychological testing	Cognitive dysfunction barely noticeable in undemanding tasks without time pressure	Cognitive dysfunction even in undemanding tasks without time pressure
Onset	Depressive mood alteration *before* cognitive disturbances	Cognitive disturbances *before* depressive mood alteration
Course history	Earlier affective disturbances	No preceding affective illnesses, usually fairly long prior history of progressive cognitive decline
Follow-up	Improvement, at least partial remission in the affective area	Progression, though fluctuations may also occur
Nosology	Dissociative disorder, e.g. Ganser syndrome with depressive mood alteration, depressive delusion of being demented Depression-induced cognitive disturbance Dementia syndrome of depression	Dementia with depressive mood alteration, subcortical dementia with apathetic features

demented (Cooper 1997b; Moss and Patel 1997; Prasher and Chung 1996). Nevertheless, caretakers are usually unaware of the connection between these behavioral changes and dementia (Duggan et al. 1996).

Schizophrenics over the age of 65 also develop dementia much more frequently than the general population, though much more slowly than patients with Alzheimer's disease (Ciompi and Müller 1976; Harvey et al. 1995). When delusional paranoid manifestations first appear in old age, their chronicity and limited responsiveness to treatment, in association with only mild impairment of personality structure and everyday activities, are evidence against (late) schizophrenia, while the lack of psychopathological manifestations and of somatic findings of cerebral disease are evidence against a productive psychotic development of dementia. On the other hand, the impression of incoherence in cases of mania, with flight of ideas, that are of the dysphoric-irritative rather than the hyperactive type may occasionally lead to an erroneous diagnosis of late schizophrenia, or indeed of dementia.

Primary personality disorders are, as a rule, easy to distinguish from mental illness on the basis of the history alone. In contrast, chronically compensated personality disorders that become decompensated only in old age, or the age-dependent exacerbation of certain personality traits, cannot always be distinguished from an organically caused personality change merely by a single examination of the patient's present mental status (see Chap. 12, Vol. 2, Part 2).

Finally, there are clearly forms of mental suffering in old age that have yet to be recognized and described, to say nothing of their classification and nosologic definition (see Chap. 9, Vol. 2, Part 1).

5 Conclusion

The differential diagnosis of mental illness, even in old age and extreme old age, is a task that cannot afford to be neglected today, because different illnesses require different methods of treatment and chronic care and also have different prognoses. The process of accurate differential diagnosis and treatment is carried out in several discrete steps. The physician must first suspect that a mental illness may be present and then evaluate the patient's problem differentially in terms of the particular disease manifestations and their intensity, arrive at a nosologic or etiological-pathogenetic diagnosis, and finally design and carry out a plan of treatment appropriate to the situation of the individual elderly patient.

Aging of People with Mental Illness

Translator: E. Taub

1 Introduction

The term "aging of people with mental illness" might be taken to refer to either the influence of time on the course of psychiatric diseases ("natural history") or, alternatively, the importance of involutional changes after an arbitrarily chosen age, e.g. age 60. Moreover, in the present era of increasing life span, it may be of interest whether diseases first appearing in the presenium have a specific course in old age, because patients developing mental illness at advanced ages today may have a subsequent course of illness lasting as long as 30 years. In this review, we aim to describe the influence of involution on preexisting diseases, but we shall also attempt to present the available data on the latter question.

2 Fundamental Problems of Longitudinal Studies

Despite the large number of publications on dementing processes that have appeared in recent years, there have been relatively few studies on the closely related problem of aging in the mentally ill. There are probably many external reasons for this discrepancy, but we feel that one important point is the state of current psychiatric nosology, which is largely descriptive. Because many psychiatric diagnoses are defined and validated on the basis of clinical symptoms in younger patient groups, the assessment of changes related to aging, i.e. the consideration of these diseases as *processes*, may be difficult. Some patients, for example, despite persistence of their subjective impairments, may migrate from one diagnostic category to another as they grow older or may drop out of the nosological system entirely, not because they have recovered, but because the combination of signs and symptoms they show in old age cannot be adequately classified.

If there is no morphological or pathophysiological correlate whose course can be followed, longitudinal studies are performed only on those comparatively few patients who are available for repeated clinical examination despite their physical multimorbidity.

The downsizing of psychiatric hospitals and the closing of wards for the aged and chronically ill lessen the availability of these groups of patients in systematic follow-up studies, particularly if they are being nursed at home.

Field studies may suffer from cohort problems if the study is to be performed over a time span of 50 years or more. Only a small number of patients survive to be studied in high old age, and this group cannot be considered representative of the entire original patient group. Furthermore, age-dependent changes of memory and informational behavior are to be expected. There will not only be memory impairments of organic origin; psychopathological episodes will be recounted differently from the viewpoint of old age than at the time they are experienced, and different age cohorts, because of their differing education, will give information about certain psychopathological disturbances in diverse ways. Thus a tangle of substantive and methodological problems complicates the study of the course of psychiatric diseases in old age. (For more on this topic, see also Chap. 8, Vol. 2, Part 1.)

3 Schizophrenic Psychoses

The relatively good state of our knowledge of this topic is mainly due to three studies (Bleuler et al. 1976; Ciompi 1980a,b, 1984, 1985; Harding et al. 1988), which document a wide spectrum of disease courses and contradict the traditional notion that schizophrenic illnesses have a uniformly poor prognosis.

Ciompi distinguished eight types of disease course, four of which tended to have an unfavorable prognosis and accounted for 48.6% of his patients; the corresponding figures for poor outcome were somewhat lower in the Burghölzli study (Bleuler et al. 1976) (40%) and the Vermont study (Harding et al. 1988) (38%). Mortality was elevated in schizophrenic patients of all types (1.5- to 1.7-fold that of the general population); catatonic types had a significantly higher mortality rate than paranoid types (2.5- and 1.4-fold that of the general population, respectively); and female patients and patients who became ill after the age of 40 also had a somewhat higher mortality rate. As might have been expected from clinical experience, the frequency of suicides among schizophrenics was higher than that in the general population, as was the frequency of death of unknown cause. More than half of the originally documented clinical symptoms improved in patients surviving until advanced age; stupor, anxiety, and agitation were the symptoms most likely to regress with age, and abulia, disturbances of affect, phonemes, mannerisms, and delusions were the least likely to do so (Ciompi 1980a). With advancing age, nonproductive residual states overshadowed the originally most prominent symptoms which had originally led to the classification as a particular type of schizophrenia; these were attenuat-

ed, and the clinical syndromes seemed to level off until they were unrecognizable. In fact, about 20% of the patients had recovered to such an extent by the time they reached old age that specific schizophrenic symptoms could no longer be demonstrated; a further 43% had clearly improved, 30% were unchanged, and only 6% had worse schizophrenic symptoms in old age than previously.

Davidson et al. (1995) retrospectively studied 393 chronic schizophrenics with histories extending back more than 60 years in some cases. The unfavorable courses in this group appeared to be characterized by an increase in negative symptoms and a rather modest decrease of positive symptoms, which clearly failed to "burn out," as might have been intuitively expected.

The prevalence of dementia syndromes in the general population over 65 years of age is exceeded by that among schizophrenics: approximately 25% of patients in this age-group in the Lausanne follow-up study suffered from moderate to severe organic cerebral psychosyndromes (Ciompi et al. 1980a,b, 1984, 1985); 17% had significant thought and memory disorders, including partial disorientation, and a further 8% had severe amnestic psychosyndromes with almost total spatial and temporal disorientation (Ciompi 1980b). Dementia syndromes were even more frequent in types of schizophrenia with a primarily unfavorable course. In their chronically hospitalized group, Davidson et al. (1995) found a steady, remarkably slow decline of cognitive function, quantitatively estimated as 1.2–4.6 points on the Mini-Mental Status Examination (MMSE) scale per decade of life. The average MMSE score of younger patients was 27.6, while the corresponding figure for patients over 65 was 16 points and for patients over 85, 9.6 points. If we consider that normal individuals aged 80 or older generally have MMSE scores of at least 24, then the degree of impairment in these elderly hospitalized patients was sufficient to support a diagnosis of dementia. The very slow decline of cognitive performance would be quite uncharacteristic for the course of a neurodegenerative disease; the annual rate of decline mentioned above is approximately one tenth of that expected in Alzheimer's disease, for example.

