Preface

Contemporary Psychiatry is an international textbook of psychiatry developed on the basis of the experience obtained with its first three editions, which only appeared in German. As such, this version incorporates the German tradition of phenomenology and diagnosis going back to Kraepelin, as well as other authors such as K. Schneider or Leonhard. However, for the first time, this tradition is combined with the Anglo-American tradition and the DSM-IV diagnostic system, making it a unique resource among psychiatric texts. Each edition has had a special focus. The first edition appeared some 15 years after the end of the Second World War and aimed to present the best of German psychiatrists' writing in order to help reestablish the links between psychiatry in Germany and elsewhere that were disrupted by the war. The second edition gave particular emphasis to social psychiatry and empirical research in psychiatry in the hope that they would become more familiar to German psychiatrists and be used by them in their research and in their administrative and clinical decisions. The third edition added a focus on the integration of psychodynamic approaches and psychotherapy in the practice of psychiatry. This present, fourth edition examines psychiatric problems systematically, combining scientific evidence and modern neurobiology with experience obtained in different sociocultural settings while paying particular attention to the insights gained by the different disciplines relevant to psychiatry.

While comprehensive in its coverage, *Contemporary Psychiatry* is not encyclopedic in the sense of listing all the issues and findings of the past two decades. It presents findings relevant to the key issues in psychiatry together with the paradigms that are necessary in order to gain a conceptual understanding of the current trends in psychiatric research, service, and training. In doing so, *Contemporary Psychiatry* naturally focuses on methods and approaches that are playing an increasingly important role in psychiatry, such as molecular biology, genetics, neuroimaging, and cognitive psychology. This method of presenting today's knowledge has been chosen because it is most likely to serve as a resource not only for psychiatrists, but also for medical students, those engaged in basic research relevant to psychiatry, and clinicians from other medical disciplines who are increasingly collaborating with psychiatrists in an effort to understand and manage psychiatric problems.

Although all the volumes of *Contemporary Psychiatry* are linked, each contains separate sections. The first volume presents the scientific basis of psychiatry and the contributions that disciplines overlapping with psychiatry can make to the resolution of psychiatric problems. Epidemiology, the neurosciences, psychology, genetics, and the social sciences are given particular prominence in this section.

The second part of Vol. 1 deals with general psychiatry. It begins with an analysis of classifications in psychiatry, paying particular attention to those included in the *International Classification of Diseases* (ICD) of the World Health Organization and in the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association. The chapters that follow deal with the skills necessary for psychiatric examinations, principles of psychiatric treatment, the structure of mental health services and their influence on the management of psychiatric problems, legal and ethical issues, and matters relating to undergraduate and postgraduate education in psychiatry. Volume 2 addresses the presentation of psychiatric problems and their management in special situations (such as that of a refugee status), in different cultures, and in combination with other mental and physical diseases. Part 2 of this Volume systematically presents knowledge about specific psychiatric disorders, including the dementia. Schizophrenias, affective disorders, personality disorders, neurotic disorders (such as anxiety disorders, obsessive-compulsive disorders), eating disorders, suicide, substance abuse, and dependence disorders are presented in Vol. 3. The epidemiological profile, genetic and pathophysiological characteristics, clinical form and course, treatment, and rehabilitation are presented for each of the disorders.

Contemporary Psychiatry combines the German tradition of psychiatry with the traditions of psychiatry in other countries, particularly that of the English-speaking countries. Its ecumenical strategy is exemplified by its approach to the classification of mental disorders, in that both clinical consensus and the guidelines contained in ICD-10 and DSM-IV have been used in organizing the parts dealing with specific diseases. The various chapters have been written by authors from 15 different countries, and versions of *Contemporary Psychiatry* in several other languages as well as in English and German are planned to be published, reflecting the aim of producing an international textbook that is useful in different settings throughout the world.

Preface

Contemporary Psychiatry is an international textbook of psychiatry developed on the basis of the experience obtained with its first three editions, which only appeared in German. As such, this version incorporates the German tradition of phenomenology and diagnosis going back to Kraepelin, as well as other authors such as K. Schneider or Leonhard. However, for the first time, this tradition is combined with the Anglo-American tradition and the DSM-IV diagnostic system, making it a unique resource among psychiatric texts. Each edition has had a special focus. The first edition appeared some 15 years after the end of the Second World War and aimed to present the best of German psychiatrists' writing in order to help reestablish the links between psychiatry in Germany and elsewhere that were disrupted by the war. The second edition gave particular emphasis to social psychiatry and empirical research in psychiatry in the hope that they would become more familiar to German psychiatrists and be used by them in their research and in their administrative and clinical decisions. The third edition added a focus on the integration of psychodynamic approaches and psychotherapy in the practice of psychiatry. This present, fourth edition examines psychiatric problems systematically, combining scientific evidence and modern neurobiology with experience obtained in different sociocultural settings while paying particular attention to the insights gained by the different disciplines relevant to psychiatry.

While comprehensive in its coverage, *Contemporary Psychiatry* is not encyclopedic in the sense of listing all the issues and findings of the past two decades. It presents findings relevant to the key issues in psychiatry together with the paradigms that are necessary in order to gain a conceptual understanding of the current trends in psychiatric research, service, and training. In doing so, *Contemporary Psychiatry* naturally focuses on methods and approaches that are playing an increasingly important role in psychiatry, such as molecular biology, genetics, neuroimaging, and cognitive psychology. This method of presenting today's knowledge has been chosen because it is most likely to serve as a resource not only for psychiatrists, but also for medical students, those engaged in basic research relevant to psychiatry, and clinicians from other medical disciplines who are increasingly collaborating with psychiatrists in an effort to understand and manage psychiatric problems.

Although all the volumes of *Contemporary Psychiatry* are linked, each contains separate sections. The first volume presents the scientific basis of psychiatry and the contributions that disciplines overlapping with psychiatry can make to the resolution of psychiatric problems. Epidemiology, the neurosciences, psychology, genetics, and the social sciences are given particular prominence in this section.

The second part of Vol. 1 deals with general psychiatry. It begins with an analysis of classifications in psychiatry, paying particular attention to those included in the *International Classification of Diseases* (ICD) of the World Health Organization and in the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association. The chapters that follow deal with the skills necessary for psychiatric examinations, principles of psychiatric treatment, the structure of mental health services and their influence on the management of psychiatric problems, legal and ethical issues, and matters relating to undergraduate and postgraduate education in psychiatry. Volume 2 addresses the presentation of psychiatric problems and their management in special situations (such as that of a refugee status), in different cultures, and in combination with other mental and physical diseases. Part 2 of this Volume systematically presents knowledge about specific psychiatric disorders, including the dementia. Schizophrenias, affective disorders, personality disorders, neurotic disorders (such as anxiety disorders, obsessive-compulsive disorders), eating disorders, suicide, substance abuse, and dependence disorders are presented in Vol. 3. The epidemiological profile, genetic and pathophysiological characteristics, clinical form and course, treatment, and rehabilitation are presented for each of the disorders.

Contemporary Psychiatry combines the German tradition of psychiatry with the traditions of psychiatry in other countries, particularly that of the English-speaking countries. Its ecumenical strategy is exemplified by its approach to the classification of mental disorders, in that both clinical consensus and the guidelines contained in ICD-10 and DSM-IV have been used in organizing the parts dealing with specific diseases. The various chapters have been written by authors from 15 different countries, and versions of *Contemporary Psychiatry* in several other languages as well as in English and German are planned to be published, reflecting the aim of producing an international textbook that is useful in different settings throughout the world.

Preface

Contemporary Psychiatry is an international textbook of psychiatry developed on the basis of the experience obtained with its first three editions, which only appeared in German. As such, this version incorporates the German tradition of phenomenology and diagnosis going back to Kraepelin, as well as other authors such as K. Schneider or Leonhard. However, for the first time, this tradition is combined with the Anglo-American tradition and the DSM-IV diagnostic system, making it a unique resource among psychiatric texts. Each edition has had a special focus. The first edition appeared some 15 years after the end of the Second World War and aimed to present the best of German psychiatrists' writing in order to help reestablish the links between psychiatry in Germany and elsewhere that were disrupted by the war. The second edition gave particular emphasis to social psychiatry and empirical research in psychiatry in the hope that they would become more familiar to German psychiatrists and be used by them in their research and in their administrative and clinical decisions. The third edition added a focus on the integration of psychodynamic approaches and psychotherapy in the practice of psychiatry. This present, fourth edition examines psychiatric problems systematically, combining scientific evidence and modern neurobiology with experience obtained in different sociocultural settings while paying particular attention to the insights gained by the different disciplines relevant to psychiatry.

While comprehensive in its coverage, *Contemporary Psychiatry* is not encyclopedic in the sense of listing all the issues and findings of the past two decades. It presents findings relevant to the key issues in psychiatry together with the paradigms that are necessary in order to gain a conceptual understanding of the current trends in psychiatric research, service, and training. In doing so, *Contemporary Psychiatry* naturally focuses on methods and approaches that are playing an increasingly important role in psychiatry, such as molecular biology, genetics, neuroimaging, and cognitive psychology. This method of presenting today's knowledge has been chosen because it is most likely to serve as a resource not only for psychiatrists, but also for medical students, those engaged in basic research relevant to psychiatry, and clinicians from other medical disciplines who are increasingly collaborating with psychiatrists in an effort to understand and manage psychiatric problems.

Although all the volumes of *Contemporary Psychiatry* are linked, each contains separate sections. The first volume presents the scientific basis of psychiatry and the contributions that disciplines overlapping with psychiatry can make to the resolution of psychiatric problems. Epidemiology, the neurosciences, psychology, genetics, and the social sciences are given particular prominence in this section.

The second part of Vol. 1 deals with general psychiatry. It begins with an analysis of classifications in psychiatry, paying particular attention to those included in the *International Classification of Diseases* (ICD) of the World Health Organization and in the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association. The chapters that follow deal with the skills necessary for psychiatric examinations, principles of psychiatric treatment, the structure of mental health services and their influence on the management of psychiatric problems, legal and ethical issues, and matters relating to undergraduate and postgraduate education in psychiatry. Volume 2 addresses the presentation of psychiatric problems and their management in special situations (such as that of a refugee status), in different cultures, and in combination with other mental and physical diseases. Part 2 of this Volume systematically presents knowledge about specific psychiatric disorders, including the dementia. Schizophrenias, affective disorders, personality disorders, neurotic disorders (such as anxiety disorders, obsessive-compulsive disorders), eating disorders, suicide, substance abuse, and dependence disorders are presented in Vol. 3. The epidemiological profile, genetic and pathophysiological characteristics, clinical form and course, treatment, and rehabilitation are presented for each of the disorders.

Contemporary Psychiatry combines the German tradition of psychiatry with the traditions of psychiatry in other countries, particularly that of the English-speaking countries. Its ecumenical strategy is exemplified by its approach to the classification of mental disorders, in that both clinical consensus and the guidelines contained in ICD-10 and DSM-IV have been used in organizing the parts dealing with specific diseases. The various chapters have been written by authors from 15 different countries, and versions of *Contemporary Psychiatry* in several other languages as well as in English and German are planned to be published, reflecting the aim of producing an international textbook that is useful in different settings throughout the world.

Psychopathology Today

Translator: S. Henn

1 Introductory Comment: Psychology in Transition

The following exposition continues the one presented in the 1989 edition of *Contemporary Psychiatry*. The predominant theme of that chapter was methodological dualism, which had thrown psychopathological research into disorder, eventually changing and diversifying it. The model of gradual changes proposed at the time has been taken up only occasionally (Frommer 1996). Instead, the prevalent tendency in the development of the field has been the diversification of research paradigms, clearly dominated by the fundamental principles of logical empiricism. Modern classification manuals have made a substantial contribution to this. Our analysis of the current situation and its inherent developmental trends will not repeat that debate on fundamental principles and the systematic examination of specialized psychopathology linked to it. Instead, it will turn directly to subsequent innovations and evaluate them from the perspective of the methodological problems described.

The goal and strategies of present research efforts in psychopathology are particularly evident in the results and limitations seen in two areas: classification research and experimental approaches that include imaging methods. These will therefore be dealt with in more detail.

2 Classification: Operational Diagnostic Systems

Although a separate chapter in this edition of *Contemporary Psychiatry* is devoted to classification (see Vol. 1, Part 2, Chap. 2), the present discussion of psychopathology also requires a critical look at this area of research.

The introduction to ICD-10 and DSM-IV and their present implementation in hospitals and research have revived the highly controversial discussion about operational diagnostic systems in the German-speaking psychiatric community (see Gross et al. 1997).

2.1 Anticipated Consequences – Reliability

As early as 1974, Spitzer and Fleiss proposed validity and reliability as fundamental research goals of psychopathological classification research. Reliability does not guarantee validity, but limits it. The association of this research goal with Kraeplin's medical model of mental illness (see Avenarius 1979) and with the reception of Jasper's descriptive psychopathology, restricted to symptom inventories, led to the desired abandonment of ideal types, perceived as integrated essences, in favor of mosaics composed of single symptoms, the combination of which could then be examined quantitatively and independently of all nosological, etiological, and pathogenetic biases. New findings and viewpoints regarding nosological categories had already been worked out in new versions of DSM and ICD, but the loss of old concepts, in part highly criticized, had to be accepted. As Mombour et al. (1990) stated, concentration on descriptive outcomes to the detriment of conceptions has been accepted in field studies; however, that was all that could be expected from those researchers who were motivated to participate in them. The authors of several reliability studies (Mombour et al. 1990; Freyberger et al. 1990; Sartorius et al. 1993; Dilling and Dittmann 1990; Mezzich 1992) found that a high degree of correspondence could be established between investigators and centers ($\kappa > 0.80$), except for in certain personality disorders, which only reached a κ value of 0.52 in the WHO study comparing different centers. Sartorius believes that a brief acquaintance with the new manual suffices to reach a high level of correspondence. Furthermore, ICD-10 is appropriate for diagnostic practices in European and non-European countries alike, especially those in the Third World, to which the ICD feels particularly committed. On the other hand, Sartorius' statement contradicts the fundamental criticism of the instruments which is increasingly present in the literature.

The reliability achieved in other field studies is far lower. Freyberger notes critically that values for personality disorders, Alzheimer's dementia, drug addiction, and depression are unsatisfactory. For a moderately severe depressive episode, a κ value of only 0.17 was reached among 134 hospitals and 10 centers in Germany. In addition, Freyberger points out that splitting up the category of dissociative disorders has caused particular difficulties in classifying corresponding phenomena.

The goal of improving the reliability of classification manuals has led a number of groups to work on developing a "family of instruments." These include symptom checklists, systematic self-assessment and objective assessment instruments with detailed instructions for use, and, finally, standardized interviews, which stipulate the diagnostic interview to be carried out, including the wording of questions. Thus, for example, the Schedules for Clinical Assessment in Neuropsychiatry (SCAN), which evolved from the Present State Examination (PSE) developed by Wing et al. (1990), was tested by Maurer et al. (1991). SCAN also contains instructions for analysis and evaluation which are derived from examined symptoms for ICD

and DSM diagnostic categories. A "modular system" is planned, which is intended to be polydiagnostic and to differentiate between data sources. As in many reports on reliability studies, the work by Maurer et al. (1991) is simply a critique inherent to the system: SCAN is still too long, the terse remarks for normal, or negative, findings are inadequate, and the statement should differentiate between question and commentary. Other things are also not considered, e.g., the effect of contact with the patient through a procedure focused on diagnosis rather than primarily upon therapy, such as concerns spontaneously presented by patients. Also principally excluded are problems of structuring, which are very important in the free interplay of hermeneutic acts between patient and therapist in psychotherapeutic diagnosis (see also Saß 1987: "Problems with data source remain unconsidered"). Personal experience with those that use standardized interviews where variable reliability was obtained shows that, even despite standardization and repeated questions, additional intuitive perceptions rank high and are included in the final diagnosis.

Another interview for assessing personality disorders, developed and preferred by WHO, is the International Personality Disorder Examination (IPDE). Dilling has added to this the Composite International Diagnostic Interview (CIDI). SCAN and CIDI have the disadvantage of much longer assessment times, a minimum of 1 h for normal results, otherwise 3 h or more. A lexicon explaining the psychopathological terms used in DSM and ICD and thus making a contribution to their use as standards is being prepared as a provisional conclusion in the "family of instruments."

Just as guaranteeing reliability is especially important in the spread and applicability of the instruments, so is feasibility. In this connection, Dilling and Dittmann (1990) point out that the new numbering system has room for 1000 classifications, about two thirds of which are now in use. Thus additional entries would not require new editions. Moreover, the approach to the DSM structure in view of expanded dementia concepts and the abandonment of qualitative elements of endogenous depression and some other older psychopathological concepts is viewed as providing "improved feasibility." Thus a high priority is given to reliability – especially comparability to the DSM-based diagnostic studies – while a discussion of reliability is more likely avoided by increasing categories such as "difficulties with the boss" on the ICD axis of psychosocial factors. Such classification requires some getting used to if we consider the highly theoretical level that had already been achieved in the conceptualization of psychosocial causal factors in German-speaking psychopathology (Kisker 1960; Tellenbach 1983). The question remains as to what knowledge is gained from empirical research into the frequency distribution of such categories over categories in axis I if the level of abstraction of a disorder cannot be conceptualized as a basic disorder. This was why stealing and kleptomania, for example, were not granted the status of a diagnosis (see Mundt 1986); they could, for example, be categorized as an expression of the fundamental disorder "frontal lobe disinhibition" or as an expression of a conflict situation in neurotic disorders, at best as a symptom. The interpretation necessary for differentiation was sacrificed to safeguard reliability.

2.2 Conceptual Changes – Problem of Validity

Dilling and Dittmann (1990) have worked out the conceptual changes in comparison with the traditional diagnostic concepts, which were largely shaped by authors of the Heidelberg School: the division into psychoses and neuroses was abandoned in order to free research from the etiological, pathogenetic, and nosological implications of these categories. The term "disorder" was used throughout, an inconsistency as DSM has been based on Kraepelin's medical model since the third edition (see Saß et al. 1994), so that it could be assumed from this that the concept of illness now more likely refers again to the biopsychosocial model of Adolf Meyer, which shaped DSM-I and DSM-II (Meyer 1960). In addition, this concept is now at the mercy of professional political battles between psychologists and psychiatrists. Baumann (1996) sees these terms in the manual as a "plan for distributing physicians' tasks," while Fydrich et al. (1996, p. 3) see the term "comorbidity" as a "reintroduction of the medical model through the backdoor." This results in a nominalistic overvaluation of terminology which obstructs research and serves professional political disputes.

The qualitative differentiation of depression categories into neurotic–endogenous or reactive–endogenous was abandoned in favor of a quantitative gradation. However, the assignment of degrees of severity has proven to be difficult (Dilling and Dittmann 1990). The severe form corresponds best in ICD to the earlier endogenous depression, and in DSM-IV to major depression with melancholic features; in this formulation, confusion with Tellenbach's melancholy type (1983) was taken into account in translation. Dysthymia corresponds best to the earlier neurotic depression, though enriched by the time criterion, but Saß (1987, 1994) considers this incorrect in relation to the corresponding DSM-IV category. Tendencies can be seen here of the various psychopathological schools incorporating their own traditions into the new system and not abandoning them.

The division of organic mental disorders into acute versus chronic and reversible versus irreversible disorders was also abandoned in favor of a purely descriptive procedure. To be consistent, ICD followed DSM in the broader dementia concept when the traditional criteria of irreversibility and lack of insight into illness no longer apply. Wieck's conception of the transitional syndrome (Wieck 1961), which was always disputed and was based upon clouded consciousness and reversibility, also no longer applies. There are now corresponding difficulties with the reliability of dementia diagnosis (Freyberger et al. 1990). As a result, special surveys are relied upon for research purposes (e.g., NADCA, AMCA; McKhann et al. 1984).

The corresponding DSM-IV chapter has also abandoned a solely descriptive approach and there is considerable confusion of etiological organizing principles, with the effect that neither of the two principles is really adhered to. This is related to the "loose" association of etiology and psychopathological appearance, to the generalization of exogenous reaction types according to Bonhoeffer (1910) and to their joint expression with nonorganic or mildly organic disorders, e.g., the earlier neuroses and psychopathies.

The schizophrenia chapter also now includes schizotypal and delusional disorders, which were formerly classified as psychopathic or personality disorders. New additions are undifferentiated schizophrenia and postschizophrenic depression. Dilling and Dittmann (1990) regret that in DSM-IV there is a difference in the time criterion of 1–6 months.

The ICD-10 chapter on "Neurotic, stress and somatoform disorders" also does not conform to the philosophy of the modern classification system insofar as it mixes etiological and descriptive elements to define the syndrome. Similarly, eating and sexual disorders are subsumed in the chapter on "Psychological and hormonal disorders."

Missing among the personality disorders is the old cyclothymic or thymopathic personality disorder, which now appears as cyclothymia under affective disorders. The accentuated personality was also omitted as a result of international advice, probably because of its stigmatizing character and difficult transcultural standardization. Newly included categories are pathological stealing, arson, and gambling, as well as artificial disorder. They were included in spite of unfavorable experiences in defining psychopathological syndromes for criteria of social behavior, e.g., the antisocial personality.

As symptomatic of the priority of reliability over validity, Dilling and Dittmann (1990) noted critically that, in spite of an exhaustive and accurate clinical description of the degree of mental retardation, the intelligence quotient is used as a definitive criterion, although this measure has been repeatedly questioned, even by psychologists.

2.3 Comorbidity Research

A major research goal, pursued by modern classification systems, was comorbidity research, which primarily separates symptom and personality levels, but also separates the symptom, or personality level on the one hand from psychosocial factors on the other. This led to the revival of the trauma theory, e.g., by discovering the increasing frequency of dissociative disorders following severe traumas. The more reliable diagnosis of personality disorders has resulted in a frequency of 10%–12% in nonclinical populations, about 27% in somatoform disorders and between 40% and 50% in anxiety and affective disorders (Fydrich et al. 1996), whereby very different clusters can be shown. Cluster C, the dependent, avoiding personality disorder, is most frequent in severe affective disorders, while cluster A, comprising the schizoid, schizothymic, and paranoid personality disorders, is least frequent. The fact that less than 30% of obsessive–compulsive syndromes (Fiedler 1995) are associated with compulsive personality disorder and, similarly, the association of dissociative disorders with histrionic personality disorders led to a differentiated view of their etiology. Studies on post-traumatic stress reactions (Fiedler 1995) have shown that dissociative phenomena are frequent, prognostically unfavorable consequences of a trauma without there necessarily having previously been a histrionic primary personality. In view of the abandonment of qualitative differentiation among depressions, a revival of this differentiation could develop from personality typology. A largely inconspicuous primary personality is mentioned in DSM-IV, namely, major depression with melancholy. This criterion had already been referred to by Weitbrecht (1966) and Schneider (1976) as a criterion for endogenicity in which, apart from signs of a weaker form, there is an autonomy of adaptation in relationships to self and the world that is very difficult to grasp.

The theoretical and strategic problem of modern classification systems is seen here quite clearly: a consistent restriction of the definition of depression to descriptive criteria also makes this diagnosis applicable to opiate addicts and cocaine users, for example. Thus the comorbidity of cocaine dependency and depression is the topic of a flood of publications in the United States. Comorbidity of depression and schizophrenia is also theoretically possible. However, inconsistently in the latter case, a separate category of post-schizophrenic depression has been introduced. The extensive discontinuation of principles of structuring, such as Jaspers' earlier stratification rule, which provided for a hierarchy according to the real severity of an illness, allows a certain disorder in category

formation to emerge to establish a new order, which is empirically better grounded but which is not, however, without assumptions. Fydrich et al. (1996) therefore advocate abandoning the personality disorder category and favor a dimensional-quantitative register of personality features with limits to the characteristic form of the groups, such that borderline cases between those personalities still socially acceptable and those recognized as pathological are included. They would then be defined solely according to categories of levels of symptoms, particularly interaction characteristics, and not according to simultaneous medical criteria, as was the case with the former concept of pseudo-psychopathy.

2.4 Critical Summary

The fact that modern systems of classification have made a fundamental contribution to the ability to compare epidemiological findings in therapy, research, administration, and quality control is indeed positive. New knowledge, gained through the philosophy of separate diagnostic axes, primarily affects the relativization of the connection of personality symptoms in former neuroses, the revival of the significance of trauma in research on post-traumatic stress disorder (PTSD), and a destigmatization of socially burdensome diagnoses. Although the operational classification systems are fundamental to an empirically meaningful and effective psychopathology and are needed in the future, critical objections prevail. They become more relevant against the background of expanded claims for the manuals.

Saß (1987, 1994) voiced the basic reservation that modern classification manuals represent a means by which one branch of psychiatry, psychopathology, is used in the service of another branch, biological psychiatry, with the consequent loss of a "pure psychopathology" (Janzarik 1988), i.e., organized thinking about structural and functional connections of the inner life.

A limitation in the differentiation of signs and symptoms occurs when reliability takes precedence over validity (see Spitzer and Fleiss 1974), and this has led in part to retrogression compared to the differentiation achieved earlier. Since behavioral and expressive symptoms can be classified more reliably than those relating to experience, an imbalance arises favoring behavioral symptoms and the corresponding methodology of objective procedures over the ideographically formed psychopathological tradition, which was more concerned with mental inner worlds. None of this would be a disaster, were it not for the inherent dynamics of the expanding claims for the validity of the manuals arising from practical considerations (see Blashfield and Fuller 1996).

The discrete character of many mental phenomena leads to a blurring of definitions of the terms (see Birley 1990), which tried to do justice to concepts such as that of ideal types (see Kraus 1991). This limited precision in defining terms should not lead to empty rituals of perfection and methodological overloading of procedures.

The neglect of conceptions derived from clinical evidence leads to an impoverishment of concepts and through editorial policy excludes one branch of psychopathology.

The "pseudo-lack of prerequisites" of logical empiricism has been repeatedly criticized, most recently by Birley (1990), who criticizes the manuals as being "essentialist scholastic wolves in the sheep's clothing of nominalists." He advocates a minimum of definition which would allow for a maximum of freedom of thought, whereby definitions would only be used for specific purposes. In view of the fact that before Kraeplin and after 100 years of the development of confusing nosological systems one was accustomed to regarding what was simple as being correct, the current increase in categories in the manuals makes one doubt advances in validation.

The manuals do not deal with the interests of psychotherapy, which requires a completely different point of view for its classification (see Mundt 1997). There is, however, a fundamental debate here among behavioral therapists in which one viewpoint with "disorder-specific", largely deindividualized techniques is given priority and the other is represented by an individual therapeutic approach oriented toward personality and biography rather than to nosology (for the controversy between Fiedler and Grawe, see Fiedler 1997). This discussion is taking place among behavioral therapists. From the outset psychoanalysts have followed and continue to follow their own diagnostic paths (see Janssen and Schneider 1994; Rudolf 1993).

With some innovations there is emotional resistance from the older generation to internalizing new ideas, not because they are diffident about accepting something new, but out of a lack of conviction and the feeling that something correct is being exchanged for something questionable.

The objections cited become more relevant due to the tendency of the manuals to claim generality and move toward radicalism. In spite of initial conciliations that the manuals were concerned with research criteria and contributed to administratively useful categories, it was first concealed, but then expressly stated, that they were intended as textbooks. The establishment of a "family of instruments" together with a textbook character, material which is the subject of examination, and editorial politics leads to a centralization and

uniformity of perception and thinking which did not previously exist.

It would therefore be desirable to relativize, though not to abolish, the system. A reappraisal of clinical evidence with a consensus of experts, an examination of quality criteria for psychopathological research as influenced by the humanities, and a revival of psychopathological research on concepts and structurally functional contexts should achieve a reversal of the instrumentalization of psychopathology through this recommendation for changeover steps: test the hypotheses by temporary blindness to meaning and return to concepts of ideal types.

3 Special Developments and Innovations in Classification Research

The studies by Klosterkötter (1988) in Huber's group of the transition from basic symptoms to fully developed schizophrenic-psychotic illness had already produced proof that the postulated functional connection exists. The process can be interpreted well using a vulnerability stress model or an intentionality model. Three stages in the development of basic symptoms were differentiated: the initial phase of nonspecific basic phenomena, the externalization phase leading to initial alienation and an "as if" character in acoustic perceptions, and, finally, the concretization phase in which there are increasing characteristic facial expressions with catathymic contexts. This differentiated result has great significance for prevention, since other basic symptoms are found more frequently in personality disorders and neurotic illnesses, especially in healthy adolescents and young adults, such as physiological instability and signs of alienation in developmental phases in which identity formation and role discovery are dealt with to a certain extent. In this respect, Klosterkötter et al. (1997) was able to show a broad predictive specificity for second-degree symptoms which already had a delusion-like and "as if" externalized character.

Good confirmation of Huber's long-term results were also shown by Marneros et al. (1991) and Häfner et al. (1992a). In a retrospective analysis of the long-term course of schizophrenics, Marneros et al. (1991) were able to compare course and outcome directly by including schizoaffective and affective psychoses. The tendency, already mentioned in the literature, was particularly clear in the slightly more favorable course for schizoaffective psychoses and still more favorable course for affective psychoses. Nevertheless, the familiar splitting into three courses also occurs in these groups, albeit at a generally better level. The primary personality is the chief predictor for all three groups. The study by Marneros et al. (1991) yields a wealth of psychopathological detail. However, to a certain extent it lacks basic symptomatological parameters of the syndrome, such as symptom linkages, number and duration of phases, as well as social aspects of course and outcome.

Häfner was able to confirm the findings clinically gathered by the Huber group with the survey instrument IRAOS (an instrument to assess the onset and early course of schizophrenia) developed by his group (Häfner et al. 1992b), in which he established that nearly all the patients who later developed schizophrenia reported such warning symptoms. He analyzed his findings to test different psychopathological concepts, e.g., the positive–negative dichotomy of Crow and Andreasen (see Häfner and Maurer 1991) and Conrad's stages model (see Hambrecht and Häfner 1993). His findings do not confirm the positive–negative model, since the precursor syndromes of his cohorts consist essentially of symptoms which can be judged as negative symptoms and which continually increase over a period of about 4 years until the first manifestation of positive symptoms, after which both positive and negative symptoms decrease. This synchronous rather than alternating pattern, or even the appearance of one or the other of the two syndromes, also described by other authors, speaks against the dichotomy. It is in this connection that the controversy about primary and secondary negative symptoms should be mentioned. Carpenter and colleagues (Carpenter et al. 1988; Kirkpatrick et al. 1989) had first been on the lookout for qualitative distinguishing features for this greater differentiation, which could not, however, be empirically validated (see Mundt et al. 1995; Barnett et al. 1996). The group introduced a time criterion that arbitrarily prescribed that negative symptoms which are long-lasting, appear at least 1 year before positive symptoms, and are not caused by medication, depression, psychotic anxiety, mistrust, or mental deficiency should be regarded as primary. This was the case for patients in the Häfner group, and even so the negative symptoms were in synchrony and did not alternate with positive symptoms.

In a study by Mundt et al. (1995) on the course of negative symptoms in a sample of schizophrenic and neurotic patients, comparable to those in Häfner's sample in which the group was between one to three hospitalizations and beginning to develop the illness, no greater differentiation into primary and secondary negative symptoms could be made in comparison with the neurotic patients. The controversy over interpretation of results (see also Amminger and Kirkpatrick 1997; Barnett et al. 1997) had placed the greatest focus of attention on special features of the samples. The characteristic affective rigidity found in many

schizophrenic patients in the postacute stage, in terms of the dynamic-structural model (dynamic constriction, as it is called by Kick 1991), indicates that disorders are more likely to be affective rather than structural-cognitive ones. In this respect, Kick's concept presents an interesting alternative to the cognitive-structural negative syndrome proposed by Crow (1980). According to Carpenter's definition of primary negative symptoms (Carpenter et al. 1988), the establishment in the group studied by Häfner et al. (1992a) of primary negative symptoms according to the time criterion would certainly be something to affirm. However, the short- to medium-term course in these patients does not show the expected positive-negative dichotomy. With Kick's dynamic constriction, it could be agreed with Carpenter that the formation of mental reaction in response to a high pressure of anxiety and processes of disintegration may possibly play a role in the development of negative symptoms, which would also be conceivable without the manifestation of positive symptoms. In this respect, Carpenter's definition of the time criterion does not fit with the absence of positive symptoms. In later publications, the Carpenter group (Carpenter et al. 1988; Kirkpatrick et al. 1989) incorporated the former qualitative-descriptive concept of the primary negative symptoms into an operationally defined deficit syndrome by introducing the time criterion. Thus Crow's syndrome of negative schizophrenia is reestablished, including the biological findings reported by the group.

Dynamic constriction also cannot be equated with the potentially composed posture of intentionality in apathy syndrome (Mundt 1985), which corresponds more to Carpenter's deficit syndrome with continuous negative symptoms and without chronic psychosis. Instead, the condition would be characterized by a tenseness and stiffening of intentional actions without a long-term effective level of relief being found or being necessary.

Late-onset schizophrenic and affective illnesses have recently received separate psychopathological consideration. Riecher-Rössler (1995) was able to show, on the basis of a large German and Danish group of representative patients, that late-onset schizophrenics do not differ in any of the major variables from early-onset patients. Psychopathological and sociodemographic variables, characteristics of the course of the illness, and biological variables suggest a continuum. Marneros, Jeste (1997), and other authors (see Marneros 1997) come to similar conclusions. An explanatory model for the high variance in age at onset of illness that is cited by most authors, particularly in the best methodological study by Riecher-Rössler (1995), is the vulnerability model, although it is still in an unsatisfactorily simplified form. The vulnerability concept is unsatisfactory for first-onset patients in that two aspects which are clinically indicated and were addressed in earlier studies of the psychopathology of first onset (see Kisker 1960) are not considered: the requirement that patients actively explore their world and develop in adolescence and early adulthood, and the distinctive interactions of the structural and dynamic constituents of personality (Janzarik 1988). Neither aspect is considered in the vulnerability model, which conceives of the individual as passively suffering. The models of structural dynamics and intentionality could enhance the vulnerability hypothesis in these points. There is good reason to believe that late-onset patients have more stable cognitive and affective structural patterns.

Once involution depression had been differentiated from affective illnesses in the interim between ICD-8 and ICD-9, the psychopathological discussion about the classification of late-onset affective disorders was focused, among other things, on the role of pseudodementia and the general interplay between factors causing depression and those causing biological dementia. A very extensive literature has now been established substantiating that late-onset depression with pseudodementia (see Morris and Rapoport 1990) carries an increased risk of actual development of cognitive deficits at a later stage; conversely, at least 30% of patients in early stages of dementia in whom no manifest disorders in self-perception and judgment have yet appeared develop depressive symptoms. A high proportion of late-onset affective disorder patients show corresponding brain morphology results.

In classification research with dementia patients, a greater differentiation in memory models has developed in a transitional area between psychopathology and neuropsychology which is also partially applicable in the theory of psychoses (see J. Schröder 1997). The differentiation developed by Squire (1986), Squire and Zola-Morgan (1991), and others between declarative and procedural memory along with the cerebral structures involved is now well established. In studies on the course of dementia using magnetic resonance imaging (MRI), Pantel et al. (1997) were able to show that the clinical psychopathological symptomatology, based essentially on disorders of declarative-explicative memory, is related in the early stage more to an atrophy of the hippocampus-amygdala complex than to an atrophy of the total area of the associative cortex. According to studies by Markowitsch (1995), procedural memory seems on the other hand to be connected to basal ganglia structures and to the cerebellum. Utilization of these findings and improved neuropsychological research methods for therapeutic training programs are still in the developmental stage.

A functional differentiation of dementia diagnosis using combined visual-spatial and semantic tests was also substantiated by Monsch et al. (1994). They were

able to show that patients with subcortical atrophy of the Binswanger type probably had disturbed access to semantic contents, though the contents themselves were not lost. With advanced cortical dementia of the Alzheimer's type, however, access is possible but the semantic contents of declarative memory are lost.

Schröder (see J. Schröder 1997) used the differentiation between declarative, procedural, and working memory as short or ultrashort storage along with further validation of psychopathological subtypes of schizophrenia as a bridge-building model to interpret patterns of cerebral activation seen in positron emission tomography (PET) and single photon emission computed tomography (SPECT). The three-factor solution, also replicated by him, of clustering of psychopathological symptoms of schizophrenics into a disorganized, a paranoid-hallucinatory, and an asthenic-apathetic subgroup corresponded to prefrontal hyperactivation, left hippocampal hypoactivation, and global hypofrontality. With disorders of mainly working, declarative, and procedural memory assigned to these subgroups, a neuropsychological model was suggested that is more concrete, better able to be tested, and less speculative in that it is closer to the results than the constructs of Liddle and Morris (1991) or Emrich (1990) of a disturbed central censor function for evaluating reality as the common "schizophrenia" of the three subtypes. The debate on subtypes continues to flare up on occasion. In addition to the most frequently replicated three-factor solution and the dichotomy model, four-, five-, and seven-factor solutions have recently been suggested (see Lindenmayer et al. 1995). In terms of clinical plausibility, statistics, patient selection, long-term stability, differences among survey instruments, and transcultural validity, the three-factor models, however, appear to be most convincing.

4 Increasing Importance of Developmental Psychopathology and Personality Research

Emotion research, coming largely from psychology, plays an increasingly important role in developmental psychopathology and in clinical research (Scherer 1993; Frijda 1986; Haviland and Lelwica 1987; Ekman 1993; Ekman and Friesen 1969; LeDoux 1989). Conceptual problems and the search for an adequate empirical methodological approach, which would at the same time do justice to phenomenology, currently dominate the field. Surveys of gestures and facial expressions and the establishment of physiological parameters, which are dependent on various emotional stimuli, are experimental and clinical parameters that are successfully used. The definition of emotion as a synchronization process of physiological oscillators (Scherer 1993) is not yet either clinically or experimentally convincing; whether basic emotions (Ekman and Friesen 1996; Machleidt et al. 1989) or a modular emotional conception are assumed still remains open. The extension of research to questions of cerebral localization and function is just beginning. As an example, Baxter et al. (1992) have shown that the emotional state connected to the manifestation of obsessive-compulsive phenomena leading to activation in the frontal caudate can be appreciably reduced and normalized by both medication and psychotherapy. This finding has led to speculations about the pathogenesis of the cerebral regulatory systems involved. Krause's group (Krause and Lütolf 1989; Krause et al. 1992), using gesture and facial expression paradigms, showed disturbed emotional interaction in communication between schizophrenic and healthy individuals and were able to clarify the significance of even the briefest and apparently meaningless facial stimuli as keys for controlling dialogue.

Apart from purely psychopathological research on personality disorders, aspects of personality and the psychopathology of their development already played an important role in the 1960s and 1970s in the interpretation of the psychopathology of endogenous psychoses. Tellenbach (1983) described the melancholic personality as a condition for clinical melancholy, and this was objectively validated by von Zerssen et al. (1994). In the course of their validation, the group was able to differentiate premorbid personality types for neurotic, schizophrenic, and affective patients (von Zerssen 1977; von Zerssen et al. 1996). Janzarik (1988) described the "preceding defect" for schizophrenia and Mundt (1985) the one for the premorbid affective personality. In the international literature, research focused on high-risk prospective studies, very largely directed at the spectrum of schizophrenic disorders, and mainly concentrated on discrete neurophysiological, neuropsychological, and psychomotor precursor symptoms of later schizophrenic illnesses.

Recently, there have been increasing numbers of studies in the field of empirically based developmental psychopathology on the etiology of depression. For example, analytical studies were carried out on the interaction of depressive parents with their children and their influence, as well as that of the entire constellation of their lives, on development of cognitive styles, regulation of self-esteem, social competence, and formation of social networks by these children. In particular, it was shown that interactions of depressive parents are generally reduced both quantitatively and in terms of their emotional breadth (see B. Schröder et al. 1996). In comparison to healthy parents, depressed ones showed more critical interactions with less involvement, less support, and more

anticipatory concern. The less beneficial styles of parental interaction were furthered by chronic burdens that the parents had – single parents, the double burden of career and household, chronic conflicts with partner or children (Brown 1996). Chronically depressive behavior patterns also have a negative effect on partnership and the partner's self-image. Brown (1996) has proven the prospective validity of these risk factors for developing a major depression in healthy adult women. Several groups have substantiated the risk of illness for children of depressive parents (Hops 1996; Hammen 1996). Depressive cognitive styles with tendencies to excessive self-criticism and self-negation, low self-esteem, and lack of social competence and acceptance in peer groups all work to bring about the development of the psychopathology. Children of insensitive mothers were shown by the Goodyear group to have retardation of cognitive, motor, and emotional development which can persist for a long time (Murray et al. 1996). The small children themselves appear to actively seek emotional rapport and attachment and, given the opportunity, to seek out responsive substitutes for their depressive mothers, if this is possible in the family.

This wealth of useful results relating to the pathopsychological and psychopathological development of manifest affective disorders provides a much clearer picture of possible risk constellations and protective factors than the previously typical features of personality that were acquired retrospectively and had a statistical/descriptive basis. Thus publications on the psychopathological development of affective disorders, particularly depression, emphasize pathopsychological models in which risk-bearing patterns of thinking, feeling, and behavior were transmitted in part by identification and in part by interaction. By comparison, results of preschizophrenic constellations are characterized more by fundamental organic disorders and the consequences of their inept handling in families, so that the impression arises sometimes that one is dealing with a special or abortive neuropsychological form of an organic brain disease.

The results of Walker and Lewine (1990) are worth mentioning in which home movies of small children who developed late-onset schizophrenia showed that discrete motor disorders were also the rule in early childhood. Resch (1996) summarized recent findings in his developmental psychopathology with the following ideas: tangential, cautious thinking, neuromotor deficits with disorders in speech development, attention deficit disorders, irritability of emotional control, and, finally, milder thought disorders describe the organic foundation. A rejecting, cold atmosphere, less active encouragement, low expectations, and active disqualification increase the developmental deficit and eventually lead to social incompetence and flattening of affect. Even for the development of a disorder which is primarily organic such as Alzheimer's dementia, Bauer et al. (1995) have shown a premorbid personality structure which is more strongly dependent in comparison to control probands. A corresponding interaction with comparable plausibility for organic/biological predispositions in patients at risk for affective disorders has not yet been developed. The enormous methodological difficulties of correlating the objective study of fundamental organic constellations and the hermeneutic study of a life history with its unfolding structure of meaning in a single comprehensible context has been recently pointed out by Bürgy and Mundt (1997) in their example of research on life themes.

Research on personality disorders as an independent nosological group, apart from continuing refinements and changes in survey inventories (see von Zerssen et al. 1996), has been enriched by the inclusion of biological aspects. Cloninger et al. (1995) have designed a repeatedly revised personality inventory, in which the categories "harm avoidance," "reward dependency," and "novelty-seeking" refer to an abnormal functional state of the dopaminergic, noradrenergic, and serotonergic systems. A genetic confirmation of this hypothesis, also indicated in view of the expression of the dopamine D_2 receptor (Svrakic et al. 1996), exists to date only for personality formations in alcoholism type 1 (late-onset, pronounced "harm avoidance") and type 2 (early-onset, pronounced "novelty-seeking"). Type 2 is thought to show a higher gene expression for the dopamine D_2 receptor than type 1. The as yet undeveloped validity of the inventory may have led to the sparse returns to date.

Herpertz and Saß (1997) have expanded personality research into experimental territory by examining the serotonin system using the fenfluramine test to attempt to stimulate affect in patients with impulsive personality disorder. They were able to show that dysfunctional affect as learned through experience is directly in conflict with impulsiveness, which is clearly biologically influenced and inherent in the personality, though cognitive performances and styles are not changed. The high degree of retention with increased control and explosive discharge of affect combined with distinctive affect change and differentiation play a role in subjective experience and have consequences for social ability.

Steinmeyer and Möller (1992) have made a valuable contribution to the statistical review of personality data generated from the inventories. Steinmeyer's facet theory analysis permits the modeling of clinically meaningful typologies gained by visualizing the overlap of clinical categories and those produced by statistical methods, e.g., factor analysis. The more or less pronounced convergence of these typologies with the empirically validated categories always remains evident.

Attempts from the field of pathopsychology (see below) to replace static-descriptive models of personality with functional models, which to some extent lack concrete ideas or empirical results, remain abstract and unclear (Becker 1995, 1996). Schmitt and Mundt (1991), Blöschl (1994), and Hops (1996) have investigated more closely the role of aggression in depressive personalities and were able to show relationships between suppression of aggression and low self-esteem as well as mechanisms of masked aggression among individuals with depression.

5 Influences of Phenomenology, Anthropology, and Philosophy on Psychopathology

The phenomenological-anthropological movement in psychopathology has a special tradition in Germany, the Latin countries, and Japan, and within Germany particularly at the hospital in Heidelberg and at the earlier centers in Marburg and Cologne. In a theoretical paper, Schmidt-Degenhard (1997a) named the two main interests of this research approach:

1. The ontic interpretation of psychopathological phenomena, i.e., explanation of the manner in which the being of the patients is adapted and its consequences for the relationship to self and the world. Husserl, Heidegger, and Sartre were all consulted as phenomenologists and existentialist philosophers concerning methodology (Husserl) and content.
2. The hermeneutic study of biographical, intentional, and mnestic structures of meaning guiding experience and action. This interest is also strongly influenced by psychoanalysis.

Schmidt-Degenhard's assertion that, because of its "existential harmony," the phenomenological-anthropological movement of psychopathology has special ethical support of higher standing than that of other research approaches should provoke criticism. He also directs this claim at "exploration as an open field" (Schmidt-Degenhard 1997b) for the effect of the patient upon the investigator and the establishment of intersubjectivity, an old demand made by von Baeyer (1955), which was already very controversial at the time. The implicit ethical devaluation of other traditions implied by such an assertion is problematic. The claim of taking the human condition as the object of investigation does not necessarily mean that it has been permanently improved. Historically speaking, important social psychiatrists have of course emerged from the phenomenological-anthropological tradition. However, a real improvement for psychiatric patients, especially since 1945, has come from the combination of many efforts, not least from the successes of psychopharmacology, evaluation of care for patients, psychotherapeutic research, clinical psychiatry and psychology, and social politics. The search for the gene for Huntington's chorea, for example, is as "in accordance with existence" as that for the transcendental organization of the ego (Blankenburg 1971).

Phenomenological-anthropological research has recently been given new stimuli in the German literature from Fuchs (1993, 1994a,b, 1995, 1996; Fuchs and Haupt 1994). In a survey of paranoid disorders in old age (Fuchs 1993), hearing losses in the speech frequency range were shown to be a possible precondition for the development of delusions in old age, as was the fate of having been refugees with particular vulnerability to intrusion into the psychophysical "inner space." Fuchs illustrated this experience with Kafka's *Bau* ("The Building") (Fuchs 1994b). The hearing deficits found in large numbers of the paranoid elderly point to an interruption of the gestalt circle, i.e., the possibility of constructing one's own reality by moving in a creative, circular process between sensory and motor interaction in the broadest sense. The modes which delusional patients use in modifying their existence, which Fuchs commented upon, and the consequent points of view for their stimulation and protection during the course of illness give important suggestions for psychotherapy with delusional patients (Mundt 1996a). Kraus (1992) recently studied the technical delusions of schizophrenics and the role-theory interpretation of affective disorders, which he interprets as the creation of a virtual reality in order to "normalize" pathological experiences that could not otherwise be categorized, an idea which Schmidt-Degenhard (1992) had already described with his work on oneiroids. According to Schmidt-Degenhard, delusion represents a modification of existence by disempowerment of the self. The lost world of socially binding common sense is replaced or added to by imagination. In a study of existential aspects of anxiety, Kraus (1996) takes up old dialectical concepts of existence and intention, of distance from self and alienation, a concept also discernible in a study on ego estrangement in melancholics, in whom there is a quasi-delusional self-accusation of lying against a culpable background. Mundt (1996b) was able to demonstrate the alienation in anxiety as a problem and difficulty in psychotherapeutic work with the compensational character of phobic patients. The predominance of the alienated nature of intentional acts in melancholia in contrast to a specific, more instrumental disorder of retardation was shown by Mundt et al. (1998) in a study involving a series of experiments with depressed patients on estimating and experiencing time.

Anglo-American phenomenological psychopathology, influenced by European phenomenologists and analytical philosophy of mind, studied the previously mentioned critique of operational classification (e.g., Radden 1994) and the discussion about popular psychology, i.e., lay psychological approaches to understanding mental disorders, among which psychopathological concepts (Radden 1994) are generally included by some American researchers (Harrison 1991). The polemic about these "eliminative materialists" (Schwartz 1991) appears sterile – the utility of the approaches will ultimately provide their legitimation, not the "metapsychopathological" dispute about them.

In the 1980s, great hopes were placed in qualitative, psychopathological research stimulated mainly by psychoanalysis, social psychology, and sociology. For a while, the leading research paradigm was the narrative interview, a research technique in which the subjective element of the interviewer involved in the hermeneutic act of determining meaning was to be restricted by better objectivity, e.g., by speech analysis of the narrative produced, i.e., the text that had not been prestructured by the investigator. The results are modest given the high cost in terms of methodology and time expended. As in many other cases, the use of more extensive methodology has confirmed what is already known (see Frommer 1996; Faller 1994), in this case, especially, the negative self-image of depressed persons, albeit with a significantly greater level of proof than the subjective evidence of individual clinicians indicates.

Bürgy and Mundt (1997) have pointed out the special methodological problems of biographical research. Methodological dualism (Mundt 1989) emerges here persistently again and again. It can probably only be overcome with an alternating model. Particularly research on life themes in the work of Thomae (1996) shows that a convergence and merger of hermeneutic and objective approaches is not possible. Instead, adherence to the subject and formulation of clearly distinguishable research paradigms is more successful. The flattening out that occurs with diary techniques (Laux and Weber 1987) or with objectified life-event techniques can be overcome by a hermeneutic examination of the results and can lead to renewed formulations, which can once again be subjected to objective investigation blinded to meaning.

6 Pathopsychology and Other Contributions of Clinical Psychology

Research on salutogenesis (positive or protective factors) has developed in recent years as a counterart to psychopathological pathogenetic research (Antonovsky 1987). It studies mechanisms of becoming and staying healthy, even under difficult conditions. In addition to classical stress research and coping concepts, recent studies on coping styles in illness and health maintenance among adolescents with and without difficult environmental influences, such as being raised in a foster home, have yielded interesting results (Bielefeld study). Earlier coping results were confirmed. Thus it was shown that active behavior, intelligence, prior experience of being effective, temperamental factors, and flexibility, including stable emotional relationships and models for crisis management, play a positive developmental role in adolescents from unfavorable circumstances and promise "resilience," i.e., elasticity (Lösel et al. 1992). Moreover, the differences in the healthy control group were slight in the Bielefeld study (see Becker 1995, 1996). It remains questionable whether a model that assumes threshold values for intelligence, for example, can explain the results better than a model of a balanced pattern of salutogenetic influential factors. Haltenhof and Vossler (1994) found distraction to be one of the most important factors for recovering from depression. Apart from aspects of severity of depression and autonomy, which must be taken into account in interpreting these findings, the methodological problem of salutogenetic research plays a greater role here than in other diagnostic groups, namely the confounding of preventive factors with variables of the current state of health as well as insufficient differentiation between short-term and long-term factors, and factors which positively influence the state of health and structure of salutogenesis.

The concepts of salutogenesis are related to research on quality of life (see Chap. 7, Vol. 2; Lauer 1997), and their development was also stimulated in psychiatry by cancer treatment. Just as in that field tumor diagnosis alone is no longer the criteria for therapeutic action, so increasingly in psychiatry psychopathological symptoms are supplemented by criteria that have quality of life as a therapeutic goal. An abundance of unsolved methodological problems still makes interpretation of results more difficult. This includes the gap between objective and subjective evaluation of quality of life. The latter is frequently judged by schizophrenics, for example, as excessively high, perhaps due to their experience of contrast and the "modesty" associated with autism. The result should by no means be allowed to lead to complacency in therapy, rehabilitation, and social policy. However, even self-determined life goals and standards, influenced by origins, can influence the subjective judgment of life quality by a realistic judgment of what is attainable or relative satisfaction based on overcoming past and more difficult circumstances. A generally accepted measure (see the so-called qualies) is still lacking.

7
Psychopathology and Cognitive Neuroscience

Cognitive neuroscience is a comparatively young discipline with roots in psychology, computer science, physiology, anthropology, philosophy, and linguistics. In this decade, the decade of the brain, extensive progress had been made in this field, which cannot go unnoticed by the science of psychopathology, particularly since cognitive neuroscience is about exactly those high-level mental functions whose pathology is at issue in psychiatry, e.g., thought, perception, affect, and volition. To give a further example, until just a few years ago, the use of the word "consciousness" in scientific discourse was taboo among neuroscientists. Today, many experimental studies are directly devoted to the neurobiological correlates of consciousness (Barinaga 1997, p. 1583). This demonstrates that the themes of psychopathology have finally become part of the scientific discourse.

To give yet another example, up until the late 1980s, the question of exactly where and when a mental image or an auditory hallucination can be localized in the brain appeared to be an error in categories rather than a serious goal of empirical research. This has changed fundamentally due to the development and use of new methods and new concepts.

The remaining parts of this chapter consists of a brief methodological section, after which some results, concepts, and interpretations regarding single psychopathological symptoms will be presented. The subsequent discussion will proceed from specific to general aspects and will close with remarks on psychopathology as a science.

7.1
Natural Sciences and Humanities: Methods

One hundred years ago, the field of brain research experienced a surge of popularity not unlike the present one. Unlike now, however, at that time new discoveries about neurons, neuron clusters, and brain modules could only be related highly speculatively to mental processes. Psychopathologists therefore distanced themselves and their discipline from the "mythologies of the brain." In doing so, they advocated the recognition of their field as belonging to the humanities, not to the natural sciences. This led to the separation of the brain and the mind in psychopathology, which was obviously a very unfortunate development, as nothing is more apparent in psychiatry than the immediate connection of mind and brain, as Andreasen (1997) recently and rightly emphasized. Like cognitive neuroscience, psychopathology is rooted both in the natural sciences and in the humanities, and it encompasses philosophy and psychology as well as computer science and neurobiology.

Given this diverse origin, it is no wonder that, from the very beginning of psychopathology, it faced major problems concerned its methodology. As Karl Jaspers (1957, p. 13) remarked in his autobiography, anyone speaking about the mind must know "what one knows, how one knows it and what one does not know." It is unfortunate that this dictum finds so little resonance in some present-day discussions of psychological issues. However, the recent *methodological* progress in the field of cognitive neuroscience enables psychiatrists to study psychopathology in new and unprecedented detail and depth.