Uncertainty remains, therefore, about the pathogenesis of this not at all uncommon disturbance. Purohit and coworkers performed an autopsy study of 100 chronic schizophrenics with an average age of 76.5 years (range, 52–101 years). Over the course of their illness, 72 patients had developed dementia of at least moderate severity (score 2 on the Clinical Dementia Rating Scale; Hughes et al. 1982). Nonetheless, in the great majority of these patients, no morphological correlate of dementia could be found. An Alzheimer-type encephalopathy was diagnosed in 9% of the patients, and other relevant neuropathological abnormalities were found in 4%, but in all other patients (87%), histological investigation yielded no clues as to the pathogenesis of dementia (Purohit et al. 1998). Other authors have also found that neurodegenerative lesions are no more common in elderly schizophrenics than in the elderly in general (Arnold et al. 1994). This is in line with Ciompi's observation (Ciompi 1980b) that cognitively impaired schizophrenic patients generally do not give the impression of having an "organic" type of cognitive impairment; the cognitive deficit of elderly schizophrenics does not fit into any known category of organic brain disease. There has been speculation about many possible pathogenetic factors, including chronically insufficient cognitive challenge, chronic neuroleptic use, and the effects of electroconvulsive therapy or psychosurgical procedures, but this problem has not yet been satisfactorily solved. Now that morphological and pathophysiological abnormalities in schizophrenia are being described increasingly often, the hypothesis of a developmentally dependent vulnerability of schizophrenics to some kind of "functional" brain disturbance, remaining compensated until old age, has also been advanced (Arnold et al. 1994; Akbarian et al. 1996). Davidson et al. (1995) found that symptoms of dementia appeared mainly in patients who had already had negative symptoms earlier in life and proposed that negative symptoms and dementia might have a common organic origin. On the other hand, it must also be asked whether the clinical methods and psychological tests generally used in the assessment of dementia are at all adequate to delineate the disturbances found in aging schizophrenics, and it is tempting to raise the concept of "schizophrenic pseudodementia" for discussion once again.

Special considerations apply to patients with schizophrenia of late onset, i.e. onset after the age of 45. These account for approximately one fifth of all schizophrenics; indeed, 3%–5% become ill only after the sixth decade of life (Jeste et al. 1995). Late-onset schizophrenia preferentially affects women, not infrequently those with a relatively high premorbid performance level (Yassa and Suranyi-Cadotte 1993). Systematizing paranoid syndromes, combined with bizarre delusional ideas and commentating phonemes, are typical in late-onset patients, as are a less common occurrence of loose association, inadequate affect, and negative symptoms; formal thought disorders are very rarely described (Almeida et al. 1995). The prognosis is hence more favorable, at least by societal criteria. These late-onset patients are relevant here in that their further course in old age, especially with respect to cognitive impairment, seems to be benign.

Nonetheless, Jeste et al. (1995) were unable to support the concept of late-onset schizophrenia as an independent nosological entity on the basis of family history, descriptions of premorbid development, and neurophysiological studies. Almeida et al. (1995), on the other hand, are proponents of the independence of this syndrome from the core group of schizophrenias.

4 Non-schizophrenic Paranoid Psychoses

The percentage of individuals with chronic non-schizophrenic paranoid psychoses who undergo psychiatric treatment is unknown. Only a small fraction of those treated remain under medical care in the long term. Thus assessment of the age-dependent course of these syndromes is fraught with uncertainty. Opjordsmoen (1989) described the course, over 30 years, of 301 patients who had been predominantly delusional at the time they entered the study, at an average age of approximately 35 years; a paranoid disorder of non-schizophrenic type had been diagnosed in 53 of these patients (average age, 40.6 years). Twenty-seven years later, 80% of this subgroup had married and had an average of two children, and 52% were employed. Among the 33 patients still available to follow-up after 30 years, 55% were not undergoing psychiatric treatment, and 27% were being treated by their family physicians. Many of them had adapted their lifestyles to the essentially unchanged paranoid symptoms. It is instructive to compare these figures with those for schizophrenics on 30-year follow-up: only 43% of the latter ever married, they remained childless significantly more frequently (average, 0.7 children), and only 20% were still employed. Out of 75 schizophrenics in the study, 45 were available to follow-up at 30 years; of these, 45% were under inpatient psychiatric treatment, and only 24% were not under psychiatric treatment. There were no cases of suicide among the 19 non-schizophrenics who had died, but among the 18 schizophrenics who had died, there had been three definite and two possible suicides. According to the Norwegian authors' findings, strongly reactive momentum of a non-schizophrenic delusional disorder at the time of its onset predicts a favorable outcome, while the continuous presence of symptoms for more than 6 months at the onset of the disease predicts an unfavorable long-term outcome (Opjordsmoen and Retterstol 1991). The prognosis of delusional, non-schizophrenic disorders is considerably more favorable than that of schizophrenia, although it seems to have remained essentially the same despite the introduction of neuroleptics (Opjoerdsmoen and Retterstol 1993).

5 Affective Disorders

The contradictory nature of the literature has already been pointed out by Müller (1989). Some of the problems lie in the unsatisfactory nosological classification of depressive syndromes. While the group of clearly phasic, bipolar illnesses possess a certain degree of homogeneity, highly disparate varieties of disease may lie concealed behind the diagnoses of unipolar or chronic depression (Goodwin and Jamison 1990). Moreover, we share Murphy's opinion (Murphy 1989) that there is still no satisfactory classification scheme for depressive disorders in all age categories.

In the *phasic* affective disorders, according to several authors, the frequency and amplitude of phases increases with age (Angst 1966, 1987), while the phases themselves become longer (Foster and Reisberg 1984). The latter effect, however, seems to be reversed after the age of 60, when, according to Matussek and colleagues (1965), depressive phases become shorter again. Müller found a reduction of phase frequency after age 65 in almost two thirds of his patients, no change in one fifth, and an increase in only one fifth (Müller 1989). Amenson and Levinsohn studied almost 1000 depressive patients with disease courses extending back more than five decades. They found an increasing prevalence of depressive syndromes with advancing age and attributed this largely to the fact that women with a prior history of an affective disorder are especially prone to a relapse in old age. This sex difference seemed to even out only after age 70 (Amenson and Lewinsohn 1981; Gurland 1976).

Partial remissions are more common in old age, largely because of the increased representation of depressions that have become chronic in this age-group, partly reinforced by the high prevalence of physical illness in the elderly (Angst 1966; Roth and Kay 1956). The common association of depressive symptoms with dementing illnesses in old age is probably not due to the group of aging persons with phasic illnesses; in any case, the literature provides no convincing evidence that this group is particularly subject to the development of neurodegenerative disease (Migliorelli et al. 1995; Van Ojen et al. 1995). A notable exception is that of the 22 patients with depressive "pseudodementia," aged between 62 and 78 years, described by Kral (1982), who were followed for an average of 8 years after the end of the acute

phase. Six patients from the entire group went on to have further, reversible depressive phases associated with severe cognitive disturbances; four of these six patients, however, and a further 16 from the entire group, were eventually given a diagnosis of Alzheimer's disease. The prior history of these patients was not reported in detail, but it would be highly relevant to the interpretation of the results. All of them apparently fulfilled the criteria for "endogenous" depression, and monopolar phases were present, at least in the subgroup of patients who suffered relapses. Possible explanations include a transient unmasking of a gradually developing encephalopathy, i.e. a comorbidity of "endogenous" depression and Alzheimer's disease, or a mainly organic cause for the phasic illnesses, possibly aggravated by anticholinergic drugs. Unfortunately, it remains unclear to what extent these patients had already suffered from affective illnesses in their youth (Kral 1982).

As other authors have stressed, within the spectrum of depressive symptoms, it is precisely the cognitive problems that tend to last the longest in a given phase, outlasting others by many months (Marcos et al. 1994). For now, it remains unclear whether these cognitive deficits, occurring in the context of depression in a minority of aging, phasically ill patients, can ultimately become irreversible even if no neurodegenerative illness supervenes, as the findings of a few authors seem to suggest (Marcos et al. 1994; Abas et al. 1990).