There is no single "optimal method" for the study of mind and brain. It is rather the task of the researcher to find the right method for the question at hand. In most cases, several methods will have to be used in concert such that their respective strengths are combined and their respective weaknesses compensated for (see Posner and Raichle 1996). In order to find the components of complex mental processes, psychologists have used the procedure of measuring reaction times for more than 100 years. By constructing specific simple tasks to which the subject can respond rapidly, the nature of the mental processes that are at work when the task is performed can be inferred. In addition to such mental chronometry (Posner 1986), functional imaging procedures provide an answer to the question as to where exactly in the brain certain processes occur (Toga and Mazziota 1996). Electrophysiological procedures, in addition, can clarify exactly when, down to the millisecond, a certain mental process occurs (Heinze et al. 1994; Snyder et al. 1995). By studying the effects of psychoactive substances, the neurotransmitters and neuromodulators that participate in or modulate a process can be identified (see Hermle et al. 1996; Kischka et al. 1996; Spitzer et al. 1996).

7.2
Results of Research

In the following sections, findings of neuroscience research that are relevant to psychopathology are presented. This is not meant to be an exhaustive review. The topics have been chosen to exemplify the achievements of the cognitive neuroscience approach in psychopathology. In the subsequent sections, the map structure of the cortex and two basic concepts pertaining to the functionality of these maps, neuroplasticity and neuromodulation, are discussed.

7.2.1 Hallucinations

Jaspers defined hallucinations as deceptive and perceptual events (*Wahrnehmung*) that have to be strictly separated from mental imagery (*Vorstellung*). He attempted to support this definition by referring to phenomenology, i.e., the philosophical approach to the nature and the constituents of mental life founded by the German philosopher Edmund Husserl. This reference to Husserl's phenomenology has remained highly controversial (see C. Walker 1993; Wiggins and Schwartz 1996). As has been pointed out elsewhere (Spitzer 1988), it appears that Jaspers' definitions of psychopathological concepts do not refer to Husserl. They actually express nothing but the prejudices of a branch of eighteenth-century psychology and, furthermore, result from his quite limited clinical knowledge. (Jaspers worked only part time in psychiatry for only a few years, and he only dealt with special cases.) It is difficult to understand why Jaspers' definition of hallucinations has been maintained up until today. From a clinical point of view (see P. Schröder 1915), hallucinations can be anything from truly perception-like to faint and idea-like. Patients often identify their deceptive nature (and hence are not deceived), which is why the term "voices" was introduced to denote these special experiences. Detailed research into the subjective nature of hallucinations induced by various experimental procedures, from drugs to electrical brain stimulation and sensory deprivation, has further shown that Jasper's strict definition of hallucinations is of little use (Beringer 1927; for a summary, see Spitzer 1988).

The studies conducted by Shepard and Cooper in the early 1970s (for a summary, see Shepard and Cooper 1982) made it obvious that mental images can be investigated experimentally, despite their being an individual's most private, most "subjective" experiences. The results of a series of reaction time experiments on the mental rotation of imagined pictures and objects allowed inferences to be made regarding the nature of mental representations. These studies suggested that mental images are highly similar to perceptions. More recent studies in the field of cognitive neuroscience on perception and imagery conducted during the past 5 years strongly supported this view in a manner which would have been thought impossible several years ago: The processing of mental images apparently activates the very same central nervous structures that become active during visual perception. The content of a mental image does not arrive from the retina via the lateral geniculate body, but instead is provided by compressed information residing in long-term storage sites in the temporal lobe. This information is projected "backwards," i.e., downstream, to the "lower" visual cortical areas. This process is computationally intensive and hence takes time. Once the mental image is built up in the visual storage buffer (see Kosslyn and König 1992), it can be manipulated there (e.g., rotated or zoomed, i.e., its size enlarged or reduced), which also takes time, as can be measured by means of skillfully planned experiments. Functional MRI (fMRI) studies directly demonstrated the activation of visual cortical areas during mental imagery; in particular, the primary visual cortex is activated about half as much during imagery as it is in visual perception (O'Craven et al. 1997). Kosslyn and coworkers (1996) demonstrated in a PET study of normal subjects that the ability of the visual cortex to become activated correlated to the performance of subjects in visual imagery tasks.

These and a number of other findings indicate that perception and mental imagery are not two fundamentally different processes, but rather two aspects of the unitary function of visual information processing. Just as centers of "perception" are involved in mental imagery, stored information and hence mental images are involved in perception, as was demonstrated decades ago by gestalt psychologists. Perception is an active process of analysis of incoming information through synthesis using the available information already stored. The structure and gestalt formation processes that are involved in visual perception and imagery can be studied in rodents and in primates, including humans, down to the level of individual neurons.

Primates, like humans, are subject to visual illusions and ambiguous figures such as the Necker cube and the Rubin cup. Such ambiguity can also be provoked by projecting different images into either eye, which causes the effect of binocular rivalry, i.e., seeing one of the images for a few seconds and then the other one, but not both at the same time. In animal studies, this effect can provoked as follows: First the animals are shown unambiguous figures. Then neurons in the occipital and temporal lobes are identified which selectively become active to one of these figures. Finally, the monkey is shown a different figure in each eye. At any one time, the monkey will see one of the two figures (which can be experimentally depicted by its behavior), and the previously identified neurons will behave accordingly. The speed of change corresponds to that for human subjects, who under such conditions will also see one figure at a time. Further studies by Logothetis and coworkers (Leopold and Logothetis 1996; Logothetis et al. 1996) suggest that the "higher" the neurons rank in the visual information processing, the greater the extent to which their activity is influenced by the processes of mental image production. If 18% of the neurons in the primary visual cortex change their activity depending upon

which figure is currently being seen (i.e., which information arriving from the retina is being synthesized), this percentage is approximately 50% around the middle of visual information processing (mediotemporal cortical area), and almost 100% upon completion of the process (inferior temporal cortical area). In other words, the higher the level of visual information processing, the more the neurons will represent what is subjectively experienced or seen, and the less they will represent the physical environment. Moreover, these studies demonstrate that the transfer from the retinal image to the subjective experience does not take place at a specific point in the brain, but rather consists, neurobiologically speaking, of a gradual transition.

This view of visual perception as an active, synthetic process distributed over a large number of cortical areas renders the phenomena known from psychopathology – from the illusions driven by affect, up to the scenic, visual hallucinations – highly plausible. For example, if we take into account the fact that the serotonergic system has the highest density of projections in the visual cortex and that a number of hallucinogenic agents act upon the serotonergic system, it becomes apparent how top-down processes can come to outweigh bottom-up processes in the course of visual perception. Once this balance is disturbed, the mode of perception may change correspondingly to any psychopathological perceptual phenomenon, from illusory modification to full-blown hallucination.

The same applies to the auditory hallucinations of schizophrenic patients who hear voices. Using functional imaging, Silbersweig et al. (1995) recently provided direct evidence for the involvement of speech-processing cortical areas in patients who reported hearing voices. Of course, auditory hallucinations were suspected to involve language-related cortical areas on purely clinical grounds before the advent of functional imaging methods. T. Early (personal communication), for example, described a patient who became aphasic following an ischemic insult to the Broca area and who maintained that the voices she had heard had difficulty finding words. This observation directly implies that the same language areas that are involved in the production of speech are involved in the production of auditory hallucinations. Nonetheless, functional imaging delivers further confirmatory evidence.

7.2.2 Obsessions and Compulsions

Obsessive-compulsive thoughts and actions have been the focus of recent research, sparked by several neurobiological developments. This increased research interest has led to an increase in the number of papers on obsessive-compulsive disorder (OCD), which in turn led to an increased awareness of the disorder by clinicians. This corresponded to a considerable increase in the frequency of diagnosis of OCD in recent years (see Kaplan et al. 1994).

Most importantly, obsessions and compulsions were placed within the framework of frontal lobe cortico-striato-thalamocortical circuits, as described by Alexander and coworkers (1990). It is assumed that this type of frontal cortical circuitry leads to the integration of information from various cortical areas. The information-processing circuits from the cortex via subcortical regions and back to the cortex possibly help to stabilize the output of the information-processing system. This is important because the system always has to respond with a single response at any given point in time. If the system becomes stuck with a single output, however, the mechanism of stabilization overshoots, and this dysfunctional state may correspond to symptoms of OCD. It should be noted that OCD is not the only psychopathological syndrome which can be put in the framework of frontal cortical circuitry (see Kischka et al., in press).

In the case of OCD, the overshooting activity of one or more of the orbito-frontal-cortical and subcortical structures (striatum) was demonstrated by means of PET (Baxter et al. 1992). Most importantly, this pathologically increased activity was shown to become decreased and to return to normal in the course of successful pharmacotherapy and psychotherapy. Thus this study was the first to render the effects of psychotherapy directly visible through neuroimaging. In subsequent studies, obsessions and compulsions have been examined using fMRI, in which patients are scanned at rest and during the provocation of symptoms (Breiter et al. 1996). The results were similar to those described by Baxter in that those areas that had been found to be active in PET and normalized after successful therapy were also shown to light up during symptom provocation.

The studies by Baxter et al. (1992) and Breiter et al. (1996) illustrate the close connection between psychology and neurobiology. This connection pervades not only research, but also the therapy of obsessions and compulsions. Deficits of the patients in different areas of life often become apparent, and often for the first time, after OCD symptoms have been contained. These call for behavior therapy and/or insight-oriented psychotherapy. The neurobiologically proven close relationship between the psychological and biological levels in obsessions and compulsions corresponds to the closely meshed corresponding therapeutic strategies.

7.2.3 Formal Thought Disorders

Ever since the time of Bleuler (1911) and the inception of the concept of schizophrenia, formal thought

disorder has been conceived of as a disorder of associative processes. These processes have been investigated using experimental procedures concerning speech production and understanding. A number of studies indicate that in schizophrenic patients with formal thought disorder, the access to stored information is disturbed, whereas the store itself remains intact. This dysfunction has been characterized in detail by Spitzer and coworkers (Spitzer et al. 1997). A large number of behavioral data and electrophysiological experiments suggest that the focus of access to networks of stored information is wider in patients with formal thought disorder. This widening of the focus leads to less precise retrieval and has been both conceptually and experimentally related to the dopaminergic system.

The cognitive neuroscience view of formal thought disorders provides a parsimonious explanation for a number of nonrelated and unexplained clinical phenomena, including clinical and experimental association behavior, temporal aspects of spontaneous speech, the apparent contradiction of concretism and simultaneous overabstract thinking, the apparent "creativity" of some patients, and sound-related word associations (Spitzer 1997a). Within a cognitive neuroscientific framework, these phenomena can be related to each other and to underlying neurobiological processes. This allows for the further generation and testing of model-driven hypotheses and for the development of new diagnostic and therapeutic strategies (see Maier 1998).

7.3 Brain Maps: Structure and Dynamics

The term "brain maps" relates to a number of issues in brain research, some of them very old. Cortical areas can be differentiated according to various criteria, which led as early as at the turn of the century to the publication of different classification systems for the various parts of the cortex. The best-known mapping was done by Brodman (1909), who employed histological differences as distinguishing features. Flechsig (1929) differentiated cortical areas according to the time point of their myelinization. Zilles et al. (1995) used multiple biochemical markers.

Before the advent of noninvasive methods for mapping cortical areas in human beings, functional mapping of the cerebral cortex was done by means of animal stimulation and lesion experiments. In humans, the past 100 years of neuropsychological investigation of patients with lesions clearly demonstrated functional specialization in the human cortex. In addition, the invasive electrical stimulation studies conducted by Penfield and coworkers corroborated the functional map structure of some cortical areas more than six decades ago.

The new procedures that have been available for the past few years have opened up the path to an entirely new field of research into the map-like structure of the human brain. This functional explanation of the human cerebral cortex is a task which may take decades and is comparable in scope to the unraveling of the human genome (Albert 1997; Toga and Mazziotta 1996). The immensity of this task can be estimated by considering several plausible additional assumptions: We may begin by assuming that the cerebral cortex is weakly organized into modules (see Kosslyn and König 1992), i.e., that a particular mental performance can be achieved by the cooperation of different areas, possibly as many as one to two dozen. From a functional point of view, the cortical areas can be distinguished either on the basis of their selective response to certain stimuli or their activation by certain clearly defined actions.

In this regard, the visual system is the one that has been most studied. At least 32 different cortical areas are now known (Felleman and van Essen 1991), which are responsible for the function of vision. Most of these areas have been defined electrophysiologically in animal experiments with primates and have been proved in humans by means of functional imaging. The maps of animals and humans can thereby be compared and indeed have been shown to be quite similar (see Sereno et al. 1995).

The average size of the visual areas of primates is 170 mm^2. In humans these areas are probably larger. Thus the area V1 in a human is twice the size of the area V1 in a monkey. If we assume the size of the human cortex to be 250,000 mm^2, the number of different functional maps located in the human cortex and yet to be discovered can be estimated at 735 (see Spitzer et al. 1998). This figure is certainly the result of a rough estimate, but it illustrates the scope of the problem.

7.3.1 Structure of Brain Maps: Neuroplasticity

Functionally specific cortical areas are referred to as maps because the cortex, due to its internal structure, organizes incoming signals according to frequency and similarity, i.e., like maps. Importantly, this order is not static, but instead changes within certain limits according to the input the cortex receives. This input-driven change of cortical representations due to a rewiring of cortical connections is called neuroplasticity.

Generally speaking, neuroplasticity refers to neuronal reorganization that depends upon the signals from the outside world as well as from the organism.

Research into neuroplasticity conducted during the past two decades impressively documents that the brain is constantly reconstructing itself depending on the input to be processed. It does so by building up new neuronal connections in order to improve its processing of incoming signals.

It is well known that neurons are post-mitotic tissue, i.e., their cells have lost the capacity to divide. It follows that neuroplasticity does not involve the growth of new neurons, but instead the genesis of new links between existing neurons (neuronal sprouting). In addition, existing but nonfunctional links between neurons – so-called silent connections – may become functionally active. A large number of studies in primates and humans have impressively documented the continuous building of structures in cortical representations dependent upon experience (Merzenich and Sameshima 1993). For example, if a person has learned braille, the cortical area responsible for the tip of that person's right-hand index finger grows (Pascual-Leone and Torres 1993); if someone learns to play the violin, the representation of the left hand grows. If a synthetic inner ear (cochlea) is implanted, the auditory processing of speech is fundamentally reorganized on the basis of the completely novel input signals (temporal input patterns). The subjective hearing experience of the patients changes accordingly: Following the operation, they hear only an unpleasant rumbling upon listening to speech. A year later, the majority of patients are able to carry on telephone conversations, i.e., can understand speech without having to lip-read.

Due to the uniform structures of the neocortex (Nauta and Feirtag 1986), it can be assumed that neuroplasticity also occurs during more sophisticated mental operations, including language and thought. In his monograph on brain plasticity, Kolb stated this as follows:

> The idea that activity might change the heart or muscles is seldom questioned. The possibility that behavior could change the structure and function of the brain is seldom considered! Nevertheless, it is an important aspect of brain plasticity. Indeed *there is little doubt that even thought can change the brain* (Kolb 1995, author's italics).

7.3.2 Semantic Maps

When we speak or understand speech, we must learn to refer to learned information pertaining to language that has been stored in map-like associative networks. The representation of the meaning of a word in such a network can be conceived of as a "node" and by the relationships to other nodes. In the course of understanding a word, for example, a node becomes activated. This activation spreads more or less rapidly to other nodes (see Spitzer 1996, 1997b). Thus in word association tasks, for example ("Which word comes to mind when you hear the word ...?"), the answers given by subjects are often amazingly stereotypical. By a similar mechanism, in lexical decision tasks, the recognition time for a word is shortened if the word has been preceded a few hundred milliseconds earlier by a word whose meaning is represented by a supposedly adjacent node (semantic priming effect). Furthermore, a number of single case studies of neuropsychological patients have been carried out which indicate the presence of a selective naming deficit for specific categories. For example, a patient may selectively be impaired in naming animals, and another may find furniture or tools or fruits difficult to name. This can be interpreted in terms of a localized representation of the corresponding contents, as suggested by Farah and Wallace (1992). Studies of such high-level maps have now been carried out using functional imaging techniques (see Spitzer et al. 1995b; for a summary, see Spitzer and Kammer 1996).

Map-like semantic networks of the kind described above have also been generated in computer simulations of neuronal networks. Ritter and Kohonen (1989) fed sentences as input to a type of neuronal network, which is set up to model certain features of cortical connectivity. These networks are called self-organizing feature maps, as their very structure leads to the formation of representational maps of whatever input is given to them. Accordingly, when short sentences were given as input, the network built up an orderly representation of words according to their semantic similarity and grammatical category. Words that occur in the same context (this is the case, in particular, for opposite terms, such as "black" and "white") were represented close to one another (semantic mapping), and in addition, words were represented ordered according to whether they were verbs, adverbs, or nouns (see Spitzer 1996, 1997b). The network thus recognized the immanent regularity of the input and used it for the generation of map-like order. Most notably, this is achieved without the explicit application of rules.

In the case of higher cognitive functions, the input of the corresponding cortical areas arrives from other cortical areas. This shall briefly be outlined for the connection between the semantic lexicon and verbal working memory, as discussed by Just and Carpenter (1992): In order to comprehend and produce speech, it is necessary not only to have access to stored lexical information, but also to be able to keep this information "online," e.g., to construct the semantics of a grammatically complex sentence. People differ with

respect to verbal working memory, i.e., their capacity to keep words in mind and construct meaningful sentences from them. Moreover, this function is modulated by the dopamine system (see below). This results in considerable individual differences regarding the capacity to process complex spoken and written language.

The extent of neuroplasticity decreases over the lifespan of an organism. During infancy and development, the cortex is so plastic, as shown in studies in hamsters, that experimental detouring of visual input to the auditory cortex prompts development there of a visual cortex capable of functioning (Frost 1997). Later in life, after brain development has been completed, the structure of the stored maps nonetheless still changes throughout life according to experience. This occurs quite rapidly in younger organisms, slowing down with increasing age. This decrease in neuroplasticity with increasing age makes sense, as the following argument shows. Each organism has to learn as rapidly as possible. Once the most essential things have been learned, however, these memories must be protected from an all too rapid dismissal in the face of few newly learned opposite experiences. To quote an example from McClelland and coworkers (1995): If you have learned that fish can swim and that birds can fly, you should not become confused upon first contact with a penguin (i.e., a bird, and not a fish, that cannot fly but can swim). Thus it is necessary for a person who has already learned a great deal to learn more slowly and to integrate the contents to be newly learned with that which has already been learned. Computer simulations of neuronal networks indicated that this can be achieved through the circuitry of two networks with different features. This appears to be the case in our brains through the division of labor between the hippocampus and the cortex informing explicit memories of important events.

In a stable environment, older people are better adjusted than younger people to their environment. The decrease in neuroplasticity (and thus in learning capacity) with increasing age is a psychosocial problem only if the environment changes rapidly. This is the case within the current cultural situation. The elderly expert with his subtle experience is only seldom needed, stability is not valued or is not even perceived, and people can easily find themselves in a situation in which the capabilities and values they have learned are no longer needed and applicable. Thus, with regard to the psychopathology of aging, problems must necessarily arise when the speed of cultural change is viewed from a neurobiological perspective.

7.3.3 Neurobiologically Motivated Psychotherapy

Within psychiatry it is important that neuroplasticity by no means represents an empty psychopathological term. It is actually of great practical relevance. This shall be demonstrated by the following brief description of studies performed by Merzenich, Tallal, and coworkers (Merzenich et al. 1996; Tallal et al. 1996) on language-impaired children.

It has been estimated that 5%–8% of all children demonstrate a slowing of information processing in the area of early auditory signal processing. This minor deficit is aggravated during the development of language, as up to 85% of children may develop reading difficulties due to deficits in decoding certain rapid sounds (Barinaga 1996). According to the latest studies, the primary disorder can be diagnosed as early as the age of 2 years, i.e., even before speech has been completely developed and long before reading instruction begins. In most cases, though, it goes unnoticed. For example, the two syllables "ba" and "pa" differ only in their first consonant, which in turn only lasts a few milliseconds. If these two short consonants cannot be analyzed quickly, higher cortical analysis and synthetic processes are not receiving the "sharp" input they require. The child will have difficulty understanding spoken speech, although hearing is not disturbed. Instead, the analysis of a rapid sequence of temporal input patterns is disturbed.

It was shown that children were able to distinguish between "ba" and "pa" when the consonants were artificially temporally lengthened in an acoustics laboratory. The children were thus able, in principle, to decode relevant input patterns but needed more time to accomplish the task.

When the children practiced using temporally stretched input patterns for about 2 h per day for several weeks, their comprehension of normally spoken speech improved (Merzenich et al. 1996; Tallal et al. 1996). Training consisted of playing on a computer whereby the children had to learn to distinguish increasingly rapid temporal sound patterns. Skilled programming ensured that the children were offered only those input patterns (i.e., temporal phonetic images and other rapidly occurring temporal sequences) which they were able to process. In addition, the child-friendly design of the practice sessions guaranteed the willingness of the children to practice. Both are prerequisites for successful therapy, as shown in the studies by Mezernich.

The studies by Mezernich and Tallal are innovative in psychiatry insofar as here, for the first time, findings and ideas from experimental *neurobiology* concerning the determinants of cortical reorganization processes led to the development and successful application of

an exclusively *psychological* method of intervention. The example thus clarifies that neurobiological findings do not necessarily mean a reduction of therapeutic strategies to biological, i.e., mainly pharmacological, methods of intervention.

7.3.4 Dynamics: Neuromodulation

A further essential functional principle of brain maps is their modulation by the diffuse release of comparatively slow-acting substances (within the range of several hundred milliseconds). Neuromodulation is defined by Kaczmarek and Levitan (1987, p. 3) as "the ability of neurons to alter their electrical properties in response to intracellular biochemical changes resulting from synaptic or hormonal stimulation." Neuromodulation is different from neurotransmission, which underlies central nervous information processing. Neurotransmission denotes the exact, rapid transmission (in the range of a few milliseconds) of information by glutamatergic and other excitatory and inhibitory synapses. Neuromodulators are the very agents which are targeted by many psychotropic drugs, the most important being the monoamines (norepinephrine, dopamine), serotonin, and acetylcholine. They modulate, i.e., fine-tune, general parameters of information processing with regard to the demands of the environment and the organism. In addition to regulating the general level of activation, neuromodulators also affect the influence of bottom-up and top-down processes and another essential parameter of information processing, the so-called signal-to-noise ratio (see Cohen and Servan-Schreiber 1992, 1993). Neuromodulatory states correspond to subjective states of alertness, anxiety, apprehension, depressed or elevated mood etc. The neuromodulatory state that corresponds to relaxed awareness and lack of anxiety, for example, facilitates the flow of thought, including creative remote ideas, as can be measured by the word associating task. Results of experiments performed by Kischka et al. (1996) suggest that in such states dopaminergic modulation is somewhat downregulated. When the dopaminergic tone is experimentally increased, the availability of remote associations decreases. We already know that this is also the case in situations of immanent threat and danger, as under such circumstances lengthy "creative" considerations would be a sign of poor adjustment. The rapid action necessary in such situations requires the use of learned and proven sequences of behavior which can be rapidly unreeled. To sum up, the conditions of anxiety and stress decrease creativity and imagination, which appears to be advantageous in evolutionary terms. However, under the conditions of life in modern civilization, these physiological neuromodulatory effects can be disadvantageous, e.g., within the framework of taking examinations.

With regard to subjective experience, the issue of neuromodulation is hard to pin to any of the classical terms of psychopathology. As mentioned above, vigilance and affect are likely subjective features of mental processes, which can be taken as a function of neuromodulation. The term "dynamics," as defined by Janzarik, appears rather well suited to characterize the subjective side of neuromodulatory changes in the serotonergic, noradrenergic, and dopaminergic systems.

Recent studies show that neuromodulatory systems are not rigid and incapable of change, but respond to experience. Animal experiments with crayfish have shown that one single social interaction that ends either successfully or unsuccessfully is sufficient to reverse the postsynaptic response of a neuron to serotonin administered exogenously (Yeh et al. 1996). Thus, for the first time, social behavior was tracked to the level of individual neurons and subpopulations of receptors whose variable expression caused the different response to serotonin. If this line of thought is transferred to human beings, defined by Aristotle as social animals, it appears that neuromodulatory systems may change ways of responding to the environment, i.e., behavioral tendencies, according to experience. Thus temperament and character are at least in part shaped by the environment.

In addition, a genetically determined neuromodulatory setup of each individual has been assumed, which forms the basis of the temperament of that individual (Cloninger 1987). Individual differences in the availability of different neuromodulators, receptors, and receptor subtypes thus lay the foundation for behavioral dispositions and ways of responding to the environment, most notably the social environment. As shown in the above example, this foundation is not fixed through lifetime, but is rather itself subject to a certain amount of change driven by experience. The concept of neuromodulation thus yields not only the background for the therapy of acute schizophrenic and affective psychoses, but also paves the way for therapeutic access to temperament and character by means of pharmacological therapy and psychotherapy.

8 Psychopathology and Psychotherapy

Psychoanalysis was the dominant paradigm in psychotherapy in the German-speaking countries 10 years ago. This is well exemplified by the contributions of Bräutigam, Peters, Lang, Mundt (see Mundt 1989), and

many others to models of psychopathology for mental disorders. While psychoanalysis is still strong in French, Italian, and South American traditions of psychiatry, its importance has decreased both in Germany and in Anglo-American psychiatry, where it has been partly replaced by behavioral therapy.

Behavioral therapy has not only brought to psychiatry concepts of illness for well-known symptom patterns of psychopathology that are in part new or at least modified, it has also enriched the catalogue of symptoms with a phenomenology developed according to its reference framework, which has even made inroads into psychoanalysis. Examples of this are the theory of depression in behavior therapy and its descriptions of obsessions and compulsions and of phenomena related to anxiety. To give an example, in cognitive behavioral therapy, autonomized negative cognitions (as assessed by means of diaries), styles of causal attribution, subjective experiences of decreased intentional behavior, and lacking reward mechanisms in inactivity and anhedonic behavior have been intensively discussed. This has produced a new phenomenology that has made important contributions to the well-known inventory of symptoms for these disorders. There has been a similar development in both the area of obsessive–compulsive disorders and, with the refined analyses of avoidance behavior described in the literature of the 1960s, also for patients with anxiety disorders. Here, the descriptive approach to psychopathological states with no influence of any traditional schools of thought may, in the long run, help to develop hierarchies of symptoms for specific disorders such that they can be modified by psychotherapy. Now that Jaspers' stratification rule has been officially abandoned in recent psychiatric classification schemes, such hierarchies have been reconstructed in the schools of behavior therapy. This development may be exemplified by Linehan's borderline theory (Linehan 1993), where covert emotional irritability is regarded as the basis for overt secondary symptoms, such as reaction or coping. Similar distinctions have been proposed for schizophrenia and depression, and they are well suited for the development of cooperative models for psychotherapy and pharmacotherapy. The development of operationalized psychodynamic diagnostics within the field of psychoanalysis mentioned above in the section on classification has also led to the systematization of psychoanalytical structure and conflict diagnoses, which represent possible contributions to a descriptive psychopathology.

The importance of combined psychotherapy and pharmacotherapy and its evaluation with regard to the patient's psychopathological outcome is currently underscored more than ever by therapy efficacy studies. These studies indicate that persistent psychopathology – particularly psychotic and depressive states – itself acts pathogenetically, contributing to a poorer course the longer it exists. Within the neurobiological framework discussed above, in particular in the light of what we know about neuroplasticity, this epidemiological finding was to be expected. We know from controlled therapy studies that the combination of psychotherapeutic and pharmacotherapeutic methods is preferable to the use of either of the two methods alone. This finding can easily be reconciled by the neuromodulatory changes brought about via pharmacotherapy and the ensuing neuroplasticity-driven changes caused by normal experiences, made possible via pharmacotherapy. Thus an idea begins to emerge of how the various dynamic principles of therapeutic interventions interact, of their foundation, and of how they might possibly be optimized and tailored to the individual needs of the patients. In the following section, this view will be fleshed out by the example of therapeutic intervention in acute and chronic delusions.

8.1 Acute Delusions and Neuromodulation

Acute delusions are generally accompanied by anxiety, distrust, and increased apprehension and vigilance (delusional mood), which can result in the overinterpretation of what are actually unimportant events. Unfounded importance is given to things and events, and things are related to one another and to the deluded person without there being any reason to do so. Once delusional ideas have been formed and linked to the current motivational background of the patient, and once their contents determined by the patient's prior experience are built into the remaining normal experiences of the individual, they are then almost immune to doubt and become chronic. Patients work at their delusions and not only systematize their delusions but more or less weave them firmly into the rest of their life history. Chronic delusions are then not so much a certain mental state, but rather a part of the thoughts, values, world view, hopes, and goals of an individual. Acute delusions often respond well to neuroleptic treatment, whereas pharmacological treatment of chronic delusions is extremely difficult.

The dopamine hypothesis of schizophrenia has recently been modified. Positive symptoms such as (acute) delusions and hallucinations are assumed to be caused by dopaminergic hyperactivity, whereas negative symptoms, such as blunted affect, loss of motivation and drive, avolition, anergia, and anhedonia are thought to result from dopaminergic hypoactivity (see Davis et al. 1991). As rapid perceptions and thoughts can only be the product of fast neuro-

transmission, the question of how dopaminergic hyperactivity is related to distrust, delusional perception, and delusional ideation needs to be answered by the modulatory effect of dopamine on neurotransmission. It has been proposed that a decreased dopaminergic tone results in a decreased signal-to-noise ratio in glutamatergic and GABAergic neuronal networks. As mentioned above, the parameter of the signal-to-noise ratio modifies the width of the focus of the activation of information stored in neuronal networks. If the signal-to-noise ratio is low, the access to stored information is unreliable. This unreliability, however, bears the advantage that unusual associations may be activated. Thus the probability is increased that remote and sometimes even "creative" ideas may occur. As has been demonstrated by neural network simulations, neuromodulatory states of low signal-to-noise ratios lead to an increased probability of changes in the stored content (increased neuroplasticity; see Spitzer et al. 1995a). Conversely, if the signal-to-noise ratio is too high, although the retrieval of stored information will occur with great reliability, the probability of changes in the network will be small. Moreover, under conditions of high signal-to-noise ratios, small environmental signals may be amplified such that even meaningless events become subjectively experienced as meaningful. Once meaning has been attributed to minor events through such processes, it may further affect perceptual and thought processes. The high signal-to-noise state of modulation further prevents the activation of alternate hypotheses, interpretations of events, and "world views" and thus any possibility of their consideration. This state therefore causes limitations in the width of processing, a narrowing of the contents of consciousness. Finally, as discussed above, a high signal-to-noise neuromodulatory state does not favor change. Hence, delusions, once developed, will not easily be changed by experience.

In high signal-to-noise neuromodulatory states, the probability of unusual, indirect associations becoming active, i.e., the possibility of creative problem-solving, is decreased. This has been demonstrated directly in word association experiments: In normal subjects, stress and anxiety lead to an increase in standard associations (e.g., black/white, mother/father) and thus to a decrease in unusual associations (Mintz 1969).

8.2 Chronic Delusions and Neuroplasticity

Neuroplasticity occurs throughout the entire lifetime of higher organisms. As far as self-organizing maps, in which representations of the external world at different levels of abstraction have been constructed and maintained in an orderly fashion, are implemented in the cortex, chronic delusion can be conceived of as deformations of cortical, high-level, map-like representations.

The term "structural deformation," coined by Janzarik, is indeed used in an almost identical way by neurobiologists to label dynamic neuroplastic changes (see Merzenich et al. 1988, Pascual-Leon and Torres 1993). It must be assumed that - similarly to what has been proved for somatosensory maps - input-driven enlargement and diminution of certain representations occurs in high-level multimodal cortical areas.

Once such deformations have occurred, they cannot easily be reversed. As stored information, they are anchored as strongly as other memory content; however, due to the substantial emotional participation in their genesis, they are anchored even more strongly. Psychological research has long known that, in the face of contradictory evidence, even healthy individuals are slow to change their attitudes, if at all. Furthermore, it is also known from experience in clinical psychotherapy that important changes in our views of things are often accompanied by anxiety. This is particularly true for delusional individuals with their already strong tendency toward anxiety. As a consequence, chronically delusional patients experience anxiety in the face of confrontation, even after the acute neuromodulatory changes have faded away or have been successfully treated. This in turn leads to an increased rigidity of the maps, particularly during confrontation with contradictory evidence.

8.3 Psychotherapy and Pharmacotherapy

The discussion of acute and chronic delusional phenomena within the cognitive neuroscience framework in terms of the principles of neuromodulation and neuroplasticity has practical consequences for the therapy of these disorders. Thus it is generally known that acute delusions respond relatively well to neuroleptic treatment, whereas chronic delusions do not. This is due directly to the fact that neuroleptics influence only the changed neuromodulatory states without having any direct influence on the deformations of long-term representations stored in cortical maps. In order to change these representations, new experiences by the patient are needed. A dull psychosocial environment can contribute as much to chronicity as inadequate medication can. This therapeutic consequence results from the neurobiological view of chronic delusions discussed. It is important to note that the neurobiological framework suggests not only pharmacotherapy alone, but also "milieu therapy"

in order to ensure new experiences in an environment. These must furthermore be as free of anxiety as possible. In other words, according to the model proposed here, the chronically delusionally ill benefit from neuromodulatory changes (pharmacologically or psychologically induced) only if their social environment changes for the better such that new healthy and normal experiences become possible.

9 Conclusions and Outlook

Clinical psychopathology, as far as it works with intuitively generated concepts and descriptions, will become of historical interest only. It will be superseded by neurobiologically derived terms and categories. The polemic debates on scientific methodology prevalent in the 1970s have given way to a methodologial pluralism rather than dogmatic, pretentious statements. In addition to what may be called "classical" psychopathology, which might also be described as macropsychopathology, empirical research will pin down and standardize the signs and symptoms of neurobiologically distinct states. The focus of research has thus shifted from the context of the individual life history of the patient to functional neurobiological mechanisms of pathology. This development has brought psychopathology (Andreasen 1997; von Praag 1998) back to the science of medicine, with the consequence of improved communication between medical specialties at the expense of decreased contact with the humanities, as represented by historians of psychiatry (Berrios and Porther 1995; Ballerini and Stanghellini 1993). Nonetheless, the life history of the patient is still an issue in emotions research and other research areas at the border of psychiatry and psychology. Future developments in the area of "classical" psychopathology are hard to predict. It appears to have become somewhat stuck, but may enjoy a renaissance, e.g., in connection with psychotherapeutic evaluation research.

There is currently no doubt that the greatest enthusiasm is generated by the "cognitive neurosciences" as the successors to classical psychopathology. These sciences of the mind have surmounted the methodological dualism and have integrated biological function and subjective experience. Their goal is to understand brain functions and subjective experience, and their methods, in particular functional neuroimaging techniques, have great potential for innovation. Nothing can better express the enthusiasm of this research approach and the belief in the integrative power of its methods than a quote from Eric Kandel (1991, p. 1030):

The boundary between behavioral studies and biology is arbitrary and changing. It has been imposed not by the natural contours of the disciplines, but by the lack of knowledge. As our knowledge expands, the biological and behavioral disciplines will merge at certain points, and it is at these points that our understanding of mentation will rest on secure ground.

It remains for the future to show whether this enthusiasm can deliver what it has promised, and to what extent the field of psychiatry within medicine can account for all aspects of the mental life of human beings.

CHAPTER

2

A.S. Henderson

Central Issues in Psychiatric Epidemiology

Appreciation is expressed to my colleagues at the NHMRC Psychiatric Epidemiology Research Centre who critically read drafts of this chapter.

1 Introduction

Most of clinical psychiatry is about individuals. However, when these individuals are considered collectively, looking for general patterns, we enter the field of epidemiology. In his Herter Lectures at the Johns Hopkins University, Greenwood (1931) gave the most succinct definition of epidemiology as "the mass aspects of disease." The word comes directly from επιδημιοσ (*epidímios*), meaning a disease that is "prevalent among the people", compounded from επι (*epí*, upon or among) and δημος (*dímos*, the people in a district or country). It is the business of psychiatric epidemiology to determine the distribution of mental disorders in populations rather than in individuals, the factors determining that distribution and measures that may help in prevention. On the one hand, everyone is unique, each individual having his or her own genetic endowment and life experiences. Such an *idiographic* paradigm is balanced by the epidemiological one, which is a *nomothetic* paradigm because it searches for recurrent and predictable patterns in the whole of humankind. In this search, there are five fundamental requirements: a hypothesis, a population, specification of the psychiatric disorders to be investigated, specification of variables that may contribute to their onset or their outcome and scientifically adequate instruments for measuring these. The enquiry can be cross-sectional, examining the situation at one point in time, or it may be longitudinal, measuring change over a certain time period and trying to determine what brings about that change.

J.N. Morris (1957) described seven uses of epidemiology in his celebrated monograph bearing that title. Although this work has been repeatedly quoted, it has not yet become trite. It provides a framework for assessing the current state of *psychiatric* epidemiology in relation to current national and global conditions and to the experience of clinicians.

The first use of epidemiology is the historical study of the health of communities and of the rise and fall of diseases in the population, with the possibility of projections into the future, e.g. the incidence of schizophrenia may be declining and the disease may be becoming more benign in its clinical course; depressive disorder may have become more frequent in young persons (their suicide rate has indisputably increased in many industrialised countries); it is likely that eating disorders have increased in frequency; and it is certain that the use of heroin and the acquired immunodeficiency syndrome (AIDS) epidemic with its neuropsychiatric sequelae are new arrivals and will be a continuing burden.

A second purpose is community diagnosis, in which estimates of morbidity are obtained at the general population level, and not just in individuals reaching professional services. Recent examples are the National Comorbidity Study in the the United States (Kessler et al. 1994) and the Survey of Psychiatric Morbidity in the United Kingdom (Jenkins and Meltzer 1995; Jenkins et al. 1997a,b).

A third purpose is the study of the working of health services, starting by determining needs and resources, then analysing services currently in action and finally attempting to evaluate these services.

A fourth use is of direct value in clinical practice and consists in using the population data to hand to estimate an individual's chances of developing a particular disease, or of recovering or of relapsing, e.g. if the annual incidence rate for schizophrenia is known in a population, and if this information is age specific, it is possible to estimate the probability that a person aged, say, 20 years, will develop this disorder within the next 12 months. This is the base rate, before one starts to consider risk factors such as family history. Likewise, if the lifetime prevalence of schizophrenia is known, the chances of an individual developing the disease at some stage in life is also known. By aggregating data on the course of schizophrenia in treated sample populations, it is possible to estimate the chances of recovery or partial recovery for a person who has just had a first episode. The central issue is that data on large numbers of subjects are used to make a probability estimate for individuals.

The fifth use is a particularly attractive one: to help complete the clinical picture. By this, Morris meant knowing about all presentations and stages of a disease and then relating subclinical cases to fully developed ones. An excellent example here would be anxiety or depressive states that are to be seen in general practice or field surveys, compared to the more severe syndromes specified in the international criteria and encountered by mental health staff.

The sixth use of epidemiology is to identify syndromes by examining the distribution of clinical phenomena occurring in sections of the population. This fits well with recent experience of repetitive strain injury, chronic fatigue syndrome and post-traumatic stress disorder or its congeners.

The seventh use of epidemiology is the most appealing of all: "the search for causes of health and of disease, starting with the discovery of groups with high and low rates, studying these differences in relation to differences in ways of living; and, where possible, testing these notions in actual practice among populations."

To Morris's seven uses of epidemiology, a further use should be added, namely, prevention, which Ernest Gruenberg (1966) referred to as its "ultimate service."

Epidemiological research has had some successes. The more basic, so-called descriptive studies were valuable in demonstrating that mental disorders occur not only in institutional settings, but also to a substantial extent in all general populations. This has helped the governments of many countries to realise that better services are needed for people with mental disorders, particularly in the community, where the bulk of morbidity occurs. Some scientifically more advanced studies, known as analytic epidemiology, have made major contributions. For example, in schizophrenia, a slight excess of births in the late winter and early spring was observed. This was followed by an association being found between maternal influenza in the second trimester of pregnancy and subsequent development of schizophrenia in offspring. A separate observation was that the median age for the onset of schizophrenia is about 5 years later in women than in men. This led to a painstaking search for possible social and biological explanations, as reviewed by Jablensky (1995). Another remarkable achievement was the *International Pilot Study on Schizophrenia* (WHO 1973; Leff et al. 1992) and the subsequent follow-up entitled the *Determinants of Outcome in Severe Mental Disorder* (Jablensky et al. 1992). These international projects, conducted through the WHO across many regions, have shown that schizophrenia is ubiquitous; presentation is similar throughout the world, while its prognosis tends to be more favourable in less industrialised countries. In the epidemiology of Alzheimer's disease, identification of several risk factors was achieved through case-control studies. The association with Down's syndrome provided a lead for molecular geneticists to focus on chromosome 21 and the mechanism for formation of amyloid precursor protein in Alzheimer's disease.

It is very desirable for clinicians to be vigilant for unexpected opportunities to carry out epidemiological studies. These may arise when a population is recognised to have some relatively uncommon attribute that could throw light on aetiology or on outcome. Such attributes may be strikingly high or low rates for some group of disorders. Alternatively, the attributes may consist in a certain type of exposure, past or present, that putatively increases the incidence of a particular mental disorder. An example is the recent investigation by Susser and Lin (1992, 1994) on the incidence of schizophrenia in the offspring of women exposed to the Dutch Famine of 1944 or studies of communities exposed to an earthquake (Carr et al. 1997).

In the development of administrative policy and the need for services for the mentally ill, epidemiological studies have at times provided powerful evidence for advocacy purposes. The Epidemiologic Catchment Area (ECA) Studies (Robins and Regier 1991) and the later National Comorbidity Survey in the United States produced estimates of the frequency of mental disorders which have done much to promote mental health issues in many countries. The latter study found that nearly 50% of respondents had experienced at least one psychiatric disorder in their lifetime, and nearly 30% had had at least one in the previous 12 months. Of this group with a recent disorder, less than 20% had had some form of professional treatment. The most common conditions were anxiety and affective disorders, with 12-month prevalence rates of 17% and 11%, respectively. An important finding was the extent of comorbidity, here meaning the occurrence of two or more psychiatric disorders in an individual over his or her lifetime. It was found that the major burden of psychiatric disorder was concentrated in about one sixth of the population.

Epidemiology can be abused or misused. This happens under four broad circumstances. First, health administrators may sometimes mistakenly accord great value to obtaining local or regional data on the pattern of morbidity in their own community. When human and financial resources for mental health services are scarce in a region, it can rarely be justifiable for these to be deployed in obtaining data when the extent of unmet need is already obvious. The repetition of prevalence estimates in many countries is probably unnecessary. The second category is common to all research and is found when the scientific quality of research is so deficient that its findings are worthless. This can be called "feckless research" and is a waste of resources and time, including that of the subjects themselves. The third form of abuse occurs when an epidemiological study is limited to an enumeration of cases, a so-called "nose count", without testing any hypothesis. Such work can be described as "fancy that!" research, because the findings are unremarkable or even self-evident, doing nothing to advance knowledge. The fourth abuse consists in fieldwork being carried out in a clumsy manner, so that the individuals interviewed obtain no benefit from this unsolicited intrusion on their lives. Unlike patients, members of the general population who are interviewed in epidemiological surveys have not sought to be examined about their mental health. They therefore need to be competently interviewed with absolute guarantee of confidentiality (see below). It is nevertheless reassuring to know that the effect of mental health surveys on respondents has been systematically investigated. Only a tiny minority say they found the interview upsetting, and these were individuals who were already known to score highly on the trait of neuroticism. The overwhelming majority did not resent the experience, and many enjoyed it.

2
A Matrix for Organising Epidemiological Knowledge

In order to organise knowledge about the epidemiology of mental disorders, it is useful to use a matrix (A.S. Henderson 1988), in which the main categories of mental disorders are listed across the top to form the columns, while the rows are made up of those variables that may contribute to the onset or course of morbidity (Table 1). This matrix proves to be a tidy way of organising what information is already available; but it also acts heuristically by proposing associations that otherwise might not have been considered but which call for investigation. The variables can be placed in

Table 1. A matrix for organising epidemiological knowledge

		Clinical psychiatric disorders	Neurotic disorders	Affective disorders	Schizophrenia	Dementia	Personality disorders	Alcohol abuse	Other psychoactive substance abuse	Suicide	Parasuicide	Intellectual disability	Psychological well-being
Sociodemographic factors	Gender Age Marital status Social class Urbanisation Regional variation Secular change Other macrosocial factors												
Experimental factors	Seasonality of birth Birth order Parental age Childhood separation Parental style Cultural or subcultural beliefs and attitudes Adverse experiences/ events Extreme experiences Bereavement Expressed emotion Unemployment Social support Migration Noise Environmental toxins Dietary factors Comorbidity Personality and temperament Genetic factors Other biological factors Interaction of two or more factors												

categories: sociodemographic, experiential, intrapersonal (psychological) and biological.

The alert observer will notice that the matrix has a limitation, because it only has two dimensions, i.e. it does not display interactions between two or more variables, interactions which can be of the greatest importance. Examples are the interaction between age and gender in the onset of schizophrenia, or the combination of adverse parental style in childhood, adverse life events in adult life and a genetic vulnerability to affective disorders. In order to consider such interactions, users of the matrix need to select their own combinations. It is also desirable for the user to construct his or her own additional variables to suit the community in which the research work is being planned.

For many of the cells in Table 1, knowledge is already available in the literature, e.g. issues such as socio-economic class and schizophrenia, education and dementia or secular change and affective disorders. What is conspicuously lacking in psychiatric epidemiology is information on higher-level interactions such as gender, adverse experiences and genetic vulnerability.

Table 2. The three population levels

Level	Advantages	Disadvantages
Community surveys	Reflect the occurrence of morbidity free of some selection biases	Labour-intensive and costly Non-random refusals or losses
	Identify persons with a wide range of severity Provide data of administrative value	Low case yield for some disorders
General practices (family physicians)	Better yield of cases	Labour-intensive
	Opportunity to study recognition of cases and their outcome	Denominator may be uncertain Selection effects from help-seeking, doctors and refusals
Mental health services	Generate operational data of administrative value	Based only on individuals reaching treatment
	High yield of cases for most diagnostic groups	May lack data from private sector
	Can be linked to other databases	May be ethical problems in access
		Quality of data may be variable

3 Levels of Epidemiological Enquiry into Psychiatric Disorders

Psychiatric epidemiology conducts its enquiries at one of three levels: (1) morbidity as it occurs in the community or general population, (2) morbidity as it occurs in primary health care (including family physicians) and (3) morbidity as it occurs in mental health services. Each offers advantages for particular purposes, and these may be summarised as set out in Table 2.

From Table 2, it will be clear that research on aetiology may often be carried out with advantage at the community level rather than on treated series, because there are less likely to be biases in a community sample, particularly in relation to likelihood of exposure to putative risk factors. This can be important in avoiding Berkson's bias (Berkson 1946), whereby some other variable, unrelated aetiologically, may influence the chances of a person reaching services. The unaware researcher might then mistakenly conclude that this variable contributed causally. Such biases are absent in community samples. Such samples also cover a wide range of severity, whereas cases of depressive disorder, for instance, will be only of the severe type in hospital or clinic series. Nevertheless, community samples have their own problems. They are laborious and costly, requiring sufficient trained personnel to contact and interview hundreds and commonly thousands of individuals in their own homes. Invariably there are refusals and people who cannot be contacted, and it is likely that the very condition being investigated will be more common in such cases. This is called "non-ignorable non-response" and is itself a topic of some scientific and statistical interest, the issue being how to correct for it in computing estimates of prevalence or incidence or of outcome.

4 Commonly Used Designs

The main designs used in psychiatric epidemiology are cross-sectional, prospective longitudinal (cohort) and case-control studies. A cross-sectional study is often an excellent start to an enquiry, because it provides a picture of how much morbidity is present in a sample at one point in time and the variables most closely associated with this. However, because it is only a "snap-shot", the cross-sectional study can rarely reveal

much about aetiology. For example, suppose that data are collected from a community sample of a thousand adults and that a measure is obtained of the symptoms each has experienced in the previous month and the exposure they have had to adverse life events in the last year. Then suppose that the data show quite strongly that individuals who have had many adversities also tend to have more symptoms of anxiety or depression than those not so exposed. It would be unwise to conclude from this that adversity contributes to the onset of symptoms. This is because individuals with anxiety or depression may be more likely to have unpleasant things beset them, or they may be more likely to report that they have had many troubles, either because of a tendency to complain or as a result of "effort after meaning", whereby they can account for feeling psychologically unwell. It may also be that individuals who have certain personality traits or lifestyles may be more likely to have troubled lives with much adversity *and* be prone to anxiety or depression.

Such problems in methodology can be resolved to some extent by graduating to a prospective longitudinal design, also called a cohort study. In this, a population sample is assessed at the start, when most individuals are psychologically well. The information obtained from these subjects is therefore unlikely to be biased by their mood state or by selective recall. It may refer, for example, to their personality, lifestyle, recent or past exposure to adversity, past health and family history. They are then re-examined at least once after an appropriate interval. Some will have developed symptoms in the area of interest. The research question to be asked is whether the potential risk factors that were assessed at the start were more frequently present in those who developed the symptoms. A design of this type yields considerably more information about the processes likely to be at work, either those leading to mental disorders or those protecting against them. However, such a study design is obviously very demanding in human, administrative and financial resources. It also takes a long time to obtain all the data. For these reasons, epidemiologists often use the case-control method.

The case-control method has been under-used in psychiatric research, but can be a powerful strategy in trying to identify risk factors for a specified disorder. The essence of its design lies in obtaining data to complete a 2 × 2 table, defined by individuals with and without the condition in question and whether or not they have been exposed to a suspected pathogenic experience (Table 3). Notice that the cohort study is prospective, because it waits for morbidity to develop. By contrast, the case-control study is retrospective. The procedure involves finding a sample of individuals with the disorder in question, preferably new or incident cases, and a similar number of subjects who are matched for age, gender and other variables but who do not (or not yet) have the disorder. Both patients and controls, or their families, are then asked about the various possible risk factors. The question asked is whether there are more subjects in cell *a* than would occur by chance. We do not know the incidence of the disorder in all individuals in the population who were exposed to each risk factor, nor do we know the number not exposed. Likewise, we do not know how many people in the population have recently developed the disorder. As a consequence, we cannot compare the incidence in those exposed and not exposed *for the whole population*. All we have are the data from the patients examined, who are necessarily only a fraction of all incident cases in the population, and data from a fraction of all healthy subjects. However, we can proceed as follows. First, the relative risk is calculated from Table 3:

Table 3. A 2 × 2 table in a case-control study

		Case	
		Yes	No
Exposed	Yes	a	b
	No	c	d

Letters refer to number of individuals.

$$\text{Relative risk} = \frac{a}{a+b} \div \frac{c}{c+d}$$

By simple algebra, this becomes

$$\frac{a(c+d)}{c(a+b)}$$

Then something very helpful can be done. Where a disorder is fairly uncommon in the general population, *a* will be very small in comparison with *b* and *c* will be small in comparison with *d*. If we assume a negligible contribution by *a* in the term $(a+b)$, and by *c* in the term $(c+d)$, the relative risk will be nearly equal to:

$$\frac{a \times d}{b \times c}$$

This is the odds ratio, which is an expression of the strength of a risk factor. A more complete account of these issues can be found in Schlesselman (1982). By way of an overview, Anthony (1988) has given a lucid exposition of the use of case-control methods in psychiatry.

5
Sampling

5.1
Principles

There are few occasions when it is practicable to examine a total population. In studies at the general population level, this would mean carrying out an assessment of every individual in, say, an entire city or region. In a primary health care setting, it would mean assessing every person who consults staff in every facility during a specified period. In a case-control study in clinics or hospitals, it would mean examining every individual who presents with a specified disorder in all of the clinics across a whole country, as well as examining an equivalent number who do not have that disorder. The solution is to take a sample of the group under investigation. The essential principle is that everyone in the true denominator, i.e. the total population within a specified age-range, must have an equal probability of being included in that sample or, if there is to be weighting, a known probability. If this is not achieved, there is a distinct likelihood of bias, whereby the achieved sample may be different in ways that could be important in the analysis. For example, the sample of cases should not differ from *all* the incident cases in that population in attributes such as the severity or duration of the disorder or in level of education, age or likelihood of having been exposed to a candidate exposure or risk factor. Thus, in a study of the association between childhood sexual abuse and depression in adult life, the cases of depression should be representative – in severity, duration of depression and likelihood of exposure to abuse – of all those in the community with depression. The same principle of equivalence should apply to the controls without depression.

5.2
Non-Ignorable Non-Response

In field surveys, it has long been accepted that not everyone who is in the "target sample" will agree to be interviewed or will be available at the time the interviewer calls. It is common to find that only 70%–90% are actually assessed. Furthermore, those who refuse or are repeatedly not available are now known often to be more likely to have the mental disorder under investigation. Next, in many cohort studies of mental disorders in which a sample of individuals are followed over several years, it is recognised that those who die are more likely to have already had the condition under study at the beginning or to have developed it during the course of the study. This means that those who are successfully re-examined are a survival élite or are different in important ways from the original cohort. These distortions could lead to mistaken conclusions if the losses are not allowed for.

Statistical methods have been available for many years for estimating how much error may have occurred due to refusals and how to correct for this in the conclusions drawn. In cross-sectional surveys, these methods include the introduction of special incentives to increase the response rate and very brief psychiatric assessments that can be conducted on the doorstep. The information obtained then allows some correction through the application of weights to the data from the achieved sample (Kessler et al. 1995). Both in cross-sectional and in cohort studies, Bayes' theorem can be applied, whereby adjustments to the final estimates can be made on the basis of prior probabilities, some of which are known (Best et al. 1996).

6
Specifying Disorders

6.1
Diagnostic Categories

Whether the epidemiological study is conducted at the level of the community, primary health care or mental health services, it is obviously essential to specify which symptoms or diagnoses are to be studied. Traditionally, psychiatric research has focused on "cases", i.e. individuals who have been given a diagnosis. This is entirely appropriate in many circumstances. The task has been made much easier with the development of the diagnostic criteria now in wide international use. The first of these is the International Classification of Diseases (Tenth Revision) (ICD-10) with its Classification of Mental and Behavioural Disorders. This comes in two mutually complementary presentations: the *Clinical Descriptions and Diagnostic Guidelines* (WHO 1992) and the *Diagnostic Criteria for Research* (WHO 1993). These sets of diagnostic criteria have been prepared after very wide consultation with expert psychiatrists in some 40 countries. They therefore represent an international consensus. Furthermore, the *Diagnostic Criteria for Research* have been used as the basis for diagnostic instruments that have computer algorithms to apply the criteria, precisely and invariably, to the information obtained (see below).

Another system is presented in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) of the American Psychiatric Association (1994). This is a national development that is used

throughout the United States and quite widely elsewhere. Through a process of extensive consultation that took place between the WHO and the architects of the DSM-IV, it is very similar to ICD-10, and "cross-walks" have been developed to allow movement between them for individual diagnoses. Together, ICD-10 and DSM-IV have brought a common language to clinical psychiatry and research. When authors submit a paper to a reputable scientific journal, it is now virtually mandatory that the disorders are described according to one or both systems. Indeed, it is highly desirable for investigators to use both simultaneously, because this carries distinct advantages for the analyses and for further knowledge to be acquired about the performance of ICD-10 and DSM-IV as diagnostic systems.

6.2 Continuous Measures of Morbidity

Case ascertainment might be assumed to be the sine qua non for any progress in the epidemiology of mental disorders, i.e. to recognise cases. However, using the traditional expression "case ascertainment" nicely illustrates the very problem that has to be rethought, because it implies a categorical structure in the morbidity that we wish to study. In a population, there are traditionally cases and non-cases. As expressed by Pickering (1968), "medicine in its present state can count up to two, but not beyond." He was referring to hypertension, but others (e.g. Rose 1993) have argued that most mental disorders are dimensional in their nature. The frequency distribution of their component symptoms, such as anxiety, depression or cognitive impairment, is usually a reversed J shape, with most people having none or only a few symptoms, and progressively fewer individuals having higher counts. A committee of clinicians in Geneva or Washington, whose experience is often limited to hospital and consulting room practice, have decided by consensus where the cut-off point should be placed for individuals to be "cases". While this is entirely appropriate for some purposes, it may not always be a true representation of the world. In statistical terms, it can sometimes lose information.

It is not disputed that disorders of mental health exist in categorical states or at least have some utilitarian value; a depressive episode, Alzheimer's disease, anorexia nervosa and alcohol dependency are clinically realistic entities, albeit not necessarily unitary ones. What is proposed here is that, in epidemiological studies at the general population level, hypotheses about aetiology are not well served unless very large numbers of respondents are interviewed, solely because the base rates for these conditions are not large. However, it is possible to identify individuals with *some* symptoms of depression, of cognitive impairment, of abnormal eating or of alcohol misuse, and a score of these symptoms can be made the dependent variable in an analysis of candidate risk factors. In other words, it can sometimes be statistically more powerful to look for associations between a putative risk factor and morbidity expressed as a continuous variable rather than as a dichotomy of cases and non-cases. Rose and colleagues confirmed that, when a continuous measure, such as the General Health Questionnaire (GHQ; Goldberg and Williams 1988) is applied to a population, a unimodal distribution curve is found, with no break between so-called cases and so-called normals. Rose went on to argue that this approach has three important consequences for studying morbidity. Firstly, a characteristic of the community as a whole emerges. This is the mean and standard deviation of its GHQ scores. Secondly, this collective characteristic may show large differences between men and women, geographic regions, social strata and income groups. These differences are based on shifts of the entire distribution. The third consequence is that differences between these groups in the prevalence of probable cases (those with a score above a threshold) are related to different average scores in these groups. As Rose put it, "the visible part of the iceberg (prevalence) is a function of its total mass (the population average)."

Rose went on to say that "psychiatrists, unlike sociologists, seem generally unaware of the existence and importance of mental health attributes of whole populations, their concern being only with sick individuals." It is an appealing notion that populations, while they are undeniably made up of individuals and as far as we know no other component, take on properties of their own, much as molecules have attributes not found in their constituent atoms. The concept of populations having different frequency distributions of morbidity, and *not just different prevalence rates for clinical cases*, carries with it the implication that one or more factors are shifting the overall distribution in some populations but not in others. The idea is that there is some pervasive force that is active in the biological or social environment and that promotes a disease or disorder. This notion is not far removed from Galen's atmospheric factor, the katastasis or miasma.

6.3 Disablement

There is a further advantage in considering morbidity as a continuum in a population. Morbidity usually refers to symptoms or disorders, but there is another universe of discourse closely linked to this, namely

disablement. This is the collective noun now used to refer to the impairment, disability and social role handicap in daily life that disorders bring with them. It is self-evident that the main categories of mental disorder, especially the psychoses, affective disorders and dementias, are almost always associated with substantial disablement. However, subclinical levels of mental disorders also carry with them a certain amount of disablement. From the point of view of a whole population, the amount of disablement from subclinical or milder conditions is cumulatively substantial. This is because such conditions have a high point prevalence. Therefore, from a public health perspective, the significance of milder mental disorders is not trivial.

7
Independent Variables: The Domains

The independent variables are traditionally those that are possibly associated with, or even contribute causally to the dependent variable, which is a psychiatric disorder or symptom score. Such variables can lie in several domains: sociodemographic, socio-environmental experiential (both past and current), psychological or biological. They can, of course, be a mixture of any of these, in which case the variables are said to show an interaction effect, either within or across domains. Psychiatric epidemiology has attended largely to sociodemographic, socio-environmental and experiential variables, as exemplified respectively by the celebrated studies of Faris and Dunham (1960) on the spatial distribution of patients with schizophrenia in Chicago, which showed a concentration in the central areas with cheap, single-room occupancy hotels; the Stirling County Study in Canada by Leighton et al. (1963a,b) with its concept of sociocultural disintegration; and the corpus of studies by Brown and colleagues on adverse life events, the presence of a confiding relationship, early childhood experiences and depression in women (Brown and Harris 1978). Psychological attributes such as personality or other indicators of vulnerability or resilience have been much less studied epidemiologically. Biological variables, including genes, are largely an untapped field, awaiting investigators with innovative hypotheses to integrate several of the above domains.

Recent years have seen unprecedented advances in molecular genetics with intense activity directed towards the genetic contribution in affective disorder, schizophrenia, alcohol dependency and Alzheimer's disease. There is good reason to believe that some of these advances, both in scientific understanding and in new methods for genetic analyses, may bring unparallelled opportunities to psychiatric epidemiology. It is therefore important that psychiatrists and epidemiologists now collaborate with experts in human genetics to construct testable hypotheses in which genetic measures can be considered alongside, and in interaction with, other markers of vulnerability. In this context, two complementary strategies could be followed. The first consists in a continuing search for genes associated with discrete disorders such as depression or schizophrenia, a search carried out at the general population level or in high-risk groups. The second strategy is quite different and involves searching not for genes that may cause the disorders, but for genes that confer vulnerability to them. Because such an approach is well suited to epidemiological designs, we shall look more closely at the thinking behind it.

Cloninger et al. (1996) have commented on the difficulties of replicating genetic associations with complex psychiatric disorders and have argued that "it may be more fruitful to map genes contributing to temperament, which has a relatively simple genetic architecture and can be quantified easily and reliably by questionnaire. Later, susceptibility to complex disorders like schizophrenia and alcoholism can be evaluated." One such attribute of temperament is the trait of neuroticism. This is a personality dimension characterised by a greater or lesser tendency to react emotionally to adverse stimuli, i.e. to get upset under stress. Because neuroticism is a relatively stable trait in contrast to the fluctuating nature of anxiety and depressive disorders, it provides a good basis for genetic investigation of the vulnerability to these disorders. Using longitudinal twin data, Kendler et al. (1993) found that approximately 55% of the genetic vulnerability to major depression is shared with neuroticism. The broad-sense heritability of neuroticism has been estimated to be about 0.42. There is some evidence that heritability is higher in women than in men and that it decreases from late adolescence to early adulthood.

While quantitative genetic studies have established a role for genetic factors in neuroticism, new developments in molecular genetics make it possible to go further and seek particular loci linked to such traits. Until fairly recently, molecular genetics techniques were mainly applied to categorical disorders thought to involve a single gene. However, psychological variables such as neuroticism form a continuum in the population and probably involve many genes, each of which is neither necessary nor sufficient for the trait. In recent years, there has been increasing interest in genes that contribute to variation in quantitative traits, of which neuroticism is one example. Quantitative trait loci (QTL) may vary in the size of their effect on a trait from infinitesimally small to modest. The aim of

current QTL research is to find the loci which have the largest effect.

There are a number of techniques available for the study of QTL, including linkage analysis in families, allele-sharing methods between relatives, association studies in population samples and experimental crosses in laboratory animals. The allelic association approach has greater statistical power than either conventional linkage analysis or allele-sharing methods to detect genes with small effect and, despite some limitations discussed below, it may be the most effective approach for QTL detection. It is argued that allelic association studies are at present the strategy of choice for detecting quantitative trait loci. Because a large number of candidate markers are being investigated, there is a risk of type I errors. In order to reduce these, the search for allelic associations can be carried out with an original community sample comprising the top and bottom 5% of the total distribution and a replication sample covering the top and bottom 1%.

The first studies on QTL for personality traits have now been reported. Using an allelic association methodology, Ebstein et al. (1996) found an association between the trait of novelty seeking and the D4 dopamine receptor gene. Benjamin et al. (1996), using both population and sib-pair association methods, found an association between extraversion and the same gene. Other candidate genes are now being examined. This work is a landmark in the study of personality, demonstrating for the first time that there is a specific biological basis for variation in a personality trait. It also marks a new era in psychiatric epidemiology in which it should be possible simultaneously to include biological, intrapersonal and social variables in aetiological research.

8 Instruments

Instruments fall into two types: symptom scales and psychiatric examinations. In any one study, either or both may be used, depending on the investigator's aims and resources.

8.1 Symptom Scales

The more simple type of instrument is a symptom scale, which can be completed by respondents themselves or administered by the interviewer. Widely used examples are the GHQ (Goldberg and Williams 1988), the Hopkins Symptom Checklist (HSCL; Derogatis et al. 1974) and the Mini-Mental State Examination (MMSE; Folstein et al. 1975). The GHQ and HSCL cover symptoms of anxiety and depression and are therefore useful for obtaining a continuous measure of these, expressed as a score; alternatively, they can be used as a screening instrument to identify those individuals in a sample who have a high, or low, probability of having a mental disorder. In an analogous manner, the MMSE can provide a score for a person's cognitive function or, by applying a previously established cut-off point to that score, it can be used to identify those who are likely to have a dementia (Brayne and Calloway 1990; A.S. Henderson et al. 1994).

When a questionnaire or self-rated instrument is used in research, its psychometric properties should be known beforehand, and these are often specific to the population being studied. Variables such as cultural patterns and education can have a significant effect on the instrument's performance. The two properties to be established are its sensitivity and specificity, both expressed as a percentage. These refer to the instrument's performance when compared with a criterion or "gold standard", such as a comprehensive psychiatric examination of established validity or a consensus diagnosis amongst experts. In Table 4, a sample is shown of individuals examined both by the screening instrument and a full examination. We consider the number of subjects who are "cases" according to both instruments (a), according to one but not the other (b or c) and according to neither (d).

Sensitivity is the proportion of individuals who screen positive who are indeed "cases" according to the criterion, i.e.:

$$\frac{a}{a+c}$$

and specificity is the number who screen negative who are indeed not "cases":

$$\frac{d}{b+d}$$

The sensitivity and specificity of a test will vary according to where the cut-off point is placed on the scores. As sensitivity increases, specificity tends to decrease, so that an appropriate balance between the two has to be determined by the investigator. For some

Table 4. Criterion

		Yes	No	
Cases by screening test	Yes	a	b	a+b
	No	c a+c	d b+d	c+d

Cases by full psychiatric assessment.

purposes, such as in screening for depression, it is more important to identify as many as possible of the true cases, but it does not matter if there are quite a few "false positives", because these can be corrected in a second stage by more extensive examination. Under these conditions, one would want a highly sensitive screening test that placed most of the true cases in cell *a* and few in *c*. It matters rather less if quite a few of the true non-cases are mistakenly placed in *b*.

8.2 Standardised Psychiatric Interviews

Even with the best-designed scales or questionnaires with the best psychometric properties, these cannot be a substitute for a psychiatric interview, which can yield something approaching a diagnosis according to the international criteria. Symptom scales do not purport to make a diagnosis. Progress of fundamental significance for all of psychiatry has been made since the late 1960s with the development of standardised examinations. These examinations are standardised in two mutually complementary ways. Firstly, the questions asked or the ratings of behaviour are not left to the idiosyncrasies of the interviewer, which would lead to different information being obtained across interviewers and across studies. Instead, this so-called information variance is reduced by having interviewers ask about symptoms in the same way. Secondly, criterion variance is reduced, the symptoms or signs elicited being assembled, like building bricks, in exactly the same way, both within and across studies. This is achieved by applying to the data an algorithm, which can easily be computerised. The algorithm is a precise expression of the diagnostic criteria in ICD-10 or DSM-IV.

There are two types of standardised psychiatric examination. This is for the good reason that, although full clinical interviews in the field by experienced clinicians may be the ideal, such resources are often not available. The first type of instrument is mainly for use by research clinicians after some training in its use. These instruments allow some flexibility in questioning and enable the clinician to use his or her judgement when making a rating about the presence or absence of each symptom or behaviour. The Schedule for Clinical Assessment in Neuropsychiatry (SCAN)[1] is such an instrument (see below). There is also another group of instruments for use by laypersons. These are said to be "fully scripted", where the questions asked are invariable and must be strictly adhered to, with only very few of the items calling for any judgement. The Diagnostic Interview Schedule (DIS) and the Composite International Diagnostic Interview (CIDI) are of this type (see below).

The SCAN is the successor to the ground-breaking Present State Examination (PSE) developed over two decades ago by Wing, Cooper and Sartorius and now revised by Wing et al. (1990) for the WHO (1992). The SCAN is a clinician's instrument, because it requires familiarity with the phenomenology of mental disorders and assumes that the interviewer is comfortable in examining individuals with a mental disorder. In complete contrast to interviews for use by laypersons, the clinician asks the main question, but is allowed to probe with further questions, if necessary, before deciding whether a symptom is present or not. The correct use of the SCAN requires formal training in one of the designated centres around the world. The SCAN has a number of modules, each dealing with a group of disorders such as anxiety states, affective disorders, substance abuse or psychoses.

The Clinical Interview Schedule, Revised (CIS-R) was developed from an earlier version by Goldberg et al. (1970), largely so that it can be used by lay interviewers (Lewis et al. 1992). It was successfully used in the National Survey of Psychiatric Morbidity in the United Kingdom (Jenkins et al. 1997a,b). The CIS-R generates diagnoses by ICD-10 and DSM-IV, but is also able to give scores for symptoms. It is known to have been well received by respondents and to have been user-friendly for interviewers. It is considerably less elaborate than the CIDI, for example.

The DIS was developed by Robins et al. (1981) as a psychiatric interview that could be administered for research purposes by non-clinicians after training. It was the instrument used in the ECA studies. Its current version allows diagnoses to be made according to DSM-IV. There is also an equivalent assessment for children, the Diagnostic Interview Schedule for Children (DISC).

The CIDI was developed by Robins et al. (1988) for the WHO and the U.S. Alcohol, Drug Abuse and Mental Health Administration Task Force on Psychiatric Assessments. It combines questions from the DIS with questions designed to elicit PSE and SCAN items. Like the DIS, the CIDI can be used by laypersons after only a few days' training. Its performance in clinical field trials has been established, and Wittchen (1994) has given a comprehensive account of its reliability and validity in studies to date. The CIDI is fully scripted and has been automated for administration on laptop computers by Peters and Andrews (1995). It is a powerful tool for epidemiological research, having a number of available modules which cover the main categories of mental disorder and generating both ICD-10 and DSM-IV diagnoses as well as symptom scores.

[1]Copies may be obtained from Publications, World Health Organization, Avenue Appia, 1221 Geneva 27, Switzerland.

8.3 Instruments for Assessing Dementia and Depression in the Elderly

Epidemiological research on mental disorders in late life calls for specially designed instruments to detect cognitive impairment, cognitive decline, depressive states and performance in the activities of daily living. Three such instruments will be mentioned here, all of which include a section for assessing elderly people and a separate section for an informant, usually a relative or close friend. The first to be developed was the Geriatric Mental State Examination (GMS; Copeland et al. 1976), which has now been widely used in several countries. The second is the Cambridge Examination for Mental Disorders of the Elderly (CAMDEX; Roth et al. 1986), which was intended as a clinician's instrument, but which can be used by laypersons after some training. A combination of parts of the GMS and the CAMDEX has recently been used in a large study of cognitive impairment and dementia in the United Kingdom. The third instrument is the Canberra Interview for the Elderly (CIE; Social Psychiatry Research Unit 1992).[2] The CIE was developed "from the bottom up", in that the authors started with the diagnostic criteria in both ICD-10 and DSM-III-R (now DSM-IV) and then constructed items to tap each element in these criteria. The CIE is available in English, German and French versions. From the CIE, Jorm and Mackinnon (1995) developed a set of compact scales, the Psychogeriatric Assessment Scales (PAS)[2] to enable non-clinicians working with the elderly to detect depression, cognitive decline and stroke in a standarised manner (Jorm et al. 1995, 1997). The PAS are now in wide use internationally.

8.4 Typical Prevalence Estimates

There are now a large number of surveys reporting the prevalence of the main mental disorders in the general population. Some of the above instruments have been used in these surveys for case-finding. Examples are shown in Table 5.

8.5 Disablement

In assessing the epidemiology of any mental disorders, it is often very useful to estimate the amount of disablement that these entail. This should be done

[2]Copies may be obtained from the Secretary, Centre for Mental Health Research, Australian National University, Canberra, A.C.T. 0200, Australia.

separately, but in a complementary way to the measurement of symptoms. There are a number of instruments available to measure disablement associated with mental disorders. The most comprehensive is the Disability Assessment Schedule (DAS; WHO 1988), which assesses an individual's functioning across a hierarchy of self-care and functioning in daily life. Another is the Groningen Social Disabilities Schedule (Wiersma et al. 1988), which gives a comprehensive assessment of functioning. A shorter, self-rated instrument is the SF-36 and its even more brief version, the SF-12.

8.6 Aetiological and Other Associated Variables

8.6.1 Sociodemographic Variables

Few epidemiological studies are likely to omit a certain amount of information on the age distribution, gender, marital status, ethnic background and socio-economic or educational level of the sample population. It is best to obtain such information using methods that are already established and known to perform well in the investigator's region, rather than to invent one's own items. This also allows comparisons with other studies to be made with more confidence.

8.6.2 Social Environment

Social environment can be considered in two parts: (1) the individual's immediate social environment – what the sociologist Cooley (1909) called the primary group – made of those around a person with whom he or she has both interaction and commitment and (2) the wider social environment, the community, with its beliefs and values. Plausibly, both may have some influence on the incidence of mental disorders and on their course and prognosis. For an account of instruments to measure the individual's immediate social environment, and the support it may afford, reference may be made to A.S. Henderson (1988).

8.6.3 Experiential Variables

Some epidemiological studies may wish to test hypotheses about depressive disorder in adults, for instance, and the experiences they report having had in childhood and adolescence or their exposure to recent adversity.

Parker (1983, 1992) investigated exposure to a specific style of behaviour in parents and the subsequent risk of non-melancholic depression in the offspring some decades later. He developed the Parental Bonding Instrument (PBI) to obtain self-reported information on how affectionate and how controlling a person's mother and father had each been. The "toxic" exposure was found to be affectionless control, i.e. parents who had been highly controlling, but not at all affectionate or caring. Parker (1992) reviewed the evidence for inadequate parental care as a risk factor in adult depression, integrating this with the evidence on parental loss and, importantly, on compensating or mitigating factors. The latter may take place through adequate parental care from a substitute source or through strong affectional relationships in adulthood.

More recently, there has been considerable interest in the effect of exposure to sexual or other abuse in childhood and the risk of mental disorders in adult life. Here, the findings point to the many adverse experiences that commonly accompany childhood sexual abuse, including physical violence, unstable and untrustworthy relationships with parents and emotional deprivation. This is a good illustration of the problem of confounding variables, in which a candidate causal variable is likely to be associated with others which have an established link with the condition being studied.

There is a wide choice of instruments for assessing a person's exposure to adverse life events and experiences. These range from quite brief checklists to the comprehensive assessment provided by the interview developed by G.W. Brown and colleagues (Brown and Harris 1978).

8.6.4 Personality Variables

The hypotheses under investigation may refer to some markers of vulnerability to a particular group of mental disorders. Some such markers may lie within the domain of personality. Among these, one of the most promising is the construct of neuroticism, as measured by the Eysenck Personality Questionnaire (EPQ). A high score on this trait confers vulnerability to anxiety or depression. Neuroticism and some other personality traits can be reliably measured in only a few minutes by a self-completion questionnaire and may provide useful predictor variables in longitudinal studies. They are therefore often worth inclusion among the independent variables.

8.6.5 Genetic Factors

Sufficient DNA for some analyses can be obtained non-invasively by asking individuals to rub a cotton wool bud on the inside of their cheek for about 1 min. This is then placed in a sterile plastic container and labelled. It is usually not necessary to keep it cold, provided that it can be delivered to the genetics laboratory within

12 h. If the study calls for larger amounts of DNA, a sample of venous blood is preferable.

9
Analysis of Epidemiological Data

9.1
Strategies

After the field data have been edited and cleaned by removal of all obvious errors in coding, it is always best to start the analysis using the most simple methods, such as inspection of frequency distributions, means and standard deviations, cross-tabulations and correlations. Later, it may be appropriate to carry out multivariate analyses, typically with the measure of morbidity as the dependent variable. These methods include log-linear analysis and multiple linear regression for continuous variables such as symptom scores. All these methods allow the possible interaction effects between independent variables to be explored.

9.2
Application of Recent Advances in Statistics

There are sometimes opportunities to apply to psychiatric epidemiology some of the techniques developed in other disciplines, such as education and econometrics. For example, latent trait analysis was originally developed in statistical research on the measurement of intelligence before being imported to psychiatry by Duncan-Jones et al. (1986). Latent trait and latent class analysis are highly attractive methods for exploring the properties of an instrument and its individual items or of assessing the behaviour of diagnostic criteria when these are applied to population-based data. Where large data sets on symptoms in general population samples have been obtained, these can be used to explore the fundamental structure of psychiatric classification by the methods of numerical taxonomy. When the sample size is large enough to allow it, testing of hypotheses about aetiology or the course of disorders over time can be undertaken using structural equation modelling. In this, the existence of causal links between a set of variables can be tested by determining the strength of the path coefficients between them.

10
Ethical Issues in Psychiatric Epidemiology

As with other areas in the health sciences, psychiatric epidemiology has had to confront several ethical issues. These should be anticipated in every instance and presented to the Institutional Ethics Committee in the research worker's hospital or university. Some ethical issues concern the research team's access to data that already exist, such as hospital records, case registers for a whole geographic region or country, health insurance companies or police records. Where individuals could be identified, these data are made available to the researchers only if the individuals concerned have given informed consent. Another issue is the researcher's obligation to guarantee, and then be able to honour, complete confidentiality regarding the personal information obtained in a research interview or from any special investigations, such as the sensitive areas of human immunodeficiency virus (HIV) testing or genotype. While the researcher may genuinely state that confidentiality will be absolute, provision should always be made for eventual destruction of the data and for the information to be protected from other agencies, such as the courts. Contemporary public attitudes to privacy and confidentiality have made it difficult at times for epidemiologists to be allowed to develop databases containing information on people's health and to have access to those registers that already exist. This is an example of the tension that exists between the need for privacy and the public benefit that may be gained from using such information for medical and psychiatric research.

A further problem is already arising in genetic research conducted at the community level. In the course of research studies, if an individual has a genetic test showing an increased risk of developing a particular disorder such as cancer, Huntington's disease or, in the near future, depression or schizophrenia, a problem arises for that individual if he or she knows about the finding and then seeks life insurance. When applying for insurance, it is usual for the individual to be required to divulge any information that might prejudice his or her health. If this is divulged, the insurance company may refuse to underwrite the policy; if the information is not divulged, the company can refuse payment in the event of a claim. No satisfactory resolution to these matters has been reached.

In the course of a community survey, the research interviewer occasionally finds a person who is in profound distress or is a danger to self or others. While there is no problem if that individual agrees to be immediately contacted by a health professional, there can be an ethical problem if he or she refuses. This can sometimes be resolved by having an expert clinician available by telephone to the field staff at all times during the fieldwork, so that the interviewers are relieved of responsibility.

11 Conclusion

Research on the epidemiology of psychiatric disorders is at an interesting stage in its evolution. There is an abundance of testable hypotheses on aetiology and on the course of mental disorders. Instruments are now available for obtaining data of good quality both on symptoms and abnormal behaviour and on social or experiential variables. Of particular significance is the emergent capability to advance our understanding of the contribution made to aetiology by specific genes in interaction with environmental exposures.

Population Genetics

1 Introduction

Population genetics consists in studying genetic transmission in families and populations. The role of genetic factors in transmitting psychiatric disorders has been documented in a wide range of studies. Different strategies such as family, twin, and adoption studies have been used to investigate genetic risk factors in psychiatric disorders. Their objectives are to investigate the genetic and nongenetic (environmental) causes of a disease and to estimate morbidity risks for relatives of an affected proband.

Epidemiological genetic studies have convincingly shown the involvement of genetic factors in bipolar affective disorder (BPAD) and schizophrenia. It is thus expected that molecular genetic studies will soon identify the gene or genes involved in the etiology of these disorders. Epidemiological strategies have also demonstrated the implication of genetic vulnerability factors in the etiology of other disorders such as unipolar affective disorder (UPAD), anxiety disorders, alcoholism, obsessive–compulsive disorder (OCD), dementia, and some personality disorders.

The limitations and methodological problems of genetic strategies will first be discussed in this chapter. The most recent or most relevant literature on the epidemiological genetic aspects of psychiatric disorders will be summarized. The interplay between epidemiological and molecular genetics research will also be highlighted.

2 Genetic Epidemiological Strategies

2.1 Family Studies

The first step when studying genetic epidemiological factors is to conduct family studies. Their aim is to detect the presence of familial aggregation, which is defined by the occurrence of a disorder at a higher frequency in relatives of affected individuals than in the general population. Familial aggregation is related to the presence of vulnerability factors, either genetic and/or environmental. Indeed, the first-degree relatives (mother, father, siblings, children) are more likely to develop a disorder than the second-degree relatives (e.g. uncle, nephew, cousins) and than the general population if that disorder has a genetic etiology. Family studies begin by identifying a proband, i.e. an affected subject, and by studying his or her relatives.

The main limitation of family studies is that shared environment and not only shared genes might be responsible for the observed familial aggregation (Ottman et al. 1991). Indeed, family studies cannot distinguish between genetic, family environment, and nonfamilial environmental factors. The relative contribution of genetic and environmental factors in disease etiology is therefore assessed by studying strategic populations such as twins and adoptees.

A second goal of family studies is to estimate the morbidity risk (MR), i.e. the probability that an individual will be affected at the age of risk. MR provided by family studies are highly relevant to genetic counseling. However, comparison of MR throughout several studies is often misleading, since different diagnostic criteria have been used. In order to reach standardized and reliable diagnoses, standardized instruments were developed such as the Research Diagnostic Criteria (RDC) (Spitzer et al. 1978), the Schedule for Affective Disorders and Schizophrenia–Lifetime Version (SADS-L), DSM-IV (American Psychiatric Association 1994), and ICD-10.

Family studies can also help to determine which clinical entities are transmitted together or independently within family members. If two disorders have distinct genetic etiologies, they will be transmitted independently in families. They provide additional evidence to validate new or controversial diagnostic entities (Feighner et al. 1972). In addition, the overlap of different diseases is examined through family studies.

New methodological standards for such studies have been well reviewed by Weissman et al. (1986a). Adequate family studies should make adjustment for potential disparities such as family size and years at risk of the relatives. Results from the majority of family studies were reported using the age-corrected "lifetime risk" or "morbid risk." Using this correction, the expected lifetime prevalence is given with all first-degree relatives having passed the age of risk of the disease. Several age-correction methods have been used (Gershon et al. 1982; Crowe and Smouse 1977), and these can also lead to discrepant results. Sex distribution in the relatives is another possible bias. For instance, the rate of affective disorder is higher in women than in men. An unequal distribution of the sex ratio in the groups of relatives compared can thus affect the results. Sample variations, differences between populations in the prevalence of genetic vulnerability, or cultural factors in the perception and description of hypomania and depression can also modify rates of MR (Gershon et al. 1982).

Data collection should be performed blind to the diagnosis of the proband. Two methods of data collection have been used to assess the presence of psychiatric disorder in the relatives: family history

data or family study data. In the latter method, all available relatives are evaluated by direct interview. Although structured interview and questionnaires such as the Family History - Research Diagnostic Criteria (FH-RDC) were designed to obtain more reliable familial information by interviewing only the proband (Andreasen et al. 1977), family studies using only family history data are considered less accurate. Indeed, probands tend to underestimate the prevalence of affective illness and other psychiatric disorders in their relatives and to overestimate the age at onset of illness in their ill relatives (Mendlewicz et al. 1975).

2.2 Twin Studies

Twin studies were designed to assess the relative contribution of genetic and environmental factors to disease development in the presence of familial aggregation. It has been traditionally accepted that monozygotic (MZ) twins are genetically identical. A discordance in the status of their disease would thus result from environmental factors, either biological or psychological. In twin studies, the difference in concordance rates for a trait between sets of MZ and dizygotic (DZ) twin pairs is analyzed. MZ twins behave genetically as identical individuals. DZ twins share only half of their genes on average and thus behave as sibs, except that they shared the same uterine environment before birth. Both types of twins are expected to share a similar environment. A genetic factor is suspected as the etiologic agent of a disease when the concordance rate in MZ twins is higher than in DZ twins.

Other designs can be used such as the study of twins reared apart since early childhood. This powerful strategic population provides another opportunity to delineate the effects between genetic and environmental factors.

A main limitation of twin studies is derived from the "equal environment assumption." The twin method has to assume that MZ and DZ twins have had the same environmental influences in order to prove a genetic contribution. Two recent studies (Kendler et al. 1994; Morris-Yates et al. 1990) supported the validity of the equal environment assumption. However, parents usually treat MZ twins more equally than they treat DZ twins. Moreover, environmental factors can differ in MZ twins as soon as their intrauterine life begins. After implantation, two thirds of MZ twins share a single chorion and placental circulation, and because of imbalance in their shared blood supply, they may differ more than DZ twins in their intrauterine experience and in birth weight (MacGillivray et al. 1975). Kendler and colleagues (Kendler 1983; Kendler et al. 1993) comprehensively reviewed studies assessing the validity of the twin method with regard to the equal environment assumption.

Other potential sources of bias in twin research exist. Probands described in several early twin studies were recruited from inpatient units (hospital-based studies), which could lead to an overidentification of concordant and more severe cases. In addition, unreliable psychiatric diagnoses for the concordance evaluation, zygosity misclassification (MZ pairs incorrectly labeled as DZ), and inadequate age at onset correction may lead to over- or underidentification of concordant cases (Kringlen 1995).

2.3 Adoption Studies

Adoption studies provide another opportunity to separate the interacting roles of heredity and environment on disease etiology. Several methodologies are used in such studies. The prevalence of the disease in adoptive and biological parents of affected adoptees can be compared. In the adoptees' design, the prevalence of disease in adopted-away children of affected parents is compared with the adopted-away children of normal control parents. Using the cross-fostering method, the prevalence of the disorder is compared between offspring of ill and offspring of normal biological parents, both reared by ill foster-parents. The prevalence of disease in biological and adoptive relatives of ill adoptees can also be compared to relatives of normal adoptees (adoptees' family study).

A limitation of adoption studies, when trying to separate the genetic and environmental endowments, is the time spent with the biological parents before adoption. Well-designed adoption studies should make adjustments for potential disparities between groups regarding family size, years at risk (up to current age, age at death, or age at diagnosis), and sex distribution in the relatives (Vieland et al. 1995). A potential confounding bias in adoption studies is that the disorder afflicting the affected biological parent may influence the likelihood and social location of the adoptive placements of their offspring. Conversely, adoptive parents represent a highly selected population, having been screened for high social stability and good mental health by the adoption agencies (von Knorring et al. 1983).

2.4 Segregation Analysis

Segregation analysis is used to determine the mode of genetic transmission or mode of inheritance of a disorder in affected families. It consists of analyzing

trait and phenotype distributions in families (phenotypes are observable features of a subject). The heritability of a particular trait is studied from one generation to the next and among members of the same generation. Such studies based on transmission probabilities are complex, requiring sophisticated statistical support. They can explore qualitative (discrete) or quantitative traits or phenotypes using different models of transmission (Weiss 1993).

Changes in prevalence or in age at onset during the last century, considered as a birth cohort effect (Gershon et al. 1987), can affect segregation analysis, which requires estimation of the prevalence of a disease in the general population. Ascertainment biases and assortative mating also have to be considered since they can alter results of segregation analyses. Indeed, assortative mating, which is a tendency for mated pairs (a couple) to be more similar for some phenotypic trait than would be expected if they were chosen at random, was observed in several psychiatric disorders and psychological traits (Merikangas 1982).

3 Bipolar Affective Disorder

Most family studies have shown that BPAD tends to cluster in families (Mendlewicz 1988). The lifetime risk for developing the disease in relatives of bipolar probands is significantly higher than in the general population. Table 1 shows that the familial rates of affective disorders averaged 5.7%–8% of BPAD and 10.2%–21.9% of UPAD in relatives of probands with BPAD. Exact rates are, however, difficult to obtain, as different diagnostic criteria or narrowed definitions of affective disorders were used throughout studies.

The MR for affective disorders were consistently higher in the relatives of bipolar than unipolar patients (Leonhard 1959; Perris 1968; Maier et al. 1993). This indicates that bipolar patients have a greater genetic loading for affective disorder than the unipolar ones. This observation generated worldwide interest from several research teams and prompted them to map genes involved in affective disorders, mainly for the bipolar form of the disease.

In a large-scale family study, the prevalence of bipolar II disorder was substantially increased (8.2%) among the relatives of individuals with bipolar II disorder, while only 1.1% of them had bipolar I disorder (Andreasen et al. 1987). This finding suggests that the disorder may breed true, providing some partial support for the independence of bipolar II disorder. No significant difference in familial aggregation was, however, observed between these two forms of BPAD by other investigators (Gershon et al. 1982). On the other hand, several studies suggest that bipolar II is closer to bipolar I than to UPAD (Dunner 1983; Endicott et al. 1985).

Early age at onset of probands with BPAD is also associated with a higher MR in relatives (Rice et al. 1987). Furthermore, BPAD patients with a positive family history of bipolar illness exhibit a more severe course of illness and have more manic episodes than patients without family history (Mendlewicz and Rainer 1974). On the other hand, no significant increase in familial aggregation of rapid-cycling BPAD is found compared with nonrapid cyclers (Lish et al. 1993; Coryell et al. 1992). However, the small sample size of these two studies does not permit definitive conclusions to be drawn.

Interestingly, a relationship between the effectiveness of lithium therapy and family history was observed. Responders to lithium stabilization more

Table 1. Morbid risks (MR) of bipolar (BPAD) and unipolar affective disorder (UPAD) in relatives of BPAD and UPAD probands

Probands	Study	At risk (*n*)	MR of BPAD (%)	MR of UPAD (%)
BPAD	Review by Gershon et al. (1982)[a]		8.0	10.2
	Gershon et al. (1982)[b]	441 (422)[c]	8.6	14.0

frequently have relatives affected with BP disorder than nonresponders (Mendlewicz et al. 1973; Grof et al. 1994). Recently, this observation was taken into account to design molecular studies with lithium responder patients in order to obtain a less heterogeneous population (Turecki et al. 1996).

A higher rate of affective illness, including BPAD, UPAD, and schizoaffective (SA) disorder, was observed in parents genetically related to BPAD probands compared with parents who adopted and raised them (Mendlewicz and Rainer 1977). Moreover, the degree of psychopathology in the biological parents of BPAD adoptees was similar to that in the parents of the nonadopted BPAD patients, while the rate of psychiatric disorder in the adoptive parents of the experimental group was similar to the rate in the adoptive parents of the normal offspring group. Cadoret (1978) studied adopted-away offspring of biological parents with affective illnesses. These probands had significantly more depressive disorders (mainly UPAD) in adulthood than did adoptees whose biological parents were well or had other psychiatric conditions.

There is a large amount of literature reporting a significantly higher concordance rate for BPAD in MZ twins than in DZ twins. The concordance rates in MZ twins vary between 50% and 92.5% (mean, 69.3%), compared with 0%–38.5% in DZ twins (mean, 20%). Although concordance rates were higher in earlier studies, the contribution of genetic factors has also been consistently noticed in the more recent ones. The differences seen across all these studies may result from diagnostic misclassifications and ascertainment biases in samples of the earlier ones.

In order to delineate the effects between genetic and environmental factors, the outcome of 12 identical pairs of twins reared apart since early childhood has been studied (Price 1968). Among these pairs, eight (67%) were concordant for the presence of the disease, a rate close to that for MZ twins reared together. This finding suggests that predisposition to BPAD will usually express itself regardless of the early environment.

The exact mode of inheritance is still not well understood in affective disorders. Some models of transmission can, however, be discarded. Thus the considerable number of families with two- and three-generation transmission of the illness is incompatible with autosomal recessive inheritance (Mendlewicz 1988). The two leading hypotheses arising from data analyses in BPAD patients are thus the single major locus (SML) model with incomplete penetrance (Strömgren 1938; Spence et al. 1995) and the polygenic model with a possible interaction between two or more loci (Perris 1972; Slater et al. 1972). Segregation data on affective disorders have been well reviewed by Rice et al. (1987), who reported the results of a very rigorous segregation analysis of BPAD. A mixed model, which allows for a SML with a multifactorial background, gave evidence for the presence of a major locus when controlling for the effects of birth cohort age at onset. This result was recently echoed by Spence et al. (1995), but neither this study nor the one by Rice et al. (1987) was large enough to test a polygenic/multifactorial hypothesis.

The SML model can also be tested by linkage analysis. For instance, linkage analysis provided evidence of X linkage in some families with BPAD (Mendlewicz et al. 1972; Baron et al. 1987). Despite exclusion of X linkage in other families, the X-linked dominant model appears to be a possible mode of transmission in some families with BPAD. Indeed, a recently published molecular study has again reported a strong linkage for BPAD with a DNA marker on chromosome X (Pekkarinen et al. 1995). This marker is closely located to the F9 locus where Mendlewicz et al. (1987) first provided evidence of a possible involvement of chromosome X in manic depression. Genetic heterogeneity and polygenic inheritance are likely to be present in BPAD, and this may be translated by the involvement of a high number of potential genes. Indeed, linkage, sib pair, and association methods have produced variable results in BPAD with loci on chromosomes 5, 11, X, and more recently 4, 18, and 21 (Souery et al. 1997).

Table 2 summarizes empirical risks for relatives of BPAD probands. Children and sibs of BPAD probands constitute high-risk groups. In second-degree relatives, the rates are smaller, suggesting that disease risks became smaller as the degree of consanguinity decreased, as expected if a genetic component explains the etiology of the disease.

4 Unipolar Affective Disorder

Most family studies have shown familial aggregation in UPAD, which favors a genetic component. The familial rates of UPAD averaged 6.5%–22% in relatives of probands with UPAD. In most studies, the relatives of UPAD patients had a higher lifetime prevalence of UPAD compared with the prevalence in the relatives of normal controls (around 6%). Early on, Leonhard (1959) and the Berlin School proposed the differentiation between bipolar and unipolar subtypes in mood disorder. Indeed, results of most family studies suggest that BPAD and UPAD have different genetic etiologies (Gershon et al. 1982; Perris 1968; Mendlewicz 1988;

Table 2. Estimated morbid risks in healthy subjects having relatives with bipolar affective disorders (BPAD), unipolar affective disorder (UPAD), and schizophrenia

	BPAD[a] (%)		UPAD (%)		Schizophrenia (%)	
	Range	Median	Range	Median	Range	Median
Monozygote twins	50–92.5	69.3	50	–	33–78	48
Dizygote twins	15–38.5	20	15–20	20	10–28	15
One affected parent	15–30	30	15–20	20	2–13	12
Two affected parents	50–75	75	40–50	50	40–50	40
Sibling	15–25	25	10–20	20	8–18	10
Parent second degree	3–7	7	3–5	5	3–5	4
General population	0.2–2	–	4	–	0.2–2	1

Adapted from Feinberg (1994) and from Gottesman and Shields (1982).
[a]The table provides the estimated risk of a healthy subject to develop BPAD if that subject has a relative (one or both parents, sibling) with BPAD.

Winokur et al. 1995). Table 1 shows the MR associated with each disorders. First, relatives of unipolar probands had no significantly elevated risk for BPAD (0.6%–3%) compared with controls (0.2%–2%), suggesting that the majority of unipolar probands are genetically distinct from BPAD (Andreasen et al. 1987; Winokur et al. 1995; McGuffin and Katz 1989). Second, as previously mentioned, family studies have consistently showed that bipolar patients have a greater genetic loading for affective disorder than the unipolar ones.

On the other hand, reports of discordant MZ pairs in which one individual developed BPAD while the other developed UPAD suggested that, in some instances, the same genotype can lead to both forms of the disease (Perris 1974; Bertelsen et al. 1977). Some UPAD patients can be misclassified and their illness can develop into BPAD, which can explain this discrepancy. This implies a different age at onset of disease for such MZ pairs, suggesting other vulnerability factors in addition to genetic ones. Moreover, a strong tendency for twin pairs to also be concordant for the affective illness type (UPAD or BPAD) was observed in one of the largest twin studies on affective disorder (Bertelsen et al. 1977). In addition, a higher concordance rate for MZ probands with BPAD (79%) was observed compared with MZ probands with UPAD (54%), also showing the greater genetic loading of the BPAD form of the disease.

Familial genetic differences in MR between early- and late-onset forms of unipolar illness were also observed. UPAD patients with early-onset disease had a greater familial morbidity for depression, alcoholism, and sociopathy than those with late-onset disease (Mendlewicz and Baron 1981). An excess of unipolar depression was also observed in female relatives of early-onset unipolars when compared to late-onset probands, regardless of the proband's sex.

The hypothesis of the "depression spectrum disease," a subtype of major depression characterized by families in which male relatives are alcoholic and females are depressed, originated from family studies (Winokur et al. 1971). Although independent family studies yielded negative results (Merikangas et al. 1985), an adoption study recently reexamined the hypothesis (Cadoret et al. 1996). Major depression in female was predicted by an alcoholic diathesis only when combined with a disturbed adoptive parent variable. This suggests that gene–environment interaction can be an etiologic factor in the depression spectrum disease. These interactions will be further discussed below.

The clinical and etiological heterogeneity of UPAD (Kupfer et al. 1975; Weissman et al. 1986b) represents a major difficulty when studying genetic aspects in UPAD, either at the epidemiological or the molecular level. Some patients can be correctly classified as having UPAD according to the DSM-IV classification system after a second episode of major depression following major stressful events. Whether all these patients represent "true genetic cases" is uncertain. On the other hand, no significant difference in familial aggregation was observed between "endogenous" and "nonendogenous depression" (Weissman et al. 1986; Andreasen et al. 1986; McGuffin et al. 1988). Interestingly, an increased risk of depression and of life events was observed in relatives of depressed probands (McGuffin et al. 1988). However, no significant association between life events and depression was observed, suggesting shared familial factors that predispose to both conditions. Although these results argue against the acceptance of earlier classifications of depression into "endogenous" and "reactive" subtypes, they cannot discard the concept of "endogenous depression." Indeed, family data is only one method of validating a classification system.

5 Schizophrenia

The presence of familial aggregation in schizophrenia was confirmed by Kendler et al. (1985). Schizophrenia was significantly more prevalent in 723 first-degree relatives of schizophrenic probands as compared to the first-degree relatives of 1056 surgical controls. Table 2 summarizes the estimated risks for relatives of schizophrenic probands. From Table 2, it is tempting to conclude that a higher difference in MR is observed between sibs and parents of schizophrenic probands than in those of probands with BPAD and UPAD. However, this difference may be related to a statistical artifact. Schizophrenia is associated with a marked reduction in reproductive fitness, and parents are therefore underrepresented, reducing the "risk" of illness in parents as compared with siblings and offspring of affected individuals (Essen-Moller 1955; Kendler et al. 1993). Family studies can examine whether the clinical manifestations of schizophrenia are correlated in affected sibling pairs. Global course, outcome, and all major symptoms except hallucinations were modestly, but significantly correlated in 256 sibling pairs concordant for DSM-III-R schizophrenia (Kendler et al. 1997).

Genetic studies suggest that there is a spectrum of disorders which could be similar to schizophrenia and could share the same genes. These disorders have been referred to as the "schizophrenia spectrum disorders." A recent large study has refined the boundaries of this spectrum. A total of 384 psychotic patients, 150 controls, and 1753 relatives were analyzed in the Roscommon family study (Kendler et al. 1993). The risk of developing schizophrenia was found to be higher in the relatives of probands with schizophrenia, but also in relatives affected with SA disorder, schizotypal and paranoid personality disorders, and other nonaffective psychotic disorders.

Family, adoption (Kendler et al. 1981, 1982), and twin studies (Torgersen et al. 1993) have documented the increased prevalence of schizotypal personality disorder among the biologic relatives of schizophrenic patients (Tsuang and Faraone 1994). Considering these studies, this disorder may be viewed as a milder form of schizophrenia. However, in the study by Kendler (1993), as in some previous family studies, schizotypal probands were hospitalized in psychiatric institutions. These patients may thus represent a sample of individuals biased in the direction of a familial relationship with schizophrenia.

The validity of Kraepelin's division into two major groups (dementia praecox/schizophrenia and manic-depressive illness) has been frequently challenged. Genetic studies offer the opportunity to investigate the overlap between these disorders and to evaluate the validity of Kraepelin's system. Most recent studies support this view (Kendler et al. 1993). Schizophrenia and the BPAD disorders were also transmitted independently in a recent study on 559 probands and 2845 relatives (Maier et al. 1993). However, schizophrenia probands had an increased familial risk for UPAD, indicating a familial relationship between the predisposition to schizophrenia and to major depression.

A review of the literature on twins revealed that a higher concordance rate was observed in all studies in MZ twins than in DZ twins with schizophrenia (Kendler 1983). Concordance rates varied from 18% to 28% for DZ twins and from 33% to 78% for MZ twins. Although the differences in concordance rates were larger in the earlier studies, a significant difference between MZ and DZ twins has still been observed in the more recent ones, suggesting a role for genetic factors in their etiology. However, using new methodological standards, the concordance rate for MZ twins remains under 50% (Onstad et al. 1991), suggesting interaction with other vulnerability factors. Gottesman and Bertelsen (1989) studied offspring of twins recruited from the Danish survey (Fischer 1973). Interestingly, the MR for schizophrenia of offspring of affected MZ twins (16.8%) was close to that of unaffected MZ co-twin's offspring (17.4%). Regarding offspring of discordant DZ twins, the MR were 17.4% for the affected DZ twin and 2.1% for the unaffected co-twin. Taken together, these data favor the hypothesis of an incomplete expression of a predisposing genotype in schizophrenia. A number of recent studies have also been designed to analyze discordant MZ pairs in order to explore developmental or environmental problems, such as maternal infections and obstetric complications (Davis and Bracha 1996). Such efforts might clarify nongenetic influences (Mednick et al. 1994) in the etiology of severe psychiatric disorders.

Large-scale adoption studies are available in schizophrenia. The extension of the Danish adoption study of schizophrenia throughout Denmark (Kety et al. 1994) confirmed the significant concentration of chronic schizophrenia (9.9%) and "latent schizophrenia" (5.7%) in the biological relatives of chronic schizophrenic adoptees as compared to adoptive relatives of schizophrenic adoptees and of normal controls. This suggests the presence of heritable genetic factors in the susceptibility to schizophrenia.

"Vertical cultural transmission" is a nongenetic factor that could explain the presence of familial aggregation in a behavioral syndrome such as schizophrenia (Kendler 1983). Vertical cultural transmission implies that a given characteristic is "learned" by the offspring from their parents. Adoption studies can provide insights on this issue. Hence children of schizophrenic parents reared by nonschizophrenic

adoptive parents should have a lower risk for schizophrenia if this form of transmission is operating in the etiology of the disease. Moreover, children of a nonschizophrenic biologic parent reared by an adoptive schizophrenic parent should have a higher risk for schizophrenia.

Although most adoption studies suggested that simple vertical cultural transmission is not likely to play a major role in schizophrenia (Kendler 1983), some of them suggested gene–environment interaction in the development of the disease. Tienari et al. (1994) observed a significantly higher rate of both psychosis and other severe diagnoses such as severe personality disorders when studying 155 offspring of schizophrenic patients compared to 186 matched control adoptees. Interestingly, notable differences between these two groups emerged only in the families rated as disturbed, suggesting gene–environment interaction.

Studies on the transmission mode of schizophrenia were well reviewed by Baron (1986). The two main transmission hypotheses are the SML and the multifactorial polygenic model. A mixed model with an SML transmission with a polygenic background is also compatible with the data (Risch and Baron 1984). Further segregation analyses using large sample size in order to test this polygenic model of inheritance are awaited. Several chromosomal regions may play a role in the etiology of schizophrenia, including genes on chromosomes 5, 6, 11, and 22 (Gurling 1996).

6 Schizoaffective Disorder

It is now well established that genetic factors are involved in the etiology of SA disorder (Zerbin-Rüdin 1988). The concept and diagnostic criteria of SA have varied tremendously during the two past decades, being either closer to the criteria for schizophrenia or to those for affective disorders. Family, twin, and adoption studies have thus generated variable results, mostly due to changes in diagnostic criteria. Although results from family, twin, and adoption studies are divergent, most support a separate classification of broadly defined SA psychoses as possibly being phenotypical variations or expressions of genetic interforms between schizophrenia and affective psychoses (Mendlewicz et al. 1980; Endicott et al. 1986; Bertelsen and Gottesman 1995). Molecular studies will hopefully determine whether SA disorders are separate entities or subtypes of affective disorders and schizophrenia. Meanwhile, it seems most appropriate to retain SA disorder as a distinct syndrome (Bertelsen and Gottesman 1995).

The overall lifetime risks for affective illness in first-degree relatives were investigated in a cohort of 172 probands and 1254 relatives (Gershon et al. 1982). Lifetime prevalences of major affective disorder (including BPAD, UPAD, and SA) were higher in relatives of probands with SA (37%), BPAD type I (24%), BPAD type II (25%), and UPAD (20%) compared to relatives of normal controls (7%). The highest overall MR of affective disorders was thus found in relatives of probands with SA, supporting the concept of SA disorder as a variant and genetically virulent form of affective illness (Tsuang et al. 1977; Gershon et al. 1982).

A model using a continuum of vulnerability factors was developed by Reich et al. (1975) in which the vulnerability of affective disorders is viewed as linear. In this model, SA disorder is expressed when vulnerability is the highest, BPAD when vulnerability is lower, and UPAD at a still lower threshold value. However, we and others (Shopsin et al. 1976; Rice et al. 1987; Winokur et al. 1995) have not reproduced these results, and the notion of a continuum of vulnerability factors remains controversial.

Similarly, probands with SA disorder had more schizophrenic first-degree relatives than other probands, which also suggests a relationship with schizophrenia (Mendlewicz et al. 1980; Gershon et al. 1982). In summary, a significant familial aggregation is observed between SA disorder and either BPAD or schizophrenia, while little familial aggregation is present between BPAD and schizophrenia. In addition, some studies suggest that SA disorder (bipolar subtype) may be more related to pure affective disorder, while SA disorder (depressed type) may be closer to schizophrenia (Andreasen et al. 1987).

7 Anticipation and Major Psychiatric Disorders

Segregation analyses in families with affective disorder and schizophrenia have not proved beyond doubt the SML or polygenic model of inheritance. Other complex modes of inheritance have been investigated in these disorders. A potential mode of inheritance is related to the concept of anticipation. Anticipation implies a progressively earlier age of onset and increased severity of disease in successive generations. It may explain the deviations from the mendelian inheritance pattern observed in some heritable diseases.

The phenomenon of anticipation has been observed in several neurological diseases such as myotonic dystrophy, fragile X syndrome, and Huntington disease (Fischbeck and Paulson 1996). Anticipation in these disorders has been correlated to specific mutations: expansion of a trinucleotide repeat sequence. These sequences are unstable and may expand in size within family members when transmitted from one

generation to the other, thereby increasing the severity of the disorder.

An exciting development in psychiatry research has been initiated by the emergence of studies assessing anticipation in psychiatric disorders. Several studies described anticipation in schizophrenia (Thibaut et al. 1995), although the study by Asherson et al. (1994) provided less conclusive results. Anticipation was also described in bipolar spectrum disorder (McInnis et al. 1993). However, this study included a wide definition of the phenotype of the 34 pairs studied, grouping together bipolar, unipolar, SA disorder (manic type), and major depressive disorder (single episode). Since the median age at onset in these four disorders differs widely, it is questionable whether these phenotypes can be compared through different generations.

Anticipation was described in 16 BPAD–BPAD pairs (Nylander et al. 1994) and in 16 UPAD–UPAD pairs (Engström et al. 1995). A total of 62 BPAD–BPAD pairs and 48 UPAD–UPAD intergenerational pairs were analyzed in a larger study on affective disorders involving 340 affectively ill patients recruited from 53 families. Changes in age at onset and episode frequency between generations consistent with anticipation were observed (Lipp et al., submitted).

However, it is not yet possible to conclude that true anticipation is present in mood disorders and schizophrenia because of various selections biases that could arise in such studies (Penrose 1948). Nevertheless, the clinical observation of anticipation in mood disorders and schizophrenia has prompted the search for dynamic mutations such as CAG repeats. We and others have observed an association between CAG repeats detected by the repeat expansion detection (RED) method and BPAD illness (Lindblad et al. 1995; O'Donovan et al. 1996). Moreover, we have recently observed a significant trinucleotide CAG repeat expansion between parental and offspring generation when the phenotype changed in severity from major depression (single episode) or UPAD to BPAD (Mendlewicz et al. 1997). These reports provide preliminary evidence for the implication of such mechanisms in the etiology of BPAD.