A change in the pattern of manic symptoms with advancing age has been described by several authors. States of vivacious, elevated mood become rarer and are replaced by irritable, aggressive, dysphoric states of increased drive. Expansive delusions and flight of ideas occur more frequently (albeit with progressively lesser intensity and velocity), as does incoherence, particularly when cognitive disturbances supervene (Post 1984; Baldwin and Tomenson 1995).

The relatively low prevalence of affective illnesses probably does not reflect the *true extent of depressive dysfunction* in the elderly (Gurland 1976; Kay et al. 1985). In a field study, Girling et al. (1995) studied 1773 individuals aged 77 and older. Of these, 6% stated that they felt depressed most of the time, 22% complained of irritability, and 35% complained of disturbing restlessness and inner tension; 21% at least sometimes felt that they did not want to continue living any longer. The origins of these low-grade chronic depressive states are varied and many have not been adequately studied. Are they long-standing disorders that remain compensated and asymptomatic in the patients' younger years, finally surfacing in old age, or do they actually first arise in the senium, constituting what the conventional classification schemes have labeled "subdiagnostic morbidity"?

6 Dysthymias

Opinions differ as to the development of low-grade depressive syndromes in old age – the dysthymias, or so-called depressive neuroses. Ernst and Ernst (1968), in their extensive review of chronic neurotic processes, state that "old age more frequently has an alleviating effect on neurotic anxiety than an aggravating effect . . . and . . . often places a relieving distance between the patients and their symptoms" (p. 41). This was later confirmed by a field study, in which the prevalence of dysthymic disorders declined from 3% in the general adult population to approximately 1% in those over 65 (Weissman et al. 1988). On the other hand, Stefansson and colleagues (1991) found a much higher prevalence (difference, 6.4%) in individuals over 50, particularly in women. In a group of 224 outpatients of a special clinic for depression, Devanand and colleagues (1994) made a diagnosis of major depression in 51% of patients over 60 and of dysthymia in just 18% of the same group. The reportedly high prevalence of dysthymic disorders and the increased frequency of the diagnosis of dysthymia in elderly patients are probably accounted for not by previously dysthymic patients who grow old, but by previously healthy individuals developing dysthymia in old age: elderly dysthymic patients had generally become dysthymic relatively late (in the sixth decade), while the onset of dysthymia before age 21, with continuation into old age, was rare. Younger dysthymic patients had frequent comorbidities with axis I and axis II disorders (major depression, anxiety, personality disorders), but such comorbidities only occurred in exceptional cases in the elderly patients. The typical finding was of a chronic depressive condition that fulfilled the DSM-III-R criteria for dysthymic disorder, but differed from the form seen in younger patients with respect to possibly important nosological features: the prevalence of the classical form of dysthymia, which begins at an early age, declines over time, but a new and "purer" form of dysthymia, i.e. one with a lesser degree of psychopathological comorbidity, apparently comes to the fore after approximately age 55, and its prevalence does not decline thereafter (Devanand et al 1994).

7 Anxiety Disorders

A description of the broad spectrum of anxiety disorders – generalized anxiety disorder, phobias, panic disorders, obsessive-compulsive disorders,

post-traumatic stress disorder (PTSD) – and of their course as patients grow older – even excluding the dysthymias – would go beyond the scope of this chapter, the more so as the problems of classification discussed in the introductory sections are particularly acute here, and there are still no relevant long-term follow-up studies utilizing the DSM-III criteria. Müller, in his review, discussed the evidence for a basically favorable course of these disorders as the patients grow older (Müller 1989); as Ernst and Ernst (1968) described, aging had a positive influence on the symptoms and signs of aged neurotics ($n = 57$); in particular, phobias and "obsessive–compulsive phenomena" (p. 407) largely resolved. Overall, half of Müller's patients were regarded as cured, and the great majority as improved. The small group of neurotics with unchanged symptoms included those with hypochondriac and, to a lesser extent, those with depressive symptoms and signs. Foster and Reisberg (1984) obtained similar findings with respect to the anxiety disorders.

Long-standing, chronic conditions of these types seem to wane in intensity and to become stabilized, while patients in whom such conditions are of late onset tend to experience a worsening of symptoms over time. In a group of men over 65, anxiety disorders were the second most common psychiatric diagnosis after dementia; in a group of women over 65, they were the most common diagnosis (Myers et al. 1984). Other field studies yielded similar findings (Regier 1988; Lindesay et al. 1991). While more specific phobias, which typically originate in the first third of life, tend to regress, the prevalence of anxiety disorders increases with age because of the occurrence of anxiety disorders of late onset. Among the latter, the most prominent types are fear of public transport and of travel. These agoraphobic syndromes first arise in old age after traumatic experiences (syncopes, accidents, assaults), tend to worsen, and are associated with significant dysfunction. Approximately one third of patients with anxiety disorders of late onset are found to have accompanying depressive symptoms; panic attacks are rare, while accompanying somatic illnesses are common. As in the dysthymias, there seem to be two types of disease course in the anxiety disorders: in the type often described by earlier authors, "neurotic" anxieties and obsessive–compulsive symptoms arising in youth tend to abate over time (Ernst and Ernst 1968), while, in the other type, symptoms arising after the age of 60 have a less favorable course. Much of what the elderly endure in terms of physical morbidity and social unsettlement can produce anxiety, but it remains unclear why one group of patients with long-standing anxiety disorders should have a stable course in the face of these challenges, while another, previously healthy group becomes symptomatic with age. A basic diagnostic difficulty in this age-group lies in the interaction between understandable anxieties about cardiovascular disease, for example, and anxiety disorders that secondarily assume an independent existence (Lindesay 1991).

Because the category of PTSD came into widespread use only after the publication of the DSM-III, relatively few longitudinal studies are available with follow-up into old age. There is, however, an extensive literature on war veterans and victims of Nazi persecution. These studies unequivocally show that, unlike other psychogenic disorders, PTSD tends to become chronic and, not uncommonly, to intensify over periods of up to 50 years and does not share the pattern of regression in old age that is typical of many psychogenic disorders. In 1997, Engdahl and colleagues (1997) studied 262 elderly veterans of the Second World War and the Korean War who had been exposed to severe trauma while being held prisoner by the enemy. A total of 53% had subsequently had PTSD at some time in their live, and 29% still had PTSD at the time of study, approximately 50 years after the traumatizing events took place. The incidence of PTSD was even higher in individuals who had endured extreme trauma in Japanese prisoner-of-war camps: among these, 84% had had PTSD at some time, and 59% had had the syndrome continuously for over 50 years and still had it at the time of the study. The psychiatric comorbidity was predictably high: 45% had other axis I disorders in old age, and only 34% had no history of axis I disorders. The frequency of chronically persistent PTSD and mortality were similarly correlated with the intensity of wartime trauma in a 50-year follow-up study of 107 veterans (Lee et al. 1995). In a cohort of 124 survivors of the Holocaust who had been persecuted on supposedly "racial" grounds and who had no history of bipolar illnesses, obsessive–compulsive disorders, or organic syndromes, examination 45 years after the primary traumatization revealed PTSD in 46%, of which the most common symptoms were sleep disturbances, nightmares, and uncontrollable memories. The prevalence of PTSD in old age was three times higher in those who had been held in concentration camps than in those who had not (Kuch and Cox 1992). A retrospective study of the course of post-traumatic symptoms in old age, including 73 individuals older than 55 (of whom 37 were older than 66), showed that the affected individuals were relatively well adapted socially, but their psychopathological problems, which were mainly attributable to PTSD, changed very little over time; furthermore, 67 subjects reported depressive mood disturbances, 29 reported suicidal thoughts, and 50 reported memory disturbances. PTSD typically appeared in individuals who had been persecuted in adolescence, and nearly all subjects showed remarkable constancy of symptoms as

they grew older, with a gradual increase in their intensity in old age (Freudenberg 1991). PTSD patients, compared to the general population, have an elevated psychiatric and somatic comorbidity lasting for many years (Boscarino 1997; Alarcon et al. 1997) and incline toward unhealthy habits such as smoking, medication, and alcohol abuse (Beckham et al. 1997). They also tend to have endocrinologic abnormalities, particularly with respect to cortisol regulation, even many years after trauma, and, at least according to the report by Bremner and colleagues, have a higher frequency of structural abnormalities in the hippocampus (Bremner et al. 1995).