8
Genetic Factors and Other Aspects of Mental Disorders

8.1
Anxiety Disorders

It has been suggested that genetic factors are involved in the pathophysiology of anxiety disorders. A greater risk of developing anxiety disorders in first-degree relatives of patients with panic disorder has been observed in family studies (Crowe et al. 1983; Mendlewicz et al. 1993). Conversely, no increased familial loading was found for generalized anxiety disorder in probands with panic disorder (Noyes et al. 1987). These results validate the concept of generalized anxiety disorder as being an illness distinct from panic disorder. It also supports the hypothesis of a genetic contribution to predisposition to panic disorder. However, a twin study examining anxiety disorders came to a different conclusion (Skre et al. 1993). In a sample of 20 MZ and 29 DZ co-twins of probands with anxiety disorder, the prevalence of anxiety disorders was compared. For both panic disorder and generalized anxiety disorder, the MZ–DZ concordance ratio was more than 2:1. From these results, it may be concluded that a genetic contribution is likely to be present in both disorders. Clearly, more work needs to be done using larger sample sizes to evaluate the genetic contribution in generalized anxiety disorder and to define its relationship with panic disorder.

8.2
Obsessive–Compulsive Disorder

In several twin studies, the concordance rates for OCD ranged from 53% to 87% for MZ twins and from 22% to 47% for DZ twins, depending on the sample and the diagnostic criteria (Pauls et al. 1995). The diagnostic criteria and methodology of assessment of OCD were not properly established until the beginning of the 1990s. Interpretation of family studies performed before this era may therefore be misleading. None of the ten family studies of OCD reviewed by Black et al. (1992) used standardized assessments, a control group, and a blind data collection together. The paper by Black and colleagues reported the results of a study using new methodological standards of family studies, but no significant increase in MR of OCD in relatives of OCD probands was observed. However, the risk for a more broadly defined OCD (including relatives with obsessions and compulsions not meeting criteria for OCD) was increased among relatives of OCD probands.

Conversely, the recent family study by Pauls et al. (1995) on 100 probands and 466 relatives, using DSM-II-R and the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) severity criteria, showed familial aggregation in OCD. The MR for OCD was significantly higher in OCD probands (10.3%) than in normal controls (1.9%). Data collection used all available information (both direct interview and multi-informant family history information), something which was not done by Black and colleagues (1992) and may explain their

negative result. On the other hand, investigators in the paper by Pauls et al. (1995) were not blind to the proband's diagnosis. Further family studies will be needed in order to legitimate familial aggregation in OCD.

8.3 Alcoholism and Substance Abuse

The concordance in diagnosis of alcoholism was 26% in MZ twins and 12% in DZ twins in a large sample of 715 male twins (Hrubec and Omenn 1981). Using two different types of statistical models, a segregation analysis was reported in 35 multigenerational families with alcoholism (Yuan et al. 1996). The hypothesis of an SML with strictly mendelian transmission was rejected. This analysis suggested a major effect with or without additional multifactorial effects.

Drug abusers without antisocial personalities were more likely to have a biologic parent with a background of alcohol problems, as shown by the adoption studies carried out by Cadoret et al. (1995). This suggested the possibility of two genetic pathways to drug abuse/dependency, one starting with alcoholism in biologic parents and the other from an antisocial biologic parent, proceeding through aggressive variables of adoptees such as conduct disorder and eventually ending in drug abuse/dependency.

8.4 Personality Disorders

Assortative mating, clinical heterogeneity, uncertain validity of phenotypes described by diagnostic criteria, and poor interrater reliability in assessing most personality disorders hamper genetic epidemiological studies. Despite these limitations, new data favor the involvement of genetic factors in some personality disorders. A weighted mean pairwise concordance rate for adult criminality of 51% in MZ twins and 22% in DZ twins was observed in seven twin studies pooled together (McGuffin and Gottesman 1985). As previously mentioned, results of adoption studies suggest a role for genetic factors in antisocial behavior (Cadoret et al. 1995). Furthermore, there is increasing interest in genetic research for dimensional aspects of personality traits (Cloninger et al. 1987). An association between characteristics of temperament (novelty seeking) and the seven-repeat allele in the locus for dopamine receptor D4 gene (DRD4) has been observed in a group of 124 unrelated Israeli normal subjects (Ebstein et al. 1996), a finding replicated by Benjamin et al. (1996).

8.5 Suicide

The role of genetic factors in transmitting suicidal behavior has been documented in twin (Juel-Nielsen and Videbech 1970), adoptees (Schulsinger et al. 1979), and family studies (Egeland and Sussex 1985). In the Amish population study, 26 suicides have been reported (Egeland and Sussex 1985). The majority of these cases (92%) were diagnosed with a major affective disorder and were situated in multigenerational families with heavy loading for BPAD, UPAD, and other affective spectrum illnesses. It is worth noting that, in other Amish families, in spite of a strong genetic loading for affective disorder, suicidal behavior was not expressed. Furthermore, liability to suicidal behavior might be transmitted familally as a trait independent of axis I and II disorders (Brent et al. 1996). These studies have provided evidence of genetic factors in both suicide and affective disorders. The distribution of depressed patients with a lifetime history of attempted suicide was also compatible with a polygenic inheritance of suicidal behavior (Papadimitriou et al. 1991). An association between tryptophan hydroxylase polymorphism and suicidality was observed (Nielsen et al. 1994). This observation was, however, not replicated (Abbar et al. 1995).

8.6 Dementia

Although results of family studies have suggested the implication of genetic vulnerability factors in the etiology of Alzheimer's disease, these studies are difficult to carry out in such disorders. The final diagnosis of Alzheimer's disease requires histopathological confirmation, the mean age at onset is very late, and the validity of the family history method is very low (Heun et al. 1996), which all constitute limitations in genetic studies. Nevertheless, it is estimated that 25%–40% of cases of Alzheimer's disease are familial, i.e. with at least one other case of dementia in the family (Van Broeckhoven 1996). Moreover, large families have been identified in which the disease was transmitted through several successive generations. Results of twin studies are rather inconsistent (Nee et al. 1987). Hence, further twin and adoption studies are required in order to separate genetic and environmental endowments in dementia. Using molecular genetic studies, four genes have been identified that predispose to Alzheimer's disease on chromosome 1, 14, 19, and 21 (Van Broeckhoven 1996).

9 Gene–Environment Interaction

The etiology of mood disorders is likely to be multifactorial, and both genes and environment may have a pivotal role as etiologic or risk factors. Indeed, several studies have pointed out the role of environmental and psychosocial factors in the pathogenesis, onset, and outcome of these diseases (Bauwens et al. 1991; Pardoen et al. 1993). Environmental factors may also include biological factors such as infections, which may affect gene expression. However, the precise contribution of genetic and environmental factors to disease etiology is not yet firmly understood in psychiatric disorders, and nor is the way in which these factors may interact.

How genes and environmental risk factors interact to produce a disease is a very complex task to investigate. True gene–environment interaction requires variations in both the environment and the genetic predisposition. So far, most of the published literature has used an "additive" model, in which genetic and environmental factors combine to produce a disease. There is, however, growing evidence that other models should be considered (Kendler and Eaves 1986). In a second model, genes do not directly alter the probability of illness. Rather, they control the degree to which the individual is sensitive to the risk-increasing or risk-reducing aspects of the environment. In this model, one allele conveys sensitivity and another one insensitivity to the environment.

In a third model put forward by Kendler and Eaves, genes control exposure to the environment. For instance, a gene can produce personality traits such as impulsiveness, personal stability, and frustration tolerance. The likelihood that this individual will experience more life events (predisposing environment) such as job and relationship changes is higher. This gene can thus predispose an individual to depression, but only by increasing its chance of experiencing life events. Moreover, to add to this complexity, genetic effects can result from the interaction of several loci, and the environmental effects are likely to be more complicated than being either "protective" or "predisposing."

The quantitative aspects of psychosocial or environmental factors can confer an advantage for genetic studies. Diseases such as hypertension and coronary heart disease are characterized by multiple intermediate quantitative traits or risk factors that are likely to play important roles in the susceptibility of individuals to develop such illness (Moldin 1994). Such quantitative traits are correlated with liability to affection and provide much more information than grouping individuals into affected or unaffected classes.

None of the molecular genetics studies performed so far has properly taken into account psychosocial factors. This prompted the elaboration of a large collaborative project investigating gene–environment interaction (BIOMED: EC Concerted Action on Affective Disorders: Interaction Between Genetic and Psychosocial Vulnerability Factors, led by J. Mendlewicz). The quantitative effects of certain relevant psychosocial vulnerability factors, such as social adjustment, the level of self-esteem, and other dimensional aspects of personality, on gene expression are evaluated through association, sib-pair, and linkage analyses. To verify the gene–environment interaction hypothesis, a model testing the relationship among selected variables, genes, and psychosocial factors has been defined. A specific statistical approach, defined as structural equation modeling (SEM) (Neale and Cardon 1990), will be used in order to test the validity of the model.

10 Future Research

Improved clinical strategies are needed to carry out genetic studies in psychiatry in order to minimize problems arising from clinical heterogeneity. New epidemiological genetic studies should focus on clinical definitions of major psychiatric disorders. Unreliability is often viewed as a major problem in psychiatric diagnosis, but this might be overestimated (Kringlen 1993). A criteria-based diagnostic system such as DSM-IV or ICD-10 can lead to reliability or agreement between clinicians. The central problem is, however, validity. How true or meaningful are these diagnostic classifications? These classifications have not solved the problems of clinical heterogeneity, and they inevitably lead to the inclusion of phenocopies.

The relationship between SA disorder, schizophrenia, affective disorders, and personality traits such as schizotypal personality disorder should be further investigated. The border between the "schizophrenia spectrum" and the "bipolar spectrum" has to be further refined. This is mandatory, since molecular linkage analyses need to specify the affected status of each family member. Hence a wrong specification of the affected or unaffected status limits the power of any linkage analysis. Inclusion of phenocopies as "genetic cases" in linkage analysis weakens the evidence for linkage. The exact mode of transmission is still unknown in the majority of psychiatric disorders. Misspecification of the genetic parameters of the phenotype may also lead to errors in linkage studies (Ott 1991). Segregation analyses using a large sample

size to test the polygenic model of inheritance still need to be performed.

Finally, genetic epidemiological studies have been traditionally used to validate nosology, diagnostic criteria, or classification. These methodologies will be useful to validate new proposed diagnostic categories (DSM-IV) such as premenstrual dysphoric disorder, simple deteriorative disorder (simple schizophrenia), and binge-eating disorder. The overlap between these new proposed diagnostic categories and depression, schizophrenia, affective disorders, and eating disorders can also be well analyzed by family, twin, and adoption studies.

Investigation of gene–environment interactions is one of the most promising areas dealing with complex and multifactorial diseases such as psychiatric disorders. Elaboration of new dimensional instruments to assess behavioral quantitative traits of psychiatric disorders, personality, and environmental factors should be a primary goal in order to refine the next generation of linkage, sib pair, and association studies. Gene–environment interactions need to be further investigated in large-scale collaborative epidemiological and molecular studies.

11 Conclusion

Strategies such as family, twin, adoption, and segregation studies have been the main source of genetic epidemiologic data in psychiatric disorders. These strategies have consistently demonstrated the implication of genetic vulnerability factors in the etiology of major psychiatric disorders. The results have prompted a fascinating worldwide effort to map the genes involved in these diseases. Furthermore, findings from genetic epidemiological studies, such as segregation data compatible with a sex-linked inheritance in some families or anticipation in BPAD and UPAD, have generated interesting molecular testable hypotheses. Hence genetic epidemiologic studies should remain in the forefront of genetic research, since they provide the rationale and clues for molecular research.

CHAPTER

4

M.C. O'Donovan, P. McGuffin

New Approaches and Findings in the Molecular Genetics of Major Mental Disorder

1 Introduction

The relatively new disciplines of molecular genetics and molecular biology have revolutionized the study of biology and medicine, and at least a passing familiarity with these subjects is now a requirement for reading and comprehending the contents of almost any major biomedical journal. Every week, disease genes are mapped or identified, and it is expected that in the near future this plethora of positional and structural genetic information will be translated into detailed functional data that will unravel the aetiology of otherwise poorly understood diseases and ultimately lead to improvements in their treatments.

After a period of false optimism in which dramatic (but ultimately unfounded) claims were made about the mapping of major genes for schizophrenia and bipolar disorder, psychiatric genetics is also now on the threshold of major advances as a result of the application of new paradigms, molecular techniques and statistical methods. In this chapter, we present a guide to the theory and rationale behind the most common approaches in molecular genetics and illustrate their utility, giving examples from studies of schizophrenia and bipolar disorder.

2 From Genotype to Phenotype

Until relatively recently, molecular genetic research was mainly concerned with observable characteristics (phenotypes) with simple patterns of transmission in which there is a straightforward relationship between genetic endowment (genotype) and phenotype. For example, if a single copy of a mutation in one gene is sufficient to cause disease, then inheritance is dominant, but if both copies of a gene are required to carry a mutation for a phenotype to be observed, then transmission is recessive. Huntington's disease and phenylketonuria are, respectively, classical examples of dominant and recessive traits of psychiatric relevance. Sex linkage represents a further form of simple transmission, complicated by the fact that males only have a single X chromosome, which is always transmitted by the mother, and females carry two copies of the X chromosome, one of which is largely inactivated.

While there are numerous examples of simply transmitted phenotypes, most common familial diseases (e.g. heart disease, diabetes, arthritis, asthma, inflammatory bowel disease and most psychiatric disorders) display more complex patterns of transmission. The expression of these phenotypes may require the inheritance of mutations within a small number of genes (oligogenic inheritance), numerous polymorphisms within numerous genes (polygenic inheritance) or a combination of both DNA variation and environmental factors (multifactorial inheritance). Common diseases may well display a mixture of the above. Thus there may be uncommon forms of a disease that are caused by single genes, some by the action of a few genes and others by a combination of a few genes of moderate effect operating in a multifactorial background. Under these circumstances, the concept of genetic susceptibility to disease is more useful than that of simple genetic causation.

3 From Phenotype to Genotype

The ultimate goal of molecular genetics is a complete understanding of the molecular basis of phenotypes, but the first task is to establish the precise nature of the DNA sequence variation responsible. Since this may be simply a single base pair change out of the 6×10^9 base pairs in the human diploid genome, this is a daunting task. The task may be simplified by clues offered by an association between gross chromosomal abnormalities and the phenotype, but commonly no such clues are available. Under this circumstance, the challenge is to identify pathogenic or susceptibility sequences purely on the basis of their map positions in the genome. The power and appeal of this approach, called positional cloning, lies in the fact that disease genes can be identified and their functions dissected even where the pathophysiology of the disease is completely unknown.

Although there are variations in detail, the first step in positional cloning is to identify the approximate chromosomal location of the disease genes by linkage analysis. Once this has been achieved, the region is narrowed to a more manageable size using more detailed linkage analysis or linkage disequilibrium methods. Finally, the genes that map within this relatively small area are identified and their sequences scanned for variations that may be responsible for the phenotype. These approaches will be described in more detail below.

4 DNA Markers

DNA markers have largely replaced the classical genetic markers (e.g. ABO blood typing) that were first used in human linkage and association studies. DNA markers are sequences with a defined map

position in the genome which show common sequence variation (polymorphism) in the general population. At present, the most commonly used markers are di-, tri- or tetranucleotide repeats, also known as simple sequence repeat markers which consist of a repetitive sequence, e.g. the dinucleotide CA, flanked by a known specific sequence. Such simple sequences often display allelic variation in the number of repeats units, e.g. a particular marker may have four possible alleles containing 16, 17, 18 or 19 repeats. Although in the past it was a cumbersome business, measurement of repeat number can now be relatively easily performed using the polymerase chain reaction (PCR), which allows chosen sequences of DNA to be amplified to detectable amounts. The size of the PCR products, and hence the number of repeat units, can then be simply determined by its relative mobility during size fractionation by electrophoresis in a gel matrix.

5 Recombination and Linkage

During meiosis, recombination events result in independent segregation of *most* of the genome, and this applies even to sequences on the same chromosome. However, within limits, the probability that a recombination event will occur between two markers is roughly proportional to the physical distance (in base pairs) between the markers, and it follows that markers located close to each other will not be randomly separated by recombination. Such markers will therefore tend to be inherited together, deviating from the law of independent segregation. This tendency for co-inheritance is called linkage. The approximate relationship between physical distance and recombination frequency gives rise to the concept of genetic distance, which is usually expressed in centimorgans (cM). A genetic distance of 1 cM between two markers means that they are separated in one meiosis out of 100, which corresponds to a physical distance of approximately one million base pairs.

From the discussion so far, it should be apparent that, in general terms, the shorter the distance between two markers, the greater the tendency for their co-inheritance and the tighter the linkage between them. However, there are limits to this principle. Recombination occurs between homologous chromosomes when they exist in a quadruple structure (after DNA replication, each chromosome is duplicated into pairs of chromatids "pinched" in at the centre) and only involves one of the pairs of chromatids for each chromosome. Therefore, the maximum recombination frequency that can be observed is 50%, because there will also be a non-recombinant copy to be transmitted, even if markers are separated by such a large distance that at least one recombination event will always take place between them. Another source of discrepancy between genetic and physical distance occurs because some chromosomal regions have greater or less than average tendencies for recombination. Markers flanking these regions will therefore be separated by genetic distances that are respectively greater and less than would be expected by their physical separation. Similarly, recombination events are more common in the female than the male germline, although the physical size of the chromosomes do not differ.

The principles of genetic linkage apply readily to simple traits exhibiting classical patterns of inheritance, because the simple transmission patterns make it easy to infer the presence or absence of the (as yet unknown) disease genotype from the phenotype. Disease and non-disease status can therefore simply be treated as different alleles of a genetic marker, and the task is then a simple one of finding mapped markers (i.e., markers of known position in the genome) that are co-transmitted with disease status more often than by chance in large pedigrees with multiple affected members.

In practice, it is possible to systematically map a dominant disease gene fairly rapidly and surely by linkage using an evenly spaced set of as few as 200 genetic markers about 20 cM apart covering the whole genome, since the sex-averaged genome length is approximately 3700 cM.

However, there are problems of simply applying linkage to complex traits with unknown modes of inheritance such as schizophrenia or manic depression. The method is most powerful when there is a simple causal relationship between the presence of a disease mutation and a phenotype. However, if only *susceptibility* to disease is transmitted, an individual may well inherit the susceptibility mutation and its linked genetic marker, yet never express the disease. Alternatively, in the absence of a test to determine susceptibility prior to the onset of disease, an individual at the time of study may be rated as unaffected only to become affected several years later. In the face of genetic heterogeneity, even if genes of fairly large effect do exist, different families may transmit disease genes on different chromosomes. All these factors conspire to create errors in the inference of genotype and therefore make it much more difficult to detect linkage.

The obstacles described above can be partly addressed by computer programmes for linkage analysis if the mode of inheritance is approximately known and if there are genes of at least moderate effect involved. However, if the mode of inheritance of the disease being studied is unknown, the factors above cannot be accurately controlled for and this leads to significant loss of power. This is particularly

problematic in studies of large pedigrees with affected individuals in multiple generations, because errors of inferred genotype made in one generation have a cumulative effect on the analysis of subsequent generations. The effect can be so severe that a change in diagnosis of a relatively small number of individuals can drastically reduce the evidence favouring linkage.

Because of these problems with classic linkage approaches, researchers investigating complex traits are turning their attention to smaller families. In this approach, linkage is detected by the transmission of a marker allele to pairs of affected siblings more often than expected by chance. This overcomes the problem of individuals that are currently unaffected yet destined to become affected; in addition, there is no knock-on effect in further generations, and smaller genetic effects can be detected. These features make this type of so-called affected sib-pair analysis more robust to diagnostic error than large pedigree approaches. More importantly, affected sib-pair methods are robust to misspecification of the mode of transmission. Furthermore, it can be argued that families with two affected individuals are more typical of complex diseases such as schizophrenia and bipolar disorder than large multi-generational families with multiple affected individuals. Therefore, the results obtained by studying affected sib-pairs may be more generalizable to the aetiology of the diseases. The main disadvantage of this approach is that it is much less powerful than classical linkage analysis when it comes to detecting genes of major effect that segregate in a mendelian fashion.

6 Linkage Disequilibrium

The apparent success of newer, more robust linkage methods in mapping disease genes that contribute to complex traits such as diabetes, asthma and multiple sclerosis gives cause for optimism that the approximate map positions of genes conferring susceptibility to major mental disorders will soon be known. However, because of the difficulties discussed above, it will be difficult to firmly establish fine mapping by linkage. Indeed, it is likely that regions defined by linkage studies for most complex traits will be so large that they may contain hundreds or thousands of genes (Schuler et al. 1996), and it is therefore essential to obtain a more precise localization before targeting individual genes for analysis.

Currently, the best solution to this problem takes advantage of the phenomenon of linkage disequilibrium. When two loci map within a small chromosomal region, they are only infrequently separated by recombination during meiosis. Because of this limited genetic shuffling, a small chromosomal segment surrounding the disease mutation is likely to contain a non-random distribution of marker alleles. Consider a marker system containing two alleles A_1 and A_2, each of which is present with a population frequency of 0.5 (i.e. 50% of chromosomes carry A_1 and 50% A_2). Subsequently, a disease mutation occurs on a chromosome at a genetic distance from the marker allele A_1 such that it is only separated by 1 cM. Because the mutation is so close to the marker, even after many generations most chromosomes carrying the pathogenic mutation will also carry marker allele A_1, which will therefore in turn be more common in affected individuals than the allele frequency of 0.5 in controls. This phenomenon, known as linkage disequilibrium, can therefore be detected in genetic studies as a difference in allele frequencies between patients and controls. Because the two loci must be positioned closely to each other for disequilibrium to last long in the population, this approach allows a much more precise localization than linkage. Why then undertake linkage studies at all? The answer is that the very property of linkage disequilibrium that allows precise mapping also means that linkage disequilibrium cannot be detected at large distances. Therefore, if the candidate region is not previously defined by linkage, a very dense marker set probably containing at least 2000 markers would be required to screen the genome. While such a map exists, the labour involved in genotyping is staggering, although this may soon be surmountable using DNA pooling. Pooling strategies allow DNA from perhaps up to 1000 individuals to be mixed and subjected to PCR in a single tube. The relative abundance of each PCR product then reflects the allele frequencies. Although there are still technical challenges, when these are overcome, the improvement in throughput will certainly make genome-wide linkage disequilibrium studies feasible.

A common problem that confounds linkage disequilibrium studies is that the control group and the sample of affected individuals must be tightly ethnically matched, because allele frequencies may vary dramatically between populations. This is called population stratification and may lead to a false appearance of linkage disequilibrium simply because there is a systematic difference in the genetic background (and therefore the allele frequencies) of the patients and controls. To overcome stratification, an important advance in study design has been to use the parental genotypes of affected individuals as a control. Disequilibrium is now identified by the preferential transmission of a particular allele to affected individuals more often than would be expected by chance. This is tested statistically by the haplotype relative risk (the relative risk conferred by each haplotype) or by

the transmission disequilibrium test (Spielman and Ewens 1996). Since the parents are a perfect control for the genetic background, this approach removes population stratification as a confounder, but does of course increase the difficulty with which a large sample can be obtained because of the requirement to have living parents willing to participate.

7 Statistical Considerations

The application of statistics to linkage studies of simple traits is relatively straightforward. Most commonly, support for linkage is assessed by a measurement called the LOD score, which is a numerical value corresponding to the logarithm of the odds that the trait and marker are inherited in a pattern consistent with linkage versus independent transmission of trait and marker. In conventional studies, where the phenotype can be designated unambiguously and the mode of inheritance is fully known, a LOD score of 3 (or an odds ratio in favour of linkage of 1000 to 1) is considered as indicating that the evidence for linkage is firm. A LOD score of minus 2 (odds of 100 to 1 against linkage) is taken as evidence for exclusion of linkage. Although these odds ratios sound extremely conservative, they correspond to conventional significance levels following a genome-wide search. Thus a LOD score of 3 corresponds to a reliability of 95% that linkage is present.

For complex traits, the situation is much more uncertain. Inflated rates of false-positive results may occur because of the use of multiple diagnostic classifications (e.g. exploring the effect of a broad versus narrow definition of the disorder) and the exploration of multiple genetic models of transmission. The net effect of these is that a LOD score of 3 cannot be viewed as conservative evidence for linkage. How then can we decide whether linkage is significant or not? In the case of a single report, the LOD score should be greater than 3, although there is no consensus on exactly how much greater this should be (Lander and Kruglyak 1995). One solution is to undertake simulation computations to estimate how frequently LOD scores of any given value are likely to be observed by chance. However, irrespective of the LOD score results and the simulation data, until findings are independently replicated, all reports of linkage concerning complex diseases should be viewed as preliminary.

Affected sib-pair linkage studies are usually evaluated by the more familiar p value, where p is the probability that allele sharing in affected siblings has occurred by chance. Again, because of the low prior probability that any linkage observed is true, some authors advocate a very conservative p value of 0.00002 (Lander and Kruglyak 1995). However, even then, replication must be regarded as essential. In practice, many groups pursue much weaker evidence for linkage in the pragmatic hope that more significant values will be generated or that suggestive reports of linkage will be generated in a sufficient number of data sets to provide strong evidence for linkage. The requirement for replication, while necessary to avoid false-positive results, carries its own problems, because even relatively large studies carry low power to detect genes of small or modest effect. Furthermore, replication of a linkage finding where multiple loci are involved in general requires a replication sample that is much larger than that used in the original study. Therefore, even a string of failures to replicate a finding may be the result of type II error.

The statistical interpretation of linkage disequilibrium studies follows the same broad rules as for linkage. Highly stringent requirements are made for results to be viewed as significant, because the prior probability of any marker being in linkage disequilibrium is small. Again, all findings are provisional until replicated.

8 Positional Cloning – The End Game

After a manageable region of interest (approximately 10^6 bases or less) has been confirmed, the next step is to identify the specific sequence variations in that region that confer susceptibility to disease. A number of complementary strategies may be used. However, most first require the creation of a complete or almost complete representation of the candidate region as cloned DNA. In brief, DNA from the whole genome, a single chromosome or even a fragment of a chromosome is broken into fragments. These are then randomly inserted into "cloning vectors" that allow replication of the human fragment in a host organism, usually a bacterium or yeast. For example, genomic DNA may be cut or physically broken into pieces of approximately 10^6 bases in length, which are then randomly inserted into yeast artificial chromosomes (YACs). The YACs are then inserted into a host strain of yeast which replicates the human DNA along with its own. After many cycles of reproduction, each single yeast organism that received a YAC will have grown into a yeast colony containing many copies of that single YAC. The YAC DNA can then be extracted, yielding large amounts of that specific human DNA fragment for further laboratory manipulation. A number of cloning systems are available, each with their own advantages and disadvantages; for example, YACs

and bacterial artificial chromosomes (BACs) carry relatively large fragments of DNA. Intermediate sizes of DNA are carried by P_1 artificial chromosomes (PACs), cosmids and some phage, and relatively small fragments of DNA are carried by phage and plasmids. Phage vectors are derived from natural viruses that infect bacteria; plasmids are circular DNA inclusions that occur naturally in bacteria (conferring antibiotic resistance, for example); and cosmids are hybrids derived from plasmids and phage. All these vectors have been modified to allow replacement of some of the original vector DNA with human fragments, allowing insertion and replication of the vector-human recombinant in bacteria such as *Escherichia coli.*

The next step is to isolate a series of individual clones containing DNA fragments originating from the candidate region until the whole region of interest is represented in the test tube. In fact, the procedures briefly outlined here are highly complex, but several genome mapping centres have now established a series of overlapping clones representing an almost complete genome. In principle, therefore, a rough but imperfect representation of almost any candidate region can be ordered "by catalogue." There is, however, still a considerable amount of work required in putting together a map with fine enough resolution for the next phase of work.

Most of the genome has no known function and is sometimes referred to (perhaps erroneously) as "junk" DNA. The next stage therefore usually involves identifying the relatively small proportion of the DNA within the region which corresponds to genes and is transcribed to messenger RNA. Again, work in a number of centres is underway to establish a complete map containing the position of every human gene, and at present 16,000 of the total anticipated 50,000–100,000 genes have been mapped (Schuler et al. 1996). When this work is complete, it will be possible to identify all the genes within a candidate region by consulting a database. Until then, the human gene map can be supplemented by maps from other species using the phenomenon of synteny. Regions of synteny are large stretches of DNA in which the order and identity of genes is conserved between species despite major differences in the organization of their genomes. Therefore, if two genes are known to map to a candidate region in humans, and their map positions are conserved in a different species, e.g. mouse, a database of the mouse genome can be consulted to see whether there are any other genes within the syntenic mouse region which may also map to the candidate region for the human disease.

At present however, individual research groups must usually identify coding sequences from their own candidate regions. This is most commonly done by elegant techniques such as "exon trapping" or "direct cDNA selection." cDNA is DNA which has been synthesized from mRNA and therefore consists of relatively "junk"-free DNA. The detail of these methods is beyond the scope of this chapter, but briefly, in exon trapping, small genomic fragments from the candidate region are inserted into mammalian cells in a special cloning vector which allows the host cells to excise non-coding (intronic) sequences, while expressing the coding sequences (exons). In direct cDNA selection, fragments of genomic DNA are mixed in solution with cDNA synthesized from a tissue of interest. By base pairing, the cDNAs corresponding to the coding parts of a specific genomic DNA fragment adhere to it and can then be "fished" out of solution (Lovett 1994).

However identified, the next stage involves looking at affected individuals and controls for differences in the sequences of genes from the candidate region. The sequence of genes can be compared definitively by sequencing in patients and controls, but while this is technically feasible it is still laborious. Therefore, short-cut methods for detecting sequence variation are usually used. These methods rely upon inferring differences in sequence from indirect measures, e.g. differences in mobility, sensitivity to enzymatic degradation and differences in thermal stability. These methods have the advantage of being much faster than sequencing, but share the common disadvantage that they are not usually 100% sensitive.

Having identified sequence variations within genes in the candidate region, the final stage in positional cloning is to determine which of these are involved in the disease. Where there is a simple relationship between genotype and phenotype, this process is relatively straightforward, since the sequence variation is not expected to be present in controls but will be present in affected individuals (for recessive conditions, two copies may be required in patients and one may be present in some controls). Where sequence variations merely confer susceptibility, they may only be present at a higher frequency in patients than controls. However, as we have seen earlier, polymorphisms flanking the relevant mutation may be in linkage disequilibrium, and therefore many that are not relevant to pathogenesis may be present at a higher rate in patients than controls.

The task of distinguishing between sequence variation resulting from linkage disequilibrium and that directly involved in a disease is not straightforward. However, as a guide, a sequence variation that has a direct involvement in disease should:

1. Have a demonstrable impact upon the abundance, function, sequence or distribution of the encoded protein and therefore be of biological importance

2. Be demonstrable in affected individuals from different populations, (because linkage disequilibrium is minimal across genetically diverse populations)

Definitive proof that a polymorphism can contribute to the pathogenesis of a disorder requires further molecular analysis, e.g. the demonstration of disturbed cellular physiology in a manner compatible with the disease process following the insertion of the abnormal gene into cellular systems in vitro. Similarly, the observation of relevant pathophysiological or behavioural changes following the "knocking out" (disabling) of homologous genes in laboratory animals is highly suggestive that at least the important sequence variation is within that particular gene. Finally, compelling evidence is provided by the "rescuing" of animals displaying relevant pathophysiological features by the insertion of "normal" (wild-type) forms of the gene.

9
Positional Cloning Studies in Schizophrenia and Bipolar Disorder

Despite the difficulties discussed in the preceding paragraphs, it now seems that progress is finally being made in the search for susceptibility genes for major mental disorders. In the discussion that follows, we will restrict ourselves mainly to a discussion of positive findings that have so far achieved some measure of support from more than one research group. The reason for this is that, while it is important to report all data (Lander and Kruglyak 1995), failures to replicate findings are not particularly convincing evidence against linkage.

9.1
Bipolar Disorder

Great interest has recently been directed at chromosome 18 following a report of linkage to markers for this chromosome and bipolar disorder (Berrettini et al. 1994a). Although no significant LOD scores were obtained in the complete sample, modest LOD scores were obtained in some families if different models of transmission were applied to different families. For reasons discussed above, a model free sib-pair analysis was then undertaken, and suggestive evidence for allele sharing was found in the complete data set. The following year, another group reported data for markers on chromosome 18 (Stine et al. 1995), but the results are difficult to interpret. Although some excess allele sharing was found within the region suggested by Berrettini and colleagues, the strongest evidence for linkage was obtained families in which transmission was restricted to the paternal side of the family. In these families, a LOD score of 3.51 and allele sharing ($p = 0.00002$) were achieved with marker D18S41, which lies a considerable distance from the area of maximum linkage identified by Berrettini and colleagues. Interestingly, the data set in which linkage to chromosome 18 was first reported (Berrettini et al. 1994a) has now been examined, and the pedigrees divided according to the gender of the transmitting parent. No pedigrees were found in which the disease was transmitted by males alone. Instead, this group was able to separate the pedigrees into those in which transmission occurred through females and those in which transmission occurred through both parents (Gershon et al. 1996). Significant allele sharing was observed primarily in the families in which both father and mother transmitted the disease. Whereas the area of maximal linkage in this study was on the short arm of chromosome 18 (Gershon et al. 1996), the previous study (Stine et al. 1995) found the maximum area of linkage to be on long arm of chromosome 18. Nevertheless, there was some overlap in the regions in which there was some evidence for linkage between studies, and it is conceivable that both groups have identified evidence for the same locus.

Another group has recently reported the results of a genome scan in Costa Rican pedigrees. Although no marker gave convincing evidence for linkage, three of the six markers giving the greatest LOD scores were located on chromosome 18 (Freimer et al. 1996). Because the Costa Rican bipolar pedigrees come from an isolated population and the disease is believed to originate from a few founders going back only about seven generations or so, large areas of linkage disequilibrium surrounding a disease locus can be expected due to the relatively small number of meiotic events separating all family members. In their study, Freimer et al. (1996) found that most of the families shared similar allelic variants across an 8-cM region of chromosome 18, and using the more familiar case control association approach, evidence for linkage disequilibrium was obtained between some markers in this region and bipolar disorder. Unfortunately, while this region may possibly overlap with the area of linkage in one of the previous studies (Stine et al. 1995), it does not overlap with the particular candidate region that is shared by Stine and Berrettini. Therefore, although several reports suggest that chromosome 18 contains a susceptibility gene for bipolar disorder, the results are as yet inconclusive.

The second region of the genome that has continued to provide controversy is the X chromosome. Reports suggestive of linkage of bipolar disorder to the X chromosome date back to the 1960s, when two large pedigrees were reported in which bipolar disorder

appeared to be co-inherited with colour blindness (Reich et al. 1969). Despite the absence of any formal evidence for X linkage in the pattern of transmission of bipolar disorder, positive reports of linkage continued to emerge, e.g. to a marker for blood clotting factor IX (F9) and also glucose-6-phosphate dehydrogenase (G6PD) deficiency (reviewed in McGuffin et al. 1994). Unfortunately, the distance between some of these markers is so large that the same manic depression gene cannot be linked to all these loci. A re-evaluation of G6PD in the linked families using DNA markers (rather than the less informative and imprecise measures of G6PD enzyme activity) has considerably reduced the previous evidence for linkage (Baron et al. 1993). Furthermore, evidence for linkage to F9 has also diminished after a re-analysis of the other main data set that had provided strong evidence for linkage (Mendelbaum et al. 1995). However, just as the tide appeared to be turning decisively against X linkage, a maximum LOD score of 3.54 has recently been obtained with markers close to F9 (Pekkarinen et al. 1996). It is therefore premature to regard the X-linkage hypothesis of bipolar disorder as disproven.

While chromosome 18 and the X chromosome are the regions of potential linkage that have sparked the greatest interest, a number of other regions are currently considered "hot spots". These include the long arm of chromosome 21, the long arm of chromosome 12 and the short arm of chromosome 4 (Risch and Botstein 1996). The latter result (Blackwood et al. 1996) appears to meet criteria for significant linkage, but as yet it does not meet the more important criterion of replication.

9.2 Schizophrenia

The first result in schizophrenia of continued interest originated from a conventional genome search in large families which yielded weak evidence for linkage to the long arm of chromosome 22. Despite an initial multicentre "replication" study that was negative, weakly positive data from this region was produced by a number of independent groups, and a meta-analysis of data from 11 centres using the more robust sib-pair approach suggested ($p = 0.001$) that there is a locus for schizophrenia in this region (Schizophrenia Collaborative Linkage Group 1996).

Linkage disequilibrium methods have been applied in an attempt to refine the putative linkage to chromosome 22. In addition to the encouraging reports of linkage, this region has been targeted because a dysmorphic deletion syndrome (velo-cardio-facial syndrome) which may carry a high risk of psychotic illness maps adjacent to this region. Two groups were able to demonstrate significant allelic association between schizophrenia and alleles of the marker D22S278 (Vellada et al. 1995; Moises et al. 1995). However, the findings of Moises and colleagues were not statistically significant after correction for multiple testing. Further studies of linkage disequilibrium in this region are required for definitive results.

A second putative gene for schizophrenia has been mapped to chromosome 6p24-p22 in two overlapping data sets consisting of more than 250 small Irish pedigrees (Wang et al. 1995; Straub et al. 1995). The data suggest that either a single major locus for schizophrenia maps to this region in 15%–30% of families or, alternatively, that there is oligogenic inheritance. Three independent groups have subsequently reported suggestive, but not significant linkages to 6p (O'Donovan and Owen 1996b). Although the exact location of the strongest evidence for linkage varies between studies, there is an overlap in the linked area, and it seems likely there is a susceptibility gene for schizophrenia in this region, albeit of small effect. It is interesting that this area also contains the HLA complex, which was explored prior to the advent of DNA markers for possible involvement in schizophrenia (McGuffin et al. 1994).

As other genome searches approach completion, more regions can now be classified as "hot spots" or potential areas of linkage. These include the short arm of chromosome 8 and the long arm of chromosome 13 (O'Donovan and Owen 1996b). None of these meet stringent levels of significance, and attempts to extend them are under way using collaborative data sets from multiple centres.

10 Candidate Gene Approaches

In the preceding discussion, we have considered strategies for identifying genes where the pathophysiology of the disease is completely unknown. However, where there are some clues to the aetiology of a disorder, a different approach is possible. Instead of identifying susceptibility genes on the basis of their map position, genes can be selected on the grounds that their function suggests a possible role. The associations between HLA genotype and several diseases in which "auto-immune" mechanisms are thought to be involved, such as ankylosing spondylitis, diabetes and rheumatoid arthritis, are probably the best known examples of these.

Initially, polymorphisms in or around candidate genes are identified in patients as described earlier, and then evidence for either linkage or linkage disequilibrium is sought using the identified sequence variations as genetic markers. The potential benefit of

this approach is that most studies benefit from a considerable increase in power if the markers are located close to the pathogenic sequence. Furthermore, if one chooses the candidate gene with skill or good fortune, disease genes can be identified without the whole complex procedure of positional cloning.

In practice, the grounds for choosing candidate genes for mental disorders are unsatisfactory because of uncertainty concerning aetiology. The more obvious candidates are genes involved in dopaminergic and serotonergic transmission in schizophrenia and genes involved in adrenergic and serotonerigic transmission in affective disorders. A large number of such studies have now been undertaken, but the findings are largely unimpressive and, at the time of writing, there are no firm findings of allelic association in bipolar disorder. There is, however, still some interest in inconclusive reports of an association between bipolar disorder and tyrosine hydroxylase (Leboyer et al. 1990), and more recently between both unipolar and bipolar disorder and the serotonin transporter (Ogilvie et al. 1996). Interestingly, a functional polymorphism in the promoter region that affects expression of the latter appears to be associated with neuroticism, although this awaits replication (Lesch et al. 1996).

In schizophrenia, there are some results that have rather more substance. The first concerns a polymorphism in the dopamine D3 receptor gene (DRD3). Several groups have now reported increased rates of homozygosity for this polymorphism in schizophrenic patients and, despite a number of negative reports, a recent meta-analysis of 23 data sets supports the findings (Williams et al. 1998). Moreover, the meta-analysis suggests that the effect is present primarily in males. A second finding of interest concerns an association between a polymorphism in the 5HT2a receptor gene and schizophrenia. This was first observed in a small Japanese study, but has now been replicated in a large European collaborative study (Williams et al. 1996). Should these findings ultimately be unambiguously confirmed, it should be noted that sequence variations in these genes make only a small contribution to the overall susceptibility to schizophrenia. Furthermore, the criteria suggestive of direct involvement in disease have not been met, because neither variation has any apparent functional consequences. The results of functional studies are therefore keenly awaited.

11
Novel Types of Inheritance

Until now, we have considered DNA sequences that (with the exception of uncommon new mutations) are transmitted unaltered between generations. However, recent evidence suggests that other mechanisms may operate in some psychiatric disorders, namely dynamic mutations and genomic imprinting.

11.1
Dynamic Mutations

Expanded trinucleotide repeats were first described in the gene responsible for fragile X mental retardation syndrome and have subsequently been discovered as the mutation mechanism underlying several neurological and neuropsychiatric disorders, such as myotonic dystrophy, Huntington's disease and a number of spinocerebellar atrophies (O'Donovan and Owen 1996a). Trinucleotide repeats are simple sequences consisting of three bases (e.g. CAG) repeated consecutively several times. Such sequences are sometimes polymorphic in the general population but, as far as is known, most of this variation is without any phenotypic consequences. However, in some circumstances, where the repeat sequence is associated with a gene, the possession of a repeat number beyond a certain threshold may cause disease. For example, Huntington's disease is caused when the CAG repeat number is greater than 36 or 37 repeats in what is now known as the *huntingtin* gene on chromosome 4p.

Pathogenic expanded trinucleotide repeats are sometimes called dynamic mutations because the repeat number may increase or decrease during transmission from parent to offspring. Another important feature of dynamic mutations is that, in most cases, as the repeat number increases, the corresponding phenotype is either more severe or is expressed at an earlier age. Consequently, changes in repeat size between generations may result in phenotypic variation between parent and offspring. Usually, there is a tendency for repeat number to increase in subsequent generations, leading to a progressively more severe phenotype or earlier age of onset in a pedigree. This progressive change is called anticipation, and its presence suggests the operation of an expanded trinucleotide repeat mechanism, although there may also be other as yet unknown biological explanations for this phenomenon.

Several recent studies have suggested that anticipation occurs in the transmission of both schizophrenia and bipolar disorder, but it is still not certain whether this is a real phenomenon or whether it results from sampling biases (O'Donovan and Owen 1996a). Nevertheless, independent evidence has recently been obtained suggesting that expanded CAG or CTG trinucleotide repeats may contribute to the pathogenesis of both disorders. Using a technique called repeat expansion detection (RED), which measures

the largest trinucleotide repeat in genomic DNA, several groups have found that patients afflicted with either disorder have, on average, larger CAG/CTG repeats than controls (O'Donovan et al. 1996). This opens the possibility that some of the apparently complex patterns of inheritance of these disorders (e.g. marked variation in phenotypic severity and a high prevalence of "sporadic" cases) might be attributable to expansion and contraction of a CAG repeat. Recently, a large European multi-centre study has provided further strong support for the involvement of CAG/CTG repeats in both disorders, but definitive proof will require the identification of the specific repeats associated with the disorders (O'Donovan et al. 1996).

11.2 Genomic Imprinting

Certain DNA sequences have different properties depending upon whether they are transmitted by the father or the mother. This phenomenon, called genomic imprinting, is illustrated perhaps most dramatically by Prader-Willi and Angelman's syndromes. Although these syndromes are very different phenotypically (McGuffin et al. 1994), they are both usually the result of micro-deletion of the long arm of chromosome 15. However, Prader-Willi syndrome occurs from a deletion of the paternal chromosome, whereas Angelman's syndrome is the result of a deletion in the maternal chromosome. Less commonly, these syndromes may be caused by uniparental disomy, which means that both copies of a chromosome are inherited from one or other parent. Prader-Willi syndrome then arises when both copies are from the mother (equivalent to a complete deletion of the paternal chromosome), and Angelman's syndrome when both are from the father (equivalent to a complete deletion of the maternal chromosome). The precise molecular mechanism underlying genomic imprinting is not completely known, but it seems likely that one mechanism is that some genes are differentially inactivated or activated during gametogenesis by the addition or removal of methyl groups from regulatory regions of DNA.

Genomic imprinting is suggested at the phenotypic level by a sex difference in the likelihood of transmission of a disease in the absence of a difference in the prevalence of the disease by gender (distinguishing it from sex chromosome linkage). Such a pattern has been observed in the families of one of the studies suggesting linkage of bipolar disorder to chromosome 18 (Stine et al. 1995), although, as discussed above, these findings are not conclusive.

12 Animal Models

As we have seen, even diseases with apparently complex inheritance are now susceptible to dissection using modern approaches to genetic analysis. However, it is also clear that major difficulties remain, particularly as the size of the genetic effect decreases. One way to overcome these difficulties is to use animal models of the phenotype. Animal models confer a number of major advantages. Firstly, most experimental animals, e.g. mice, produce large litters in a short period of time, thus providing large numbers for analysis. Secondly, environmental variables can be strictly controlled and therefore minimized (or maximized) in animal experiments. Thirdly, animals can be subjected to specific breeding programmes designed to maximize the detection of genes of small effect. Several breeding paradigms have been successfully used to map complex traits such as stroke, cancers, epilepsy, obesity and diabetes (Frankel 1995). Here, we will just mention one that has recently been used to map genes of neuropsychiatric interest; the F_2 intercross.

The first step is to identify inbred strains of animals (usually mice) that have high (strain A) and low (strain B) scores for the phenotype of interest. It is a characteristic of inbred strains that members of each strain are effectively genetically identical and are homozygous for all alleles in the genome. Thus strain A has genotype AA at every map position, and strain B possesses genotype BB. The two inbred strains are then crossed to produce an F_1 generation. Each F_1 member carries a single copy of every allele from both progenitor strains and is also effectively genetically identical (genotype AB at every locus). Members of the F_1 generation are then bred or intercrossed, which allows recombination to take place and results in F_2 offspring. At any given locus, an F_2 animal may possess one of the following genotypes: homozygous AA, heterozygous AB or homozygous BB. If progenitor A has high scores for the phenotype, then animals in the F_2 generation that have high scores for the phenotype should tend to be homozygous for the A alleles, and low scorers should carry homozygous alleles from strain B (ignoring any dominant gene effects). Moreover, because there is effectively only one generation during which recombination has taken place (the F_1 generation, being genetically identical, does not count), large chromosomal regions surrounding the mutations of interest will be in linkage disequilibrium, and therefore fairly distant markers will also tend to display the genotype AA or BB around the mutation of interest in high and low scorers, respectively. The task is then one of testing for allelic association, but

because of the large areas of linkage disequilibrium, only a few hundred markers are required.

Regions of putative linkage can then be more precisely defined by examining animals that are more distantly related, e.g. by examining outbred animals strains. This is similar to a case control association study in humans. Finally, the identification of the genes responsible for the phenotype in the animals is, in principle, similar to end-point positional cloning in humans. These genes then become candidate genes in human linkage disequilibrium studies.

Although this approach is very appealing, there are few obvious models for major mental illness. No animal model can expect to fully emulate the complexity of behavioural traits such as schizophrenia and manic depression. However, even modelling some of the features of a disease affords the possibility of uncovering some of the genes that contribute to it. At present, models of alcoholism, drug abuse, anxiety and depression are available and have been used. For example, an approach which modelled "emotionality" has recently mapped a number of loci (Flint et al. 1995), and similar approaches have been successful in mapping loci that may be related to drug abuse and alcoholism (Berrettini et al. 1994b). However, it remains to be seen whether the genes associated with the phenotypic traits in rodents contribute to the modelled behaviour in humans.

13 Concluding Remarks

In contrast with the dramatic "advances and retreats" of the past (O'Donovan and Owen 1992), research into the molecular genetics of mental disorders is now entering a period of slow, consolidating advances (O'Donovan and Owen 1996b). Tentative, but suggestive findings of linkage are emerging for both schizophrenia and bipolar disorder, and as more genome scans reach fruition, more of these can be expected. The main challenge remains how to move from these results to precisely delineated regions of linkage. This will almost certainly require the use of large samples of families containing affected relative pairs and of unrelated individuals for linkage disequilibrium mapping. A second challenge will be to develop methodologies to facilitate the genotyping of large samples, and several promising strategies are now on the horizon, including DNA pooling and DNA chip technologies. Data from genetic studies of animal models may be useful here, both in the primary identification of potential regions of linkage by synteny, but also of specific genes within candidate regions by homology. Finally, methods are required that will allow the selection and mutation screening of the large number of candidate genes that are expected to map to a particular candidate region. Again, we can be optimistic that data from the Human Genome Project and technical advances in mutation detection will mean that these difficulties should not prevail.

Using Transgenic Mice to Probe the Role of Specific Genes in Behavior

1 Introduction

This chapter will describe transgenic techniques that permit experimental manipulation of gene expression in the mouse. These techniques create specific and permanent changes to the germline of experimental mice, and these strategies have been fruitfully applied to the study of oncology, immunology, development, and more recently neurobiology and behavior. Specifically, in the area of neurobiology, modification of gene expression in the mouse has permitted direct assessment of the role of specific genes in the development of neural physiologic processes and in regulating behavior. Since this technique and its application to mouse behavior may seem far removed from the subject of human psychiatric disorders, we will first begin with a review of some basic concepts in molecular biology, followed by a brief introduction that will place the transgenic mouse strategy in the context of other genetic approaches to studying behavior.

2 Molecular Basis of Gene Expression

2.1 Chromosomes and Genes

Figure 1 will be a helpful aid to the reader in this section. A chromosome is a linear piece of DNA that is comprised of elements called genes. The human genome is comprised of 23 chromosome pairs that are packaged in the nucleus (mice have 20 chromosome pairs). Genes contain two parts: a coding region that specifies the sequence of a messenger RNA (mRNA), and a promoter region that specifies the temporal and spatial expression properties of the mRNA. Consistent with these two aspects of a gene, the chromosomal DNA serves two functions: it acts as a stable record of an organism's genetic information, and it is a dynamically regulated template that allows for selective expression of genes. The information-carrying function of DNA is intrinsic to its double-stranded structure and its mode of replication. The dynamic aspects of gene regulation are provided by the promoter. The promoter region confers the ability of a gene to be expressed during certain times in development and to be expressed in some cells but not others. This regulatory function is crucial, because each cell in an organism (except for the gametes) contains exactly the same genetic information – a complete copy of all genes. What determines the fate of a cell is the genes that it expresses. Thus a neuron is a neuron and not a kidney cell because of the repertoire of genes that it expresses. Each cell expresses approximately 15%–30% of the available genes (15,000–30,000 of an estimated 100,000 genes in the human genome). In Fig. 1, the promoter is shown to be comprised of an enhancer (that confers temporal and cell-specific expression) and a TATA box (where the RNA polymerase will begin transcription). A gene becomes transcriptionally active when the enhancer elements of a gene loop toward the RNA polymerase binding site and activate the RNA polymerase. Thus an RNA copy of one strand of the gene is made (transcription).

2.2 Ribonucleic Acid

An RNA intermediate between genes and protein is required because chromosomes stay in the nucleus, but proteins are made in the cytoplasm of cells. Thus an intermediate step is needed to get a copy of the gene out to the cytoplasm. Enzymes in the nucleus (RNA polymerases) create copies of genes in the nucleus in a process called transcription. The nuclear RNA transcript is a "raw" copy of the gene, containing both exons and introns.

2.3 Exons and Introns

As shown in Fig. 1, the coding region of the gene is comprised of exons and introns. The coding information for a protein is carried on exons. Exons are separated by stretches of sequence called introns. Only eukaryotic organisms have introns that interrupt the exon sequences, and their function is not known (prokaryotes do not). As shown, a gene always begins with an exon and ends with an exon. The first and last exons of a gene will contain some sequence that will never be translated into protein (therefore called the 5′- and 3′-untranslated region of the mRNA).

2.4 RNA to Protein

Before an RNA can be turned into a protein, it must be modified before it leaves the nucleus. First, the exons must be joined together to make a contiguous stretch of RNA. This means that the introns must be spliced out. The spliced RNA transcript is then modified with a "cap" on one end and a polyadenosine (polyA) tail on the other. These modifications confer stability to the RNA, which in its modified form is called messenger RNA or mRNA. The mRNA is then transported to

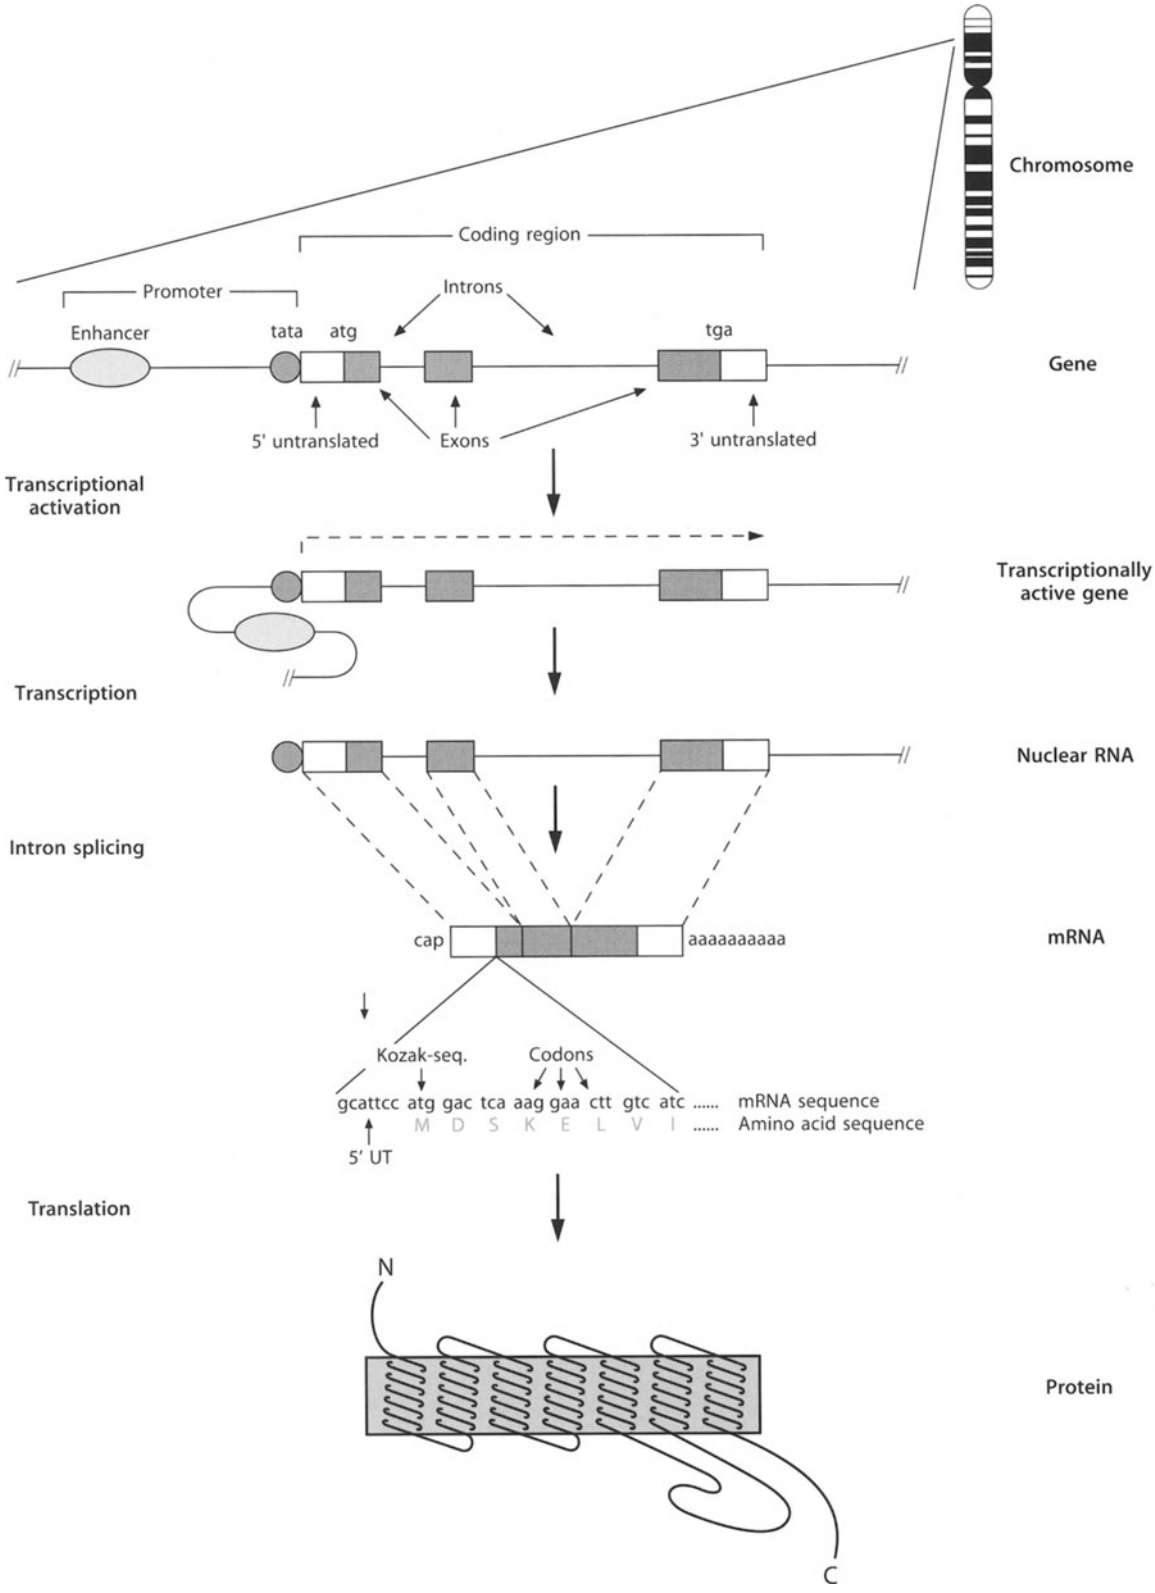

Fig. 1. The path from DNA to protein. See text for details

the cytoplasm of a cell, where ribosomes decode the sequence of the mRNA to synthesize a polypeptide chain or protein. The process of generating protein from mRNA is called translation. The ribosome begins translation of an mRNA from a sequence element called the Kozak site (named after Marilyn Kozak, who defined it). Within the Kozak site is the first codon, ATG, which begins every eukaryotic protein and codes for the amino acid methionine. The information that allows the ribosome to "decode" the mRNA is the codon. Codons are three nucleotide bases in length. Nucleotides are of four types: thymidine, adenosine, cytosine, and guanine (or T, A, C, and G as they are commonly abbreviated). Any three nucleotide bases can form a codon, and $4^3 = 64$ different possible codons can therefore be generated. Different codons specify one of 20 possible amino acids or a stop signal for the ribosome. In the example shown in Fig. 1, a G protein-coupled receptor is being made. This family of receptors comprises integral membrane proteins that traverse the lipid bilayer seven times.

3 DNA Engineering

Over the last 30 years, the technology has been developed that allows researchers to isolate, manipulate, and reengineer DNA in almost any form imaginable. A basic understanding of the techniques of DNA engineering will be helpful in understanding the more technical parts of this chapter.

3.1 Cloning

Cloning is the process of isolating a fragment of DNA that represents a gene or a DNA copy of an mRNA (so-called cDNA). In order to clone a gene, it is necessary to know something about it: some partial nucleotide sequence or a function that can be easily assayed in cells. If the sequence of a gene is known, the gene can be cloned by making a probe using the sequence. The probe can be used to find the gene in a collection of clones known as a library. The ability of a probe to identify a gene depends on the property of single-stranded DNA sequences to bind or hybridize to complementary strands. Once a clone is identified in a library by a probe, the clone can be amplified to generate large amounts of this DNA. This amplification is possible because isolated DNA fragments can be propagated conveniently in bacteria in the form of plasmids (circular forms of DNA that grow in bacteria). Plasmid DNA can be easily grown in large quantities in bacteria (amplification) and purified to yield pure plasmid DNA that is free from the bacteria's genomic DNA or RNA. In this pure form, the plasmid DNA can be manipulated with different enzymes.

3.2 Polymerase Chain Reaction

Another way to generate large amounts of specific DNA sequences without the need for cloning uses a process called the polymerase chain reaction (PCR). Successful PCR also depends on some knowledge of the sequence of a gene. In this case, the sequence information is used to generate small synthetic pieces of DNA called oligonucleotide primers. The primers are chosen to flank the part of the gene that is to be amplified. When a double-stranded DNA template is heated to 95 °C, the two strands separate (denature). Upon cooling, the primers will bind to their complementary sequence on each strand, and a DNA polymerase added to the reaction then synthesizes another complementary strand from the primer (which is why they are called primers). This process of heating and cooling is called a cycle. In this one cycle, the amount of DNA between the primers has doubled. If another such cycle is performed, the doubled DNA is doubled again. Repeating this process with 30 or 50 cycles can amplify a given DNA sequence from 2^{30}- to 2^{50}-fold (or in excess of a billionfold). This technique has been optimized over the last 10 years to incorporate a thermostable DNA polymerase that can withstand the repeated cycles of high temperature needed to denature double-stranded template. PCR now permits amplification of specific sequences from the DNA contained within a single cell. The revolution that this technique has created in molecular biology cannot be overstated.

3.3 Restriction Enzymes

DNA can be cut very specifically using enzymes known as restriction endonucleases (or restriction enzymes). These restriction enzymes recognize specific sequences in DNA from four to eight nucleotides in length and cleave the DNA strand within or nearby this recognition sequence. Examples of such enzymes are *Eco*RI, *Bam*HI, *Hin*dIII, and *Xho*I. The ability of these enzymes to cut a gene allows a type of map to be created known as a restriction map. DNA fragments generated in this way can be ligated to other similarly cut DNA fragments in a process that resembles cutting and pasting. In this way, genes can be cloned,

modified, and used to make targeting constructs for making knockout mice.

4 Behavioral Genetics

The field of behavioral genetics is the study of the heritable component of behavior and personality. The goal of this research is no longer to establish that behavior is influenced by heritable factors, but to precisely determine the genes involved, the nature of their interactions, and their interaction with the environment. In humans, genetic factors are believed to influence as much as 30%–50% of the variance of intelligence, cognition, and personality traits such as extroversion (sociability, impulsiveness, and liveliness), neuroticism (moodiness, anxiousness, irritability), agreeableness (likability, friendliness), conscientiousness (conformity, will to achieve), and culture (openness to new experience). Most behavioral and psychological traits exist on a continuum and thus appear to have multiple genes that contribute to the "phenotype" of an organism.

Like normal personality characteristics, psychiatric disorders also appear to have a genetic component. The genetic contribution to illnesses such as schizophrenia, autism, and bipolar disorder are more substantial than that measured for personality traits. Disorders such as depression and anxiety also have a genetic contribution, but less than that found for the aforementioned psychiatric conditions. It has also become accepted recently that complex behaviors and disorders such as schizophrenia are not the result of a single aberrant gene, but rather the result of the interaction of multiple genes. Thus geneticists are no longer looking for the schizophrenia gene, but rather one of the many genes that may contribute to this disorder. The influence of genes on normal behavior and on abnormal clinical psychiatric conditions is therefore complex and likely involves complex interactions such as gene–gene, gene–environment, and environment–gene interactions. The difficult problem facing behavioral genetics is how to identify the genes involved and understand their contribution to behavior, personality traits, and psychiatric disorders. To address this problem, two conceptually distinct approaches are taken: so-called forward genetics, which begins with a phenotype and searches for the gene or genes that play a role, and so-called reverse genetics, which creates a specific genotypic change (mutation) in an organism and searches for the phenotypic changes that result from the mutation. The transgenic strategy falls into the latter category and will be discussed in detail. The concept of forward and reverse strategies is outlined in Fig. 2.

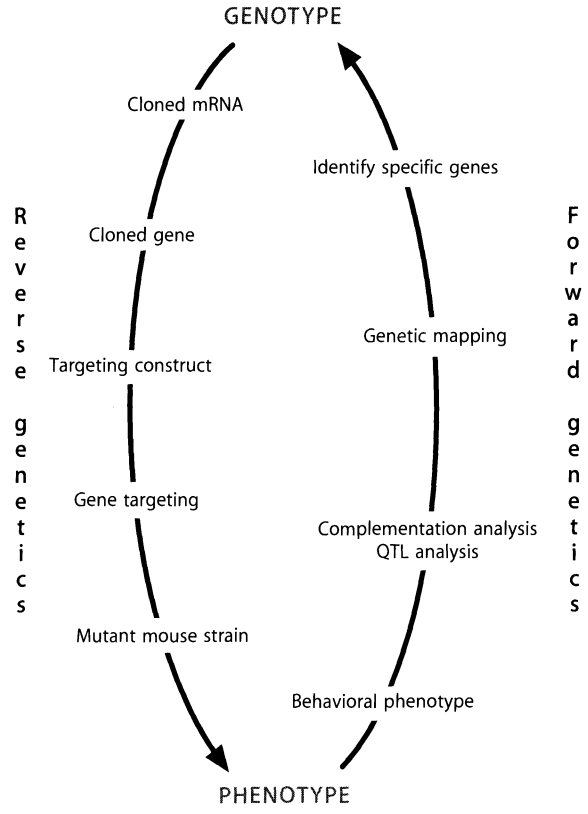

Fig. 2. Forward and reverse genetic strategies. See text for details

4.1 Forward Genetic Strategies

Other chapters in this volume describe different strategies used to identify the genes that contribute to a given behavior. Most of these methods fall into the category of so-called forward genetics. The massive efforts to identify genes that contribute to disorders such as schizophrenia and bipolar disorder are an example of this approach. In these studies, investigators begin with a rigorously defined phenotype (usually DSM-VI or Research Diagnostic Criteria for a disorder) and attempt through various strategies to identify genetic loci that are associated with the disorder.

These types of searches are simplified when there is only a single gene involved with nearly complete penetrance of its phenotype. Many of the neuropsychiatric disorders such as Huntington's disease, fragile X syndrome, dystonia syndromes, muscular dystrophy, and even some cases of Alzheimer's disease have been found to be single-gene disorders. The search for

genes in more complex, multigene disorders has moved less rapidly, but the first such genes for disorders such as schizophrenia and bipolar disorder are beginning to appear and be replicated independently.

In the nonhuman animal realm, a more controlled approach to this type of problem is possible due to the existence of genetically homogeneous strains that exhibit different behaviors. Genetic analysis of such strain differences (quantitative trait loci or QTL analysis) can identify the number of genetic loci that contribute to a given behavior (as well as its contribution relative to the other loci). Similarly, new strains of animals can be created by breeding successive generations for their difference on a given behavioral trait. Once such lines have been sufficiently separated phenotypically and genetically, and stabilized by inbreeding, a similar approach can be undertaken to identify loci that contribute to the behavior of interest. Such QTL approaches have been only one of the trends over the past 30 years that has marked the convergence of efforts of quantitative geneticists and molecular geneticists to identify particular genes that contribute to a given behavior.

4.2
Reverse Genetic Strategies

A more direct approach to studying the effect of genes on behavior uses techniques that mutate selective genes. This approach has been applied extensively in simple organisms such as bacteria, *Caenorhabitis elegans*, and *Drosophila* using chemical mutagens and selection procedures to find organisms that differ on a given behavior. Such approaches have led to the identification of dozens of genes that contribute to chemotactic behavior in organisms such as bacteria, paramecium, and *C. elegans*. This approach in *Drosophila* has identified genes that are involved in more complex behaviors such as learning, locomotion, and sexual behavior.

Animal models continue to be essential tools for the study of neuropsychiatric disorders. For example, specific animal models have been most widely used to screen for potential psychotropic medications. In addition, animal preparations have been crucial to investigate mechanisms of brain function (such as development, plasticity, neurotransmission), behavioral states (such as anxiety, depression, and aggression), and behavioral processes (such as learning, appetite control, locomotion, and biological rhythmicity). These models take many forms, and thorough discussions of this topic can be found elsewhere in this volume.

5
Techniques of Genome Manipulation in Mammals

This section describes the methods that have been developed to manipulate the genome of experimental animals – primarily mice. Some confusion arises among those unfamiliar to this field regarding the differences between the different techniques, e.g., the difference between a transgenic mouse and a so-called knockout mouse. In fact, both types are technically considered transgenic given that the definition of a transgenic mouse is an animal that has foreign DNA stably integrated into its genome and passable to its offspring (germline transmission). There are three established techniques for introducing foreign DNA into the mouse germline: (1) retroviral vectors, (2) direct injection of DNA into pronuclei of fertilized eggs, and (3) use of embryonic stem cells that have been transfected with foreign DNA. Each of these methods will be considered.

5.1
Infection of Developing Embryos with Retroviral DNA

This technique of infecting developing embryos with retroviral DNA is useful for studying development, including neurodevelopment, generating mutant animals by insertional mutagenesis, and to a lesser degree as a method to introduce functional genes into the genome. This last use has been largely supplanted by the other techniques that we will discuss in this chapter. The retroviral method has been reviewed elsewhere (Rossant 1990; Babinet et al. 1989) and will not be discussed further in this chapter. The two remaining methods of creating transgenic mice that will be discussed in more detail include random introduction of foreign or engineered transgenes into the mouse genome and techniques that permit site-specific integration of foreign or engineered DNA into the mouse genome.

5.2
Random Integration of Transgenes

This approach depends on the direct injection of foreign DNA into the pronuclei of fertilized eggs. This technique was first demonstrated in mice in 1980 and has subsequently been applied to the creation of numerous mutant mouse lines. The concept of this method is to use DNA engineering to create a fusion construct of a functional promoter region with a gene to be expressed. This construct is then injected directly into the pronuclei of a fertilized single cell embryo.

The engineered DNA construct then inserts randomly into the germline of the mouse. Typically, multiple copies of the transgene are integrated in tandem head-to-tail arrays.

The choice of the promoter and the gene used to make the construct (i.e., transgene) provides almost limitless possibilities for expression strategies. For example, promoters have been characterized that drive gene expression in limited anatomic or tissue-specific patterns or that provide strong expression in many different tissues. The gene that is transcribed can be of any variety, including genes normally expressed in the animal, mutated genes, or so-called antisense genes that express the complementary strand of an existing gene. How these various strategies can and have been applied to modeling neuropsychiatric disorders will be discussed in the next section.

5.3 Specific Gene Targeting Strategies

The specific gene targeting strategy, commonly known as the "knockout" approach, differs from the transgene approach in that the mutation occurs in a specified gene locus, modifying or ablating an existing gene. This technique depends on the property of cells to undergo a process called "homologous recombination." This process is presumably similar to the process of recombination that occurs between two sister chromosomes during meiosis: namely, two homologous stretches of DNA can recombine, essentially replacing one DNA sequence with another. For the purpose of the knockout strategy, the experimenter introduces an engineered version of the gene to be disrupted into an embryonic cell line. The targeting construct possesses two "recombinogenic arms" that will "target" the engineered construct to the native gene locus. Different types of recombination events can occur depending on the nature of the targeting construct. As shown in Fig. 3a, when an "omega" targeting construct undergoes homologous recombination with its target gene, a substitution of the targeting construct for the endogenous gene occurs. If the targeting construct is engineered to delete a crucial exon, introduce a frame-shift mutation, or interrupt the coding sequence with another gene (such as a gene that confers neomycin resistance to cells), the targeted gene is effectively inactivated. This strategy also permits introduction of additional DNA sequences without loss of the endogenous gene (so-called knock-in strategy; Fig. 3b). This is an important strategy for creating inducible or tissue-specific knockouts, which will be discussed in the next section. In Fig. 3b, the example shown simply places a reporter gene, *lacZ*, into the locus of the gene of interest. In this example, neurons that would normally express the gene of interest will now express the *lacZ* gene, whose gene product can stain the neurons a blue color for tracing purposes. Such a construct has been elegantly used to study the organization of the olfactory bulb in relation to olfactory receptors (Mombaerts et al. 1996).

The second type of targeting construct that has been used (but less so recently) is the "O-type" construct shown in Fig. 3c. When such a construct undergoes homologous recombination, a duplication event occurs (Bronson and Smithies 1994). Even if the two ends of the targeting construct have a large gap between them, endogenous processes in the cell permit this gap to be filled. Thus even a very large gene and its regulatory (promoter) regions can be duplicated using a targeting construct that contains only a small portion of the total gene. This strategy creates the opposite of a knockout, namely an increase in the function of a given gene (Smithies and Kim 1994). This strategy allows the experimenter to increase gene dosage rather than to decrease it. Although less commonly performed, such mutations may prove to be an important compliment to the knockout approach.

Although we have explained the concept of homologous recombination and its differences from the transgene approach, we have not discussed the methods by which a targeting construct can be introduced into a viable animal. Whereas the transgene is injected directly into a fertilized embryo, the ratio of homologous recombination to random integration is too low (often greater than 1:500) for this approach to be viable. The number of embryos that would need to be injected in order to obtain the desired recombination event would not be practical. To address this problem, a new strategy needed to be developed. Thus nearly all homologous recombination experiments are performed in a cell line derived from pluripotent embryonic stem (ES) cells. These cells can be grown in standard cell culture conditions and be propagated in an undifferentiated state. The targeting construct is introduced into these cells by a process of electroporation in which a high-voltage shock temporarily renders these cells permeable to a solution containing the linearized DNA targeting construct. The DNA enters only a small portion of the cells, and only a small portion of the cells that take up the construct will integrate the DNA into their genome. Of those cells that integrate the targeting construct into the genome, only a small fraction will undergo the process of homologous recombination (1/10 to 1/1000) that integrates the targeting construct in the intended locus. To appreciate the low probability of this process, in a typical experiment the researcher electroporates 10 million cells, of which perhaps 5000 cells will integrate the DNA randomly in their genome and 50 cells will undergo homologous recombination. Thus

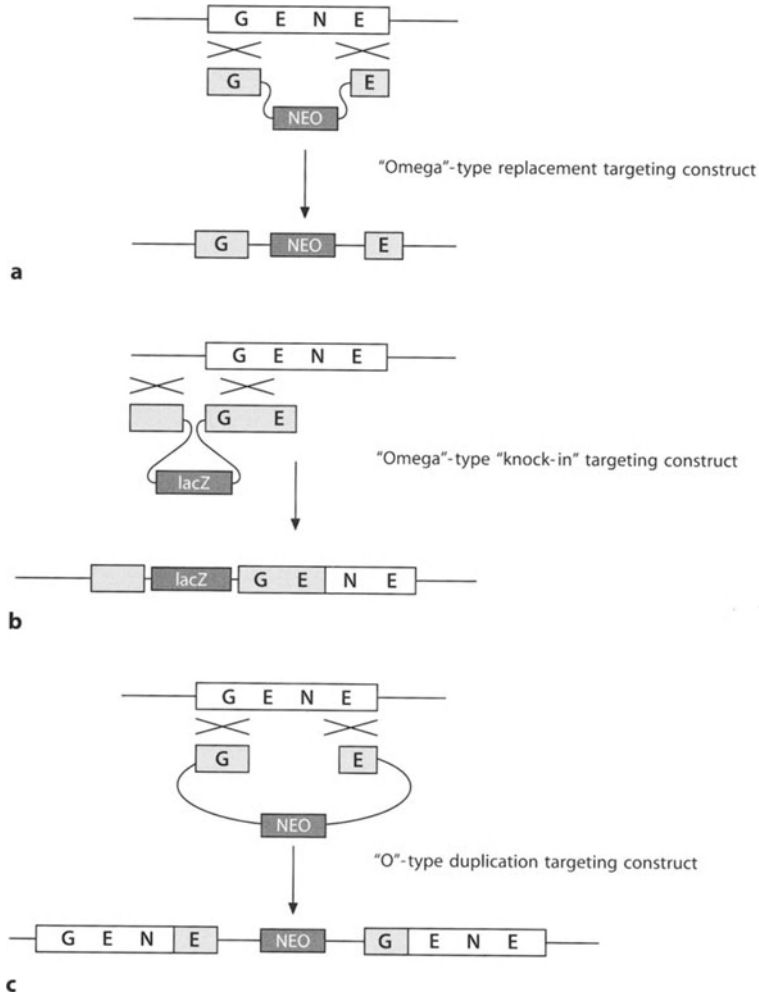

Fig. 3a–c. Different strategies for gene targeting. **a, b** An omega-targeting construct is used to generate either a "knockout" or a "knock-in." **c** An O-type construct is used to create a gene-duplication event. See text for details. (Adapted from Smithies and Kim 1994)

the task for researchers making a knockout is to find those 50 cells in the 10 million cells from which their experiment started. For this purpose, a selection procedure is used to distinguish cells that have integrated DNA from those which have not. The most commonly used selectable marker is the gene from bacteria that confers resistance to the toxin neomycin. Thus growth of electroporated cells in neomycin-containing medium eliminates the vast majority of cells that did not integrate the target DNA (conveying neomycin resistance), and we are left with the more reasonable task of finding the homologous recombination events within this background of nonspecific integration events.

Two strategies are used at this step: (1) a brute force approach in which the experimenter screens large numbers of clonal cell lines (200–1000 lines) using techniques such as Southern blot analysis or PCR to distinguish specific from nonspecific integration, or (2) a second selectable marker, thymidine kinase (TK), can be incorporated into the targeting construct on one extremity of the construct. By incorporating TK on the outside portion of a homologous arm of the construct, it will be lost in all homologous recombination events but be retained in nearly all random integration events. Thus clonal cells grown in the presence of neomycin and gancyclovir will eliminate most unwanted clones (gancyclovir in the presence of TK is toxic to cells) and simplify the process of screening.

When a desired clone possessing a homologous recombination event is obtained, it is amplified in number and then hundreds of the mutated cells are injected into the hollow core of a developing blastocyst. The "host" blastocyst is derived from mice of the C57/B6 strain. Importantly (as will be seen), C57/B6 mice possess a black coat color. The ES cell line is derived from a male embryo of the C129 mouse strain. In contrast to the C57/B6 strain, 129 mice possess a yellow coat color (agouti). The injected blastocysts, now filled with mutant 129 cells, are transferred to a foster mother. As the embryo develops, the mutant cells and the wild-type cells of the blastocyst will both

be integrated into the young mouse. The resulting pups are chimeric or mosaic in the sense that a portion of their body is derived from the mutant cells and a portion from the wild-type C57 strain. This chimerism is reflected in their coat color, which is typically a mix of yellow (agouti) and black. Based on the predominant coat color, the percentage of mutant cells that comprise the resulting animal can be estimated. Researchers are interested in chimeras that will be able to transmit the mutation created in the ES cells onto its progeny. This ability is called "germline transmission." When sufficiently mature, male chimeras are mated with wild-type C57/B6 females (remember that the ES cells were male, and thus the chimeras most likely to transmit the mutation will be male). Because the agouti coat color is dominant over the black coat of the wild-type mice, offspring that bear the mutation will necessarily also have the yellow coat. Despite their uniform yellow coat, these offspring will nonetheless have a mixed genetic (129/C57) background. This heterogeneity can confound behavioral experiments, and thus it is often preferred to have the mutation on a pure genetic background. To achieve this, the chimeric males must be mated with 129 wild-type females. Heterozygote offspring will necessarily be of a pure 129 genetic background (since if they transmitted the mutation, the germline must be derived from the 129 strain). Since coat color cannot be used to follow the mutation, a sample of DNA has to be obtained from the offspring (usually a short snip of the tip of the tail) and PCR or Southern blot analysis used to determine the genotype. The heterozygote offspring can of course be of either gender, and once males and female heterozygotes are obtained, they can be mated to produce offspring homozygote for the desired mutation.

5.4
Advantages and Problems of the Knockout Strategy

The power of the transgenic technique lies in its specificity and the absolute nature of the lesion created. Even in genes of unknown function, or receptors for which no known antagonist exists, an experimenter may investigate the function of the gene and its resulting protein using the transgenic approach. In this sense it represents a new and complementary approach to pharmacological techniques.

5.5
Problem of Inferring Function from Dysfunction

From the point of view of understanding the role of a gene in the functioning of an adult animal, the knockout approach has several drawbacks. First, function has to be inferred from looking for the dysfunction that occurs in an animal in the absence of the gene. Using an automobile analogy, if we tried to infer the function of a steering wheel by trying to see how a car functioned without it, several conclusions might be reached. The car will appear normal from the outside. It will start and idle normally, but problems would quickly become apparent if someone tried to drive the car. If the person operating the car drove slowly to compensate for the lack of directional control, an outside observer might incorrectly conclude that the steering wheel must influence the speed of the vehicle and its absence results in a much slower car. If we were trying to understand the function of the fuel pump by studying car function in its absence, we would quickly conclude that the car does not start or move without it. However, unless we had more detailed assays to perform on the car, the function of the fuel pump would remain largely mysterious. Thus one way of appreciating the knockout strategy is that an experimenter creates a "broken" animal and tries to understand the role of the mutated gene by observing and testing the animal bearing the mutation under a variety of conditions.

5.6
Lack of Tissue Specificity in Knockouts

One reason that the dysfunction can be difficult to interpret is the fact that the gene is inactivated everywhere. Often, the same gene is expressed in different tissues and can serve different functions depending on where it is expressed. For example, tryptophan hydroxylase (TpH) is found in serotonergic neurons and the pineal gland. In serotonergic raphe neurons, TpH is the rate-limiting enzyme for serotonin (5-HT) synthesis. In the pineal gland, TpH helps turn tryptophan into melanin. An animal without a functional TpH gene may thus exhibit mixed effects (melatonin and serotonin absence) of the gene deletion in these two different processes.

5.7
Developmental Problems and Compensation by Other Genes

Another problem that often confounds the interpretation of a dysfunction seen in a mutant animal is the question of the role that such a gene plays in development. Remember that the gene in question has been disrupted in the germline and consequently will never be present. This means that the gene will be absent during crucial periods of ontogeny; if the gene

is involved in development, this could have disastrous consequences for the adult animal (even creating the ultimate phenotype, nonviability). Again, returning to the automobile analogy, if the part being removed is crucial to the subsequent installation of other parts, or if it contains crucial instructions for the ongoing assembly of the automobile, the resulting car could be so badly assembled that examining the finished product would be almost useless for the purposes of understanding the role of the part in a normal car. Likewise, if a deleted gene is an important gene in development, the study of an adult may reveal abnormalities that indicate very little about the role of the ablated gene in adult behavior. Rather, the phenotype is predominated by the developmental defects of the mouse. In such cases, the development of embryos needs to be studied to understand at what point the normal developmental pattern went awry. A similar, but somewhat different problem is the seeming ability of an organism to "compensate" for a missing gene by enhancing expression of normally dormant genes or overexpression of other active genes. A familiar example of this is seen in patients with sickle cell disease or thalassemia, who express high amounts of fetal hemoglobin to compensate for the absence or poor functioning of adult hemoglobin. If such a compensatory process occurs following a gene knockout, such an animal may have no discernible phenotype, i.e., it appears completely normal. In such a case, it is difficult to determine whether the ablated gene simply has no function or whether compensation has obscured the phenotype. Another related possibility is that, in the process of compensating for an absent gene, the animal may create another unexpected phenotype (similar to the steering wheel analogy given earlier). Again, this can cause confusion regarding the role of the gene in adult animals.

5.8
New Technologies to Address the Limitations of the Classical Knockout Approach

To overcome the problems of compensation and development, many groups are working to develop an "inducible knockout" strategy. The idea is to give the experimenter temporal control over the inactivation of the gene. This would allow the animal to develop with the gene present. When the animal reaches adulthood, the gene could then be inactivated. Many strategies are being developed to allow such temporal control of gene activity and are beyond the scope of this chapter. However, the interested reader is referred to the discussion of this topic by Lucas and Hen (1995).

The other new technology being developed will allow for regional or tissue-specific loss of a gene. This strategy involves creating somatic mutations in mice resulting in loss of a gene in certain tissues or brain regions but not others. Again, the technology involved in this "tissue-specific" knockout strategy is beyond the scope of this chapter, but some early successes have been achieved in this area. For example, a group was successful in eliminating the tyrosine hydroxylase gene only in dopaminergic neurons while sparing catecholaminergic neurons (Zhou and Palmiter 1995). In another example, researchers were able to explore the role of the *N*-methyl-D-aspartate (NMDA) receptor in a specific region of the hippocampus by selective disruption of a receptor subunit only in CA1 cells (McHugh et al. 1996; Tsien et al. 1996a,b; Wilson and Tonegawa 1997). Of course, the "holy grail" of transgenic researchers is the development of technology that will allow both temporal and regional anatomic control over the process of gene inactivation. At the time of writing, this remains a topic of active investigation, but without definitive success.

5.9
Knockouts as Models of Human Genetic Disorders

It is worth emphasizing that most of the knockout mutations that are created in mice have no known analogue in humans. However, there are many known single-gene mutations in humans that could be (and have been) effectively modeled in transgenic mice. In the cases in which a knockout mouse is modeling a known human gene mutation, any developmental abnormalities in the mouse will be an interesting feature to study, not necessarily a confounding variable. Indeed, to fully mimic the human gene disorder, a classical knockout needs to be studied. Tissue-specific and inducible knockouts will be valuable in helping to dissect the phenotype that is observed in a classical knockout animal. Indeed, the classical knockout and the other types of knockouts (tissue-specific and inducible) should be seen as complementary approaches that are useful for answering specific biologic questions.

6
Using Knockouts to Study Aggressive Behavior

6.1
Knockouts and Aggression

We have chosen to discuss aggression and knockouts because we believe it illustrates both the promises and the problems associated with the knockout strategy. As we will see, aggression is an important behavioral state

that can be studied in laboratory animals and humans. However, the biology and genetics of aggressive behavior are poorly understood. The transgenic approach holds the promise of uncovering genes that influence aggressive behaviors. Indeed, the study of aggression in different transgenic and knockout strains has led to the discovery of different genes and transmitter systems whose contribution to aggression had been previously unappreciated. These mutant mice have opened new avenues of research into aggression and its control and will prove valuable tools for ongoing studies.

The problems posed by the transgenic approach in this area are the same ones discussed above: namely confounding aspects of development, compensatory processes, and lack of tissue specificity. We will begin this section with a brief overview of the biology of aggression and then discuss individually different transgenic mice that have alterations in their aggressive behavior. In each case, we will endeavor to highlight the strengths and weaknesses of the resulting mouse to illustrate the points we have made above.

6.2 Aggressive Behavior in Mice and Humans

Several functions of aggressive behaviors have been suggested for various species, including mice. These include establishment of territoriality, establishment of dominance (to secure access to food and female mating partners), predatory violence (attacking other species to provide nourishment), and defensive aggression (responding and repelling attacks by predators or other members of the same species). In addition, aggression in mice can be elicited by various stressful stimuli (social isolation, foot shock, food deprivation), but the adaptive value of this type of aggression is less clear. Some of these categories are similar to some forms of human aggression, while others are less so. Different behavioral tests have been designed to study aggression in mice (and other rodents). These include the resident–intruder test (test of territorial aggression), isolation-induced or pain-induced aggression (stress-induced aggression), mouse defensive test battery (defensive aggression), maternal aggression (mother attacks intruders entering nest area during lactation), and predatory aggression (attacking and killing insects).

6.2.1 Genetics of Aggression in Mice

There is a strong genetic contribution to aggressive behavior in mice that can be demonstrated either by examining inbred stains (Guillot and Chapouthier 1996) or by selectively breeding mice for different forms of aggressive behaviors (Lagerspetz and Lagerspetz 1971; Sandnabba 1996). Different functional types of aggressive behavior appear to be under distinct genetic control when inbred stains are examined (Popova et al. 1993). In contrast, breeding studies have found that different functional aggressive behaviors (e.g., isolation-induced and predatory aggression) segregated together during selective breeding (Sandnabba 1995). Not surprisingly, environmental factors greatly influence the expression of aggressive behavior in mice. In particular, early exposure to aggression enhanced later expression of this trait (Sandnabba 1996). The role of the preweaning maternal environment is controversial. In selective breeding studies, the influence of the mother appeared to have little influence on the development of aggression (Hoffmann et al. 1993; Sandnabba 1996), while cross-fostering certain inbred strains with one another was able to influence aggressive behavior in some (Southwick 1968), but not others (Fredericson 1952; Geinsburg and Allee 1942).

Using the kind of forward genetic strategies that were outlined earlier in this chapter (Fig. 2), different research groups have attempted to identify loci that contribute to aggressive phenotypes. One focus of attention has been the Y chromosome, since large sex differences in aggression have been noted (Roubertoux et al. 1994). Other efforts to delineate the loci that contribute to the strain-to-strain differences in aggression are proceeding, but currently no other loci have been identified.

6.2.2 Genetics of Aggression in Humans

In humans, the contribution of genetic factors has been much more difficult to establish. Adoption and twin studies have revealed both environmental and genetic modulators for aggressive behavior in humans (Coccaro et al. 1997; Miles and Carey 1997). In addition, there is evidence that, among the DSM-IV axis II disorders, antisocial personality disorder has a strong genetic contribution (Dahl 1993). Criminal behavior also has a considerable genetic component, but paradoxically this association only holds true for nonviolent or property crime (Brennan et al. 1996). Of course there is a large environmental contribution to aggressive behaviors, but studies have suggested that environment contributes more to attributes such as hostility and less to attributes such as angry aggression and irritability (Gustavsson et al. 1996). Environmental factors such as perinatal problems and not genetic transmission appear to influence the development of violent criminal behavior (Mednick and Kandel 1988).

6.3 Brunner's Syndrome

Thus far, the only characterized mutation that might be associated with violent behavior is a point mutation in the monoamine oxidase A (MAOA) gene that changes a glutamine codon to a stop codon, leading to an inactive, truncated form of the enzyme (Brunner et al. 1993). The MAOA gene codes for a protein that metabolizes serotonin and other bioamines. MAOA appears to be a major pathway by which synaptic serotonin is inactivated. Individuals lacking a functional MAOA gene were found to suffer from borderline mental retardation and altered behavior including impulsive aggression, arson, attempted rape, and exhibitionism. This mutation and the accompanying behaviors have been called "Brunner's syndrome."

The MAOB gene is functionally and structurally related to the MAOA gene. It metabolizes dopamine and phenethylamine derivatives in the brain. The MAOA and MAOB genes are found in a tandem array on the X chromosome, and thus inheritance of a single mutated or deleted copy of either gene leads to complete deficiency of the gene in males but not females. Since the initial report of subjects deficient in MAOA, microdeletions of the X chromosome in this locus have been characterized that affect either MAOA, MAOB, or both. Double mutations lead to severe mental retardation, whereas selective MAOB deficiencies lead to no abnormal behavior or mental retardation (Lenders et al. 1996). The study of such individuals is providing much information about the role of these enzymes in brain development and behavior (Lenders et al. 1998), but an animal model of these disorders would allow a level of inquiry not possible with human subjects. Specifically, such models would allow a detailed study of the behavioral effects of altered monoamine metabolism.

In a striking example of serendipity, a group of researchers who introduced a transgene for interleukin (IL)-β into the mouse genome noted that one of their mouse strains appeared significantly more aggressive than other strains. Further analysis of these aggressive mice found that one of the copies of the IL-β gene had inserted into a crucial portion of the coding region of the MAOA gene. As this gene is found on the X chromosome, a single mutation was sufficient to create a complete absence of MAOA activity in male mice. These mice had striking abnormalities in their bioamine metabolism and behavior. In pup brains, serotonin concentrations were increased by up to ninefold, and norepinephrine by twofold. In adults, serotonin and 5-hydroxyindoleacetic acid (5-HIAA) levels returned to normal, but adults displayed a specific set of behavioral alterations, including enhanced intermale aggressive behavior, increased attempts to mount nonreceptive females, and decreased immobility in a forced swim test (a test used to screen for antidepressant activity). The enhanced aggressive behavior displayed by mice lacking MAOA parallels the finding of Brunner's subjects lacking a functional MAOA. The ability to reproduce the aggressive phenotype in transgenic mice suggests that their unusual behavior may therefore be a consequence of the MAOA mutation rather than the result of some unusual environmental or genetic background in that family. Consistent with the characterization of individuals with microdeletions affecting the MAOB gene, knockout mice lacking the MAOB gene did not display overt changes in aggressive behavior (Grimsby et al. 1997). No report of a double MAOA/B mutant has been described.

6.4 Serotonin and Aggression

To many researchers, the finding of a hyperaggressive phenotype in the MAOA mutant mice and in Brunner's syndrome came as a surprise. The MAOA mutation in each case increases brain serotonin, and aggression is normally associated with low brain serotonin levels. Indeed, one of the more robust findings in psychiatry has been the association of suicide (Mann et al. 1990), type II alcoholism, and violent behavior (Linnoila and Virkkunen 1992) with low brain serotonin levels. Low cerebrospinal fluid (CSF) serotonin metabolites are found in aggressive nonhuman primates (Mehlman et al. 1994), and serotonin depletion in the brains of rodents yields hyperaggressive animals in tests of predation (Valzelli et al. 1981), offensive aggression (Vergnes et al. 1986), and stress-induced aggression (Sheard and Davis 1976). Moreover, certain serotonin agonists have antiaggressive properties in animal models (Olivier et al. 1995). MAOA inhibitors, which were widely used as antidepressants, have not been reported to induce aggressive behavior.

The MAOA knockout mouse is a good example of a classical knockout providing a surprising phenotype that would not have been predicted from pharmacology alone. For example, it is not widely observed that inhibitors of MAOA can cause increased aggressive behavior either in human subjects or in animal models. In fact, if MAOA inhibitors have any effect on aggression in adults, it would be to decrease aggression. Thus the MAOA knockout mouse mimicked Brunner's syndrome likely because of the developmental and compensatory effects of not having this gene during brain development. For example, to compensate for high serotonin levels, postsynaptic serotonin receptors might be downregulated, which could in turn result in a phenotype similar to low serotonin activity. Consistent

with this possibility has been the unexpected finding that in children who come from a cohort of adjudicated siblings, the children with higher indices of serotonin activity have higher rates of behavioral aggression (Pine et al. 1997). Thus it may be speculated that, similar to the MAOA knockout mouse, low serotonin activity in adults with aggression may be the result of elevated activity in early life. While such an interpretation is very speculative, we suggest it in order to illustrate how findings in a mouse model may eventually inform hypotheses to be tested in human disorders.

Another intriguing parallel between Brunner's syndrome and the MAOA mutant mice is the possibility of aberrant neurodevelopment in each case. Serotonin is also known to be an important modulator of growth and morphogenesis (Lauder and Krebs 1978; Moiseiwitsch and Lauder 1995; Yavarone et al. 1993). If MAOA mutations lead to dramatic changes in serotonin in the brain, this might produce structural changes in the brain. Indeed, mice lacking MAOA display neuroanatomic abnormalities such as an absence of the cortical barrels field that are the somatosensory representation of the vibrissae (Cases et al. 1996). This is a situation where inducible or tissue-specific knockouts may help disentangle a complex but relevant phenotype.

6.5 Aggressive Behavior and the 5-HT1B Receptor Knockout

As discussed in the last section, there appears to be an important role of serotonin in controlling aggression and impulsivity in several species, including humans. One of the serotonin receptors that is thought to be involved in the effect of serotonin on aggression is the 5-HT1B receptor. The 1B receptor functions as an autoreceptor and a postsynaptic heteroreceptor that controls the release of other neurotransmitters such as γ-aminobutyric acid (GABA) or glutamate in response to serotonin (Saudou and Hen 1994). Pharmacological compounds that stimulate the 1B receptor have antiaggressive properties (Olivier et al. 1995). To better understand the role of the 5-HT1B receptor in aggression, mice lacking 5-HT1B receptors were generated by gene targeting (Ramboz et al. 1996; Saudou et al. 1994) in our laboratory.

The homozygous mutants developed normally and did not differ from their wild-type litter mates anatomically. In a number of behavioral tests aimed at measuring feeding, locomotion, and anxiety, either no differences or only small differences were found between the wild-type and the mutant mice. However, when analyzed in the isolation-induced aggression test, the male homozygous mutants displayed increased aggressive behavior (Saudou et al. 1994). In this test, wild-type or mutant males that have been isolated for 4 weeks are confronted with a male intruder that has not been isolated. The wild-type mice attack the intruder only after an initial investigative period that includes sniffing and aggressive displays such as tail rattling. In contrast, the mutant mice attack immediately or after a short latency. In addition, the number and the intensity of the attacks were significantly higher in the case of the mutants. The short latency of attack displayed by these mutant mice is reminiscent of the impulsive behavior often associated with deficits in central serotonin in primates.

To investigate whether the aggressive phenotype extends beyond isolation-induced aggression (a stress-induced aggression), we subjected 1B knockout mice to other tests of aggression, including territorial aggression and maternal aggression tests, and discovered that the 1B knockout mice did indeed display increased aggression in these functional types of aggression as well.

Unlike the example of the MAOA mutant mouse, where the phenotype was not predicted by pharmacology, 5-HT1B agonists have been shown to decrease aggressive behavior in a number of rodent models, including the isolation-induced aggression test. It is therefore consistent that mice lacking this receptor display the opposite phenotype. However, it is still possible that developmental or compensatory changes are responsible for the aggressive behavior of these mutant mice. Indeed, we have observed compensatory changes in the expression of various genes, including dopaminergic genes, serotonergic genes, and genes in the *fos* family. We are in the process of developing mice that will have either temporal control over 1B gene expression, tissue-specific control, or both. We plan to use these animals to understand more fully the aggressive phenotype that is observed in the classical 1B knockout.

Finally, we would again like to emphasize that, unlike the MAOA mutation, which is found in at least some human families, a mutation in the human 5-HT1B receptor gene has not been reported. Thus the 1B knockout mouse is an example where we have created our own "accident of nature" to investigate its potential role in aggressive behavior. Despite the absence of a human counterpart, this mutant mouse has been and will continue to be a useful tool in investigating the biology of aggression and in screening for new medications that can help remedy some of the problems posed by human aggressive behavior.

6.6 Aggressive Behavior in Other Knockout Strains

A number of other knockout mice have been reported that display changes in aggressive behavior compared

to their wild-type litter mates. Different examples of these mice will be discussed in the context of the promise of knockouts to open new avenues of research as well as the potential confounding factors that can affect interpretation of their phenotype.

6.6.1 Neuronal Nitric Oxide Synthase

Nitric oxide (NO) has recently been implicated as a nearly ubiquitous signaling molecule that controls many renal, gastrointestinal, cardiac, and brain functions (Zhang and Snyder 1995). NO is synthesized by two different isoenzymes: neuronal and endothelial NO synthases. Neuronal NOS (nNOS) is expressed widely both in the developing and in the adult nervous system. Mice lacking nNOS display an increase in offensive aggressive behavior and altered sexual behavior (Nelson et al. 1995). In the resident–intruder paradigm, mutant males attack male intruders more often and more intensely than wild-type males, while the latency to the first attack is the same in both groups. The male nNOS knockout mice also have inappropriate sexual behavior in that they tried to mount unreceptive females. The absence of prior reports linking the NO system to aggression led many to speculate that the aggressive phenotype was the result of neurodevelopmental or compensatory mechanisms in these mice. However, a follow-up study demonstrated that nNOS inhibitors can produce hyperaggressive behavior in two different models of aggression to a degree found in the nNOS knockout mice (Demas et al. 1997). The mechanism by which NO can modulate aggression is not known. A parsimonious hypothesis would tie together an effect of NO on known modulators of aggression such as serotonin. In fact, nNOS is commonly colocalized with bioamine neurons, and a large percentage of serotonergic neurons in the raphe that project to the cortex coexpress nNOS and serotonin (Blottner et al. 1995). Although intriguing, the effect of NO on serotonin target neurons is unknown. In summary, the nNOS knockout mouse is an excellent example of how transgenic techniques were able to open new avenues of exploration in an area such as aggression. However, questions still remain regarding the mechanism of NO actions on aggression, the brain structures involved in this response, and the ontogeny of this response.

6.6.2 Calcium Calmodulin Kinase II

Mutant mice that are heterozygous for a mutation in the gene encoding the enzyme CaMKII display increases in defensive aggression but not in offensive aggression in the resident–intruder paradigm (Chen et al. 1994). This hyperaggressive phenotype came as a surprise, because, like nNOS, this enzyme had not previously been linked to aggression. However, if we look for connections to the serotonin system, we can see that these mice display decreased serotonin release as measured by extracellular and whole-cell patch-clamp recordings from brainstem slices. This may be explained by the role of CaMKII-mediated phosphorylation in the activation of TpH, the rate-limiting enzyme for serotonin synthesis. A reduction in TpH activity might therefore explain the aggressive phenotype of the CaMKII heterozygous mice. As an example of how a phenotype can be confounded by other factors, it was found that homozygous mutants for the CaMKII gene are not aggressive. However, these animals display a large number of other behavioral abnormalities. The homozygote mutant animal may be an example of developmental abnormalities affecting even a phenotype seen in heterozygote mice.

6.6.3 Preproenkephalin Gene Knockout

Enkephalins and endorphins are two endogenous peptides that appear to function as natural analgesics in animals. A well-known phenomenon in different species including humans is the development of a profound analgesia during periods of stress and danger (Miczek et al. 1982). In humans, such profound analgesia has allowed wounded soldiers to continue to fight without awareness of their wounds. This stress-induced analgesia has both opiate and nonopiate mechanisms (Grisel et al. 1993). In mice, the ability to develop an opiate-analgesic response during aggressive encounters is thought to influence the type of strategy the animal pursues to defend itself and may therefore influence social hierarchy (Miczek et al. 1994). The enkephalins are thought to be the primary mediator of stress-induced analgesia (Raab et al. 1985). It might have been predicted that, in the absence of enkephalins, stress-induced analgesia would be impaired and the mice would exhibit less aggression. Although this hypothesis appears sound, the problem was that enkephalin-deficient mice had a normal analgesic response to stressful situations (Konig et al. 1996). In addition, an increase in offensive aggressive behavior was observed compared to wild-type mice. These knockout mice were also found to be more anxious than wild-type mice, but the contribution of this anxiety state to aggression is unclear. Thus, the enkephalin-deficient mice have a surprising phenotype in many respects. They will prove to be an interesting model to study the link between the enkephalin system and aggressive behaviors.

6.6.4 Neurokinin 1 Receptor Knockout

Substance P is known to mediate transmission of some painful stimuli and to modulate inflammatory responses. It is also found in the limbic regions and basal ganglia of the brain. The main receptor for substance P is the neurokinin (NK) 1 receptor. When the gene for this receptor was disrupted in mice, the resulting animals were found to have alterations in nociception, stress-induced analgesia, and aggression (De Filipe et al. 1998). Since the NK1 receptor appears to signal pain, as expected, these NK1 knockout mice had a reduced response to painful stimuli. In contrast, NK1 knockout mice had impaired stress-induced analgesia. Based on our reasoning outlined for the preproenkephalin knockout, we predicted that, based on their inability to develop analgesic responses during stress, these animals may be less apt to engage in aggressive encounters. Consistent with that prediction, NK1 knockout mice displayed decreased aggression compared to wild-type animals. NK1 knockout mice did not display any differences in a test of anxious behavior.

6.6.5 Adenosine A_2 Receptor Knockout

The purine adenosine is thought to act as a neurotransmitter in the brain and the periphery. Adenosine receptors are found in the brain in high concentrations and appear to be involved in a number of different processes. The A_{2a} adenosine receptor subtype is found in the basal ganglia and appears to be the major target for the stimulant properties of caffeine. Although caffeine, an antagonist at A_{2a} receptors, can potentiate aggressive behavior, and agonists at this receptor can have serenic-like effects, the purinergic system has not been classically implicated in the modulation of aggressive behavior. Nonetheless, A_{2a} knockout mice were found to be more aggressive in resident–intruder tests of aggression, a finding consistent with the proaggressive effects of A_{2a} antagonists such as caffeine. Like the enkephalin knockout mice, these animals were also found to be more anxious than their wild-type litter mates, but the connection of anxiety to aggression is not clear. Indeed, other knockout mice with elevated anxiety (see Table 1) have not been observed to be more aggressive than nonmutants. Perhaps more relevant to understanding the aggressive phenotype was the finding that these A_{2a} knockout mice were less sensitive to painful stimuli than control mice. If the ability to develop pain insensitivity during stress is important for expression of aggressive behavior, the low pain sensitivity seen in A_{2a} knockout mice may partially explain the aggressive phenotype. As in our previous examples, the implication of adenosine as a major modulator of aggression was unexpected and has generated another tool with which to study the biology of aggression.

6.6.6 Estrogen Receptor Knockout

Aggressive behavior and social dominance in animals is often associated with elevated testosterone levels. Social defeat typically leads to long-lasting decreases in serum testosterone (Bonson et al. 1994; Koolhaas et al. 1997; Lisciotto et al. 1990). As estrogen often acts functionally to antagonize the effects of testosterone, it might be expected that mice lacking an estrogen response would be hypermasculine. However, the aggressive behavior of male mice was dramatically decreased with an almost complete absence of male-typical offensive attacks (Ogawa et al. 1997). At first, this result would seem surprising but , it has been demonstrated that in many animal species there is a paradoxical affect of estrogen receptors on masculinization. In rats, the hypothalamus contains the enzyme aromatase, which converts testosterone to estrogen. It is aromatized testosterone in the hypothalamus that induces masculine behavior in the rat via estrogen receptors. Thus the absence of the estrogen receptor in male mice may lead to paradoxical feminization due to the failure to stimulate these hypothalamic estrogen receptors. In contrast to male estrogen receptor knockout mice, female mice exhibited increased aggression against other females and mothers tended to cannibalize their pups more often. Interestingly, female estrogen receptor knockout mice were treated as "male" intruders by resident male mice and were thus attacked rather than mounted (Ogawa et al. 1996). Thus ablation of the estrogen receptor has complex behavioral effects that are paradoxical in males (demasculinization, decreased aggression) but are more expected in the female (masculinization, increased aggression).

6.6.7 Oxytocin and Oxytocin Receptor Knockout

The hormone oxytocin performs a role in a variety of functions, including milk ejection, birth, and behavior, especially affiliative and social behaviors and aggression (Young et al. 1997). In particular, it has been observed that monogamous prairie voles and nonmonogamous montane voles have different patterns of oxytocin receptor expression that are thought to play a role in social behaviors. To further explore the role of oxytocin in behavior, knockouts of the oxytocin

Table 1. Various behavioral phenotypes of knockout and transgenic mice with potential relevance to psychiatry

Mutation (genotype)	Phenotype	Reference
Aggressive mice strains		
5-HT1B Receptor (−/−)	Increased offensive aggression Increased maternal aggression	Sadou et al. 1994 Unpublished
MAOA (−/−)	Increased intermale aggression Inappropriate sexual behavior	Cases et al. 1995
nNOS (−/−)	Increased offensive aggression Inappropriate sexual behavior	Nelson et al. 1995
αCAM kinase II (+/−)	Increased defensive aggression No change in offensive aggression	Chen et al. 1994
Preproenkephalin (−/−)	Increased offensive aggression	Konig et al. 1996
Oxytocin receptor (−/−)	Decreased intermale aggression	DeVries et al. 1997
NK1 receptor (−/−)	Decreased intermale aggression	Babinet et al. 1989
Adenosine receptor 2a (−/−)	Increased isolation-induced aggression	Ledent et al. 1997
Estrogen receptor (−/−)	Decreased intermale aggression Increased interfemale aggression	Ogawa et al. 1997 Ogawa et al. 1996
NCAM (−/−)	Increase offensive aggression	Stork et al. 1997
TGF-α	Increased offensive aggression Low brain 5-HIAA	Hilakivi-Clarke et al. 1993
Memory and learning-impaired strains		
PKC-γ (−/−)	Impaired hippocampal LTP Impaired spatial learning Impaired contextual learning	Abeliovich et al. 1993a Abeliovich et al. 1993b
αCaMKII (−/−)	Impaired hippocampal LTP	Silva et al. 1992
CREB (−/−)	Impaired long-term memory Intact short-term memory Impaired hippocampal LTP Intact PPF and PTP	Bourtchuladze et al. 1994
PKA Cβ1 (−/−)	Impaired mossy fiber LTP	Huang et al. 1995
PKA R1β (−/−)		Huang et al. 1995
nNOS (−/−)	Normal LTP, learning	O'Dell et al. 1994
eNOS × nNOS (−/−)	Impaired LTP CA1	Son et al. 1996
Type I adenylyl cyclase (−/−)	Impaired CA1 LTP Impaired spatial memory	Wu et al. 1995
mGluR1 (−/−)	Impaired hippocampal LTP Impaired associative learning Impaired cerebellar LDP Impaired motor learning	Aiba et al. 1994a Aiba et al. 1994b
αCaMKII inducible	Impaired LTP Impaired spatial learning Impaired fear conditioning	Mayford et al. 1996
αCaMKII-activated mutation		Mayford et al. 1995; Rotenberg et al. 1996
PKA R(AB) (−/−)	Impaired L-LTP Impaired spatial learning	Abel et al. 1997
Anxiety and stress-altered mice strains		
CRF1 receptor (−/−)	Decreased anxiety Decreased stress response	– –
5-HT1A receptor (−/−)	Increased anxiety	Unpublished
Serotonin transporter (−/−)	Decreased anxiety	Unpublished

Table 1 (*Continued*)

Mutation (genotype)	Phenotype	Reference
Transgenic strains		
CRF overexpression	Increased anxiety	Stenzel-Poore et al. 1994
Type II glucocorticoid antisense transgenic	Decreased stress response	Pepin et al. 1992
Mice strains altered in catecholamine systems		
Dopamine D2R (−/−)	Parkinson-like motor impairment	Baik et al. 1995
Dopamine D3R (−/−)	Hyperactivity in novel environment	Accili et al. 1996
Dopamine D1R (−/−)	Hyperactivity in novel environment Cocaine-induced hypolocomotion Reduced cocaine-induced stereotypies	Xu et al. 1994b Xu et al. 1994a Moratalla et al. 1996
Tyrosine hydroxylase (−/−)	Embryonic lethality E11.5–E15.5 Rescued by L-dopa	Zhou et al. 1995
Tyrosine hydroxylase (DA specific)	Severe hypoactivity, adipsia, aphagia Rescued by L-dopa	Zhou and Palmiter 1995
Dopamine transporter (−/−)	Increased spontaneous locomotion Impaired locomotor response to cocaine and amphetamine Slow weight gain Early death Impaired maternal behavior	Giros et al. 1996
DBH (−/−)	Embryonic lethality Rescued by dihydroxyphenyl serine	Thomas et al. 1995
α2C adrenergic receptor (−/−)	Impaired clonidine hypothermia	Link et al. 1995; Sallinen et al. 1997
α2B adrenergic receptor (−/−)	Impaired hemodynamic effects of α2 agonists	Link et al. 1996

MAOA, monoamine oxidase A; NCAM, neural cell adhesion molecule; TGF, transforming growth factor; CaMK, calcium calmodulin kinase; NK, neurokinin; 5-HIAA, 5-hydroxyindoleacetic acid; PKC, protein kinase C; LTP, long-term potentiation; PKA, protein kinase A; CREB, cAMP response element binding protein; nNOS, neuronal nitric oxide synthase; eNOS, endothelial NOS; CRF, corticotropin-releasing factor; DA, dopamine; DBH, DA-β-hydroxylase.

peptide and its receptor were both created (DeVries et al. 1997; Nishimori et al. 1996). Interestingly, the oxytocin receptor knockout mice were much less aggressive in two different tests of aggression than either wild-type or heterozygous mutants. The mutation of the oxytocin gene (OKO) exhibited no behavioral phenotype except for an inability to nurse pups (defective milk ejection) that was correctable with exogenous oxytocin injections. The reduced aggressiveness seen in the oxytocin receptor knockout mice is consistent with the findings that this peptide can play a role in social behaviors.