8 Alcoholism and Other Addictions

While the problem of alcohol and substance abuse in old age is increasingly being recognized (Ruppert 1996; Ades and Lejoyeux 1994; Bristow and Clare 1992), most longitudinal studies provide a follow-up of no more than 10 years' duration (Finney and Moos 1992; De Soto et al. 1989). As Müller (1989) pointed out, hardly any studies have been performed with follow-up into old age, so that we are obliged to extrapolate from the trends in the course of these diseases as they affect younger individuals. Müller attributed the lack of suitable studies to the greatly elevated mortality rate in alcoholics, due to frequent somatic comorbidity (Feuerlein et al. 1994) and a suicide rate ten times that of the general population (Rossow and Amundsen 1995). Among those who lived to age 65 in the Lausanne follow-up study, Müller noted a favorable course in old age, with relatively little somatic and psychoorganic damage, even if total abstinence had not been achieved. The same selection process was observed in substance-dependent individuals, whose mortality rate may be as high as 29 times that of the general population: no further deterioration was observed in abusers of narcotics or sleeping pills who survived until old age (Müller 1989). A study in which 286 college students and 456 inhabitants of large cities were regularly followed until age 60 revealed that many surviving individuals were still abusing alcohol to a clinically relevant extent even in the seventh decade of life. A total of 205 had become alcoholics by age 47, and, by age 60, 18% of the students and 28% of the large-city inhabitants in this subgroup had died; among those who survived to age 60, 70% and 39%, respectively, were still regularly drinking alcohol, and 59% and 28%, respectively, were alcohol abusers. The course of the latter two subgroups remained constant for decades (Vaillant 1996). In another study, 9% of 650 patients older than 65 were alcohol abusers, and most of these had been so since their youth; only 10% reported having decreased their alcohol consumption in old age (Bristow and Clare 1992). The high prevalence of substance abuse, including sleeping-pill abuse and alcohol dependency, is becoming even higher according to recent studies; in several reports, the figures lie above 10% (see above for references). This fact is likely due to the contribution of surviving long-term sufferers from these conditions to the total. It was found in a French study, however, that one third of subjects had become alcohol abusers only after age 60, typically after devastating losses, such as the death of a spouse. These late-onset alcoholics had a bland and rather stable course and little psychiatric comorbidity (Ades und Lejoyeux 1994). Alcoholics surviving until old age and late-onset alcoholics were similar in this respect. In summary, the few available studies support the notion of a stable, comparatively benign course in the small group of alcoholics who survive to old age, while showing a surprisingly high percentage of late-onset alcoholics.

9 Personality Disorders

In the early and intermediate stages of life, personality disorders are important vulnerability factors for psychiatric disease and important determinants of disease course (Quinton et al. 1995). While the accentuation of personality traits in old age is frequently described, the development of personality disorders is a very complicated issue. If we consider that aging itself is an important stress factor, associated, as it is, with impairment of physical health, independence, and the ability to carry out activities of daily life, then we may expect inflexible personality types to decompensate. It is also conceivable, however, that personality styles held to be deviant at younger ages might confer certain advantages in old age. Paranoid or schizoid personalities would cope better with loneliness, while dependent personalities would gladly cast off their occupational duties and assume a newly legitimated dependency. Empirical studies must take account not only of cohort effects and selective mortality (as in borderline personality disorder), but also of altered behavioral criteria in old age. Impulsive, suicidal, or self-destructive behavior may, in the elderly, take forms that do not fit easily into current systems of psychiatric classification, appearing, for example, as noncompliance or refusal of treatment. Fearful, clinging behavior that would be pathological in a younger person may seem appropriate, or at least understandable, in old age.

Several studies have revealed a low prevalence of most personality disorders after age 55 (Cohen et al. 1994; Gurland 1984); this is particularly true of paranoid, schizoid, schizotypal, antisocial, and borderline disorders, and less so of histrionic and dependent disorders. In a group of 427 patients with "psychopathic personalities," Müller found that the great majority of features associated with personality disorders improved over the course of 30 years, less because of late maturation than because of a decline in the intensity of these features, and a relaxation of affect, as the patients grew older (average age, 71.9 years). Hypochondriac syndromes and hysterical personalities, however, developed in the opposite direction (Müller 1981). These observations from Lausanne were borne out by the findings of Tölle's study in Germany of a group of patients who were approximately 15 years younger (Tölle 1986) and by a long-term follow-up study from the Soviet Union (Semke 1964). Tölle found an unfavorable course in 33.9% of patients and a favorable course in 31.3%, while the remaining 34.8% coped with life by means of compromise strategies, involving a mixture of adaptation to, and narrowing of, their living conditions. McGlashan (1986) followed the life histories of 81 patients with the diagnosis of borderline personality disorder. Their ages at the time of diagnosis ranged from 16 to 55, and follow-up examinations were performed 2–32 years later, so that a number of patients could be observed up to and during old age. After a stable phase in approximately the second decade after diagnosis, these patients' conditions deteriorated again in old age (the age of involution). McGlashan and colleagues saw this process as the expression of a decline in cognitive performance and of the associated degree of social compensation in occupational life, through which the patients became increasingly dependent on their typically fragile and deficient personal relationships. It was thus not the personality style itself that had changed over the course of life, but rather the capacity to deal with, and partly compensate for, the difficulties created by it.

10 Conclusion

The intuitively predictable alleviation and waning dynamics of many disease processes in old age was described by early authors and is confirmed by the more recent studies. The traditional notion that schizophrenia has a uniformly poor prognosis certainly cannot be retained. In a fairly large subgroup of patients, however, cognitive impairments appear that are difficult to define clinically and to classify. Although many elderly, non-schizophrenic psychotics are relatively well adapted, their psychotic symptoms do not respond to pharmacotherapy. The class of patients with affective disorders, heterogeneous enough at any age, is even more so in advanced age, and this situation is reflected in the contradictory literature; the likeliest conclusion from the available data is that phasic processes have a tendency to become chronic, while bland, chronic processes of many years' duration have a tendency to become stabilized. In patients with affective disorders, too, as in schizophrenics, cognitive residual syndromes tend to occur whose classification and possible relation to organic changes in the brain are problematic. Aging generally has a favorable effect on preexisting psychogenic syndromes and personality disorders, with a few notable exceptions, particularly the post-traumatic syndromes. Aged alcoholics and substance addicts, despite the massive physical and mental stresses to which they are subjected, constitute a group of survivors whose further course is relatively unremarkable, even though abstinence is often not achieved. With the increased life expectancy of large segments of the population, the time over which the aging process can interact with mental illness has become considerably longer. Only a few longitudinal studies have as yet been able to address this recent development. Such studies inevitably run up against the inadequacy of current systems of psychiatric classification, which are not always able to accommodate the realities of geriatric psychiatry. The generally favorable course of elderly patients who were mentally ill before they reached old age stands in contrast to the considerable morbidity of patients who become mentally ill only once they are old.

Old-Age Depression

1 Introduction

Depression in older people is probably no more but no less frequent than in younger people. The detrimental effect it has on life remains the same. It is a powerful determinant of quality of existence and is strongly associated with suicide. Although its aetiology may be somewhat different, based on the disabilities and losses which are increasingly frequent with older age, it remains a condition that is eminently treatable by multidisciplinary professionals. The major problem appears to be the suffering that occurs in silence – older people do not realise that their distress can be helped, and some professionals are likewise frozen with therapeutic nihilism. This chapter outlines areas where depression in old age is different from the condition encountered earlier in life, but the overriding emphasis must be the similarity across the age span in the importance of recognising those who are depressed and offering appropriate help.

2 Epidemiology

The important National Institute of Mental Health/Epidemiologic Catchment Area (NIMH/ECA) community studies suggested that major depression, as they identified it, declined in older age-groups, where it was therefore less of a clinical problem. This finding did no service to the many clinicians who encounter depression so frequently among their older patients. But who is to be believed? Apparent failure to identify morbidity in epidemiological studies can be founded upon the idiosyncrasies of case definition, sampling frame and means of assessment. These problems are perhaps greater across the age span, where, because of clinically identified differences in the presentation of depression and the confusion that physical illness brings in the aetiology of symptoms, separate epidemiological measures have been used to determine the prevalence of "caseness" for those above the arbitrary age of 65 years.