7 Conclusion

In conclusion, we have attempted in this chapter to demonstrate the power of transgenic techniques to more directly understand the connections between gene function and behavior. The advantage of this technique is the power to create mutations that are not found in nature and to study their effects on animals. These mutations are absolute and precise. We have also attempted to enlighten the reader concerning some of the confounding problems that complicate interpretation of some knockout experiments. In the future, more precise control of the temporal and anatomic specificity of the mutation may be possible and will help address many of the criticisms of current knockout techniques.

We have chosen to illustrate many of these principles using the phenotype of aggression to demonstrate that many different genes can contribute to the modulation of aggressive behavior in mice. Mutations in mice have been used to mimic a human mutation in the MAOA gene to create other mutations in the serotonin system that also affect aggression (5-HT1B receptor gene) but for which no human counterpart exists. Lastly, we have described several other knockout mice that have alterations in their aggressive

behavior. These animals are interesting in several respects. First, they have often implicated new genes and neurotransmitter systems in the control of aggression that had not been previously studied. Second, these animals often exhibited paradoxical or unexpected phenotypes that may be explained by developmental abnormalities or compensatory processes that are inherent to "classical" knockouts. Lastly, these mutant animals demonstrate that different mutations can modulate aggressive behavior in either direction – up or down.

Finally, in Table 1, we present a sample of the knockout strains currently available which may be of interest in understanding behaviors related to psychiatric conditions. Since new knockouts are continually being created, this cannot be thought of as a complete list, but rather as a representative sample of what is currently available. The knockouts involve either receptors for neurotransmitters, enzymes involved in neurotransmitter synthesis, enzymes involved in second messenger pathways, or growth factors. All these classes of compounds will be involved in multiple behaviors and neuronal systems, making simple interpretations of the resulting phenotype difficult. The aggressive mutations have been discussed in some detail. In addition, there are several strains of mice which have been utilized in the study of memory and learning. Interestingly, almost all these mice involve alterations in second messenger pathways or transcription factors activated as a consequence of second messenger activation. The clearest information comes from those knockouts which do not impair learning, such as NOS knockouts, which suggests that these systems are not involved in the learning process. Definitive interpretations will only be possible with conditional site-specific knockouts, but these data provide suggestive clues. The mice which show changes in stress response can be used as models for anxiety and depression and generally involve the catecholamine systems and the hypothalamic–pituitary–adrenal (HPA) axis. Again, interpretation is difficult, but the models in which a substance is overexpressed point to a role for corticotropin-releasing factor (CRF) in anxiety. The catecholamine knockouts have provided less information about mood disorders or schizophrenia than might be expected until we consider the difficulty in defining the phenotype in a mouse model. In general, dopamine changes involve drug effects and motor function, while noradrenergic changes are either lethal or involved the vascular system.

Thus we believe that the transgenic technologies described here will hold promise for helping researchers to dissect the role of different genes in influencing behavior. As the human genome approaches being fully sequenced in the next 5–10 years, the application of these technologies to newly described genes will continue to provide insights into the genetic regulation of behavior.

Neurochemistry: The Basis of Psychopharmacology

1 Introduction

For ages, man has taken psychic comfort in the effects of drugs such as alcohol, morphine and cocaine. However, it was not until the 1950s that drugs became available with a demonstrated efficacy in the treatment of psychiatric disorders such as schizophrenia and depression. Attempts to understand the mechanisms of action for these drugs have been essential in the development of modern concepts in biological psychiatry. For example, the dopamine (DA) hypothesis of schizophrenia largely derives from experiments showing that antipsychotic drugs such as haloperidol and chlorpromazine affect the metabolism of DA but not other neurotransmitters (although at the time this hypothesis was formulated in the early 1960s, there were relatively few "other" neurotransmitters). Roles for norepinephrine (NE) and serotonin (5-HT) in depression developed from the observation that reserpine produces a "depressed" behavior in rodents and humans which is associated with the depletion of these transmitters. Further, it was found that the "depressed" behavior could be reversed by the administration of precursor molecules which elevate NE and serotonin levels. Soon thereafter, it was demonstrated that the first generation of antidepressant drugs block the synaptic reuptake of NE and serotonin, thus securing a prominent role in depression for these transmitters. Benzodiazepines were first synthesized in the late 1950s and introduced into clinical practice as anxiolytics soon thereafter. However, it was not until the 1970s that benzodiazepines were discovered to both potentiate the binding and enhance the neurophysiological effects of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Drugs which show cross-tolerance to and dependence on the benzodiazepines, e.g. the barbiturates and ethanol, were also found to similarly affect GABA neurotransmission.

Drugs have also been used to induce transient states which model psychiatric disorders. As early as 1845, Moreau suggested that hashish intoxication provided a model psychosis useful in the study of insanity. The use and abuse of cocaine and amphetamine led to the recognition that these drugs could induce a paranoid delusional state (see, e.g. Bell 1973). There was a brief period of scientific interest in the psychotomimetic properties of mescaline in the early 1900s and again in the 1930s. However, the modern era of psychotomimetic drugs begins with the synthesis of lysergic acid diethylamide (LSD) in 1943 by Stoll and Hoffmann (1943) and the discovery of its remarkable potency. Subsequent studies showed that LSD bound to serotonin receptors, and soon thereafter it was recognized that a wide variety of indolealkylamines had psychotomimetic properties. These included dimethyltryptamine (DMT) and psilocin. Even the psychotomimetic phenylalkylamines such as mescaline and dimethoxyamphetamine (DMA) were considered to act via a LSD- or indolealkylamine-like mechanism. Finally, it is important to remember that the rediscovery (from a scientific perspective) of natural psychotomimetics (e.g. mescaline) and the discovery of new agents (e.g. LSD) were important components of a view popular from the 1950s to the early 1970s which held that schizophrenia was due to the production of some abnormal natural product. This line of reasoning reached its zenith with attempts to cure schizophrenia via renal dialysis (Wagemaker and Cade 1978; Emrich et al. 1979). Interestingly, the development of Li^+ for the treatment of mania followed a related path. While investigating psychotoxic nitrogenous substances in the urine of mental patients for testing in guinea pigs, Cade administered lithium salts to the animals in an attempt to increase the solubility of urates. Cade noticed that lithium carbonate made the animals lethargic and decided to try lithium carbonate in manic psychiatric patients (Cade 1949). Fortunately, lithium was effective in the first few patients, and lithium remains the standard against which new drugs for the treatment of mania (e.g. valproic acid) are assessed.

Finally, pharmacological developments in nonpsychiatric areas have contributed significantly to modern concepts in biological psychiatry. For example, the development of 3,4-dihydroxyphenylalanine (dopa) therapy for the treatment of Parkinson's disease solidified the evidence for DA as a neurotransmitter. The finding that some Parkinson's patients on dopa therapy developed psychotic symptoms further strengthened the DA hypothesis of schizophrenia. Phencyclidine was developed as a "dissociative" anesthetic agent, but was abandoned because of the high incidence of postoperative delirium with hallucinations. Nearly 30 years later, it was found that phencyclidine and related compounds (e.g. ketamine and MK-801) bind to the *N*-methyl-D-aspartate (NMDA) glutamate receptors, an observation which in part led to the glutamate hypothesis of schizophrenia (Carlsson and Carlsson 1990).

To understand the significance of these historical observations, the current concepts of psychiatric disorders, and the future directions of psychiatric and psychopharmacological research, one needs to develop a perspective which integrates neuroanatomy, neurobiology, neurochemistry, neuropharmacology, and behavior. We begin with a brief review of cellular elements of the central nervous system

(CNS) that are especially relevant to psychopharmacology.

2 Cells of the Nervous System

An understanding of the action of drugs on the nervous system demands that we look at what is special about the nervous system, and that begins with the cells from which it is constructed, nerve cells or neurons. These cells possess two special properties related to information transfer and processing not found in other cells of the body. First, they can transmit electrical signals over long distances without loss of signal strength, and second, they have special areas for intercellular communication, synapses. There are also other cells in brain called glia. The two main types are the astrocyte and the oligodendrocyte, which latter of which wraps around the long axonal processes forming a mylin sheath to insulate the axon transmitting the electrical signals. In general, there are three types of nerve cells: (1) unipolar cells, such as sensory neurons, which transmit information from a sensory receptor to the dorsal root ganglion, (2) bipolar cells, such as granule cells, and (3) multipolar cells with an efferent axon and a dendritic tree. This latter structure is the receptive end of the cells where messages arrive and often can be a complex network like the branches of a tree.

The special property of neurons relates to electrical excitability. When these cells are at rest, they have an electrical potential across the cell membrane like all cells in the body. This is due to the distribution of ions inside the cell as opposed to outside the cell. The interior is low in sodium and free calcium and high in potassium and compares to the extracellular fluid. The ions move across the membrane through specific ion channels (see Vol. 1, Part 1, Chap. 7), and the membrane potential is maintained through metabolic pumps which maintain the ion gradients across the membrane. In nerve cells, when the membrane is depolarized from its resting potential, a sudden, rapid change in membrane potential is seen in which the potential actually reverses polarity for a short period of time, going from -70 mV to +20 mV, for example. This is termed electrical excitability; it is unique to nerve cells and is due to short-term changes in ion permeability. This is the electrical signal which is propagated down the axon and causes the release of neurotransmitters at the synapse. It is through the action of neurotransmitters at the synapse that most of the drugs which we use in psychiatry act, and we need to consider this area in more detail.

3 Neurotransmitters, Receptors, and Transporters

3.1 What Is a Neurotransmitter?

The role that psychopharmacology has had in the development of biological psychiatry requires an understanding of the neurotransmitters which provide the mechanisms of action for psychoactive substances. Surprisingly, the definition of what makes a substance a neurotransmitter has been changing ever since the original proposals for neurohumoral transmission by Lewandowsky (1898) and Langley (1901). Some of the criteria which have been more or less constant include the following:

1. *The transmitter must be present in the presynaptic terminal of the synapse.* One historical corollary to this criteria was that the ability to synthesize the neurotransmitter must also be present in the presynaptic terminal. However, this criteria would eliminate the neuropeptides, which are synthesized in the cell body and transported to the terminal from consideration as neurotransmitters.
2. *The transmitter must be released from the nerve terminal in response to neuronal activity.* Thus the putative transmitter must be released under conditions (electrical or chemical stimulation) which are known to increase the rate of neuronal firing. Acetylcholine (ACh) was the first neurotransmitter to satisfy this criteria. Loewi (1921) observed that, when he stimulated the vagus nerve of a perfused frog heart, the perfusate caused a second heart to respond (slowing of the heart rate) in the same way as the donor heart. Subsequently, Loewi and Navratil (1926) identified ACh as the substance being released. In vivo microdialysis is a modern adaptation of Loewi's classic experiments, in which a small region (0.5–1 μl) of the brain is perfused and the transmitter present from synaptic overflow is collected and measured. Although an indirect measure, in vivo electrochemical detection accomplishes essentially the same goal. Overall, these and other techniques have provided compelling evidence that all of the transmitter-like substances shown in Table 1 are released by neuronal activity.
3. *Exogenous application of the putative transmitter substance to the target cells must produce the same physiological response as that seen from increasing synaptic release.* Until recent years, meeting this criteria without ambiguity was difficult in brain because of the problem of measuring the transmitter effect on a single cell. However, this problem was largely overcome by the development of whole-cell

patch clamp technology (see Aston-Jones and Siggins 1994).

In general, the original idea of neurotransmitter activity involved point-to-point signaling. However, it is now clear that many substances such as the catecholamines, originally identified as neurotransmitters, may in fact involve modulation of an effect, and the term neuromodulator is often used. Modulation is often effected through actions on second messenger systems such as cyclic adenosine monophosphate (cAMP). A list of transmitters and modulators active in the CNS is presented in Table 1 along with the site of action either on ion channels or second messenger systems.

The discovery of and characterization of neurotransmitters in the brain (including the spinal cord) has developed from several directions, including those mentioned below.

3.1.1 Technology

For the student of the 1990s, it is difficult to recognize that, until the mid-1950s, the only reliable methods for assessing neurotransmitters were bioassays. With the development of the spectrophotofluorometer, it became possible to detect microgram quantities of epinephrine, NE, DA, and serotonin. One of the first pharmacological applications of this technology was the demonstration that reserpine depleted the biogenic amines from the brain; further, the recovery of amine levels was associated with the recovery from reserpine associated "depression." The fluorescence technology was extended to histochemistry, which permitted the visualization of the amines within intact tissue (see Bjorklund et al. 1968). When applied to the brain, this technique revealed the presence of catecholamine and later serotonergic pathways and cell bodies with quite specific regional localizations. The terminology used to describe these groupings, e.g. A9 and A10 to describe the DA neurons of the substantia nigra and ventral tegmental area, respectively, is still found in the current literature. Subsequently, the availability of radioisotopes made it possible to study transmitter metabolism, to visualize the uptake of transmitters into specific brain areas, to study transmitter release, and to characterize the transmitter receptors. The availability of new, highly sensitive detection systems, e.g. gas chromatography/mass spectrometry, made it possible to detect transmitters present in only minute amounts. Advances in molecular biology have made it possible to clone, sequence, and investigate the active sites of neurotransmitter receptors (see Vol. 1, Part 1, Chap. 5).

3.1.2 Brain–Gut Connection

With the advancements in technology, new transmitters, particularly new neuropeptides, were discovered outside the CNS. The intestine was a particularly rich tissue for discovery. A number of the peptides first isolated from the intestine, e.g. cholecystokinin and gastrin, were later found in brain and to be associated with specific transmitter systems. In addition to the intestinal peptides, small peptides first identified either as pituitary peptides (e.g. vasopressin) or as pituitary-releasing factors were subsequently shown to have a transmitter role in the CNS. Corticotropin-releasing factor (CRF) is one such peptide; from the psychiatric perspective, the CRF neurons which project from the central nucleus of the amygdala to the locus ceruleus appear to be important, especially in the regulation of fear, anxiety, and stress.

The neuropeptides are generally colocalized with another transmitter, e.g. DA and neurotensin. The idea that more than one transmitter-like substance is found in a nerve terminal was only grudgingly accepted. Dale (1935) proposed that a neuron releases the same substance at each synapse. However, the recognition that most (if not all) neurons contain more than one transmitter substance has led to a revision of Dale's hypothesis, and it is now generally held that each neuron releases the same set of transmitters at each synapse. However, one wonders whether even this view may be an oversimplification. Consider the DA neurons which release DA from both axonic and dendritic synapses. We really do not know whether the same neuropeptides are released at both types of synapse and in the same proportions.

3.2 Synapse

The general features of the synapse are familiar (Fig. 1). Neurotransmitters, the chemical messengers, are stored in synaptic vesicles; the vesicle membranes contain specific transporters for the neurotransmitters. When the action potential reaches the presynaptic terminal, an influx of Ca^{2+} causes these vesicles to fuse with the presynaptic membrane and release either excitatory or inhibitory transmitters into the synaptic cleft (Fig. 1). Many details of the release process have been characterized. Special proteins, the synapsins and Rab3, control the trafficking and mobilization of vesicles. The docking of the vesicles to release sites on the plasma membrane is controlled by other proteins, synaptagmin and synaptobrevin, in the vesicle membrane and the neurexins and syntaxins

Table 1. Overview of transmitter pharmacology in the central nervous system

Transmitter	Receptor subtype and motif	Effector mechanisms
GABA	$GABA_A$ (ion channel) α, β, γ, δ, σ isoforms $GABA_B$ (G protein)	↑Cl^- conductance ↓cAMP ↑K^+ and Ca^{2+} conductance
Glycine	α and β subunits of (IR)	↑Cl^- conductance
Glutamate	AMPA (IR)	↑Na^+ and K^+ conductance
Aspartate	GLU 1–4 (IR) KA (IR) GLU 5–7; KA 1, 2 (IR) NMDA (IR) NMDA 1, 2_{A-D} (IR)	↑Na^+ and K^+ conductance ↑Na^+ and K^+ conductance ↓cAMP ↑IP_3/DG
Acetylcholine	Nicotinic (IR) α_{2-4} and β_{2-4} isoforms Muscarinic M1–4 (GPCR)	↑Na^+, K^+ and Ca^{2+} conductance M1, M3: ↑IP_3/DG M2, M4: ↓cAMP, ↑K^+ conductance
Dopamine	D1–5 (GPCR)	D1, 5: ↑cAMP D2: ↓cAMP, ↑K^+ and ↓Ca^{2+} conductance D3 + D4: ↓cAMP
Norepinephrine	α_{1A-D} (GPCR) α_{2A-C} (GPCR) β_{1-3} (GPCR)	↑IP_3/DG ↓cAMP ↑K^+ and ↓Ca^{2+} conductance ↑cAMP
Serotonin	5-HT_{1A-F} (GPCR) 5-HT_{2A-C}(GPCR) 5-HT_3 (IR) 5-HT_{4-7} (GPCR)	↓cAMP; ↑K^+ conductance ↑IP_3/DG ↑Na^+ and K^+ conductance 5-HT4, 6, 7: ↑cAMP
Histamine	H_1 (GPCR) H_2 (GPCR) H_3 (?)	↑IP_3/DG ↑cAMP
Vasopressin	$V1_{A,B}$ (GPCR) V2 (GPCR)	↑IP_3/DG ↑cAMP
Oxytocin	(GPCR)	↑IP_3/DG
Tachykinins	NK1 (SP>NKA>NKB) (GPCR) NK2 (NKA>NKB>SP) (GPCR) NK3 (NKB>NKA>SP) (GPCR)	↑IP_3/DG
CCK	CCK_A (GPCR) CCK_B (GPCR)	↑IP_3/DG
NPY	Y1 (GPCR) Y2 (GPCR)	↓cAMP, ↓Ca^{2+} and ↑K^+ conductance
Neurotensin	(GPCR)	↓cAMP ↑IP_3/DG
Opioid peptides	μ (β-endorphin) (GPCR) δ(Met^5-Enk) (GPCR) κ(Dyn A) (GPCR)	↓cAMP ↓Ca^{2+} and ↑K^+ conductance
Somatostatin	$SRIF_{1A-C}$ (GPCR) $SRIF_{2A,\ H}$ (GPCR)	↓cAMP ↓Ca^{2+} and ↑K^+ conductance
Purines	P_1 ($A_{1,\ 2a,\ 2b,\ 3}$) (GPCR) P_{2X}(IR) P_{2Y} (GPCR)	↓cAMP ↓Ca^{2+} and ↑K^+ conductance ↑Ca^{2+}, K^+, and Na^+ conductance ↑IP_3/DG

IR, ionophore receptor; GPCR, G protein-coupled receptor.

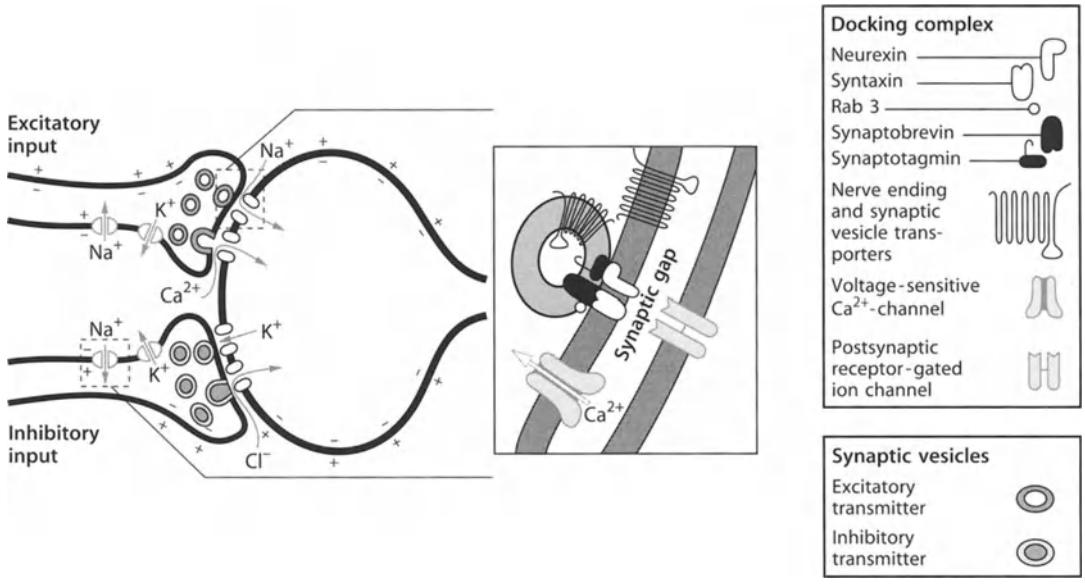

Fig. 1. The synapse. Neurotransmitters are stored in vesicles which fuse to the cell membrane and release transmitters in the postsynaptic cleft, which then interact with post- or presynaptic receptors

found in the plasma membrane. Synaptophysin is important for the formation of the fusion pore.

Once released, some of these transmitter molecules diffuse across the synapse and interact with postsynaptic receptors. The transmitter molecules may also interact with presynaptic receptors, of which there are two types, release-regulating and synthesis-regulating receptors. The binding of the transmitter to these receptors decreases release and inhibits local transmitter synthesis (for the neuropeptides, this mechanism is not operational since the peptides are synthesized in the cell body or soma). When the presynaptic receptor binds the transmitter released from the terminal, it is designated as a presynaptic homoreceptor. When the presynaptic receptor binds a different transmitter, it is termed a heteroreceptor. There are also receptors on the soma and dendrites (somatodendritic receptors); these may be either homo- or heteroreceptors.

The action of the neurotransmitter may be terminated by three processes: metabolism, reuptake, and diffusion. For some transmitters (e.g. the biogenic amines), reuptake into the presynaptic terminal is the most important mechanism of terminating transmitter action. The reuptake, however, may not occur into the terminal from which it was released; in fact, some data suggest that there is considerable diffusion of the transmitter from the synapse of origin before reuptake occurs. The transport of the transmitter need not occur into neurons; glial cells which surround the synapse also contain the transporters for some neurotransmitters (e.g. for glutamate and GABA). For other transmitters, metabolism is the primary mechanism for terminating transmitter action. Acetylcholine esterase (AChE), which is located on the membrane surface, rapidly metabolizes ACh into acetate and choline. The choline is then taken back up by the nerve terminal by a specific transporter for resynthesis into ACh; choline is also provided for ACh biosynthesis from the breakdown of membrane phosphatidylcholine. Metabolism by both specific and nonspecific proteases is important for terminating the action of the neuropeptides.

3.3 Neurotransmitter Receptors

In addition to listing the major CNS neurotransmitters, Table 1 also lists their receptor subtypes and their effector mechanisms. The neurotransmitter receptors come in essentially two motifs: ionophore receptor (IR) and G protein-coupled receptor (GPCR). However, it is important to remember that other receptor mechanisms operate in the CNS just as they do in other tissues. Ionophore receptors, which are also known as ligand-gated ion channels, act when the binding of the neurotransmitter results in the opening of a specific ion channel. These ionophore receptors are usually composed of multiple subunits (usually tetramers or pentamers). Each subunit contains four transmembrane domains, composed of hydrophobic amino acids. The subunits frequently contain one or more sites for phosphorylation by protein kinases and

dephosphorylation by protein phosphatases; in addition, there are frequently sites for voltage gating. Receptors of this type include the nicotinic cholinergic, some of the receptors for GABA and glutamate, the aspartate, glycine, and one subtype of serotonin receptor.

The G protein-coupled receptors may be directly or indirectly linked to ion channels, e.g. activation of a G protein-coupled receptor could activate a protein kinase which phosphorylates the ion channel proteins. G protein-coupled receptors are monomeric and contain seven transmembrane domains. The G proteins are heterotrimeric molecules composed of α-, β-, and γ-subunits; the complex is defined by the α-subunit composition. For example, α_s is associated with stimulation of adenylyl cyclase, while α_i is associated with inhibition of the enzyme. The agonist–receptor interaction facilitates the disassociation of GDP and the binding of GTP. At this point, the equilibrium is strongly in favor of the α-GTP subunit disassociating from the βγ-subunit. The α-GTP subunit can then interact with various effectors, e.g. adenylyl cyclase. The activity of the α-GTP subunit is terminated by the endogenous GTPase activity of the α-subunit.

Two of the principal targets of the G protein-coupled receptors are adenylyl cyclase and phospholipase C (PLC) (Fig. 2). The PLC-mediated metabolism of phosphatidylinositol-4,5 bisphosphate (PIP_2) nicely illustrates the interactions between two second messengers cAMP and Ca^{2+}. The PIP_2 signaling cascade is of particular interest in psychiatry, since Li^+, which is used to treat mania, blocks the reutilization of inositol for PIP_2 synthesis. The metabolism of PIP_2 yields two products, diacylglycerol (DAG) and inositol triphosphate (IP_3). IP_3 releases Ca^{2+} from internal stores, which in turn can interact with protein kinase C (PKC), calmodulin (CaM) kinase and cAMP. DAG is involved in the activation of PKC. Additional interactions are illustrated in the figure, which illustrates the cellular interactions of just two of the many second messengers and the complexity of the relationships.

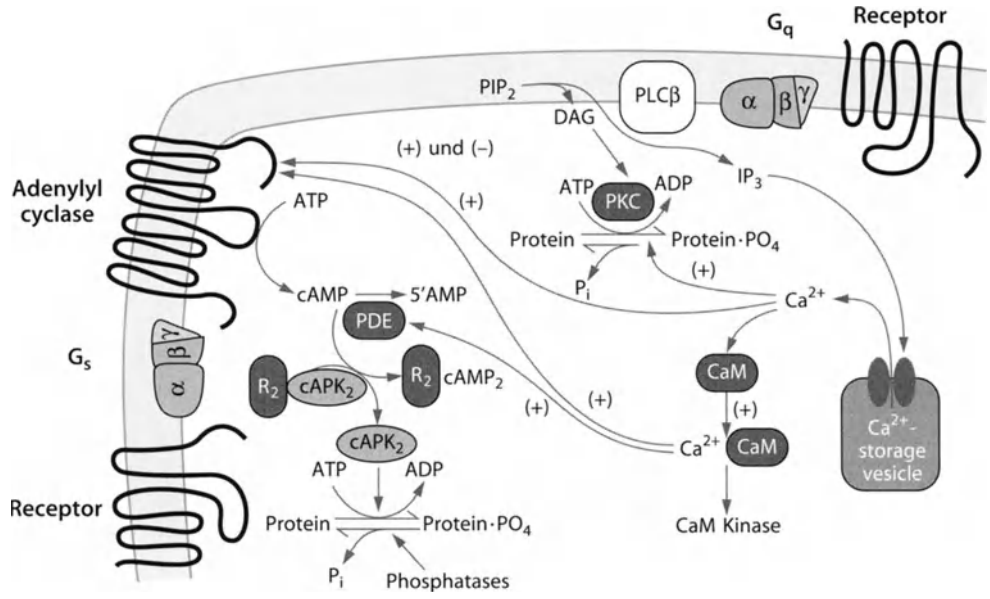
Fig. 2. Interactions between the second messengers cyclic AMP and Ca^{2+}. *CaM*, calmodulin; *DAG*, diacylglycerol; *PDE*, phosphodiester; *PIP_2*, phosphatidylinositol 4,5-bisphosphate; *PKC*, protein kinase C; *PLC*, phospholipase C

4 Specific Neurotransmitters

4.1 Catecholamines

Synthesis

The pathways for the synthesis and metabolism of the catecholamines are shown in Fig. 3. Tyrosine, either formed by the hepatic metabolism of phenylalanine or from dietary sources, is actively transported across the blood–brain barrier (BBB). The first enzyme in catecholamine biosynthesis is tyrosine hydroxylase (TH), which converts tyrosine to dopa. TH is the rate-limiting enzyme in catecholamine biosynthesis and requires both Fe^{2+} and tetrahydrobiopterin. In catecholamine-containing neurons, TH is the main target for the regulation of catecholamine biosynthesis; in particular, the phosphorylation and dephosphorylation



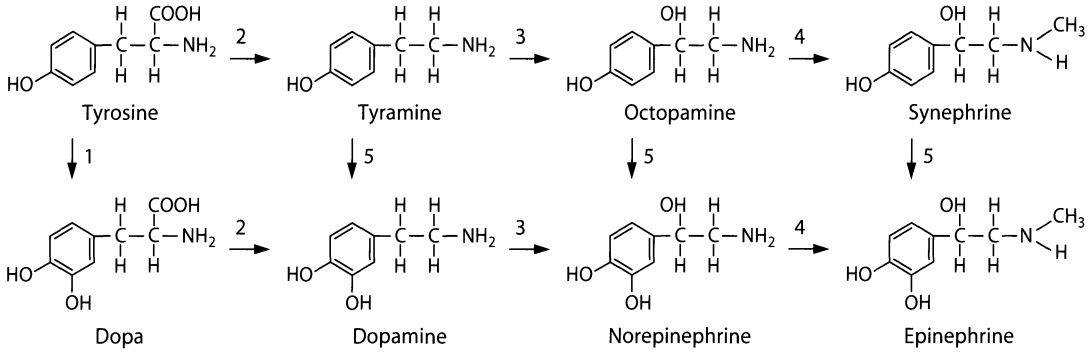


Fig. 3. Pathways in the formation of catecholamines. *1*, tyrosine hydroxylase; *2*, amino acid decarboxylase; *3*, dopamine β-hydroxylase; *4*, phenylethanolamine-*N*-methyltransferase; *5*, catechol-forming enzyme

of TH is used to regulate the enzyme affinity for tetrahydrobiopterin. Normally, the brain concentration of tyrosine is several times greater than the K_m (affinity) of TH for tyrosine, and thus enzyme activity is normally not substrate limited. However, in some pathological conditions, tyrosine becomes scarce (e.g. phenylketonuria, PKU) and an adequate production of dopa is not maintained. TH does not have an absolute specificity for tyrosine; for example, TH will convert α-methyl tyrosine to α-methyl dopa, which is then subsequently decarboxylated to α-methyl DA, a false transmitter. False transmitters can displace the endogenous transmitter. Further, when the false transmitter is released, it frequently has lower efficacy at the relevant receptor sites. Tyrosine analogues such as α-methyl-para-tyrosine (α-MT) reversibly inhibit TH activity; α-MT has been found to block the behavioral effects of some central stimulants, e.g. amphetamine, but not the effects of others, e.g. cocaine and methylphenidate. Such data may suggest that intact catecholamine synthesis is required for the full expression of amphetamine's behavioral effects.

The second step in catecholamine synthesis is catalyzed by aromatic amino acid decarboxylase (AAD) and converts dopa to DA. AAD is ubiquitously distributed in the brain and this step is not rate limiting. AAD also converts 5-hydroxytryptophan (5-HTP) to 5-hydroxytryptamine (5-HT) or serotonin.

The third step in catecholamine biosynthesis occurs only in noradrenergic and adrenergic neurons and catalyzes the conversion of DA to NE. The enzyme responsible is DA-β-hydroxylase (DBH). Thus it is possible to distinguish noradrenergic and adrenergic neurons from dopaminergic neurons on the basis of the presence of DBH (which may be detected by immunocytochemical techniques). A relatively sparse distribution of catecholamine neurons, largely in the hypothalamus and brainstem, synthesize epinephrine and thus require the fourth enzyme associated with catecholamine biosynthesis, phenylethanolamine-*N*-methyltransferase (PNMT). The presence of PNMT can be used to distinguish noradrenergic from adrenergic neurons.

Metabolism

The metabolism of catecholamines is shown in Fig. 3. Both NE and DA can be sequentially metabolized by monoamine oxidase (MAO) and catecholamine-*O*-methyltransferase (COMT) or vice versa. In brain, the primary metabolites detected for DA are dihydroxyphenylacetic acid (DOPAC), 3-methoxytyramine (3-MT), and homovanillic avid (HVA); the primary metabolites detected for NE are normetanephrine (NM) and 3-methoxy-4-hydroxy-phenylglycol (MHPG). There are two forms or isoenzymes of MAO in the brain. MAO-A is found intraneuronally and preferentially metabolizes NE and serotonin. MAO-B is found in glial cells and preferentially metabolizes phenethylamine (PEA).

Like MAO-B, COMT is also localized extraneuronally. Thus the presence of the COMT metabolites NM and 3-MT has been taken as an index of NE and DA release. Although this index has been largely supplanted by direct measures of release, e.g. in vivo microdialysis, measures of NM and 3-MT levels were historically important in understanding the mechanisms of drug action. For example, amphetamines and related compounds release both NE and DA, which is evidenced by an increase in NM and 3-MT levels.

4.1.1 Dopamine

Dopamine Pathways

From a psychiatric perspective, the three DA pathways of importance are the nigrostriatal, the mesolimbic/cortical, and the tuberoinfundibular (Fig. 4). The nigrostriatal projects form the substantia nigra zona reticulata to the striatum. Degeneration of this pathway results in Parkinson's disease; similar symptoms are

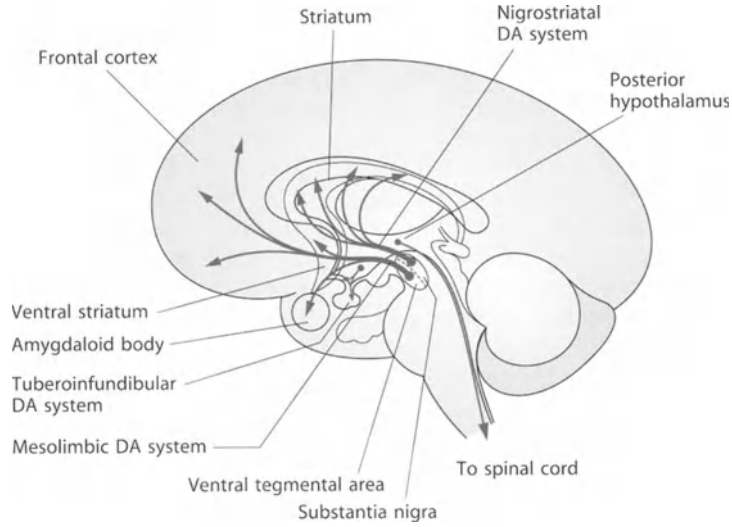

Fig. 4. Dopaminergic (*DA*) pathways. The nigrostriatal DA system originates in the substantia nigra and terminates in the main dorsal part of the striatum. The ventral tegmental area gives rise to the mesolimbic DA system. The tuberoinfundibular system innervates the median eminence and the posterior and intermediate lobes of the pituitary. (From Heimer 1983)

produced by the administration of typical antipsychotic drugs, e.g. haloperidol and chlorpromazine, which block D_2 DA receptors (see below). Activation of these receptors, e.g. after the administration of a direct DA receptor agonist such as apomorphine, produces a pattern of behavior known as stereotyped activity. These highly repetitive behaviors frequently involve cleaning and grooming activities. In the early days of antipsychotic drug development, new drugs were chosen for their ability to block such stereotyped activity in laboratory animals. Not surprisingly, all drugs chosen in this way produced extrapyramidal symptoms (EPS) when used clinically.

The mesolimbic/cortical DA pathway originates from DA cells located more medially to those of the nigrostriatal pathway. It has been useful to collectively name the nuclei which contain these cells the ventral tegmental area (VTA). This collective VTA actually contains the ventral tegmental area, the pigmented parabrachial nuclei, the rostral linear nuclei, and the paranigral nuclei. Historically, it was considered that the DA neurons of the VTA projected largely to the ventral striatum, particularly the shell of the nucleus accumbens, and to the cortex, in particular the orbitofrontal and dorsolateral prefrontal cortices. There are also projections to the amygdala and hippocampus. More recent evidence suggests that the nigrostriatal and mesolimbic pathways are not as compartmentalized as originally thought and some DA neurons of the VTA have targets in motor areas of the striatum, while some DA neurons in the substantia nigra have limbic targets. It is the mesolimbic/cortical pathway which has long been seen as important in a wide variety of behaviors, including drug reinforcement and psychosis; thus blocking the DA receptors of this pathway is seen as the locus for antipsychotic drug action.

The DA cell bodies of the tuberoinfundibular pathway are located in the arcuate and periventricular nuclei of the hypothalamus and project to the anterior pituitary and the infundibulum. DA inhibits the release of prolactin; thus blocking DA receptors in the pituitary increases prolactin release. This increase in prolactin levels can be measured with standard techniques and thus provides some indirect measure of DA receptor blockade.

Dopamine Receptors

For nearly 30 years prior to the actual cloning of DA receptors, it was recognized that the typical antipsychotic drugs must exert their therapeutic actions by blocking some population of these receptors (Carlsson and Lindquist 1963). Ligand-binding studies (Creese et al. 1975; Seeman et al. 1975) revealed that the typical antipsychotic drugs blocked DA receptors in direct relation to their clinical potency. Spano et al. (1978) and Kebabian and Calne (1979) classified the DA receptors into two groups, D_1 and D_2; DA stimulated adenyl cyclase activity at the D_1 receptor and inhibited adenyl cyclase at the D_2 receptor.

The D_2 receptor was cloned in 1988 (Bunzow et al. 1988) and not unexpectedly had the structure of a typical G protein receptor. Five classes of DA receptors have been cloned. The D_1 and D_5 receptors fall into the class of the D_1-like receptors; these receptors are coded by genes on human chromosomes 5 and 4, respectively and are more than 80% homologous. The receptors have similar agonist/antagonist profiles, except that DA appears to be more potent at the D_5 receptor. D_1 receptors are the major DA receptor subtype in the brain and as such play an important role in the regulation of the "direct" output pathway in the basal ganglia (see below).

The D_2, D_3, and D_4 receptors fall into the class of D_2-like receptors, and the genes are found on human chromosomes 11, 3, and 11, respectively. The D_2 receptor has two main variants, D_{2S} and D_{2L}; the long version has an additional 29-amino acid insert in the third cytoplasmic loop. In most brain regions, the long version is present in a higher concentration than the short version. However, no consistent functional difference between the long and short version has been detected. In addition, there has been no demonstration associating a specific psychopathological state with a change in the ratio of the long and short isoforms. Some recent studies have suggested that a polymorphism in the receptor gene is associated with substance abuse and alcoholism, although other studies have not confirmed this relationship. Finally, animal studies have found that a polymorphism in or near the receptor gene is associated with increased receptor density (Kanes et al. 1996).

In comparison to the D_2 receptor, the D_3 and D_4 receptors are present in much lower quantities and appear to have some preferential distribution for limbic areas. Moreover, some data suggest that a relatively higher proportion of D_3 receptors are autoreceptors. Like the D_2 receptor, the D_3 receptor has both a long and short form as well as several nonfunctional variants. D_4 has several variants (Seeman and Van Tol 1994), each of which consists of a multiple of a 16-amino acid insert in the third cytoplasmic loop. Most humans have four repeats, although this varies widely among different races. In addition, there are 19 different types of repeating units; in general, the first and last repeats are the same. No specific psychopathology has been associated with variants in the D_4 receptor.

Dopamine and the Regulation of the Basal Ganglia

More than 95% of the cells within the striatum are inhibitory efferents which receive excitatory glutaminergic input from the cortex. It is convenient to consider that these cells contain either D_1- or D_2-like dopamine receptors, although it is likely that some cells contain both receptor subtypes. (Interestingly many cells in the striatum contain the mRNA for both subtypes, but the expression of the receptor protein appears to be compartmentalized.) The D_1 receptor-containing or -preferring cells are part of the "direct output pathway". The release of DA onto these cells increases GABA (an inhibitory transmitter) release at the main output nuclei – the internal aspect of the globus pallidus and the substantia nigra reticulata – and thus decreases the activity of the inhibitory GABA output neurons in these regions. The D_2 receptor-containing or -preferring cells are part of the "indirect output pathway." The release of DA inhibits the activity of these inhibitory GABA efferents, which send projections to the ventral pallidum; the GABA neurons project to glutaminergic neurons of the subthalamic nucleus, which in turn project to the output nuclei. Enkephalin is colocalized with GABA in the striatal efferents of the indirect pathway. This pathway also has the potential for greater interaction with the limbic system at the level of the ventral pallidum and subthalamic nucleus. Overall, the simple schematic of the direct and indirect pathway would suggest that increasing inhibition of either pathway would have rather similar behavioral consequences. For example, the administration of either a D_1 or a D_2 receptor antagonist should produce a Parkinson-like syndrome (the inability to initiate movement). However, it is important to remember that the regulation of these pathways is complex. D_2 receptors are also autoreceptors, and blockade of these receptors will stimulate the dopaminergic neurons and increase DA release. Thus, depending on the relative difference in pre- and postsynaptic blockade, the behavioral outcome may be quite different.

There is an age-related loss of both DA neurons and D_2 receptors. A substantial loss occurs in the first years of life (>40%). Then there is an age-related loss of approximately 5% per decade beginning in the third decade. For most individuals, this loss of neurons appears to have no behavioral consequences. The remaining neurons synthesize more DA. However, the combination of a more sparse innervation, increased rate of synthesis, and preserved function is more consistent with DA acting as a neurohormone which diffuses a considerable distance from the site of release. When the loss of neurons is greater than approximately 80%, regulation of the system fails, and the symptoms of Parkinson's disease appear. Overall, it is important to recognize that substantial changes in neurotransmitter systems may occur with no apparent loss of function; many systems have remarkable adaptive mechanisms which sustain function. However, once a threshold is reached, deterioration of function is rapid, irreversible, and generally resistant to pharmacological manipulation.

It has long been recognized that there are substantial interactions between brain DA and serotonin systems and that these interactions may be of clinical importance. For example, it has been proposed that the relative ability of a drug to block D_2 and 5-HT_{2a} receptors will determine whether or not a drug is a typical or atypical antipsychotic (atypicals are defined as drugs which will produce little or no EPS). Importantly, it appears that serotonin can regulate DA release by interactions with dendritic, somatic, and terminal serotonin receptors.

Drugs Which Affect Brain Dopamine Systems

The typical antipsychotic drugs, e.g. haloperidol, fluphenazine, thiothixene, preferentially block D_2 DA

receptors, although most of these drugs also block D_1 receptors at higher concentrations.[1] Drugs which block D_2 receptors generally also block D_3 and D_4 receptors, although there are some notable exceptions. The substituted benzamides, such as raclopride and s-sulpiride, have a very low affinity for D_4 receptors; these drugs also bind poorly to D_1 (and D_5) receptors. Interestingly, spiroperidol, a butryphenone-like haloperidol, has more than a 1000-fold selectivity for D_2-like as opposed to D_1-like receptors; spiroperidol and *N*-methyl-spiroperidol are widely used to measure D_2-like receptor densities in both animals and clinical imaging strategies such as positron emission tomography (PET). The atypical antipsychotic clozapine has a significantly higher affinity for D_4 than for D_2 and D_3 receptors. However, olanzepine, which has the pharmacological profile of an atypical drug, i.e. does not produce EPS, binds with relatively equal affinity to D_2 and D_4 receptors. Thus the D_2/D_4 dichotomy cannot explain the unique actions of the atypical antipsychotic drugs. There are no D_1 antagonists approved for clinical use; SCH 23390 has been used in a variety of clinical trials, but the results have been difficult to evaluate because the drug has a short half-life.

The direct DA agonists (drugs which bind directly to DA receptors) include DA, apomorphine, and bromocriptine. DA (like NE and serotonin) is not clinically useful to treat CNS disorders, since it does not penetrate the BBB. It binds with an approximately tenfold higher affinity to D_1-like than to D_2-like receptors. Apomorphine is an emetic agent; the drug binds with relatively equal affinity to the D_1 and D_2 receptors and with tenfold lower affinity to the D_3 and D_4 receptors. When administered at subemetic doses, apomorphine produces marked sleepiness; apomorphine is important in psychiatry since it has been widely used to stimulate the hypothalamic DA systems and affect the release of pituitary hormones, e.g. growth hormone and prolactin. Bromocriptine is still used clinically in the treatment of Parkinson's disease. Bromocriptine has a high affinity for D_2 and D_3 DA receptors and a poor affinity for D_1, D_5, and D_4 receptors.

The indirect DA agonists which increase the synaptic concentration of DA include drugs such as cocaine, methylphenidate, and amphetamine. These drugs act by blocking DA reuptake and/or increasing DA release. The antiviral drug amantidine increases DA release and has been used to treat the dyskinesias induced by antipsychotic drugs.

[1]The law of mass action shows that the percentage of receptors bound is equal to the amount of unbound or free drug divided by the sum of the amount of free drug plus the concentration of drug which just occupies 50% of the receptors. This 50% occupancy concentration is known as the K_D concentration and is frequently discussed as the receptor affinity for compound: the lower the number, the higher the affinity. Many drugs used in psychiatry have affinities of 10^{-7} M or lower. Consider a typical antipsychotic drug which blocks both D_1 and D_2 receptors but with a tenfold greater affinity (lower value of K_D) for the D_2 receptor. Thus, when such a drug occupies 75% of the D_2 receptors, D_1 receptor occupancy will be 23%.However, if 90% receptor occupancy at the D_2 receptor is required for therapeutic effect, D_1 receptor occupancy will be 47%, thus greatly increasing the likelihood of D_1 related side effects.

4.1.2 Norepinephrine

Norepinephrine Pathways

The major noradrenergic pathways in the brain are illustrated in Fig. 5. The highest concentration of noradrenergic cell bodies is found in the locus ceruleus in the pons. It is important to note that these noradrenergic neurons project throughout the cortex, to the hippocampus, the amygdala, and also to the cerebellum. Because of this widespread distribution, drugs which affect the noradrenergic neurons have profound behavioral effects. When examined physiologically, the major effect of activating the locus ceruleus neurons has been a hyperpolarizing response in the target cells, followed by an increase in membrane resistance. Pharmacologically, this response appears to be associated with the activation of β-receptors (see below). Many noradrenergic neurons are found outside the locus ceruleus and are scattered throughout the lateral tegmental area. Many of these neurons project to areas in the basal forebrain such as the amygdala. The adrenergic neurons arise from the same sources, but the terminals appear to be largely localized to the brainstem.

Adrenergic Receptors

The receptors for both the adrenergic and noradrenergic pathways are referred to collectively as the adrenergic receptors. The concept of receptor subtypes began in 1948 with the classification by Ahlquist of the adrenergic receptors into the α- and β-categories based on the responses of tissues to epinephrine, NE, and isoproterenol (Ahlquist 1948). The recognition that a subclass of the α-receptors was acting presynaptically to inhibit NE release led to a further subdivision of the α-receptors into α_1 (postsynaptic and excitatory) and α_2 (presynaptic and inhibitory). Unlike the situation for the DA D_2 receptor, where the same gene encodes the pre- and postsynaptic receptor, the α_1- and α_2-receptors are different gene products. It is now recognized that there are three subtypes of α_1-receptors (A, B, and D) and three subtypes of α_2-receptors (A–C). In addition, there are three subtypes of β-receptors (1–3). A summary of these receptors and

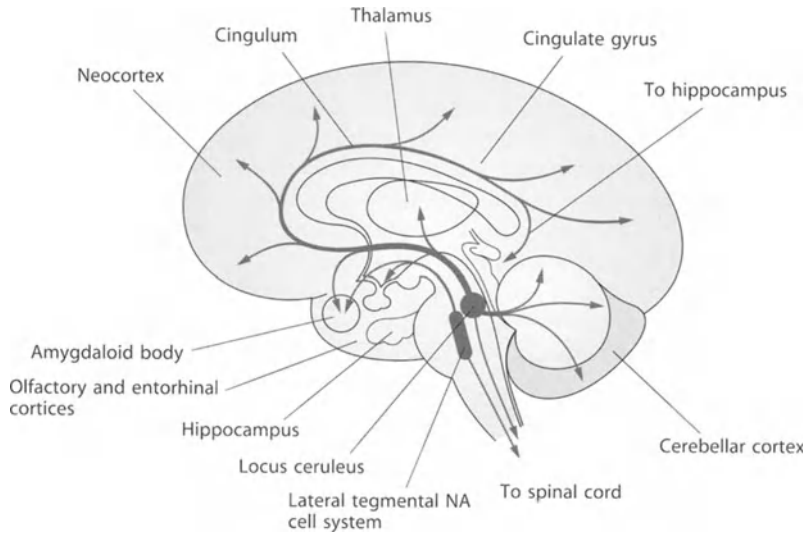

Fig. 5. Noradrenergic pathways. The locus ceruleus projects to many areas in the forebrains, the cerebellum, and the spinal cord. Noradrenergic neurons in the lateral brainstem tegmentum innervate several structures in the basal forebrain, including the hypothalamus and the amygdaloid body. (From Heimer 1983)

their effector systems is found in Table 1. Originally, it was considered that the α_1-receptors were coupled to PIP_2 breakdown, the α_2-receptors to the inhibition of adenylyl cyclase, and the β-receptors to the stimulation of adenylyl cyclase. However, as indicated in Table 1, the effector systems are somewhat more complicated. Furthermore, it appears that the presynaptic/postsynaptic dichotomy between the α_2- and α_1-receptors has some exceptions; it is now clear that some α_2-receptors are postsynaptic.

The adrenergic receptors have been important in understanding at the molecular level the mechanisms which regulate receptor desensitization. When a drug or neurotransmitter is repeatedly applied to the receptor, the physiological effect diminishes over time and more rapidly than could be accounted for by a change in receptor synthesis. For β-receptors, two types of desensitization have been detected, homologous and heterologous. Homologous desensitization is limited to the β-receptors and appears to involve the activity of a receptor-directed protein kinase termed the β-adrenergic receptor kinase (β-ARK). When an agonist (e.g. NE) interacts with the β-receptor, it causes G_S to disassociate into α- and βγ-subunits. The βγ-subunit binds to the plasma membrane, where it appears to stabilize the association between β-ARK and the receptor protein, leading to phosphorylation of multiple sites (serine residues) near the carboxy terminus of the protein. However, this phosphorylation is not sufficient to completely desensitize the receptor. Another protein, β-arrestin, is required, which binds to the phosphorylated protein and sterically inhibits its interaction with G_S. Heterologous desensitization refers to a process whereby stimulation of the β-receptor leads to desensitization of other G protein-coupled receptors. Here, the mechanism appears to involve the activation of the cAMP-dependent protein kinase A (PKA), which in turn phosphorylates the receptor. The phosphorylation sites have been mapped to the third cytoplasmic loop and to a location on the carboxy terminus (but a site different from the sites phosphorylated by β-ARK).

Drugs Which Affect the CNS Noradrenergic Systems

The CNS noradrenergic systems have long been associated with depression and the mechanisms of action of the antidepressant drugs. This association began with the observation that reserpine depleted brain NE and produced behavioral depression in laboratory animals. Further, the depression could be reversed by the administration of the synthetic amino acid dihydroxyphenylserine (DOPS), which is decarboxylated in the brain to NE. The first tricyclic antidepressant was imipramine. Imipramine was synthesized during the 1940s and is structurally similar to the phenothiazines (e.g. chlorpromazine) and quite similar to the substituted benzamide antipsychotics such as raclopride. In 1958, Kuhn began to test imipramine and related phenothiazine analogs for antipsychotic efficacy (Kuhn 1958). Although imipramine was not an effective antipsychotic, it did appear to have some efficacy in depressed patients. This observation led to the discovery and synthesis of a wide variety of tricyclic antidepressants. The first generation of these compounds were found to be potent inhibitors of both NE and serotonin reuptake and strongly anticholinergic (muscarinic receptor antagonists); drugs in this category included imipramine, amitryptyline, and doxepin. The second-generation tricyclic antidepressants were secondary amines and showed a much greater specificity for

blockade of NE as opposed to serotonin reuptake and showed less anticholinergic effects.

MAO inhibitors (MAOI) have been found useful in the treatment of some depressive disorders. Iproniazid was the first clinically useful MAOI. Iproniazid was developed for the treatment of tuberculosis; however, in some patients it was noted that the drug produced euphoria-like symptoms. It was also found that, in animals, iproniazid reversed the "depressive" state produced by reserpine. These observations led Kline (1958) to propose that iproniazid might be useful antidepressant. Because it produces hepatotoxicity, iproniazid is no longer used clinically; however, it is important historically because it helped to establish a relationship between the metabolism of neurotransmitters and psychiatric disorders.

4.2 Serotonin

Serotonergic Pathways in the CNS

The major serotonergic pathways are shown in Fig. 6. The serotonin-containing cells are restricted to clusters of cells lying in or near the midline of the upper pons and midbrain and specifically include the median and dorsal raphe nuclei, the caudal locus ceruleus, the area postrema, and the interpeduncular area. The more caudal cell groups are thought to project largely to the medulla and spinal cord; some of these spinal projections play an important role in the regulation of pain. The more rostral serotonergic groups project throughout the diencephalon and telencephalon, including the basal ganglia, the limbic system, and the association cortex.

Serotonin Synthesis

As with the catecholamines, serotonin is primarily synthesized in the nerve terminal. The first step in serotonin synthesis is the hydroxylation of tryptophan. In contrast to the synthesis of the catecholamines, this step is not limited by the availability of the enzyme tryptophan hydroxylase, but rather by the availability of the substrate. Thus dietary manipulations or the administration of exogenous tryptophan can significantly affect brain serotonin levels. 5-HTP is rapidly decarboxylated to serotonin by the nonspecific aromatic amino acid decarboxylase (Fig. 7). In the nerve, serotonin is metabolized by MAO-A to 5-hydroxyindole acetic acid (5-HIAA). Low levels of 5-HIAA in the cerebrospinal fluid (CSF) have been consistently associated with impulsive behavior and suicide. In the pineal, serotonin is a precursor for the synthesis of melatonin.

Serotonergic Receptors

Gaddum and Picarelli (1957) defined serotonin responses as being mediated by either D or M receptors. The D receptors were found mainly in smooth muscles (e.g. uterus), and their responses were blocked by D-LSD. This observation led investigators to postulate that a similar antagonist mechanism may be operating in the CNS. However, the observation that 2-brom-LSD, which is not a hallucinogen, also blocked the smooth muscle responses shed doubt on this theory. Further, it was found that, at low doses, LSD had agonist-like properties; thus LSD appeared to meet the criteria for a partial agonist. The D receptors of Gaddum and Picarelli are now recognized to be the serotonin receptors, of which there are three subclasses (A–C). These are G protein receptors, are linked to PLC, and largely modulate the breakdown of

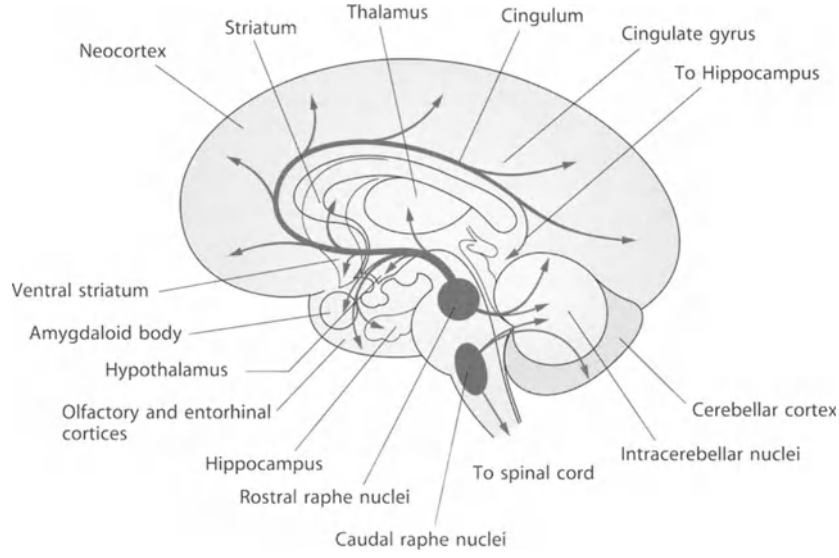

Fig. 6. Serotonergic pathways. The rostral raphe nuclei project laterally through the internal and external capsules to widespread areas of the neocortex (not indicated)

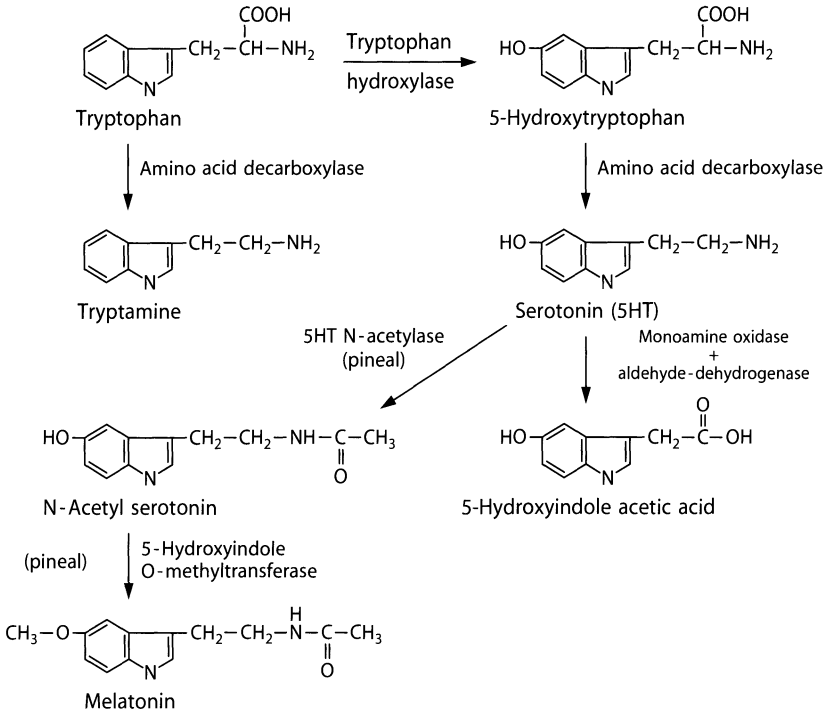

Fig. 7. The metabolic pathways for the synthesis and metabolism of serotonin

PIP_2. 5-HT_{2A} receptors are abundant in the neocortex and the olfactory tubercle, but are also found in some limbic areas and the basal ganglia. 5-HT_{2C} receptors are enriched in the choroid plexus. When applied directly to raphe neurons, LSD inhibits firing, suggesting that it is acting as an agonist at somatic 5-HT_2 autoreceptors. This action of LSD could be consistent with the drug's hallucinogenic activity, since the serotonergic system tonically inhibits visual and other sensory systems; thus LSD would act via *disinhibition*. However, other data suggest that the actions of LSD are more complex and may involve interactions with other serotonergic receptors.

The M receptors of Gaddum and Picarelli were defined by their ability to mediate the release of ACh. These M receptors are now recognized to be 5-HT_3 receptors. The 5-HT_3 receptors are not G protein-linked receptors but rather ligand-gated ion channels and thus are more similar to the $GABA_A$ or nicotinic cholinergic receptors. Activation of the 5-HT_3 receptor leads to increased Na^+ and K^+, but not Ca^{2+} currents. Clinically, the 5-HT_3 receptor antagonists are used to treat chemotherapy-induced emesis. In the laboratory, these antagonists have been found to block both the increase in synaptic DA and some of the behaviors associated with the administration of the central stimulants such as cocaine.

There are 5 subtypes of 5-HT_1 receptors (A, B, D–F). These are all G protein receptors linked to the inhibition of adenylyl cyclase or to the regulation of K^+ and Ca^{2+} channels. 5-HT_{1A} receptors are found on the serotonergic neurons of the raphe nucleus as well as throughout the limbic system, e.g. the hippocampus and amygdala. Activation of these receptors leads to an inwardly rectifying K^+ current and neuronal inhibition. The novel anxiolytic agent buspirone is an agonist at these receptors. $5HT_{1B}$ receptors are presynaptic heteroreceptors, associated with increased transmitter release; in humans, the $5HT_{1B}$ was formerly the 5-$HT_{1D\alpha}$ receptor. No specific agonists or antagonists for these receptors have entered into clinical practice. However, mice with the $5HT_{1B}$ gene "knocked out" show increased aggressive behavior and elevated ethanol consumption (see Vol. 1, Part 1, Chap. 5).

The $5HT_4$, $5HT_6$, and $5HT_7$ receptors are linked to activation of adenylyl cyclase. Two gene products with distinct anatomical distributions, 5-HT_{5A} and 5-HT_{5B}, have been identified, but coupling to specific effectors has not been demonstrated.

Drugs Affecting the CNS Serotonergic Systems

The hallucinogens and buspirone were discussed above. Drugs used in the treatment of depression have long been associated with the serotonergic systems. Thus the first-generation tricyclic antidepressants affected both NE and serotonin transport. The second-generation compounds suggested that blockade of NE transport was sufficient for antidepressant efficacy. The introduction of the serotonin-specific reuptake inhibitors (SSRI) showed that blockade of serotonin reuptake was also sufficient. The first of these compounds was fluoxetine, which was quickly followed by others, e.g. paroxetine and sertraline. Given the

complexity and number of serotonergic receptors, the precise antidepressant mechanism of the SSRI remains unclear. However, some data would suggest that it is the serotonin–NE interaction which is important. The SSRI are also useful in the treatment of obsessive compulsive disorder (OCD), which is thought in part to involve a dysregulation of the limbic loop of the basal ganglia and in particular the orbitofrontal cortex.

4.3 Acetylcholine

Cholinergic Pathways in the CNS

Mesulam and Geula (1994) note that the brain's cholinergic systems appear to be phylogenetically ancient, anatomically ambiguous, and do not respect traditional nuclear boundaries. Thus cholinergic pathways are intermixed with noncholinergic cells. There are eight major cholinergic groups which project to other CNS structures; the Ch1–Ch8 nomenclature was introduced to describe these cell groups. In addition, there are the intrinsic cholinergic neurons of the ventral and dorsal striatum. The location of the various cell groups is as follows: Ch1, medial septal nucleus; Ch2, vertical nucleus of the diagonal band; Ch3, horizontal limb of the diagonal band; Ch4, nucleus basalis of Meynert; Ch5, pedunculopontine nucleus; Ch6, laterodorsal tegmental nucleus; Ch7, medial habenula; and Ch8, parabigeminal nucleus. The major targets of these cell groups may be summarized as follows: Ch1 and Ch2, the hippocampal complex; Ch3, the olfactory bulb; Ch4, the cerebral cortex and amygdala; Ch5 and Ch6, the thalamus; Ch7, the interpeduncular nucleus; and Ch8, the superior colliculus. All regions of the cortex receive intense cholinergic innervation, and the function of these neurons appears to be complex. A recurring theme is the modulatory role of the cholinergic neurons. For example, in the primary visual cortex, Steriade and McCarley (1990) have found that cholinergic stimulation does not affect the orientation specificity of a given neuron, but does increase the likelihood that it will fire in response to its preferred stimulus. The Ch1–Ch4 cell groups are known to have an important role in memory, and in particular lesions of the Ch4 cell groups produce marked memory deficits. The precise mechanisms by which these cholinergic neurons affect memory are not clear, but some data suggest that the cortical cholinergic innervation may help to channel (or gate) sensory information into and out of the limbic system in a way that is sensitive to the behavioral salience of the associated experience (Mesulam and Geula 1994). Thus the Ch1–Ch4 cells are necessary for effective sensory–limbic communication. Cholinergic neurons are also known to have an important role in arousal mechanisms, e.g. the shift from the synchronized electroencephalography (EEG) of deep sleep to the desynchronized EEG of waking and rapid eye movement sleep; in this later respect, the Ch5–Ch6 cell groups appear to be important.

Acetylcholine Synthesis and Metabolism

ACh is synthesized in the cholinergic nerve terminal from acetyl coenzyme A and choline by the enzyme choline acetyltransferease (ChAT). Once released, ACh is metabolized in the synaptic cleft by AChE; thus termination of the activity of ACh does not depend on reuptake. The choline liberated by the metabolism of ACh is taken back up into the nerve terminal for resynthesis to ACh.

Cholinergic Receptors

Dale (1914) originally defined cholinergic receptors on the basis of their responses to certain agonists and antagonists. Muscarinic receptors were activated by the alkaloid muscarine (isolated from the poisonous mushroom *Amanita muscaria*) and antagonized by atropine (isolated from the flowering plant deadly nightshade, *Atropa belladona*). Nicotinic receptors were defined by their response to nicotine and blockade by curarae. Subsequent research has identified a number of snake toxins which block nicotinic receptors, including α-bungarotoxin (α-BGT). Nicotinic cholinergic receptors (nAChR) are multi-subunit (pentameric) ligand-gated ion channels which increase Na^+, K^+, and Ca^{2+} conductances. In muscle, the receptor may contain α-, β-, ε-, and δ-subunits (adult muscle) or α-, β-, γ-, and δ-subunits (embryonic muscle). However, in neurons, the receptor appears to be largely, if not completely, formed from both α- and β-subunits, with one notable exception. In brain, the mRNA for six α-subunits (α_{2-7}) and three β-subunits (β_{2-4}) are routinely detected. However, it is not clear whether all of these subunits are expressed in functional receptors. The most common receptor conformation appears to be $(\alpha_4)_2(\beta_2)_3$. Two types of brain nicotinic receptors can be detected from binding studies, those receptors which recognize α-BGT with a high affinity and those that do not. The former has a low affinity for nicotine, while the latter has a high affinity for nicotine. The brain α-BGT-binding sites, which are enriched in the hippocampus and hypothalamus, appear to be composed of a homopentamer formed from α_7-subunits. Recently, Freedman et al. (1997) have shown that a polymorphism in the α_7-subunit may be linked to schizophrenia and deficits in sensory gating.

Nicotine is known to have diverse and potent effects on CNS function. For example, nicotine interacts with presynaptic nAChR to increase the release of a variety

of neurotransmitters, including DA, NE, serotonin, GABA, and glutamate, all of which are important in regulating behavior. In animal models, nicotine can both enhance learning and memory and reverse deficits in cognitive performance, e.g. those induced by septal lesions. The loss of the Ch1–Ch4 cell groups in Alzheimer's diseases has been associated with the cognitive and attentional deficits of this disorder, and to some extent these deficits (at least early in the disorder) may be reversed by nicotine. This also appears to be the set of action of the newer drugs used to treat Alzheimer's disease, such as rifastigmin and donepezil.

Five muscarinic receptor genes (m_1–m_5) have been cloned and all are G protein-coupled receptors. The m_1, m_3, and m_5 subtypes are coupled to inositol phosphate release, while the m_2 and m_4 subtypes are coupled to inhibition of adenylyl cyclase. There are marked regional differences in the distribution of the various subtypes; for example, in the striatum, the principal subtypes are m_1 and m_4, while in the medulla and pons and cerebellum, the principal subtype is m_2. A moderate level of the m_3 subtype is expressed in most brain regions; m_5 expression is low to negligible in most areas. To date, there are no clinically useful drugs which discriminate among the various subtypes.

Drugs Affecting CNS Cholinergic Systems

The reversible and irreversible AChE inhibitors have marked CNS effects; accidental poisoning from these agents (e.g. from pesticides) frequently causes a syndrome which is not unlike endogenous depression. Muscarinic receptor antagonists such as benztropine are widely used to treat movement disorders, especially the EPS induced by the typical antipsychotic drugs. Dopamine inhibits the release of ACh from the cholinergic interneurons within the striatum; blocking the DA receptors increases ACh release, leading to stimulation of the striatal GABA efferents. A wide variety of drugs have moderate to strong anticholinergic activity; these include some of the typical antipsychotics such as chlorpromazine, the tricyclic antidepressants, and some antihistamines, e.g. diphenhydramine.

4.4 Glycine

Glycine serves two transmitter roles in the CNS. First, it acts on inhibitory glycine receptors which are primarily located in the brainstem and spinal cord (on the basis of observed receptor density). However, from a neurophysiological perspective, nearly all neurons in the brain show an inhibitory response to the application of glycine, suggesting a somewhat more widespread distribution of receptors. The inhibitory glycine receptor is a pentamer formed from homologous 48-kDa and 58-kDa subunits which form an intrinsic Cl^- channel. Four isoforms of the α-subunit (α_1–α_4) and one variant of the β-subunit have been detected. All subunits have four transmembrane domains. Further molecular diversity is generated from alternative splicing of the intracellular loop domains. The α-subunit contains the ligand-binding site, while the β-subunit is a major determinant of channel conductance. Endogenous ligands for the receptor include glycine, β-alanine, and taurine. Strychnine is the best-known glycine antagonist.

Glycine also binds to the NMDA type of glutamate receptor and is required for receptor activation (see below).

4.5 γ-Aminobutyric Acid

GABA is the most abundant inhibitory neurotransmitter in the CNS. However, because of this ubiquitous distribution, it was argued that GABA could not act specifically and the acceptance of GABA as a neurotransmitter was therefore somewhat slowed. In 1950, Roberts and Frankel and Awapara et al. independently discovered GABA in the brain (Awapara et al. 1950; Roberts and Frankel 1950). In 1953, Florey discovered "factor I" in mammalian brain and showed that it inhibited the crayfish stretch receptor neuron (a typical example of the early bioassay approach; Florey 1953). Subsequent work showed that factor I was GABA and that it could duplicate transmitter action at certain crayfish synapses. However, it was not until the late 1960s and early 1970s that GABA was fully accepted as a neurotransmitter in the mammalian brain. Importantly, Roberts and colleagues (1950) were able to show that GABA synthesis is localized to only certain neurons.

As noted in previous sections, some regions, e.g. the striatum, are almost completely composed of GABA neurons. By some estimates, GABA neurons comprise 30%–40% of all neurons in the brain. Further, essentially all neurons in the brain respond to GABA application. GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD); there are two isoforms of the enzyme, both of which require vitamin B_6 as a cofactor. Once released into the synapse, GABA is taken up by specific transporters in both the neurons and glia. GABA is metabolized by GABA-transaminase (GABA-T), a mitochondrial enzyme. The transamination to form succinic semialdehyde can take place only if α-ketoglutarate is the acceptor of the amine group. This transforms the α-ketoglutarate to glutamate, the precursor of GABA.

There are two types of GABA receptors, denoted as $GABA_A$ and $GABA_B$. $GABA_A$ receptors are in the class of ligand-gated ion channels, while the $GABA_B$ recep-

tors are typical G protein-coupled receptors. $GABA_A$ receptors appear to be composed of multiple subunits (generally a pentamer) formed from various combinations of six α-, four β-, four γ-, one δ-, three ρ-, and one ε-subunit. In addition, alternatively spliced versions exist of the α_6-, β_2-, β_4-, and γ_2-subunits. The ρ-subunits appear to be found only in the retina; α- and β-subunits form fully functional GABA receptors. A γ-subunit is required for benzodiazepine potentiation of the GABA facilitated Cl^- flux, although the site of benzodiazepine binding appears to be the α-subunit. Probably the most common form of the $GABA_A$ receptor is $\alpha_1\beta_2\gamma_2$, which has a high affinity for benzodiazepines and related ligands. Other subunit combinations, e.g. those which contain the α_6-subunit, have a negligible affinity for traditional benzodiazepines. In addition to the benzodiazepine-binding site, there are binding sites for the barbiturates and the neuroactive steroids. Progesterone also binds to this steroid site. Other drugs, including the volatile anesthetics and ethanol, potentiate the effects of GABA at the $GABA_A$ receptor, although the mechanism or mechanisms of interaction at the molecular level are poorly understood.

$GABA_B$ receptors were first detected indirectly in the late 1970s from the observation that GABA could block the release of NE but the effect was not blocked by typical GABA antagonists such as bicuculline. Subsequently, it was found that β-*p*-chlorophenyl-GABA (baclofen) was inactive at $GABA_A$ receptors but active at $GABA_B$ receptors. Activation of $GABA_B$ receptors increases K^+ conductance in many regions, leading to membrane hyperpolarization. Since this effect is blocked by pertussis toxin, it is assumed that most $GABA_B$ receptors are coupled to G proteins.

4.6 Glutamate and Aspartate

Glutamate and aspartate are both found widely distributed and in a high concentration in brain. Both amino acids excite nearly all neurons in the CNS, and there is now general acceptance that glutamate and aspartate function as the classical fast-excitatory transmitters. Glutamate can be synthesized from several sources in the CNS, including the metabolism of GABA (see above). After release into the synapse, glutamate can be taken up via specific transporters into either the presynaptic neuron or the adjacent glia in order to terminate the postsynaptic receptor effects. There are two broad classes of glutamate receptors, the ionotropic (or ligand-gated ion channel receptors) and the metabotropic (or G protein-coupled receptors).

The ionotropic receptors are further subdivided into three subclasses on the basis of agonist specificity: these are the *N*-methyl-D-aspartate (NMDA), the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and the kainic acid receptors. The best known of these receptors is the NMDA subtype. The NMDA receptor requires two molecules of glutamate and one molecule of glycine for activation. The glycine-binding site on the NMDA receptor is not strychnine sensitive, which distinguishes this binding site from the site on the inhibitory glycine receptor. Additional modulators of the NMDA receptor include zinc, some neurosteroids, arachidonic acid, redox reagents, and polyamines including spermidine. The NMDA receptor is permeable to both Na^+ and Ca^{2+}; the counterion is K^+. The NMDA receptor is a typical multi-subunit ligand ion channel, formed from Grin1 (glutamate receptor inotropic NMDA) and $Grin2_{a-d}$ subunits. Alternative splicing generates eight isoforms of the Grin1 subunit (one nonfunctional), each with differing pharmacological properties. The $Grin2_d$ exists as two splice variants.

Several lines of evidence point to the importance of the NMDA receptor subtype. First, it has been shown that the chemically related compounds phencylidine ("angel dust"), ketamine, and MK-801 (dizoclipine) are all noncompetitive open-channel NMDA antagonists. Not all the behavioral effects of these compounds can be entirely attributed to NMDA antagonism, e.g. phencylidine is also a sigma opiate receptor antagonist. However, the confusion, disorientation, and psychoses induced by these compounds have contributed to the "glutamate" hypothesis of schizophrenia. Second, exposure of neurons to high concentrations of glutamate for only a few moments can result in cell death; this effect is mediated by excessive stimulation of NMDA receptors and the enhanced influx of Ca^{2+} into the cell. This mechanism has been evoked to explain the cell death which occurs after ischemia or hypoglycemia. Third, long-term potentiation (LTP) is in part associated with activation of NMDA receptors. There are two types of LTP, associative and nonassociative. The associative type of LTP, especially in the CA_1 region of the hippocampus, is perhaps the best understood and will be briefly reviewed here. When a stimulus train of strong intensity brings a relatively large population of presynaptic neurons to threshold, there is a resulting synaptic enhancement which persists for hours or in some cases days, i.e. LTP. As noted by Kandel (1991) in the CA_1 regions of the hippocampus, LTP has three interesting properties: (1) cooperativity (more than one fiber must be activated to produce LTP), (2) associativity (the contributing fibers and the postsynaptic cell need to be active together, in an associative way), and (3) specificity (LTP is specific to the active pathway) (Fig. 8). The non-NMDA glutamate receptors are the AMPA/kainate receptors described below. Some evidence suggests that

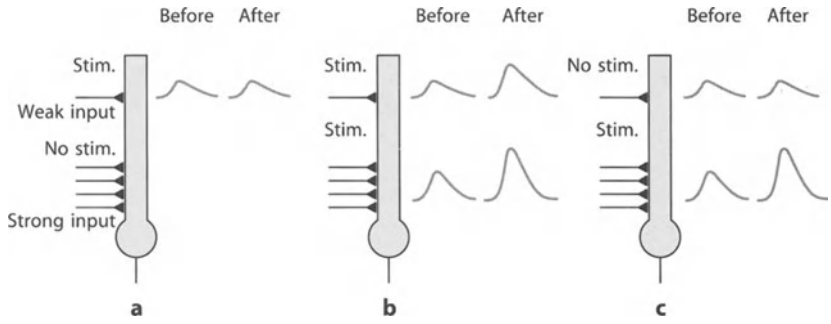

Fig. 8a–c. Single pyramidal cell receiving weak and strong synaptic inputs. Long-term potentiation illustrating **a** cooperativity, **b** associativity, and **c** specificity

the diffusable retrograde messenger is nitric oxide (NO). Is LTP involved in learning and memory, in particular the spatial learning which is so clearly dependent on the hippocampus? Until recently, the data to support such an association was largely pharmacological in nature, i.e. drugs which block the NMDA subtype of glutamate receptors which are required for LTP also block spatial learning. More recently, genetic strategies have been brought to bear on this problem. For example, mice genetically engineered to be deficient in Ca^{2+}/calmodulin-dependent kinase II (so-called knockout mice) show poor LTP and poor spatial learning. However, these mice perform nearly normally on simple, conditioned response paradigms, suggesting the deficit in the knockout mice is selective for certain types of associative learning.

AMPA receptors are formed from Gria1–4 subunits and may exist in homomeric or heteromeric form; each of the polypeptides can exist in two forms generated by alternative splicing known as "flip" and "flop" that differ in their desensitization kinetics. The flip forms give rise to a larger sustained current (slower to desensitize) than the flop forms. Gria1, Gria3, and Gria4 are Ca^{2+} permeable; through RNA editing and the consequent change in composition of a single amino acid, Gria2 is converted from Ca^{2+} permeable to impermeable. Kainate receptors are formed from Grik1–5 subunits. Autoradiographic studies show that both AMPA and kainate receptors are largely localized to telencephalic regions, but each receptor class shows a distinct distribution. Kainate receptors are principally localized in the CA_3 region of the hippocampus, the striatum, the deep cortical layers, the reticular nucleus of the thalamus, and the granule cell layer of the thalamus. AMPA receptors appear to principally localized to the CA_1 region of the hippocampus, the outer cortical layers, the lateral septum, and the molecular layer of the cerebellum. This distribution is similar to that for the NMDA receptors and is consistent with the idea that these receptors act in concert. Overall, the molecular diversity of the glutamate receptors is apparently necessary to maintain fine control.

4.7 Others

4.7.1 Peptides

As noted in previous sections, in most (if not probably all) neurons, neuropeptides are colocalized with the more traditional neurotransmitters. By some estimates, there may be more than 300 neuropeptides in the brain. A partial list of the peptides identified to date is presented below:

- Adrenocorticotropic hormone (ACTH)
- Androgens
- Angiotensin I, II, and III
- Bradykinin
- Calcitonin
- Cardioexcitatory peptide
- Carnosine
- Cholecystokinin
- Corticotropin-releasing hormone (CRH)
- Cortisol
- Endogenous opioids
- Estrogens
- Follicle-stimulating hormone (FSH)
- Gastrin
- Gastrin-inhibiting peptide
- Glucagen
- Gonadotropin-releasing hormone
- Growth hormone
- Growth hormone-releasing factor
- Insulin
- Luteinizing hormone
- Melanocyte-inhibiting factor
- Melanocyte-stimulating hormone (MSH)
- Melatonin
- Motilin
- Neural growth factor
- Neuronal polypeptide
- Neuropeptide Y
- Neurotensin
- Oxytocin
- Progesterone

- Prolactin
- Secretin
- Sleep-inducing peptide
- Somatostatin
- Substance K
- Substance P
- Thyroid hormones
- Thyroid-stimulating hormone
- Thyrotropin-releasing hormone
- Vasoactive intestinal peptide
- Vasopressin

Some well-established examples of coexistence of biogenic amine transmitters and neuropeptides are given in Table 2. It has been postulated that neurotensin and cholecystokinin may be involved in the pathology of schizophrenia because of their colocalization with DA; however, pharmacological data to support this position has been inconsistent. Substance P, a tachykinin, is best known as the neurotransmitter in most primary sensory neurons; substance P is colocalized with DA and serotonin and has been hypothesized to be involved in a variety of psychiatric disturbances.

Of all the neuropeptides, the endogenous opioids have probably received the most attention. There are several reasons for this focus.

1. Morphine and related compounds are widely used in clinical practice for severe pain. Attempts to develop morphine-like compounds which do not produce tolerance and dependence dates back to the synthesis of heroin in the late 1800s and continues to this day. Nearly 50 years of highly sophisticated structure–activity studies led pharmacologists to the conclusion that there were specific CNS opiate receptors. This led to the synthesis of a variety of very powerful synthetic opiates, e.g. fentanyl. Receptor models were proposed that could accommodate both the natural and synthetic opiate agonists. However, until the discovery by Hughes, Kosterlitz, and colleagues of methionine-enkephalin (Hughes et al. 1975), there was little or no interest in the possibility that endogenous opiate-like compounds existed which could interact with these receptors. Subsequently, other peptides with opiate-like activity were identified, including leucineenkephalin, dynorphin, and β-endorphin. Recently, two new endogenous opiate peptides have been identified, endomorphin-1 and endomorphin-2 (Zadina et al. 1997). It has been suggested that these tetrapeptides may be the specific ligands for the μ-opiate (or morphine-like) receptor. Endomorphin-1 displays a 4000- and 15,000-fold selectivity for the μ-opiate receptor as compared to the δ- and κ-opiate receptors (see below). Overall, the initial discovery of the endogenous opioid peptides was significant in stimulating research to find endogenous ligands for receptors (e.g. the benzodiazepine receptors) which were known to be present in the CNS.
2. Morphine and related compounds have marked effects on mood; interestingly, there is a substantial body of older literature suggesting that morphine is an effective antidepressant.
3. The abuse of opiates is a significant contemporary problem, complicated by the favored route of administration (i.v.) and the associated spread of certain infectious diseases, e.g. hepatitis and human immunodeficiency virus (HIV).
4. Specific opiate antagonists have been available for more than 40 years; this greatly facilitated advances in opiate pharmacology and also led directly to the discovery of the opiate peptides.
5. The opiate receptors were among the first of the brain receptors to be characterized (early 1970s) through simple binding assays.

Table 2. Examples of biogenic amine and peptide coexistence in neurons

Acetylcholine	Vasoactive intestinal peptide Substance P
Dopamine	Cholecystokinin Neurotensins
GABA	Somatostatin Cholecystokinin
Norepinephrine	Somatostatin Enkephalin Neuropeptide Y Neurostensin
Serotonin	Substance P Enkephalin

Three distinct families of opiate peptides have been identified – the enkephalins, the endorphins, and the dynorphins, each of which is generated from a distinct precursor polypeptide. The endorphins and enkephalins are widely distributed throughout the CNS; the distribution of the enkephalins is especially enriched in areas which might be considered the extended limbic system. β-Endorphin has a more limited distribution. It is derived from proopiomelanocortin (POMC) (Fig. 9). POMC is processed to produce γ-MSH, ACTH, and β-lipotropin (β-LPH); within β-LPH is β-endorphin and β-MSH. In addition to a high concentration in the pituitary, the POMC peptides are found in a high concentration within the arcuate nucleus, which projects both to the limbic system and spinal cord; this distribution of the POMC peptides corresponds to the areas of the human brain where electrical stimulation can relieve pain.

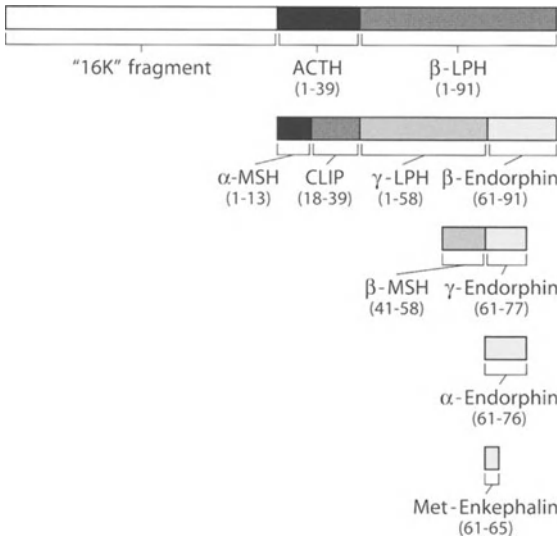

Fig. 9. Bovine precursor molecule, indicating an NH_2-terminal fragment and the following adrenocorticotropic hormone (*ACTH*) and β-lipotropic hormone (*LPH*) sequence. *CLIP*, corticotropin-like intermediate lobe peptide; *MSH*, melanocyte-stimulating hormone

The POMC protein illustrates at the molecular level a mechanism for the coordinate regulation of response to stress and pain. In addition to their effects as neuropeptides, ACTH increases adrenal function, β-LPH increases the mobilization of fat as source of energy, and β-endorphin can have "morphine-like" effects on a variety of organ systems, e.g. the intestine. It is also important to note that the release of the POMC peptides is synergistic with the stress effects mediated by CRF. CRF is not only required for the release of ACTH and β-endorphin from the pituitary, but, as noted previously, also serves as an important neuromodulator of the stress responses. Importantly, when injected into the brain, the CRF antagonist α-helical CRF blocks the pituitary and nonpituitary responses to stress.

There are three main classes of opiate receptors, μ, δ, and κ. On the basis of pharmacological profiles and receptor cloning, each of these classes have two or more subtypes. All of the cloned opiate receptors are of the G protein-coupled type. Most of the clinically used opiates exert their pharmacological effects through the μ-receptor, reflecting their similarity to morphine. The enkephalins and β-endorphin bind with a relatively high affinity to the μ- and δ-receptors, but with a fairly low affinity to the κ-receptors. The dynorphins bind with a high affinity to the κ-receptors and moderate affinity to μ- and δ-receptors. Some of the physiological functions affected by the various receptors include pain, appetite control, sedation, and lymphocyte mitosis.

4.7.2 Purines

It is now recognized that adenosine monophosphate (AMP), adenosoine triphosphate (ATP), and free adenosine can act as neuromodulators. Adenosine can act presynaptically, especially in the cortex and hippocampus, to inhibit the release of amino acid and amine neurotransmitters. Adenosine also inhibits the release of mesopontine ACh through the activation of an inwardly rectifying K^+ current and inhibition of hyperpolarization-activated conductance. Since these effects are blocked by the methylxanthines (caffeine, theophylline, and theobromine), it may account for the stimulant effects of these drugs. Two broad classes of purine receptors have been identified. The P1 class is G protein coupled and has four subtypes (A1–A4); only the A1 and A2 subtypes are inhibited by the xanthines. The P2 class refers to receptors for ATP and uridine triphosphate (UTP); the $P2_x$ subtype is a ligand-gated ion channel, and the $P2_y$ subtype is a G protein-coupled receptor.

4.7.3 Histamine

It has long been recognized that antihistamines have marked behavioral effects. Since many of these compounds were also strongly anticholinergic (e.g. diphenhydramine), it was easy to associate the behavioral effects with muscarinic receptor blockade. However, a well-established network of histamine-containing neurons has now been described; most of these neurons are located in the posterior hypothalamus, but project widely in a manner reminiscent of the other amine transmitters. Three subtypes of histamine receptors have been described; the H_1 and H_2 subtypes are G protein-coupled receptors. The H_1 subtype acts to mobilize intracellular Ca^{2+}, while the H_2 subtype activates adenylyl cyclase. The H_3 subtype is very sensitive to the effects of histamine and is enriched in the basal ganglia and olfactory regions of the brain. Interestingly, there appears to be no active reuptake mechanism for histamine, and the release of histamine from neurons has never been described.

4.7.4 Nitric Oxide

NO is thought to be an important modulator of neuronal function. Four isoforms of the enzyme which synthesizes NO (nitric acid synthase) have been described. NO has been proposed to have a role in LTP, transmitter release, and NMDA receptor-mediated toxicity. Some data also suggest that CO may be an important neuroregulator, especially of guanyl cyclase activity.

4.7.5 Cannabinoids

The pharmacological effects of marijuana include changes in mood, perception, and motivation; in addition, marijuana reduces nausea, is an anticonvulsant, and reduces intraocular pressure. These effects are related to the cannibinoids found in marijuana; Δ-9-tetrahydrocannabinol is responsible for most of the pharmacological effects. Two cannabinoid receptors have been cloned, CB1 and CB2; these are G protein-coupled receptors where the effector is $G_{i/o}$ for both receptors. A number of potential endogenous ligands for these receptors have been identified; the most widely studied is the arachidonic acid derivative arachidonoylethanolamide (anandamide). Both the receptors and the endogenous ligands are widely distributed in the brain, with the highest concentrations being in the cerebral cortex, cerebellum, striatum, and hippocampus.

5 Conclusion

This overview of the major neurochemical components of synaptic transmission has provided the building blocks on which almost all psychopharmacologically active substances act. However, as we have seen, neurotransmission is only the cell-to-cell signaling mechanism, and what is signaled within the cell is central to changing the output of the system. We have mentioned several of the second messenger cascades which can be activated or inhibited by cell-to-cell signaling. Sites within these cascades could clearly be critical for the development of psychiatric diseases, and sites beyond the second messenger systems, involving the regulation of specific gene expression within nerve cells, will almost certainly play a role in psychiatric disease.

As an example of how programmed gene expression can regulate behavior, consider the case of egg-laying behavior of aplysia. Here stimulation leads to a set of stereotypical behaviors culminating in egg-laying. Two sets of cells are involved, the bag cells and the atrial gland, and once the system is set in motion subsequent behavior appears to be rigidly programmed. Genes are activated which express two hormones in the bag cells leading to both long-term and short-term effects. The hormones arise from a common precursor, and through postprocessing the timing of short- versus long-term effects is regulated. The atrial gland expresses two closely related peptides which appear to come from closely related genes and direct the CNS output which leads to egg-laying behavior. Thus, in this case, behavior is rigidly programmed through the influence of specific hormones which appear through the activation of specified genes; it really is all in the hormones, and if appropriate signals arrive intracellularly, the subsequent behavior is programmed. Similar activation of specific hormones and neuromodulators may play a role in mammalian systems, although perhaps with less specified programming. There are, for example, several experiments which suggest that cellular connections can be changed due to the activation of genes. One example which may play a role in psychiatry involves NE activation of β-receptors leading to the activation of the gene for brain-derived nerve growth factor (BDNF), which has been shown to alter LTP and perhaps learning ability. These examples suggest that the next stage in understanding the neurobiology of mental illness may involve understanding how changes in signal transduction result in specific gene activation and changes in CNS function.

Fundamental Cellular Principles of Psychological Disturbances

Translator:
S. Coupland-Heimann

1 Introduction

Virtually no other field of modern science has been subject to such rapid development in knowledge as seen in neurobiology in the last decade. Many of the known functions of nerve cells represent targets for pathophysiological changes. However, we are still very far from the development of pathogenetic models which could be useful in determining the prognosis of diseases or in providing causal-based treatment.

The discussion of possible pathophysiological mechanisms is based upon normal neurobiology. As this is so complex, the reader is referred to a good and readable standard work (Kandel et al. 1995).

2 Basic Neurobiology

2.1 Physiology of Nerve Cells

Our current understanding of neurons is mainly based upon extensive biochemical investigations. These investigations chemically extracted and measured the concentrations of certain substances and their molecules from cells, which were rendered non-functional in the process. Important functional characteristics of the cell are lost in such experiments, in particular the time-related functions of the cell. Time-dependent electrical discharge patterns of neurons are essential information. It now has to be assumed that the discharge pattern of nerve cells is just as important for their function, and in their disturbances, as changes in the amount of neurotransmitters, receptors or subcellular factors. These functional aspects can only be determined with a few techniques such as extra- or intracellular recording or the patch clamp technique (Neher and Sakmann 1992). Only by combining these results with those of biochemical studies is it possible to achieve a relatively complete picture of the functions of nerve cells.

The complex functions of the central nervous system can be summarised as follows:

- The processing of registered information
- The programming of motor and emotional responses
- Learning and memory

Each of these functions can be traced to the level of the nerve cells and their interactions. It can be assumed that the complex disturbances which have also been described in psychiatry are due, at least theoretically, to disturbances of such functions and their cellular correlates.

Nerve cells can be understood as biochemically and electrophysiologically interactive units which are modulated by a continuous exchange of acquired and genetic transferred information.

Neurons express larger amounts of genetic information than cells of other organs, with approximately 200,000 differing sequences of messenger RNA (Spudich 1993). The proteins which are subsequently synthesised remain either in the cytoplasm or are integrated into the cell nucleus, the mitochondria or the cell membrane system.

The cytoplasmic proteins consist of the fibrillary elements, which form the cellular skeleton, responsible not only for the structural consistency of the cell but also for the functioning of axonal transport. Other cytoplasmic proteins include multiple enzymes required for the metabolic functioning of the cells. The proteins of the cell nucleus regulate genetic expression. Membrane proteins contribute to a large extent to the structure of the cell membrane in the form of both ion channels and cellular receptors. They are also involved in the production and release of neurotransmitters and neuropeptides. With the opening and closing of the ion channels, the proteins undergo a change in their conformation. They therefore represent a connection between the electrical and biochemical functions of the cell (Table 1).

The cell membrane is closed to ions in the resting phase. Through the activity of various ion pumps, a disparity or potential is created across the cell membrane, which underlies the excitability of the nerve cell. In the resting phase, the concentration of Na^+ is high externally, and that of K^+ is high internally. This results in an intracellular and extracellular electrochemical balance, creating a negative resting phase potential (Hille 1992). On stimulation of the neuron, the ion channels open and a current of

Table 1. Ion currents of nerve cells

Signal	Characteristics	Ion currents	Mechanism
Resting potential	Stabile, –45 to –90 mV	K^+, Cl^-	Leaky currents, voltage-dependent K^+ currents
Action potential	"All or nothing"; amplitude approx. 100 mV	Na^+, K^+	Voltage-dependent channels

positively laden Na^+ passes into the cell, causing a reverse of the transmembrane potential. This is followed by an outward current of K^+, leading to membrane repolarisation (Hodgkin 1964).

A special role is played by calcium ions (Ca^{2+}); in the resting phase, a concentration gradient of approximately 10^{-6} *M* exists between the extracellular and intracellular spaces. Thus only a few Ca^{2+} ions are required in the inner part of the cell before an enormous signalling effect occurs. This takes place via a cascade of calcium-binding structures, including calmodulin and calbindin. Ca^{2+} is thus one of the most important second messengers in addition to cyclic adenosine monophosphate (cAMP).

Since an increase in the internal concentration of Ca^{2+} represents a "risk" to the cell – as a concentration of 10^{-5} *M* calcium phosphate can be detected (Kretsinger 1979) – a number of mechanisms exist to prevent this. The Ca^{2+}-dependent K^+ current is particularly interesting in neurophysiology; when the intracellular concentration of free ionised calcium ($[Ca^{2+}]_i$) increases above a critical value during the stimulation phase, the Ca^{2+}-dependent K^+ current ($I_{K(Ca^{2+})}$) is activated and results in the hyperpolarisation of the cell. Consequently, a membrane potential is produced, which prevents penetration of the Ca^{2+} ions into the inner part of the cell and thereby prevents neuronal stimulation. $I_{K(Ca^{2+})}$ is therefore fundamental for phasic cell discharge. $I_{K(Ca^{2+})}$ occurs in neuronal structures such as the hippocampus, the locus coeruleus and the cell nuclei of the thalamus and the hypothalamus and therefore plays a decisive role in determining the spectrum of activity in the central nervous system (CNS). The metabolic performance of a cell is also influenced by the $I_{K(Ca^{2+})}$-determined phasic activation pattern; since cell metabolism is triggered by an increase in $[Ca^{2+}]_i$, it must be assumed that cell metabolism is activated and inactivated in a phasic manner.

Ion channels consist of characteristic units. The so-called α-unit makes up the central part of the voltage-dependent canal for Na^+, K^+ and Ca^{2+}. It consists of a chain-like polypeptide structure in which a six-transmembrane α-helix is repeated four times. The fourth α-helix is most likely to be the voltage detector. Channel structures for the other ions consist of other units, e.g. β and γ (Catterall 1995, 1996a,b). The various ion channels consist of these basic elements.

The channel types are not homogeneously distributed across the nerve cell; instead, they are found grouped in areas which correspond to their function.

The post-synaptic part of the dendritic tree collects and transmits impulses arising from other nerve cells and transfers them to the body or soma of the nerve cell. Both stimulatory and inhibitory potentials are integrated into the existing activation phase of the cell. The dendrite and soma do not react passively to the input, but integrate the information received via the synapses into the cells' spontaneous activity (Llinas 1988).

Again, the K^+ currents, particularly $I_{K(Ca^{2+})}$, play an essential role here. The state of the K^+ currents determines what type of potential (stimulatory or inhibitory) is ultimately generated and transmitted along the axon; if $I_{K(Ca^{2+})}$ is strong, the transmission is blocked; if it is moderate in strength, phasic activation is demonstrated; and in the case of weak $I_{K(Ca^{2+})}$, the signal is directly transmitted. It is apparent that the inhibitory capacity of the K^+ currents represent a protective mechanism against overexcitability of the CNS.

The signal is not changed by the axon, which transmits all threshold depolarisations in the form of action potentials. In the synapsis, the action potentials produced by Na^+ and K^+ release Ca^{2+} currents of the N-type, which in turn lead to the opening of synaptic vesicles and the release of the neurotransmitters (Neher 1992).

All neurons have 1000 synapses and receive information from approximately 10,000 connections. Synapses have always been considered to be stable structures. As a matter of fact, electron microscopy examinations have demonstrated that the "spines", "spikes" or sack-like processes of the dendrite tree, which are probably responsible for cell communication, are continuously being dismantled and rebuilt (Murphy and Segal 1997; Rusakov et al. 1996). Important influences on the size of the inflows include the activation of the synapses and hormones such as oestrogen (Lewis et al. 1995).

The electrical transmission at the so-called gap junctions, channels through which a direct ion transfer can take place between cells (Bennett 1997), is essential for the synchronisation of neighbouring cells. The chemical transmission at the synapses involves the release of transmitter substance by the presynaptic cell and its binding on the postsynaptic cell. Upon binding to the postsynaptic cell, there is either a direct or indirect interaction with ion channels and the chemical signal is therefore transformed into an electrical one again.

Ion channels are controlled through various stimuli:

- Ligand-controlled channels open when a ligand combines with its receptor.
- Second messenger-dependent channels are opened and closed via protein phosphorylation.
- Potential-dependent channels open or close in response to changes in the membrane potential.

Ion channels can be grouped into families according to their common genetic origins (Stevens 1987). Thus potential-dependent channels, which are selective for

Ca^{2+}, Na^{+} or K^{+}, belong to one family. A second gene family is responsible for the ligand-controlled channels, which are activated via acetylcholine (ACh), gamino butyric acid (GABA), glycine or glutamate. A third family codes for the gap junctions.

2.2 Neurotransmitters

Neurotransmitters either bind directly to a receptor which is bound to an ion channel and thereby activate or end an ion current, or they bind to a receptor which activates a G protein, resulting in the activation of the second messenger cascade. This ultimately causes the opening of the ion channel via its phosphorylation.

In order to define a substance as a "neurotransmitter", certain criteria have to be fulfilled (Cooper et al. 1996). These include the following:

- Its synthesis by a neuron
- Its storage and sufficient release from a presynaptic terminal in order to produce a defined postsynaptic effect
- The reproducibility of this effect by exogenous application
- A specific mechanism which removes or inactivates the neurotransmitter in the synaptic space

There is a definite grey zone between the "classical" neurotransmitters and other substances, such as peptides, which do not fulfil all these criteria.

"Classic" neurotransmitters and neuropeptides are often located together in one cell and are released simultaneously. The functional significance of this is not known.

The various mechanisms which remove a neurotransmitter from the synaptic space are interesting. The smaller molecules are for the most part degraded enzymatically, whereas the larger peptides remain in the synapsis and can only be removed via diffusion and proteolysis. For several neurotransmitters, there are many high-affinity transporters which take up the neurotransmitter in the terminals or in the glial cells. The majority of the transporters belong to the so-called superfamilies. These are proteins which pass through the membrane 12 times, bind the neurotransmitter and divert them into the internal parts of the cell (Amara and Kuhar 1993).

The border between "neurotransmitters" and "neuromodulators" is also not clear, since many substances can take on the functions of both. Whereas neurotransmitters are important in various theories regarding the development of depression or schizophrenia, neuromodulators perhaps arouse more interest in connection with psychiatric illnesses. In the case of neurotransmission, a substance functions as a transmitter between two nerve cells. In the case of neuromodulation, on the other hand, the existing activity pattern of a nerve cell is altered in that $I_{K(Ca^{2+})}$ is reduced. For example, a phasic activation pattern in a cell can be modulated to a regular one. The reasons for such neuromodulation cannot be explained at the cellular level and may only be clarified in the context of a neuronal network or the homeostasis of the organism. Two examples of differing activating neuromodulation are given in detail below:

Noradrenaline (NA) is a biogenic amine; NA released in the CNS arises to a large extent from a syncytium of nerve cells in the upper brain stem, namely the locus coeruleus (Foote et al. 1983). These cells demonstrate a synchronous phasic activation pattern, which is determined mainly by $I_{K(Ca^{2+})}$. Their discharge occurs when an external, often strong stimulation is to be processed. NA projections occur in the cortex, hippocampus, thalamus, cerebellum and other important areas of the brain (Nieuwenhuys 1987). Correspondingly, following such a stimulus, there is a simultaneous release of NA in these areas. NA increases the effect of the local transmitter; in other words, the incoming stimulation is increased at the point of the target neuron ("enabling") (Bloom 1984). According to the receptor involved ($\alpha 1$, $\alpha 2$, β), NA increases excitatory or inhibitory potentials.

Corticotropin-releasing hormone (CRH) is a peptide. The distribution of CRH reflects its neuroendocrine function; CRH-containing interneurons and projections are not only found in the hypothalamus and locus coeruleus but also in the higher brain regions such as the hippocampus and cortex. Via a mechanism which was determined in vitro, a reduction of the $I_{K(Ca^{2+})}$ (Aldenhoff et al. 1983a) results in an increase in the phasic activity pattern found predominantly in these neurons. These cellular mechanisms might correspond to the CNS "alarm" or stress reactions postulated by Selye which allow the CNS to respond more rapidly to life-threatening situations. The above-described excitatory effect of NA is driven further by the activation of the locus coeruleus, for example. It is apparent from behavioural experiments with CRH (Koob et al. 1984) that the effectiveness of this "stress" reaction decreases with increasing dosage of CRH. A hyperexcited state no longer improves the reactive ability of the organism to the threat; in contrast, it worsens it. It is currently assumed that a CRH overdrive such as this could be the cause of neuroendocrine and vegetative symptoms seen in patients with depression (Holsboer 1989; see also below).

The receptors for glutamate represent a special situation, as glutamate controls two types of ionotrope receptors. The *N*-methyl-D-aspartate (NMDA) receptor controls one channel which allows the passage of Ca^{2+},

K^+ and Na^+. The non-NMDA receptor, on the other hand, binds the glutamate agonists kainat, quisqualat and aminomethyl propionic acid AMPA and regulates a channel which allows the passage of Na^+ and K^+. Further, glutamate functions via second messenger activation; when glutamate binds to a metabolically effective receptor, it activates phospholipase C (PLC), inositol phosphate (IP) and diaglycerol (DAG).

The standard model in which long-term potentiation (LTP) (Nicoll et al. 1988) is experimentally examined is the binding between CA3 and CA1 neurons in the hippocampus, the so-called Schaffer collaterals. With a strong stimulus which activates many fibres simultaneously, it is possible to produce persisting changes in the excitability of a chosen neuron. In this way, certain events occur which are reminiscent of conditioning processes in psychology; should both mild and strong excitatory stimuli activate a pyramid cell, the weaker stimulus can be permanently amplified only if it arrives in close association with the stronger stimulus. The permanent amplification of stimuli is restricted to the associated synaptic structures, which are correspondingly activated.

The decisive prerequisite for the occurrence of LTP is sufficient depolarisation of the postsynaptic cell. A simultaneous discharge of pre- and postsynaptic cells occurs in this way.

There are both NMDA and non-NMDA receptors at glutamate synapses; only the non-NMDA receptors play a role during normal synaptic activation, because the NMDA receptors are blocked by magnesium ions. With a stronger depolarisation of the postsynaptic cell, the positively charged magnesium ions are released from the NMDA receptor channel and the channel thus becomes permeable to Ca^{2+}. It is presumed that the Ca^{2+} current is the decisive factor for the triggering of LTP (Schneggenburger et al. 1993).

The ion channel of the NMDA receptor represents a unique form of channel, namely one with double activation. The channel only becomes permeable to Ca^{2+} when a simultaneous depolarisation of the cell and the binding of glutamate on the receptor occurs. The permanent increase in the postsynaptic excitability is probably transmitted by two Ca^{2+}-dependent protein kinases, protein kinase C and Ca^{2+} calmodulin kinase. The activation of gene expression also plays an essential role in LTP (Tully 1997; see also below).

LTP can only be maintained when an increase in the excitability of the postsynaptic neuron occurs together with an increase in the presynaptic transmitter release. It must be assumed that a retrograde transfer of information occurs from postsynaptic to presynaptic neurons. Nitrous oxide (NO) is considered to be a promising candidate for this function (Holscher 1997).

LTP is a physiological description of a process which was described 50 years ago by Hebbs Law (Bonhoeffer et al. 1989).

LTP is of great significance for complex neurological functions. Its most obvious role is probably memory, but it can be generally assumed that all processes may involve the NMDA receptors, which require the coupling of various experience-dependent neuronal systems. Further, one of the most interesting theories for the explanation of schizophrenia includes the NMDA receptor as an essential structure (see below).

2.3 Receptors and Second Messenger Systems

Various receptors are associated with differing second messenger systems. They transfer the signal carried by the neurotransmitter or neuromodulator to the centre of the cell.

The NA-binding β-adrenergic receptor functions in this way via adenylate cyclase and a G protein, which produces cAMP (Lefkowitz and Caron 1988). ACh binds to the muscarinic ACh receptor, which in turn activates a G protein and PLC. This leads to an increase in inositol triphosphate (IP_3), Ca^{2+} and diaglycerol (Nathanson and Harden 1990). Histamine, together with phospholipase A_2 (PLA_2), produces arachnidonic acid.

Here, again, there is a close connection between biochemical and electrical functions: cAMP activates a biphasic current response, consisting firstly of a faster inward current of Ca^{2+} and Na^+, followed by a slower K^+ outward current. The production of cAMP below the cell membrane results in a shorter excitatory and a longer inhibitory period for the individual cell. These currents might contribute to the phasic activation pattern in the neurons of the locus coeruleus (Wang and Aghajanian 1987), which are characteristic of this syncytium's function.

Ion channels and receptors occur not only in the outer cell membrane, but also within the internal parts of the cell. Ca^{2+} is therefore released from the intracellular stores via the IP_3 receptor in order to achieve optimal concentrations for Ca^{2+}-activated structures.