With the pathway to care and the "filters" through which people need to pass in order to become patients and receive care, there are three levels at which surveys into depression can measure morbidity: the community, primary care and hospitals (outpatients and inpatients). The results of surveys at each level are not comparable because of the distribution within the referral system; large numbers of cases remain hidden in the community, many accumulate in primary care and an excess of more severe and resistant cases tend to collect in clinics. We will therefore examine prevalence at each of these levels.

2.1 Community

Depressive symptoms do appear to become more frequent with increasing age (Gaitz and Scott 1972) and its concomitant disability. However, as already mentioned, results from the NIMH/ECA studies indicated that depressive syndromes, as they identified and defined them, were less prevalent in adults aged 65 years or older than in younger age-groups (Weissman et al. 1985). The Diagnostic Interview Schedule (DIS) was used to assess depression, and somatic symptoms, which may have been due to accompanying physical illness, were excluded from the diagnostic algorithm. The prevalence of major depression in old age was reported as 1.1% (excluding bereavement), which is two or three times less than younger age-groups. There have been many criticisms of the findings of the NIMH/ECA studies. Although large samples were used with good response rates (approximately 74%), a quarter of the interviews were incomplete and/or completed by informants. Moreover, the findings from older people in institutions were not included. The DIS excluded from diagnosis minor episodes of depression and those complaints, as indicated, which could conceivably be associated with physical disorders.

Blazer (1989) used results from the NIMH/ECA with those of his own studies and stated that the majority of older adults do not fit Diagnostic and Statistical Manual (DSM) criteria for depression, but rather have depressive symptoms associated with physical illness and/or adjustment to life stress. Even if this proves to be true – and it is disputed – any health policy based only on the prevalence of defined major depressive disorders will be ineffective if significant losses of function are associated with depressive symptoms that are substantial and widespread but not congruent with the diagnosis of a major disorder (Kennedy et al. 1989).

Because of the difficulties in identifying clinically relevant depression in older populations, schedules specifically designed for older people have been developed. The Comprehensive Assessment and Referral Evaluation (CARE) (Gurland et al. 1983) was developed to identify cases of depression in older people severe enough to warrant some form of intervention (probable pervasive depression). It was used to demonstrate very similar levels of depression in New York (13%) and London (12.9%). Copeland et al. (1987) utilised the "psychiatric" concept of caseness in the development of the Geriatric Mental State (GMS), which is linked to a diagnostic computer

programme (AGECAT) in order to analyse in a repeatable fashion the responses to this semi-structured interview. Rates of 3.0% more severe depression and 8.3% milder depression were identified in the older community in Liverpool (UK). From the results of a 3-year follow-up, an estimated incidence of GMS depression caseness of 23.7 per 1000 per year was made (Copeland et al. 1992). Blanchard et al. (1994) used a different methodology but calculated a similar incidence rate (18.2 per 1000 per year) within inner London.

Cross-cultural comparisons in Europe, the EURO-DEP studies (Copeland et al. 1999), have examined the variation in the prevalence of depression between countries in people aged 65 years and over. They have compared the clinical features and the mode of presentation of depression in each centre and, where possible, have studied the social support net works, adverse life events, daily life stresses and risk factors, and reasons for failure to receive treatment in primary care. The GMS interview, with its AGECAT determination of caseness, was used to make comparisons in the original studies. To allow further meaningful comparisons to be made with centres which did not use the GMS, a method which identified common ground between the different measures used was developed, the Euro-D.

Differences in the prevalence of depression were found across Europe: Amsterdam, 12%; Berlin, 17.6%; Dublin, 11.9%; Iceland, 8.8%; Liverpool, 10%; London, 17.3%; Munich, 23.6%; Verona, 18.3%; and Zaragoza, 10.7%. However, the cause of this variation was not obvious. The prevalence in women predominated over men, but there was no constant association between prevalence and age. A meta-analysis ($n = 13,808$) gave an overall prevalence of 12.3%, 14.1% for women and 8.6% for men.

With the closure of National Health Service (NHS) psychiatric long-stay hospital beds, more mentally ill and frail older people are being cared for in residential and nursing homes within the community in the United Kingdom. Ames (1990) examined the residents in 12 part III residential homes in North London using the Brief Assessment Schedule (a derivative of the CARE). A total of 24% of the residents had evidence of depression. The screened cases were then further assessed for specific diagnosis: half were found to have a primary affective disorder, while one third had depressive symptoms in the presence of an organic mental disorder. At 1 year follow-up, a quarter of the participants had died, while only 28% of those assessed for depression showed evidence of recovery. This study highlights the fact that community residential homes contain a large number of disabled residents with severe and enduring depression who require specialist support and management.

2.2 Primary Care

There are few surveys of depression in older people in primary care. Subjects in this setting have decided to consult their doctor, and consultation may well be for a physical condition. Recognition of any depression will depend upon general practitioner diagnosis; those who are recognised as depressed become part of the conspicuous morbidity in primary care, while those not recognised constitute part of the hidden morbidity. General practice surveys are therefore of self-selected groups who are likely to have an increased physical morbidity. Iliffe et al. (1991) examined a random sample of patients aged 75 years or older registered with London general practitioners and used the short version of CARE (Gurland et al. 1984). They found evidence of depression in 22% of subjects (total morbidity). The majority of these cases of depression were mild in nature. A study from the United States (Borson et al. 1986) used the Zung Self-Reporting Depression Scale (ZSRDS; Zung et al. 1983) to measure depression in people attending veterans' primary care facilities. They discovered 24.4% caseness in these men aged over 60 years, with an estimated 10% prevalence of DSM major depression. Only 1% of the depressed reported the use of mental health services.

That a large proportion of depression does remain "hidden" from mainstream medical services has been indicated by several studies (Koenig et al. 1988; Blanchard et al. 1994). Blanchard and co-workers studied the "declaration" of depressive symptoms by older people to general practitioners and discovered that only one third of depressed older people believed that their doctor was aware of their current depression. Iliffe et al. (1991) examined general practitioners' notes and found that only 6% of their "screened" depressed cases were recorded as such. There is clearly a need to improve the identification of depressed older people in primary care, as without this subsequent management or referral cannot occur. The means to do this could involve the use of screening questionnaires such as the self-CARE (Bird et al. 1987) and the development of training programmes for primary care physicians and other primary care personnel (Gask 1992; Waterreus et al. 1997).

2.3 Psychiatric Inpatients

The population of older patients admitted to hospital for care is heavily determined by the health system operating within individual countries. Most depressed

older people in Britain are dependent upon primary care referral in order to obtain specialist care. The majority of psychiatric research, which inevitably forms our knowledge base of depression, has been carried out on this rather select group of patients. Depression in older people is associated with an increased use of primary care services, but there is no indication that depression itself leads to preferential referral to specialist services. There are probably many factors that determine the referral or otherwise of depressed older people to specialist facilities, but these have not been investigated in any systematic way. Probable factors would include some measures of severity of depression, e.g. psychotic symptoms, lack of social support in the light of observed self-neglect, mention of suicidal ideas, attempts at self-harm, request for psychiatric help by the patient or carers, repeated annoyance of the general practitioner by patient or carers and a concomitant psychiatric condition such as alcoholism or phobia.

Depression is the commonest single condition dealt with by most specialist old-age mental health services. The locus of care for an individual will depend upon the current organisation of local services. The trend is towards expanding community-based nursing support with a concomitant reduction in inpatient facilities. The established efficacy of electroconvulsive therapy (ECT) for certain depressive subtypes, and its use in life-threatening states and where pharmacotherapy is contraindicated or ineffective, is also likely to indicate the need for inpatient status in this new climate.

2.4
Physically Ill

There has also been considerable research on depression in older physically ill people in hospital settings. Patients with untreated depression may have impaired physical recovery and reduced compliance to physical treatments. Koenig et al. (1988) examined older patients admitted to a medical ward and identified major depression in 11.5% and other depressive syndromes in 23%. Those more likely to be depressed were older, had less formal education, had cognitive dysfunction, suffered from more severe medical illness (particularly recent myocardial infarction), had a history of psychiatric illness, were unmarried and had more severe disability. Within the outpatient setting, Kukull et al. (1986) used the ZSRDS and resurveyed a cohort of older general medical clinic outpatients at 33 months. They found point prevalence of 20% depression (score, >60) at both times with half of the patients depressed at both points, a marked level of chronicity. The number of new physical diagnoses was the best predictor of depression at retest with positive associations between chronicity of depression and the number of co-existing physical diagnoses.

3
Comparative Phenomenology

3.1
Young Versus Old

The possible existence of a depressive syndrome particular to older people – differing from younger adults in terms of aetiology and phenomenology – has been debated. Depression in old age has at times been thought to be more "melancholic", psychotic or hypochondriacal. However, there are difficulties in determining differences in the phenomenology between older and younger depressed patients because of the need to examine equivalent populations. Kramer-Ginsberg et al. (1989) studied 70 consecutive patients aged 60 years or older who were admitted to an acute psychogeriatric unit diagnosed as suffering from DSM major depression. A total of 60% of these patients had hypochondriacal symptoms as measured on the Hamilton Depression Rating Scale (HDRS), and 12% of these were of delusional intensity. In marked contrast to this, Blanchard et al. (1994) found, within their cases of depression identified by GMS in a community population of older people, only three out of 59 (5%) reached subcase level, and another three out of 59 (5%) reached case level on the hypochondriasis scale. These conflicting results demonstrate clearly the importance of population selection upon the phenomenological profile of depression. Two studies by Oxman et al. (1990) and Musetti et al. (1989) compared samples of old and young patients with depression and found similar symptom profiles; a stereotype of old-age depression as one of somatisation and hypochondriasis was not confirmed.

In a consensus document produced by the Royal Colleges of General Practitioners and Psychiatrists (Katona et al. 1995), the difficulties in diagnosing depression in some older people and the traps that physicians may fall into are highlighted. In particular, it should be noted that somatic symptoms and cognitive deficits might be the presenting features for some depressed older people and confusingly depressed mood as such may be absent.

3.2
Early Versus Late Onset

Baldwin and Tomenson (1995) compared early-onset (59 years or younger) and late-onset major depression

in 57 depressed inpatients. They found that symptoms between the two groups differed little; however, heritability was greater in the early-onset group, and there was a striking association of vascular disease and/or risk with late-onset patients. Thus, although phenomenology may be similar, there is the possibility that depression in later life has more of a 'biological' basis in late-onset illness, and more research is needed in this area.

Koenig et al. (1993) profiled the depressive symptoms of younger and older medical inpatients with major depression. There were great similarities in their symptom profiles, but in older people it was found that somatic symptoms might be more important in this group in diagnosing major depression, than previously realised.

3.3 Depression Versus Dementia

Depression and dementia are the two most common clinical problems in the psychiatric care of older people, and difficulties in diagnosis can occur as not only can the symptoms of the syndromes overlap, but up to about a quarter of patients with cognitive impairment warrant a diagnosis of depression, and up to a fifth of depressed patients appear to have cognitive problems. Yesavage (1993) states that more than a quarter of patients with dementia may be initially misdiagnosed as having an affective disorder, and inaccuracy in the diagnosis of dementia may be as high as a third. Symptoms such as flattened affect, paucity of speech, slowness, poor concentration, persecutory delusions, hallucinations, aggressivity or irritability, diurnal rhythm changes and anxieties can all occur in both conditions. There are, however, symptoms primarily associated with depressive disorder, namely pervasive unhappiness, excessive guilt and suicidal ideation, which along with factors in the clinical presentation can help with the differential diagnosis (Yesavage 1993). There is currently no biological test or marker which can help in diagnosis, but O'Brien et al. (1994) suggest that temporal lobe magnetic resonance imaging may be useful.

The term "pseudodementia", which has been used widely in the debate about the depression/dementia interface, and which literally means a false dementia, is based on the ideas of non-progression, non-organicity and reversibility. It may have a variety of causes, one of which is depression. It implies a falseness of deficit, almost an absence of pathology, and the authors suggest that the term no longer be used. It is more useful to discuss the genuine depressive dementia that can occur in older people. Emery and Oxman (1992) discuss the idea of three intersecting continua of depression, cognitive impairment and degenerative dementia. They suggest that five conditions may occur:

1. Major depression with minimal cognitive deficits (noting that depression in individuals aged over 40 years nearly always involves some cognitive disadvantage)
2. Depressive dementia possibly associated with the pathology of mood disorders and controversially with the physical changes associated with late-onset mood disorders
3. Degenerative dementia without depression
4. The depression of degenerative dementia either directly caused or secondary to demoralisation
5. Independent co-occurrence

The need to make an exact differential diagnosis is eased to some extent by taking this continuum perspective and recognising depressive dementia, dual diagnosis and the idea of excess disability within dementia. The fact that depression may precede dementia is another intriguing factor in this complicated topic (Jorm et al. 1991).

4 Aetiology

4.1 Role of Physical Illness

There is a strong association between depression and physical ill health in older people. Certain illnesses may have a direct aetiologic role, either through physiological or cognitive mechanisms, while others may act as perpetuating factors. It is therefore very important to assess and manage physical illness as an integral part of the management of depressed older patients. Specific illnesses which have particular relevance to older people and depressive illness are stroke (Starkstein and Robinson 1989), Parkinson's disease (Dooneief et al. 1992), hypothyroidism (Tappy et al. 1987), dementia (Wragg and Jeste 1989) and hip fracture (Shamash et al. 1992).

Kennedy et al. (1989) used the Centre for Epidemiological Studies Depression Scale (CES-D) to study older community residents and found a hierarchy of characteristics associated with the substantial levels of depressive symptoms: illness, disability, isolation, bereavement and poverty. The prevalence and relative risk of depressive symptoms was related to the number of medical conditions, the number of problems in activities of daily living (ADL), disability, perceived health and the number of visits to a physician. The fact that people felt that they had little or no control over their health also appeared to be important. There is

evidence that it is disability and handicap that are the important correlates of depression rather than physical illness per se. Prince et al. (1997) discovered from their household enumerated population of older people that impairment, disability and handicap were all strongly associated with depression and that this association was strongest with handicap, with an odds ratio of 24.2 in the most handicapped quartile.

Physical illness as an important associate with depression also has an impact on prognosis. Kennedy et al. (1990) studied characteristics that may predict persistence or remission of depressive symptoms in their community population. They re-interviewed 1577 people at 24 months and compared the characteristics of 97 people whose depressive symptoms persisted over the 2 years with 114 people whose symptoms remitted. Increasing disability and declining health preceded the emergence of depressive symptoms and accounted for 70% of the variance in their discriminant analyses. Advanced age and worsening health were associated with persistent symptoms, and improved health with remission.

4.2 Role of Bereavement

Old age is a time of bereavements and losses which could naturally be expected to precipitate depressive states. It has been argued, however, that this type of life event is to be expected in old age and therefore may be less damaging in its psychological impact than when it occurs earlier in life. The vast majority of bereaved people do pass through the natural process of grief without recourse to doctors, least of all psychiatrists. However, given the fact that the majority of depression in older people is not recognised or treated, it is important to examine the relationship between bereavement and depression in a representative community sample. Bruce et al. (1990) used NIMH/ECA data and compared depressive episodes and dysphoria between newly bereaved ($n = 39$) and married ($n = 1047$) people aged 45 years and older. They found that bereavement greatly increased the risk of depression and dysphoria, and that the "bereaved depression" patients reported significantly fewer symptoms of guilt when compared to the non-bereaved depressed. None of the bereaved depressed patients had experienced a prior depressive episode. Blanchard et al. (1994) reported that 27 out of 96 depressed community patients became depressed in the 6 months following a bereavement, and of these, 23 had their depressive symptoms for more than 2 years. In an attempt to determine the relationship between recent bereavement and suicide, Bunch (1972) studied 75 consecutive cases of suicide and compared them with 150 matched controls living in the same area. She found that significantly (up to five times) more suicides than controls had been widowed within the previous 3 years and that more widows than widowers killed themselves. It is probable that bereavement does play a greater aetiologic role in depression and suicide in older people than perhaps is generally appreciated and that this has important implications for its management.

4.3 Role of Social Factors

There are few studies in older people using detailed methodology such as that employed by Brown and Harris (1978); community studies tend to use methodologically simpler techniques for the measurement of social factors and to use measures of depressive symptoms rather than clinical caseness criteria. Despite this, there is evidence that social factors can influence onset and course of depression in older people. Murphy (1982) compared a group of 100 older depressed people referred to local psychiatric services with a group of age- and sex-matched non-depressed people from the general population. Taking 1 year before interview or 1 year before onset of depression as the time periods of interest, 48% of patients compared with 23% of non-depressed subjects had a severe life event in the year before onset; 42% of patients and 19% of the non-depressed had a major non-health difficulty; 39% of patients and 26% of the non-depressed had major health difficulties. Emmerson et al. (1989) studied 101 patients with DSM-III major depression and compared them with 85 non-depressed community residents who scored 4 or less on the General Health Questionnaire. They found that significantly more of the depressed patients (24% vs. 7%) reported at least one severe life event in the 3 months prior to onset of illness. The fact that life difficulties were rare in their sample was attributed to the fact that they were studying a relatively affluent population. Pahkala (1990) studied 1529 people born in Ahtari, Finland in 1923 or before. The ZSRDS was used as a postal screen and then anyone scoring 40 or more, plus a random sample of those scoring less, were interviewed. This cross-sectional study demonstrated that depression was associated with retirement through sickness, lack of intimate friendships and the occurrence of long-standing and current social stressors.

Social factors are also important in the prognosis of depression. Kivela and Pahkala (1989) performed a prospective follow-up with a mean duration of 14.9 months on 264 community depressed older people. Outcome was good in 41% of patients. Poor

outcome was associated with low social participation, low frequency of visiting contacts and low perceived health. Oxman et al. (1992) attempted to examine the effect of the characteristics of social networks and support on depressive symptoms. They utilised results on surveys carried out on 1962 community residents aged 65 years and older first seen in 1982 and followed up in 1985. Baseline depression, functional disability in 1982 and change in disability by 1985 contributed mainly to variance and required adjustment along with sociodemographic variables for their multiple regression analyses. Loss of a spouse, inadequate emotional support and its change between 1982 and 1985 made the largest social contributions to depression and its outcome. Other significant factors were "tangible" support adequacy and its change, loss of a confidant, number of children making weekly visits and any change in this, and the absence of a confidant in 1982. This study highlights the need to consider specific dimensions of social support. Ong et al. (1987) investigated the role of a support group for depressed older people and found that a simple weekly support group resulted in significant reductions of relapse and readmission over 1 year. The effect of re-establishing social interaction has been demonstrated by Schonfield et al. (1985), who examined two groups ($n = 42$, $n = 47$) aged 55–91 years. They followed one group through a mental health treatment programme, which emphasised the strengthening of social networks, and the other through a nutrition programme. Initially, the mental health programme group scored significantly higher on the Beck Depression Inventory and had fewer friends as measured on the Social Support Network Inventory. "Graduates" of the mental health programme improved significantly in their Beck scores with a concomitant increase in friends. Their conclusion was that continued socialisation in later years might serve to allay depression.

4.4
Role of Genetic Factors

When the presence of a family history of depression in older depressed patients is assessed, a difference appears between the unipolar depression that first occurs late in life and the depression that continues from earlier in the life cycle. These findings were concluded for hospital patients, and it must be remembered that the determination of a previous history of depression in older relatives may be difficult. Baron et al. (1981) examined age at onset data in 1468 first-degree relatives of 252 probands with unipolar and bipolar affective disorders. Early-onset (< 40 years) probands had more early-onset relatives and a greater risk for affective disorder in their relatives than late-onset probands. This suggested a familial factor in early-onset illness tending to breed true, but of course an entire follow-up of relatives would be needed to complete the picture with respect to late-onset depression. Maier et al. (1991) also investigated the notion that late-onset depression (>60 years) was believed to be associated with less risk of depression in first-degree relatives. They compared older inpatients with unipolar major depression ($n = 92$) with aged-matched controls ($n = 33$). They also discovered that relatives of probands with late-onset depression were at less risk of depression than those with early-onset depression. Similar differences, with late-onset depression being more "event precipitated", having less evidence of family history and earlier "personality inadequacies", are reported by Musetti et al. (1989) and Brodaty et al. (1991).

4.5
Brain Biochemistry, Physiology and Structure

Developments in imaging and neurobiochemical research techniques have stimulated investigations into the depression of older people. It does appear that there are specific subgroups of older people with depression who differ from the depressed population as a whole in terms of structural brain changes and neurotransmitter status. These results indicate the possibility of a "biological propensity" towards onset and/or poor prognosis of depression in some older people.

Jacoby et al. (1983) examined an index of brain tissue density from the computed tomography (CT) scans of 37 elderly depressed patients calculated using Hounsfield units (HU) in 12 predefined areas of brain. They compared their study group with 36 healthy controls and 23 subjects with dementia. The controls showed the highest HU values and dementia sufferers the lowest. There was no correlation between HU values and age. In the depressed patients, ventricular dilatation was associated with lower HU levels, but this was not the case in controls. The authors suggested that these results might indicate a specific pathological process underlying depression in a certain subgroup of depressed older people, especially as the changes did not appear to be related to future dementia on follow-up. Significantly, 2-year mortality was increased in the depressed people with ventricular enlargement as shown on CT scan (Jacoby and Bird 1981). Greenwald et al. (1996) studied patients with depression ($n = 48$) and discovered that they were more likely to manifest magnetic resonance imaging (MRI) abnormalities than non-depressed older people with similar demographic features ($n = 39$). After allowing for age and gender,

depressed patients had a greater degree of hyperintensities in the subcortical grey matter than controls. It appears that depression in late life can be associated with a remarkable amount of overt pathologic change in the brain, and this has been reviewed by O'Brien et al. (1996).

Older and younger people appear to differ in their aminergic systems, differences likely to lead to greater levels of depression in older people when considered within the context of the current amine paradigm. Robinson et al. (1971) examined the monoamine oxidase (MAO) activity in blood plasma and platelets of 113 healthy subjects aged between 21 and 84 years. Activity was found to correlate highly with increasing age when measured in plasma and platelets. Women had higher activity than men only in the platelet measures. In addition, Nemeroff et al. (1988) discovered a marked reduction in the platelet-tritiated imipramine-binding sites in older depressed patients. In terms of possible neuroendocrine abnormalities in depression in older people, Heuser et al. (1996) compared the effects of 6-week treatment with amitriptyline on hypothalamic-pituitary-adrenocortical (HPA) regulation in older depressed patients ($n = 39$) and age-matched controls ($n = 14$). The depressed patients had profoundly abnormal HPA responses, which began to disappear after 1 week of treatment with amitriptyline. In contrast, amitriptyline did not affect neuroendocrine regulation in the comparison subjects at any time during the test period. This raises the possibility that the normalisation of the HPA feedback control is related to the antidepressive effect of amitriptyline and is therefore significant in aetiology.

Another physical measure used to differentiate "biological" depression from depressive symptoms is that of sleep patterns. A recent study has cast doubt upon the nosology of depression and bereavement reactions found in various research and clinical diagnostic criteria. This is an important issue in older people where so much depression is discounted as a "normal reaction" to circumstances. Reynolds et al. (1992) studied 31 older volunteers with recent spousal bereavement who were stratified by the presence ($n = 15$) or absence ($n = 16$) of major depression; they had no personal history of psychiatric disorder. Those with major depression had lower sleep efficiency, more early morning wakening, shorter rapid eye movement (REM) latency and a greater percentage of REM. These depressed patients resembled older patients with recurrent unipolar major depression. Sleep in bereavement without depressive symptoms was similar to 15 healthy controls. The findings suggest that the current concept of uncomplicated bereavement is unconfirmed, because many of the depressed bereaved would have fallen into this category and yet they had identical sleep patterns to those found in major depressive episodes.

5 Prognosis

5.1 Relative Prognosis

Studies on the prognosis of depression in older people can again be separated into those based upon hospital populations and those examining depression within a community setting. Initial studies appeared to show a poor overall prognosis in the more severe cases of depression in older people, but further research has indicated that reality may not be quite so gloomy. Alexopoulos et al. (1996) compared older and younger depressed inpatients and found them to have an equal recovery rate of 60% at 6 months. Cole and Bellavance (1997) conducted a comprehensive review of the literature on prognosis from 1955 to 1993. Their meta-analysis indicated that about 60% of patients treated in the hospital setting either remained well or had treatable relapses. Only one in five patients developed chronic symptoms.

5.2 Secondary Care Prognosis

Murphy (1983) performed a 1-year prospective study of 124 older patients referred to psychiatric services for the first time; only one third of her group had a good outcome. Poor outcome was associated with the severity of the initial illness and the presence of psychotic symptoms and with physical health problems and severe life events in the follow-up year. Baldwin and Jolley (1986) performed a retrospective analysis of between 42 and 104 months on 100 elderly patients admitted to hospital with severe, non-neurotic depressive states, none with previous hypomania. They found that 60% remained well or had one or more further episodes followed by full recovery, while 7% suffered continuous depressive symptoms. This more optimistic result contrasts with that found by Murphy (1983) and may in part be due to their less rigorous methodology (retrospective) and differences in treatments (more ECT used by these authors). Male sex and poor physical health at presentation or developing subsequently were the only predictors of poor outcome. Cole (1983) examined age, age at onset and the course of primary depression following hospital admission among older people. He found that the effect of age was not significantly related to the

prognosis of depression in the absence of persistent organic signs and severe physical illness. The severity of illness and continuing physical ill health were the two most important factors determining outcome. People with late onset depression were more likely to remain completely well during follow-up than those with early life onset (55% vs. 25%). Cole (1985) also studied the course of 55 older depressed outpatients whom he followed for 24–63 months. A total of 38 (69%) remained well for more than 60% of the follow-up period, and 17 patients (31%) remained chronically ill. Treatment compliance, absence of physical disability, long-term follow-up and maintenance antidepressant therapy were associated with favourable outcome.

5.3 Community Prognosis

Copeland et al. (1992) examined the prognosis of depression in the community by following their cohort over 3 years. They found an increased mortality and a marked chronicity (30% remained cases) among their depression patients. This apparently poor prognosis probably reflects the lower overall severity of depression found in the community compared to inpatient studies and also the lack of recognition and paucity of treatment known to occur (Livingston et al. 1990; Blanchard et al. 1994).

5.4 Suicide as an Outcome

Although suicide is increasingly more frequent among young men, suicide rates are highest among older people throughout the world (Moscicki 1995). In England and Wales, the suicide rate is estimated to be about 10–20 per 100,000 per year. In a survey of older people who committed suicide in the United States, 64% used violent means, whereas in the rest of the Western world, where firearms are less accessible, 85% committed suicide by self-poisoning, jumping, hanging or car exhaust inhalation. There does appear to be a clearer relationship between depression and suicide in older people than is the case with younger people (Barraclough et al. 1974; Conwell and Caine 1991). This theoretically could make strategies for reducing the rates of suicide in older people less complex. Other important factors include sex (male), separation or divorce, previous suicide attempts, a family history of psychiatric illness or suicide and recent severe life events. Recent major political changes in Eastern Europe appear to have increased the rate of suicide in this area; however, among those aged 75 years or over, the rates have decreased (Sartorius 1995).

6 Treatment

6.1 General Principles

Many of the guiding principles for the treatment of depression in younger people are true for older people as well. However, differences do include the fact that the majority of first assessments and follow-up appointments of depressed older people are carried out in their own homes and that informant interviews and an assessment of family support may be more pertinent. Once a diagnosis of depression has been reached, then a comprehensive assessment of the patient's physical, psychological and social history and current state needs to be made before it is possible to produce a management plan. It is essential that the depression is treated within its context; no two depressions are the same in this respect.

6.2 Pharmacotherapy

McCusker et al. (1998), in a review article, examined acute-phase pharmacological and psychological treatments in older people in outpatient, community or nursing home settings. Forty out of 233 articles met their selection criteria, 26 on pharmacological treatment and 14 on psychological treatment. Antidepressants were found to be more effective than placebo, and rational therapies more effective than a no-treatment control.

Older patients may be more prone to the side-effects of antidepressants and, certainly with the older tricyclics, dosage may require careful titration. This is less of a problem with the newer selective serotonin re-uptake inhibitors (SSRI). Older patients may take longer to recover (Schneider et al. 1994), so that a reasonable course of antidepressants may be longer than in younger adults, lasting up to 6–8 weeks.

Anstey and Brodaty (1995) stated that there are no high-quality randomised, placebo-controlled trials of drug or psychological therapy in the acute phase of old-age depressive illness of whatever severity, and none could now be done for ethical reasons. Jacoby (1998), in a commentary to the McCusker article, makes some important points about older depressed people: that they are a heterogeneous group, that many studies are far too short, lasting only a few weeks, and

that the Hamilton Depression Scale is commonly used as an outcome measure, a scale that has a heavy weighting on somatic items, which makes it less suitable as a measure, as non-depressed older people can score positively on these items. He goes on to consider that, certainly among those with mild to moderate depression, time spent talking might in some ways be as effective as any drug.

Callahan et al. (1994) studied the effect that training in the recognition and management of depression in older people had on the actions of primary care physicians. They provided patient-specific treatment recommendations and guidelines for prescribing to their intervention group and compared them with a usual care group. Intervention patients were more likely to receive a written diagnosis of depression and be prescribed antidepressants (nortryptyline or fluoxetine); however, over a 9-month follow-up, there were no differences in outcome between the two groups. This may have been due to problems of compliance or, as the authors suggest, there may be a need to provide more integrated interventions, including attempts to target psychosocial stressors, in the management of depression in older people; this is probably outside the purview of primary care as services are currently organised.

6.3 Electroconvulsive Therapy

ECT remains an important treatment for the few older people with severe depression in whom a rapid response is necessary or who are resistant to other treatments. It is a relatively safe procedure with clinical improvement in approximately 80% of those who receive it (Katona 1994). Cognitive side-effects can be a particular problem in older people, especially in those with organic mood disorders, but in most cases any amnesia resolves almost completely (Benbow 1989). There are no absolute contraindications to ECT, but great care needs to be taken in patients with uncontrolled cardiac disease, recent stroke or raised intracranial pressure from another cause. The relative risks need to be weighed up against alternative treatments or no treatment, and, with the advances in psychopharmacology such as the SSRI, it is the authors' clinical impression that the need for ECT is diminishing.

6.4 Psychotherapies

There is no reason to assume that research findings on the efficacy of behaviour and cognitive therapy in younger people should not be applied to older people. However, earlier this century, Freud made an observation which unfortunately, because of his influential status, had a powerful inhibitory effect on the development of psychotherapy for older adults for decades. "Near and above the fifties, the elasticity of the mental processes on which the treatment depends is, as a rule, lacking - old people are no longer educable, and, on the other hand, the mass of material to be dealt with would prolong the duration of the treatment indefinitely" (Freud 1924). His conclusion was that mental health problems were not as amenable to psychological interventions in old age as in youth. In contradiction to these beliefs, Gallagher-Thompson et al. (1990) reported on a 2-year follow-up of 91 older adult volunteers with major depression who had been treated with 4 months of brief cognitive, behavioural or psychodynamic psychotherapy. Seventy per cent of them remained non-cases, and there was no difference in outcome according to the type of treatment received. However, this was a relatively young (mean age, 67 years) and physically healthy group of people.

In his extensive review of psychological therapies in older people, Woods (1992) highlights the importance of coping with physical illness and disability in old age and the relative neglect of this as a major psychological issue requiring more attention from therapists and researchers. Mossey et al. (1996) examined the response to psychological intervention of subdysthymic depression, which occurs in 20%–50% of older people hospitalised for physical illness. Such depression is associated with physical and social disability, delayed recovery and excess health service use, and yet little work has been done either to describe its nature or to examine its response to treatment. In a randomised clinical trial, the efficacy of interpersonal counselling (IPC), a short-term psychotherapy, delivered following hospital discharge by psychiatric clinical nurse specialists, was assessed in patients with a Geriatric Depression Scale (GDS) score of more than 10 but not meeting DSM-III-R criteria for major depression or dysthymia. At 6 months, a statistically significant difference in the rate of improvement in GDS, indicated by scores of 10 or less, was observed for IPC compared to control (usual care) members (60.6% vs. 35.1%).