As an intracellular "excitable medium" (Berridge 1997), it contributes to the amplification and transmission of Ca^{2+} signals in cells (Jacobs and Meyer 1997). Further, it appears that intracellular stores of Ca^{2+} contribute to a high concentration of calcium in the nuclei of hippocampus neurons following glutamate application, suggesting a transcriptional significance of Ca^{2+} (Korkotian et al. 1996). The induction of LTP in the hippocampus requires the release of calcium from the endoplasmic reticulum (ER) (Reyes and Stanton 1996).

A subsequent oscillating uptake and release of Ca^{2+} ions occurs until this process comes to rest (Berridge 1993). The calcium response correlates to the various parts of the signal transduction. In neurons and lymphocytes, for example, the non-receptor kinases of the *src* subfamily, in particular the *fyn* kinases, play an important role in the commencement and arrest of the calcium response (Grant et al. 1992). In all cell types, the Ca^{2+} response is dependent upon the metabolism of phosphatidylinositol. The IP3-sensitive Ca^{2+} channel of the ER is a point of attack for the dismantling of IP3 produced by phosphatidylinositol 4,5-bisphosphate (PIP2). In both neurons and lymphocytes, the IP3-sensitive intracellular Ca^{2+} stores are important. It has also been demonstrated that the so-called Ca^{2+}-induced Ca^{2+} release (CICR) is transmitted by the ryanodine-sensitive receptors. Not only can Ca^{2+} increase its own release from the intracellular stores, but it can also inhibit it depending on the concentration present.

As a result of these complex interactions, a Ca^{2+} response occurs not only as a simple increase in the $[Ca^{2+}]_i$, but mainly in the form of oscillations. Recent results demonstrate that the frequency, amplitude and length of the signal has functional consequences for the cell. B cells, for example, demonstrate differing activations of transcription factors according to the amplitude and length of the calcium signal (Dolmetsch and Lewis 1997). It has also been shown in T cells that, although a sufficient stimulus was required for the cells to respond, there was no difference in the Ca^{2+} response following various stimuli if they exceeded the threshold for a response.

The structures required for the development of Ca^{2+} oscillation vary from cell to cell. Those cells with so-called membrane oscillation have a periodic opening and closing of the potential-dependent Ca^{2+} channels. In contrast, the development of Ca^{2+} oscillation by so-called cytosolic oscillators is dependent upon the release of ions from the ER. Cytosolic oscillators include nerve cells and hormone-releasing cells of the pituitary gland.

Activation of cellular mechanisms via a transmitter may have effects of varying duration. For example, the binding of NA to the α_2-receptor leads to the phosphorylation of a Ca^{2+} channel via the cAMP system and in turn to an outward K^+ current, which inhibits the excitability of the cell for several minutes. Should this process be repeated or should binding of NA to the receptor be amplified, an activation of gene expression follows through the phosphorylation of transcription-regulatory proteins. Such proteins can influence the channel directly and may produce changes in the neuronal excitability over a period of days or weeks. This mechanism, which influences the rate of mRNA transcription, has largely been clarified (Strachan and Read 1996). It is particularly interesting, as it appears to be modified in psychiatric diseases and therefore may play a role in their pathogenesis.

Normally, certain genes are expressed, whereas others are not in a transcriptable form. This situation can be changed by proteins which bind to the regulatory parts of the gene. They are controlled via receptors, which bind substances such as steroid hormones, growth factors and neurotransmitters. The regulatory parts of a DNA strand contain two control elements, a promoter and an enhancing region. The promoter region has many genes with adenine and thymine and is therefore called the TATA box. It brings the RNA polymerase to the region where transcription should commence.

The structures of the enhancer region are the binding points for the proteins which decide whether a gene will be transcribed or not. They are called response elements. Examples include the cAMP response element (CRE), which recognises the CRE-binding (CREB) proteins (these proteins are activated under the control of the cAMP-dependent protein kinases); the phorbolester response element and the glucocorticoid (GC) response element. Some enhancer regions continually activate, whereas others are only active when gene expression occurs as a result of hormonal influence or learning processes (Yin et al. 1995).

It was considered for many years that the subcellular functions described above could not contribute to understanding complex brain functions. This opinion only changed with the help of molecular biology techniques which managed to turn off single receptors or kinases by manipulating their RNA.[1] CREB-knock-out mice, for example, show a definite disturbance of long-term memory following adverse stimulation (Bourtchuladze et al. 1994). Similarly, the turning off of Ca^{2+} calmodulin kinase α*CaMKII* or the *fyn* tyrosine kinase, both of which are involved in Ca^{2+} regulation, leads to disruption of LTP and memory processes (Grant et al. 1992; Rotenberg et al. 1996).

These results converge to a uniform mechanism of the storage of information; the decisive mechanism occurs when a particularly large inward Ca^{2+} current is allowed into the cell. This can occur via a non-specific cation channel with activation of the NMDA receptor or via another non-specific channel leading to an intracellular increase of cAMP. The usually effective controls for an increase in $[Ca^{2+}]_i$ are bypassed via the use of these non-specific channels. The $[Ca^{2+}]_i$ increase

[1] Such techniques include the development of transgenic animals or the antisense knockout technique (Montkowski and Holsboer 1996).

favours enzymatic changes, the time period of which can be influenced by gene expression.

2.4 Summary

The cellular apparatus, which integrates both biochemical and electrical functions, has a relatively high threshold of functional stability in both the resting and activation phases. Modulating influences use the second messenger systems of cAMP and Ca^{2+} via biogenic amines, peptides and hormones. These systems allow medium- to long-term modification of the expression of genes which are not usually expressed. A further possibility for modification is the cellular storage of information.[2]

Neuronal activity can thus be altered at several cellular levels:

- Through the balance between excitatory and inhibitory ion channels
- Through short-term involvement of second messenger systems of cAMP and Ca^{2+}
- Through the expression of existing but "silent" genetic information
- Through new information via processes of cellular information storage

In terms of the pathophysiology of psychological disease, these alterations also represent points at which disturbances may develop. The various therapeutic options to date can also be placed in a pharmacological hierarchy. Furthermore, the description of new mechanisms such as second messenger-activated gene expression should allow for new therapy options.

3 Pathophysiological Mechanisms

It will probably never be possible to undertake a direct examination of the neurons of psychiatric patients. Indirect conclusions, however, can be made in a number of ways:

- The "pharmacological bridge": the effect of a substance on behaviour in an animal experiment is compared with the clinical effect of the substance and a mechanism of action is then postulated (Aldenhoff 1989). Examples of this process include many therapeutic agents, including the pharmacological hierarchy of new substances, which support the developmental history of CRH, etc.
- Cellular research models in humans: certain cellular functions can be investigated on peripheral human cells, e.g. K^+ channels in fibroblasts or lymphocytes (Cohen 1996), $[Ca^{2+}]_i$ in lymphocytes (Aldenhoff et al. 1997) and PLA in thrombocytes (Gattaz et al. 1996). The advantages of this model lie in the availability of the human cell and its identical genome. A disadvantage is the differing functions of the cells.

3.1 Disturbed Balance Between the Excitatory and Inhibitory Ion Channels

A typical example can be considered to be the disturbance of interactions between the hormones of the hypothalamus, the cortex of the adrenal glands and their peripheral target nerve cells. These are presumed to be associated with depression (Holsboer 1989).

Following environmental stress stimuli, a release of CRH occurs from the neurons of the hypothalamus, the central cortical CRH neurons and the neurons of the hippocampus. The above-mentioned neuronal activation begins as a result of an inhibition of $I_{K(Ca^{2+})}$. When the levels of corticosteroids released by the endocrinal effect of CRH are sufficiently high, they have an inhibitory effect on and, ultimately, arrest neuronal activity (Vidal et al. 1986). This neuroendocrine feedback loop is turned off when a CRH overdrive occurs as a result of moderate (but not overly strong) external stresses. Following such stimuli, the $I_{K(Ca^{2+})}$ is further inhibited via a continuous dominant excitatory influence. In addition, as a result of the continuously high levels of cortisol, there is a down-regulation of the GC receptors, which, in contrast to the mineralocorticoid (MC) receptors, have a inhibitory effect on corticosteroids (de Kloet et al. 1990) and, consequently, lead to a weakening of the effect of cortisol. The normal feedback loop is thus hypersensitised. This is accompanied by a CRH-induced noradrenergic stimulation. Under high doses of CRH, the nerve cells of the locus coeruleus lose their phasic activation pattern and discharge in an increased and continuous way (Valentino et al. 1987).

The target neurons of the locus coeruleus also lead to an increased NA effect, which is no longer sensitive to environmental stimuli but increases in excitability independently of this.

This could be an explanation for a decrease in ability to concentrate and in perception in patients with depression. A further explanation could be the

[2] It does not seem appropriate to use the terms "learning" and "memory", as these describe complex abilities which differ with time and objects. Even if new molecular biological techniques support the dependence of differentiated and complex abilities of an individual on subcellular mechanisms, the relationship of storage of information is meant here.

downregulation of GC receptors. Mice that have been treated with antisense to the GC receptor have a definite loss of cognitive capabilities (Montkowski et al. 1995). Interestingly, the impaired capabilities improved after treatment with anti-depressants.

A further example of the disturbed balance between the excitatory and inhibitory ion channels are the cellular changes in addiction and tolerance development. Benzodiazepines increase the physiological effect of the transmitter GABA via the benzodiazepine receptor complex-coupled chloride channel. In other words, they increase the inhibitory effect of the chloride current. With regular use of benzodiazepines, this effect decreases until the appearance of a rebound phenomenon.

This can be explained electrophysiologically by the weakening of the inhibiting GABA effect, leading to a predominant excitatory influence on the membrane potential. From the clinical viewpoint, it is interesting that, during a withdrawal syndrome, anxiety can be initiated by other cellular excitatory substances, such as yohimbine, coffee or intrinsically effective benzodiazepine antagonists.

Similar to alcohol dependence, there is an adjustment of the excitatory balance; on the one hand, there is a decrease in the inhibitory mechanisms of the cell with the regular supply of alcohol. On the other hand, new Ca^{2+} channels are produced (Dolin et al. 1987). Both effects lead to an adjustment of the excitability balance, which can explain most of the clinically observed phenomena of alcohol withdrawal, such as increased transfer in all sensory channels and increased vegetative and epileptic fits.

3.2 Disturbances of the Second Messenger Systems of Cyclic Adenosine Monophosphate and Ca^{2+}

The influence of various anti-depressive medications and treatments, such as imipramine, monoamine oxidase (MAO) inhibitors and electroconvulsive therapy, on the β-receptor of activated cAMP-dependent protein kinase A, has been investigated in detail in clinical trials (Nestler et al. 1990). It was demonstrated that these therapeutic measures, which have completely differing mechanisms of actions from the pharmacological viewpoint, all lead to a translocation of kinase from the cytosol to the cell nucleus, suggesting a possible change in gene expression. A significant decrease in the activity of kinase was demonstrated in depressive patients (Shelton et al. 1996).

Direct investigations of $[Ca^{2+}]_i$ on human peripheral nerve cells do not exist, but there is indirect evidence that a second messenger might be involved in the development of psychiatric disturbances.

One of the most attractive models for the development of bipolar affective illness involves the phenomenon of kindling (Post et al. 1986). Following repeated stimulation of the amygdala, there is a permanent increase in the excitability level ("sensitisation"). Although occurring in a different location, kindling is similar to LTP. This observation led Post et al. to the conclusion that a similar process might be responsible for the development and acceleration of the phases of affective illnesses. According to this hypothesis, it is possible that spontaneously occurring affective episodes lead to biological scars in the form of kindling, which favour the further development of the illness phases. Each of these phases collides with the pathological process and enhances it, so that the time difference between each phase decreases. In the worst case, rapid cycling occurs. Supporting this hypothesis are the effects of the main therapeutic agents used in bipolar illnesses – lithium and carbamazepine – i.e. the regulation of $[Ca^{2+}]_i$ (see below).

The observation that an increase in $[Ca^{2+}]_i$ above a critical value leads to cell death resulted in a hypothesis that age and, in particular, dementia are associated with an increased level of intracellular $[Ca^{2+}]_i$ (Landfield 1987). Supporting this theory is the observation that the $I_{K(Ca^{2+})}$ increases in the hippocampus of old rats (Landfield and Pitler 1984). However, the difficulty of fitting such acute effects into a gradual process such as aging speaks against this model. By directly measuring $[Ca^{2+}]_i$ in single T lymphocytes, we found that the Ca^{2+} signals in the cells of older patients did not differ significantly from – and indeed were less than those – of younger patients (Sulger et al., in press). In T lymphocytes of patients with Alzheimer's disease, we also demonstrated "above normal" Ca^{2+} signals in normal resting phase concentrations. These results cannot support the original thesis and instead suggest a decrease in Ca^{2+}-binding proteins such as calbindin in dementia.

The introduction of antisense technology in neurobiology has recently brought better understanding of the effects of $[Ca^{2+}]_i$-regulating kinases.

On turning off the *fyn* tyrosine kinase, a "syndrome" of effects occur which obviously have an intimate causal relationship with one another (Grant et al. 1992); spatial memory in the water maze becomes considerably worse; the LTP effect is electrophysiologically weakened; and in anatomical studies of the hippocampus, which is considered to be responsible for spatial memory, there is a disintegration of granula cells and of pyramid cells. The *fyn* tyrosine kinase appears to attack at several points in the memory process, as this is essential for the development of kindling (Cain et al. 1995). Similarly, disturbances of *CaMKII* lead to damage in spatial but not contextual memory (Bach et al. 1995).

Olney and Farber (1995) postulate that subfunctioning of the NMDA receptor is a central mechanism which can explain the pathophysiological and clinical aspects of schizophrenia. This proposal is based upon the clinical effect of the substances such as phencyclidine and ketamine which block the NMDA receptor-channel complex. Phencyclidine induces schizophrenia-like psychoses in normal subjects and results in relapses in stable schizophrenic patients. The anaesthetic ketamine also induces psychoses in adults, but not in the young. Olney and Farber support their hypothesis with neuropathological findings which demonstrate that NMDA antagonists result in neurodegenerative changes in corticolimbic regions.

Glutamate functions via the NMDA receptors on the GABA and noradrenergic nerve cells and via a tonic inhibitory control of multiple stimulating afferents to the posterior cingulum and to the retrosplenial cortex (PC/RS cortex). The PC/RS neurons regulate their activity through recurrent collaterals, the inhibitory influence of which is in turn determined by the effect of glutamate on the GABA neurons. In such a network, NMDA hypofunctioning leads to a loss of inhibitory controls in the region of the PC/RS cortex. Consequently, a massive disruption of the second messenger systems occurs. These are subsequently activated and lead to severe neuropsychological disturbances. This model represents a fascinating connection between physiological, pharmacological, neuroanatomical and clinical findings of the cell, which integrate many observations and findings of research in schizophrenia.

3.3 Genetics of Psychiatric Illnesses

The discovery of enhancer proteins – and thereby of the function-dependent expression of genes that were previously not transcriptable – demonstrated many new possibilities for interactions between function and the genome. Long-term application of anti-depressants leads to an increased expression of CREB in the hippocampus of the rat (Nibuya et al. 1996). This effect is specific to anti-depressants. We are sure to see very interesting results from these pharmacological measures in the near future.

To date, there are no reports which describe a psychiatric disturbance as a result of a gene mutation. As far as we know, the main psychiatric illnesses appear to be polygenetically determined (Propping et al. 1994). This may have several reasons: the diagnostic entities of the psychiatric disturbances, as they are defined in the DSM-III classification, may group together multiple neuropsychological subsyndromes. The latter may develop incompletely or subclinically following the appearance of pathogenetic mechanisms and only develop into the complete disturbance, as defined in the classification, following a long latency period. It must be assumed that a genetic mutation occurring in a cell will be initially compensated for by multiple mechanisms. Only when these compensatory mechanisms no longer function effectively do the symptoms become clinically apparent. Individual genetic defects that lead to striking behavioural changes in antisense experiments appear to be compensated for and therefore remain subclinical in humans for a longer period.

One way to clarify the role of mutations in psychiatric disease would be to take the evidence obtained from research, e.g. from experiments with transgenic animals and the antisense technique, and apply it in clinical practice. The absence of the serotonin ($5\text{-}HT_2$) C receptors, for example, leads to eating problems and cerebral fits (Tecott et al. 1995). Further, the loss of α-calcium calmodulin kinase II leads to an abnormal angst response and aggressive behaviour in addition to the above-mentioned memory disturbances (Chen et al. 1994). When the corresponding behavioural disturbances occur in patients, we could narrow our search to the respective genes rather than conducting large population genetic studies, as done previously.

Disturbances of the genetic codes of the ion channels, which could also be relevant in psychiatry, were recently published. These disturbances occur predominantly in the region of the Ca^{2+} and K^+ channels. Missense mutations in the region of the gene for an α_1-subunit of a Ca^{2+} channel of the P7Q type were found in patients with familial migraines and episodic ataxia (Ophoff et al. 1996). Similarly, a false genetic coding for a K^+ channel was demonstrated in patients with episodic ataxia (Browne et al. 1994). A detailed discussion is being conducted presently in the literature about the *weaver* gene, whose product blocks G protein-coupled K^+ channels (Liao et al. 1996). Apart from functional and anatomical peculiarities in the cerebellum, a specific and progressive loss of dopamine neurons has been observed. This may be of possible relevance to Parkinson's disease (Oo et al. 1996).

The ionic mechanisms can be explained as follows: in the case of a wild type, as a result of the binding of ligand, a G protein-coupled K^+ channel, which contributes to the resting phase of the cell, is opened, and a gene transcription is activated, which has an influence on the further differentiation of the cell. In the case of the mutant GIRK2, a large amino acid blocks the K^+ channel, resulting in depolarisation, excitotopic cell death and a blockade of the genetic transcription results (Goldowitz and Smeyne 1995). Interestingly, the consequences of such mutations are not constantly observed, but only occur episodically; this is of particular relevance to psychiatric illnesses. Such

evidence could promote the search for the subtypes of otherwise genetically but not clinically obvious depression. Absence seizures are similarly determined by a mutation in the potential dependent Ca^{2+} channel (Fletcher et al. 1996).

3.4 Cellular Targets for Pharmacological Effects

A typical example of a cellular clarification model is the synaptic model for the effect of anti-depressants. At the time of the production of these medications, the actual function of synapses was not really known. This led to a one-sided overinterpretation of the re-uptake mechanism as the principle mechanism of action of these medications. The effect of the anti-depressants can now be explained via a functioning neuroendrocrine model at the cellular level (Barden et al. 1997; Karanth et al. 1997; Modell et al. 1997). Other pharmacological mechanisms can be explained via the neuromodulatory effects of lithium.

This example clearly demonstrates the interaction between electrical and biochemical effects. In the nerve cells of the snail *Helix pomatia* – some (Burster cells, D cells) of which regulate their activation pattern predominantly via $I_{K(Ca^{2+})}$ – a disintegration of the phasic activation pattern is observed under lithium treatment. The measurement of $[Ca^{2+}]_i$ demonstrates that lithium clearly slows down the intracellular feedback of $[Ca^{2+}]_i$ following stimulation (Aldenhoff and Lux 1985). It can be postulated that this effect must vary according to the excitability of the cell; if the excitability is low, the Ca^{2+} signal is likely to be increased, whereas in the case of a cell with high rate of discharge, the Ca^{2+} transients overlap and there is a gradual increase in $[Ca^{2+}]_i$; the latter can be demonstrated experimentally. As a strong activator of $I_{K(Ca^{2+})}$, this increase of $[Ca^{2+}]_i$ should lead to a more rapid commencement of neuronal inhibition, i.e. it should have a "dampening" effect on neuronal activity. These alterations in function were confirmed years later when the biochemical mechanism of the action of lithium on IP was demonstrated (van Calker et al. 1987).

If the physiological model is discarded, the effect of lithium can be summarised as a calcium antagonism. Such considerations have led in the past to attempts to treat affective illnesses with calcium antagonists, e.g. verapamil. Whereas the effect of this treatment was not clear in older studies (Aldenhoff et al. 1986), recent investigations with elaborate study designs clearly support this hypothesis (Soares and Mallinger 1997). Carbamazepine, which has a similar clinical effect to lithium, also appears to function via the phosphoinositol system (Biber et al. 1996) and further to reduce Ca^{2+} currents (Schirrmacher et al. 1995).

One research path which has been pursued for many years is the functional effect of second messenger systems in relation to the effects of anti-depressants (Shelton et al. 1996). This has recently come into the limelight as a result of the discovery of enhancement factors (see above).

4 Relationship Between Cell Physiology and Psychiatry: The Compensatory Potential of the Brain

Circumscribed defects in the regions of genes or receptors do not necessarily lead to observable changes in behaviour, as they can be compensated for over a long period of time. Important cell functions are often protected by many mechanisms; if one cellular or intercellular mechanism does not work, it will therefore be compensated for by another. Although this leads to the survival of the individual, it makes it more difficult to interpret the role of gene mutations from the phenotypical or clinical viewpoint. Similarly, the application of substances against theoretical interventional targets, i.e. using the antisense knockout techniques and transgenic animals, produces no obvious effect on behaviour. This is particularly true when certain defects are apparent in embryonal and early development. Under such conditions, the pressure for the application of compensatory mechanisms appears to be very high.

A reasonable alternative experiment would be to construct certain genetic defects in an inactive form, which can then be activated at the planned time of investigation. This is possible in some cases via a sensitivity for substances such as tetracyclines (Gossen et al. 1995); certain constructed genetic defects can be activated via tetracycline in adults and completely behaviourally competent animals.

On the other hand, it has to be presumed that the manifestation of a disturbance or a disease requires the dysfunctioning of multiple cellular functions. On construction of a research model, it is often overlooked that most of these models are very simple and are not multifactorial. The majority are not suitable for the application of the complex theories, such as the chaos theory, which is still very much in the early stages of clinical observation.

Even now, the fundamental cellular principles of classical psychopathology are not clearly understood, e.g. ego disturbances, affect, impulse. The relationship between global terms such as psychosis or depression and the cellular level can be best understood via the so-called pharmacological bridge (Aldenhoff 1989). It

becomes more difficult when we try to go into more concrete detail, but the interaction of neuropsychological and neuroanatomic methods may provide assistance.

Discrete new treatment strategies are being defined with newer techniques of modern neuropsychology, such as animal experiments where the respective lesions are demonstrated. This has been shown very clearly and impressively with the combination of the results of animal experiments and neuroanatomical and neuropsychological work on the clinical symptoms of schizophrenia.

Older neuromorphological findings have shown that schizophrenic patients have a higher cell density and a disturbed cell architecture in the prefrontal cortex (Beckmann 1992). In an impressive series of animal experiments (Friedman and Goldman-Rakic 1994) and magnetic resonance imaging (MRI) examinations (McCarthy et al. 1996), Goldman-Rakic's research group was able to show that the dorsolateral prefrontal cortex plays an important role in activities in which the individual has to maintain a purpose despite many intermediary steps. According to recent neuropsychological investigations, this mechanism appears to be one which may help explain the typical characteristics of schizophrenia. In schizophrenia, there are defects in working memory, namely the inability to allow behaviour to be guided by representation and to differentiate between inner representations and external stimuli. These neuropsychological deficits lead to the clinical symptoms, i.e. the inability to keep to a conscious plan and to monitor it during its progression, which can lead to disorganised speech and thoughts; the inability to maintain a purpose, which can lead to negative symptoms; and the inability to differentiate between specific external or internal experiences and associative memory, which in turn can lead to madness and hallucinations (Andreasen et al. 1997).

Thus it does seem possible to demonstrate a relationship between clinical phenomenology and the cellular substrate.

CHAPTER

8

I. Heuser

Psychoneuroendocrinology

Translator: W. VanSyckel

1 Historical Overview

References to biological disturbances as the basis of specific psychiatric disorders can be found in works from as early as the *Corpus Hippocratum* dating back to the fifth century B.C. Within this context and in keeping with humoral theory, psychological disorders were also ascribed to an imbalance (dyscrasia) of black and yellow bile, mucus and blood, with melancholy being attributed to a predominance of black bile, pointing, once again, to a humoral interpretation of psychiatric abnormalities. In contrast to this scholastic approach to medicine, Paracelsus (1491–1541), who also laid the foundations for the development of iatrochemistry (which gained particular importance during the seventeenth century), saw the human body as a chemical system whose ailments could therefore also be cured using chemical compounds. His findings concerning the relationship between struma and cretinism first pointed to endocrinological changes in association with psychiatric disorders.

The term "endocrinological psychiatry" first came in use in connection with a conference of psychiatrists in Dijon in 1908, during which Laignel-Lavastine encouraged his audience to intensify research efforts exploring the interaction between personality and endocrine systems. However, it was the work of Manfred Bleuler which first provided a detailed account of the relationship between endocrine disturbances (e.g. hypothyroidism, acromegalia, Cushing's syndrome, and Addison's disease) and psychiatric disorders or "defects." Based on his observation that the onset of psychoses often coincided with phases of endocrinological change (pregnancy or postpartum), Bleuler (1948) posted the hypothesis that "psychiatric and endocrine control mechanisms not only influence each other but are also highly integrated." He further noted that all endocrine diseases, even those with a rather mild and nonacute course, are generally accompanied by disturbances in mood, vitality, and motivation (Bleuler 1948).

2 The Brain: Endocrine Target Organ and Endocrine Gland

Present theories assume a model of bidirectionality involving the brain and endocrine systems; a change in peripheral hormone activity may not only be the result of disturbances in the central regulatory function, but may also be the cause of a change in brain function, thus modifying behavior. During the last few decades, modern neurobiological methods and biotechnology have broadened this conceptual idea in as much as the brain is no longer simply seen as an endocrine target organ, but also as an endocrine gland; in addition to housing the receptors of so-called peripheral hormones (e.g. somatostatin, vasoactive intestinal polypeptide, cholecystokinin), the brain itself is also the site at which various hormones such as prolactin are synthesized, governed by the so-called classical neurotransmitters, e.g. dopamine, or other central peptides.

Thus a vast number of neurons in the hypothalamus synthesize and secrete peptides, while individual neurons also express more than one neuropeptidergic hormone. While some of these neurons release their peptides into the synaptic cleft, where they act as neurotransmitters, others deliver neuropeptidergic hormones directly into the circulatory system, where they either act as true hormones on a number of tissues and/or as neuromodulators on more remote cells.

Within this context it is important to understand that hormones serving as neurotransmitters also have behavioral effects. Thus thyrotropin-releasing hormone (TRH), for example, causes increased motoric activity; corticotropin-releasing hormone (CRH) lowers food intake and decreases libido and slow-wave sleep; and cholecystokinin (CCK) is known to exert anxiogenic effects. The aforementioned are only a few examples illustrating the psychotropic effects of different hormones in order to underscore the importance that neuroendocrinology holds for psychiatry.

These findings have also resulted in the development of therapeutic strategies. Observations of the anxiolytic effects of CCK have, for example, led to the development of a neurokinin-3 receptor antagonist presently undergoing clinical studies. This is based on the assumption that mesolimbic dopaminergic neurons are involved in the development of anxiety, as are noradrenergic neurons located in the locus ceruleus. Administration of this functional tachykinin antagonist is aimed at inhibiting these neuron clusters, thereby reducing the level of anxiety.

According to their mechanisms of action, hormones may roughly be divided into two large groups:

1. Aminergic and peptide hormones act through receptors located on the cell surface: ligand binding to the receptor causes a change in the permeability of ion channels or the modulation of second-messenger systems (e.g. adenylcyclase, phosphorylase).
2. Steroid and thyroid hormones have an intracellular effect as they readily pass through cell membranes due to their lipophilic properties. Binding of these

hormones to their respective receptor proteins within the cytoplasm causes a conformational change in the receptor protein. This allows the hormone receptor complex to bind to specific regions, so-called hormone responsive elements, within the promotor region, thereby either stimulating or inhibiting the production of the gene products. However, only recently a second, so-called nongenomic, rapid steroid effect has been described; this effect is mediated by steroid receptors located on the cell surface (Wehling et al. 1998).

As a characteristic feature, hormonal secretion follows a specific temporal pattern. Accordingly, many hormones, particularly those of the pituitary gland such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH), are released in a pulsatile manner. This basal hormone release follows a rhythm which can either be ultradian (shorter than 1 day), circadian (a period of approximately 24 h), or infradian (a period of longer than 24 h). In determining the exact rhythm, the suprachiasmatic nucleus plays an important role as pacemaker.

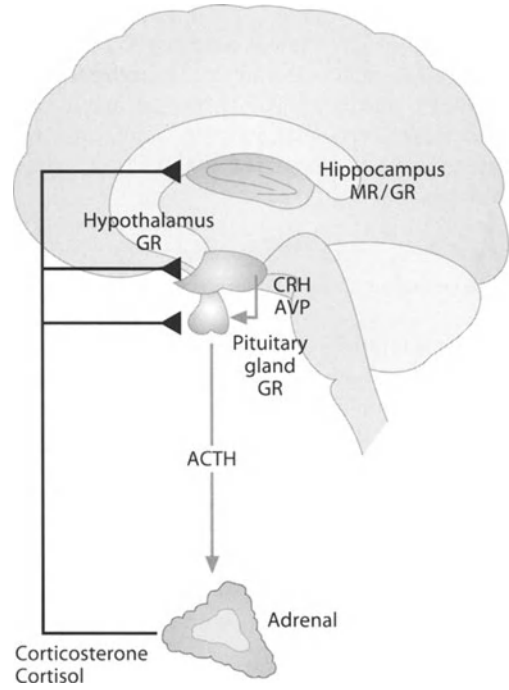

Fig. 1. Hypothalamic–pituitary–adrenal system. *MR*, mineralocorticoid receptor; *GR*, glucocorticoid receptor; *CRH*, corticotropin-releasing hormone; *AVP*, arginine–vasopressin; *ACTH*, adrenocorticotropin-releasing hormone

3
Endocrine Systems and Psychiatric Disorders

Kraepelin was the first to note that the onset of the first clinically relevant episode of a psychiatric illness can be triggered by adverse life events. Early research from the 1960s and 1970s was then able to show that depressed patients display similar endocrine changes as mentally healthy individuals subjected to stress. These findings proved to be tremendously stimulating for neurobiological research. Using depression as an example, the following will provide a more detailed illustration of this fact.

3.1
The Hypothalamic–Pituitary–Adrenal System

The hypothalamic–pituitary–adrenal system is the most significant system of hormonal stress regulation (Fig. 1). It is governed by a complex regulatory mechanism which is equally influenced by both peripheral factors and aspects of the central nervous system (CNS). Within this mechanism, the hypothalamus with its afferent and efferent connections represents a central regulatory structure. While receiving neuronal afferents from the hippocampus, the amygdala and septum, the cortex, thalamus, reticular formation, and autonomous centripedal nerve fibers of the spinal cord, it also receives direct input from the eyes via retinohypothalamic connections.

Neuroendocrine changes are aspects of a stress reaction aimed at enabling the organism to adapt to stressful situations; thus activation of sympathetic portions of the CNS leads to heightened vigilance and attention, while specific vegetative functions such as libido, hunger, and need for sleep decrease ("flight response").

3.1.1 The Stress Cascade

The transduction of "psychological" stress into "physical" events (reactions) takes place in the hypothalamus. Whenever the organism is exposed to stressors, this results in the increased hypothalamic release of CRH and also, in specific cases, arginine–vasopressin. Both neuropeptides are synthesized and stored in the paraventricular nucleus of the hypothalamus and augment each other's effect on the pituitary release of adrenocorticotropin hormone (ACTH) and β-lipocortin from their common precursor pro-opiomelanocortin (POMC). Independent of this mechanism, epinephrine and norepinephrine, as well as other peptides (e.g. angiotensin II), also stimulate the secretion of ACTH from the pituitary gland, while the atrial natriuretic peptide (ANP) inhibits ACTH release (Fink et al. 1991).

As a tropic hormone, ACTH increases both the biosynthesis and release of glucocorticoids from the adrenal cortex, while catecholamines are released from the adrenal medulla. The hypothalamic–pituitary–adrenal system regulates its own activity by way of negative feedback loops at the adrenal, pituitary, hypothalamic, and hippocampal level.

3.1.2 Hippocampal Glucocorticoid Receptors

The hippocampus is thought to be of particular importance for both the inhibition and activation of the hypothalamic–pituitary–adrenal system. Two different receptors, the mineralocorticoid receptor and the glucocorticoid receptor, are responsible for binding glucocorticoids in the hippocampus. Although they have different functions, both receptors are involved in the homeostatic control of the hypothalamic–pituitary–adrenal system (Funder 1994).

Through their research on agonists and antagonists, the research group of de Kloet was able to demonstrate that, in rats, the mineralocorticoid receptors in the brain are almost exclusively expressed within the hippocampus, while glucocorticoid receptors are found throughout the entire brain. Later studies then described the hippocampal mineralocorticoid receptor as having a tenfold greater affinity for glucocorticoids than the central glucocorticoid receptor with generally more than 90% of its binding sites occupied by glucocorticoids. The glucocorticoid receptor, on the other hand, is only occupied by its ligand as the result of increasing glucocorticoid concentrations, e.g. in the course of diurnal fluctuations or following stress (de Kloet 1991).

In summary, this indicates that, compared with mineralocorticoid receptors, glucocorticoid receptors possess a significantly lower ligand affinity, which, as already mentioned, acts in the hippocampus as a receptor with a clear preference for glucocorticoids. By means of animal experiments, it has been shown that mineralocorticoid receptors are mainly responsible for the regulation of basal rhythms such as sleep–wake cycles and food intake, while glucocorticoid receptors appear to play a role in terminating stress-responsive glucocorticoid secretion (McEwen 1998). As a result of repeated severe stress or chronic glucocorticoid treatment, hippocampal glucocorticoid receptors are down-regulated.

Furthermore, it has been demonstrated that hypersecretion of glucocorticoids in the presence of other noxious stimuli, such as hypoxemia, may lead to cell death within the CA_3 region of the hippocampus. This observation led Sapolsky to formulate the so-called cascade theory. Heightened glucocorticoid exposition of the brain may result in the disturbed arborization of dendrites, inhibition of glucose-3 transporters (which are mainly expressed in hippocampal neurons), and increased excitatory amino acid function (Sapolsky 1996). Accordingly, the impact of glucocorticoids may either cause increased vulnerability, temporary damage, or even neuronal death.

3.1.3 Clinical Results of Neuroendocrine Research on Depression

Patients with hypercortisolemia are known to frequently suffer from depressive syndromes (Wybrow and Horwitz 1976). In a follow-up study on depressed patients, Gibbons (1964) was also able to demonstrate that cortisol concentrations in remitted patients were significantly lower than during preliminary examinations, i.e during their acute episode. Recent findings were able to confirm this observation (Deuschle et al. 1997). Furthermore, patients suffering from depression typically display a number of symptoms pointing to hypothalamic malfunctioning, such as sleep disorders, loss of appetite and libido, circadian abnormalities, and autonomous dysregulation.

In 50%–70% of all depressed patients, it was noted that, in contrast to healthy controls, the administration of small doses of the synthetic glucocorticoid dexamethasone did not lead to a decrease in cortisol concentrations (dexamethasone suppression test; Carroll et al. 1981). Together with the findings of increased basal cortisol levels in depressed patients, this points to an apparent dysregulation in the hypothalamic–pituitary–adrenal system in these patients.

In endocrinology, the CRH test has come to provide a reliable differential diagnosis for Cushing's syndrome (for an overview, see Müller 1987). In addition, the CRH test has been carried out with patients suffering from depression. Within this context, it was demonstrated that hypercortisolemic patients exhibit a reduced ACTH response, while their cortisol response follows the same course as in healthy controls. This reduction in ACTH response has been termed ACTH blunting (Holsboer et al. 1984, 1987; Gold et al. 1986).

Following pretreatment with metyrapone, a 11-β-steroid hydroxylase inhibitor which inhibits the biosynthesis of cortisol from its precursor, followed by stimulation with CRH, depressed patients show both a normalized ACTH response and a normal cortisol response. These findings seem to suggest that the increased plasma cortisol concentrations found in depressed patients have a particular braking effect on CRH-induced ACTH release, i.e the cortisol feedback loop between the adrenal cortex and pituitary gland in depressed patients appears to be intact.

In order to further investigate this inverse relationship between basal plasma cortisol concentrations and

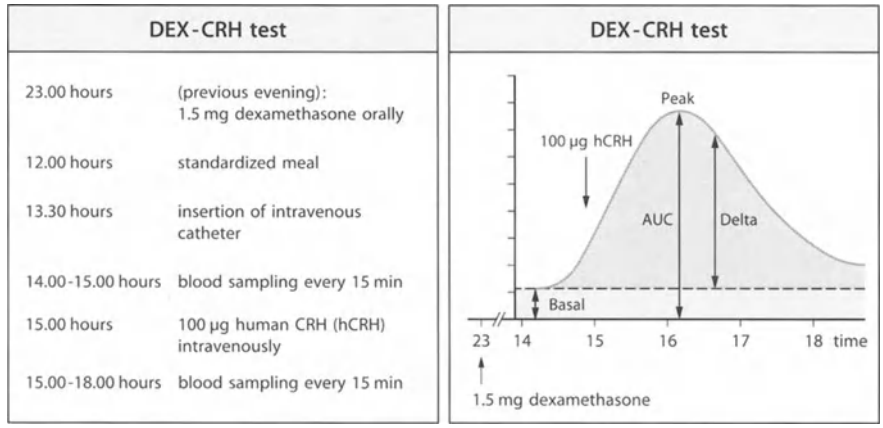

Fig. 2. Dexamethasone suppression/corticotropin-releasing hormone (CRH) stimulation test. *AUC*, area under the curve

CRH-induced ACTH release, hypercortisolemic patients suffering from depression and healthy normocortisolemic controls were both given dexamethasone (at 23:00 on day 1), followed by CRH stimulation 16 h later (at 15:00 the following day), a procedure known as the combined dexamethasone suppression/CRH stimulation test.

It had been assumed that in depressed patients the increased overall cortisol level (endogenous and exogenous) would result in significantly diminished ACTH stimulation through CRH. However, the complete opposite was true: in hypercortisolemic, depressed patients, the additional dose of dexamethasone and subsequent CRH injection led to both an excessive ACTH and an excessive cortisol response. In healthy controls, however, a decrease in both the cortisol and the ACTH response was noted, as expected, with increasing dexamethasone doses (Heuser et al. 1994; Fig. 2).

To date an explanation for this apparently paradox phenomenon is still lacking, particularly in light of the fact that "standard" CRH testing (without prior dexamethasone treatment) in depressed patients seems to point to regular functioning of pituitary–glucocorticoid receptor-mediated feedback. To explain this phenomenon of the dexamethasone suppression/CRH stimulation test, we might either look to an increase in the number of CRH receptors, and/or a decrease in glucocorticoid receptors, and/or a decrease in sensitivity on the different levels of the stress-responsive hypothalamus–pituitary–adrenal systems.

3.1.4 The Corticotropin-Releasing Hormone-Overdrive Hypothesis of Depression

Findings in depressed patients point to suprapituitary changes as the cause of the hypercortisolemia found in these patients. In all likelihood, increased hypothalamic release of CRH plays a major role but is not the only factor involved, as changes in glucocorticoid receptors with associated feedback disturbances also have to be taken into consideration. In order to test this so-called CRH-overdrive hypothesis of depression-associated hypercortisolemia, a number of studies have recently been performed (Heuser 1998; Heuser et al. 1998). Most but not all of these cerebrospinal fluid (CSF) studies showed that, compared to healthy controls, depressed patients have significantly increased cerebrospinal CRH concentrations, which return to normal levels following successful antidepressive treatment. Within this context, it was further shown that patients in remittance whose test results continued to be pathological in either the dexamethasone suppression or the dexamethasone suppression/CRH stimulation test are at an increased risk for suffering a relapse and yet another depressive episode (Zobel et al. 1999).

In summary, it can be noted that both increased activity and abnormal regulation of the hypothalamic–pituitary–adrenal system represent a frequent endocrine symptom of depression. It is assumed that the noted increase in hypothalamic–pituitary–adrenal system activity associated with depression may, among other factors, be caused by increased hypothalamic release of CRH, since a number of studies were able to illustrate increased CRH concentrations in the CSF of depressed patients, reduced CRH receptor density in the frontal cortex of suicide victims, and the activation of CRH neurons in the hypothalamus of depressed patients (Nemeroff et al. 1984, 1988).

Two distinct CRH receptors, CRH-1 and CRH-2, have been identified in rodents. CRH-1 is largely found within the adenohypophysis, neocortex, hippocampus, amygdala, and cerebellum. Recent findings have been able to demonstrate that transgenic mice who do not

express this CRH-1 receptor not only show an atrophy of the adrenal cortex, but also a diminished stress-induced release of ACTH and corticosterone. Furthermore, these mice also displayed less "anxiety" and a reduced "stress response" (Timpl et al. 1998).

Based on such animal experiments, a number of laboratories are presently developing human CRH receptor antagonists as antidepressant and/or anxiolytics for the treatment of affective disorders. However, other neuropeptide hormones, such as substance P, which was recently shown to have an antidepressive effect similar to that of paroxetin, also appear to be promising in this context (Kramer et al. 1998).

Thus far, this chapter has provided a detailed account of the hypothalamic–pituitary–adrenal system with all its connections and effects during stress and depression. This account also provided an exemplary illustration of the "cross-fertilization" between clinical observations and preclinical animal experiments within the field of psychoneuroendocrinological research and the resulting developments for new therapeutic approaches. In the following, we will outline the somatotropic system (hypothalamic–pituitary–growth hormone system) and the hypothalamic–pituitary–gonadal system.

3.2 Hypothalamic–Pituitary–Growth Hormone System

During the course of a lifetime, the secretion of growth-stimulating hormones differs depending on age. Low secretion rates after birth are followed by increased rates during childhood growth, which then decrease with advancing age. Regulation of the somatotropic effect occurs by way of peripherally active insulin-like growth factors (IGF), which, as the name indicates, exert an insulin-like effect and are involved in protein synthesis, lipolysis, and carbohydrate metabolism.

IGF represent a structurally related family of growth factors. IGF-1 and IGF-2 are responsible for transforming the growth-stimulating effect of the growth hormone on the peripheral reacting organs. In addition to these circulating IGF with an endocrine action, their local production in different tissues, such as the bones, is also important for an autocrine or paracrine effect.

The formation and secretion of IGF-1 in the liver, the main site of its synthesis, is stimulated by the secretion of growth hormone from the pituitary. The release of GH again is stimulated by the hypothalamic growth hormone-releasing hormone (GHRH) and inhibited by somatostatin. Along with its neurons, GHRH is located in the arcuate nucleus and is regulated by numerous transmitter systems. Special mention should be made of the stimulatory effect of norepinephrine via α_2 receptors and its inhibitory effect via β_2 receptors.

The hypothalamic concentration and the release of somatostatin are increased by growth hormones, while ACTH leads to a reduction. Somatostatin itself mainly exerts inhibitory effects on the secretion of neuropeptide hormones. It is generally assumed that somatostatin inhibits its own release through autoreceptors located on the cell body or dendrites of somatostatin-containing neurons (Epelbaum 1986). In addition to GHRH, naturally occurring molecules, such as the synthetic growth hormone-releasing peptide, an encephalin-derived hexapeptide, may function as ligands for receptors increasing growth hormone release. At this point we should also briefly mention the pituitary adenylate cyclase peptide (PACAP), which stimulates somatotropic activity and, differentially activating two distinct second-messenger systems, appears to be a hypophysiotropic factor (Spengler et al. 1993).

Depressed patients frequently display a weakened growth hormone response to GHRH (GHRH test). In addition, they have also been shown to have reduced nocturnal growth hormone secretion amplitude and frequency. It has been suggested that this might be the result of increased depression-associated CRH release, as CRH is a functional antagonist of GHRH. According to the hypothesis postulated by Ehlers and Kupfer (1987), this reciprocal interaction between GHRH and CRH plays a particularly important role in sleep regulation. In keeping with this hypothesis, Steiger et al. (1994) were able to show that in depressed patients, who typically suffer from sleep disturbances (particularly difficulty falling asleep, disrupted sleep, and waking up early), the administration of GHRH led to a marked improvement in sleep architecture. The same holds true for older healthy probands, who typically display diminished GHRH system activity in association with reduced growth hormone release and who complain about "poor sleep."

Within this context, Rudman et al. (1990) reported that older healthy probands described an increased sense of well-being following a 12-week regimen of subcutaneous growth hormone injections. At the same time, they also showed an increase in muscle tone, physical activity, and energy. These findings suggest that growth hormone substitution in elderly, otherwise healthy probands might represent a "psychotropic" strategy within the field of geriatric medicine; clinical studies on this topic are, however, yet to be carried out.

3.3 Hypothalamic–Pituitary–Gonadal System

The hypothalamic–pituitary–gonadal system regulates the production of sexual steroids and gametogenesis. The hypothalamic gonadotropin-releasing hormone

(GnRH), a decapeptide, stimulates the release of LH and FSH from the pituitary gland. GnRH neurons are located in the preoptic area of the hypothalamus, with their axons projecting mainly to the median eminence. In addition to its effect on LH and FSH secretion, GnRH also exerts behavioral effects such as intensifying an existing lordosis in rats.

The pituitary glucoprotein hormones LH and FSH are made up of α- and β-subunits, are secreted by the same cell, and bind to receptors within the ovaries and testicles. In males, LH stimulates testosterone production in the Leydig cells of the testes, while FSH stimulates testicle growth; both hormones must be present for spermatogenesis.

In females, LH stimulates ovarian estrogen and progesterone production. A rapid increase in LH in the middle of the menstrual cycle causes ovulation, with the continued influx of LH stimulating the corpus luteum to produce progesterone. While maturation of the follicle is mainly controlled by FSH, the secretion of estrogen from the follicle requires both FSH and LH. Finally, both FSH and LH are released episodically depending on the sleep–wake pattern.

Behavioral effects associated with the hormones of the hypothalamic–pituitary–gonadal system have been demonstrated within the framework of animal studies. Their findings suggest that the two gonadal steroids testosterone and estradiol play a modulating role with regard to aggression, motivation, and "emotionality" in general. Overall, however, these animal findings must be considered preliminary, and applications to humans are not yet permissible.

The effect of sexual hormones on cognitive processes, on the other hand, are well documented; here, estradiol appears to be responsible for the consistently noted female superiority in the areas of verbal fluency, verbal comprehension, and analogous thinking, while male superiority in solving visuospatial problems can be attributed to testosterone (Sherwin 1998a,b). Based on very recent epidemiological and practical animal experiments, it can be concluded that estrogens have a neuroprotective effect on the particularly sensitive neurons of the hippocampus.

It has long been a well-documented fact that chronic stress or severe acute stressors can impair the functioning of the hypothalamic–pituitary–gonadal system, a phenomenon which finds expression in the term "distress amenorrhea." As was shown, stress-induced CRH hypersecretion inhibits GnRH, thus leading to reduced pituitary LH and FSH secretion. In addition, high plasma glucocorticoid concentrations reduce ovarian and testicular sensitivity to LH, again resulting in diminished estradiol, progesterone, and testosterone secretion.

The relationship observed between the stress-induced increase in activity in the hypothalamic–pituitary–adrenal system and the associated inhibition of activity in the hypothalamic–pituitary–gonadal system has given rise to a number of studies on gonadal functions in depressed patients. The range of typical symptoms of moderate to severe depression includes loss of libido, erectile dysfunction, impotence, anovulatory menstrual cycles, and/or amenorrhea. Within this context, a recent study on severely depressed men showed that, compared with a healthy, age-matched control group, these patients have significantly lower testosterone concentrations, which negatively correlate with the level of their plasma cortisol concentration. At the same time, these men also showed signs of lowered LH pulse frequency (Schweiger et al. 1999).

4 Neurosteroids

Within the CNS, the de novo synthesized steroids are termed neurosteroids (Banlieu and Robel 1990). Based on the fact that substantial amounts of pregnenolone, dehydroepiandrosterone (DHEA), and their metabolites were found in the brain of mice, rats, pigs, and primates, Mathur et al. (1993) formulated the hypothesis that the CNS consists of steroid-producing tissue. Here, it is important to note that the presence of neurosteroids within the CNS appears to be independent of gonadal and adrenal synthesis, as they could be detected there even following adrenalectomy and gonadectomy (Corpéchot et al. 1993).

In contrast to the classical, genome-mediated steroid effects, neurosteroids interact with γ-aminobutyric acid $(GABA)_A$ and *N*-methyl-D-aspartate (NMDA) receptors located on the cell membrane. Furthermore, incubation of glial cell cultures of rats with a cholesterol precursor led to the production of cholesterin, pregnenolone, 20-OH-pregnendone, and progesterone (Jung-Testas et al. 1989). These results of animal experiments were then substantiated by postmortem studies in humans, which also showed many times higher concentrations of neurosteroids in the CNS compared to the amounts found in plasma (Lanthier and Patwardhan 1986).

Independent of their location of synthesis, glucocorticoids, mineralocorticoids, androgens, estrogens, and progestins exert their effects in the CNS by means of intracellular steroid hormone receptors, with their expression being influenced by specific genes (McEwen 1991). In addition, it has been demonstrated that neuronal functions may also be regulated by modulating gene expression, whereby intracellular progesterone receptors are known to play a crucial role (Rupprecht et al. 1993).

Neurosteroids act as allosteric agonists on $GABA_A$ receptors by increasing the frequency and duration of

chloride channel permeability and by potentiation of the inhibitory effect of GABA (Majewska 1992). Sulfated neurosteroids, e.g. pregnenolone sulfate and DHEA sulfate, act as noncompetitive antagonists on $GABA_A$ receptors and inhibit GABA-induced ion transportation by reducing the frequency of ion channel permeability (Demirgoren et al. 1991).

While benzodiazepines, barbiturates, anticonvulsants, and GABA all bind to subunits of $GABA_A$ receptors, neurosteroids in all probability bind at a different location of the GABA receptor (Costa et al. 1994). Due to their effect on GABA and NMDA receptor systems, neurosteroids might be of clinical relevance in the treatment of memory deficits, pain syndromes, and affective and panic disorders. This assumed potential of neurosteroids suggests their use in pharmacotherapy and is presently the topic of intense study efforts (Rupprecht 1997).

5 Outlook

The admittedly arbitrary insights into the field of neuroendocrinology given in this chapter were intended to show that our understanding concerning the relevance and effect of hormones has considerably increased; hormones not only act as the effectors and regulators of metabolism and are not restricted to controlling endocrinological functions in the narrower sense, but also have distinct behavioral, i.e psychotropic effects. On the other hand, the discussion of affective disorders, in particular depression, was aimed at illustrating that so-called "mental" disorders have both "somatic" causes and consequences, a fact which needs to be recognized, described, and taken into account in order for treatment to be successful.

Psychiatric Neurophysiology

Translator: E. Taub

1 Relevance of Neurophysiology to Psychiatry

Electroencephalography (EEG) is a highly sensitive method of detecting alterations of brain function. It was, in fact, the first technique of biological measurement with which conscious human thought processes, such as mental calculation, could be detected. EEG became well established in clinical use shortly after its introduction, primarily as a diagnostic tool in neurology, but the early hope that it would provide a better knowledge of the physiology and pathophysiology of mental processes remained unfulfilled for many years. Only later, with the advent of computer technology, could event-related potentials (ERP), frequency spectra, and reconstructions of cerebral electric fields begin to be studied. The use of these neurophysiologic methods has yielded major insights into higher brain function, e.g. regarding the chronology of sensory perception and of decision processes. The physiologic background of these modern methods of analysis in psychiatric neurophysiology will be briefly discussed in what follows.

The cerebral cortex is organized for the processing of a very large amount of information concerning the structure of incoming sensory stimuli. In a system of sufficient complexity, it would be conceivable that a single neuron, at the end of a long chain of transformations, might represent all of the information originally contained in the pattern of activation of the receptor cells. This model, though pleasing in its simplicity, cannot be fully realized because of the unrealistically high number of "grandmother cells" that would be needed to represent the experiences of an entire lifetime. Neuroanatomical considerations and evidence from cell physiology have lead to the current assumption that the higher integrative functions of the brain, such as conscious perception, ideation, and the planning and execution of voluntary movements, depend on the simultaneous, concerted activity of spatially distributed neurons on all relevant hierarchical levels, including the primary brain areas. The flexibility and capabilities of the system derive from the high degree of organization of these patterns of spatial activation.

From this perspective, consciousness corresponds to the totality of the cortical electrochemical pattern of activation, which is subjectively experienced either as conscious perception or as ideation according to the differential weighting of its exogenous and endogenous portions. In fact, neuropsychological and neurophysiological studies imply that such a pattern of activation, in the form of a subliminally activated search pattern, can assume a filtering function by admitting only those sensory stimuli that match it, while rejecting others (Freeman 1983; Wilson and McNaughton 1993; Eichenbaum 1993).

These background considerations explain why cerebral electrical activity and its spatial configuration play such an important role in the study of higher brain function. The spatial resolution of the EEG is more than adequate for the detection of macroscopic changes of cerebral electrical activity: varying degrees of activation of different cortical areas are reflected in topographical variations of the cerebral electric field. The direct measurement of cerebral electric fields has yielded valuable insights into the characteristics and chronology of cortical activation associated with mental processes in terms of its intensity (amplitude), time point (latency, with a resolution of up to approximately 1 ms), spatial pattern (topography), and oscillating changes (frequency). This method has not yet been supplanted even by modern imaging techniques such as functional magnetic resonance imaging (fMRI) or proton emission tomography (PET), as the latter are currently directed at the measurement of slower, secondary metabolic processes.

Psychiatric disorders affect the highest, and often specifically human, functions of the brain, such as language, thinking, voluntary movement, emotion, and mood. Thus psychiatric neurophysiology, unlike its neurological counterpart, is not concerned with local, isolated manifestations of neural activity such as epileptic foci, early evoked potentials, or the excitation of individual nerve pathways. Of interest here are events associated with cognitive processes, such as ERP and spontaneous cerebral activity.

2 Measurement of Cerebral Electrical Activity

The difference in electrical potential between two electrodes is the net result of all electrical activity occurring between them. The EEG is presumably generated by the activity of large aggregates of neurons, primarily through the summation of excitatory and inhibitory postsynaptic potentials. These potentials diminish as the inverse square of the distance from their source; hence superficial activity rather than deeper activity is predominantly measured. The surrounding tissues – cerebrospinal fluid, bone, meninges, and scalp – alter the fields to some extent.

Cerebral electrical activity is measured as the potential difference between two electrodes. It is customary in clinical EEG to measure either the potential difference between scalp and reference electrodes (so-called monopolar recording) or a potential

gradient (the potential difference between neighboring electrodes, so-called bipolar recording). As both types of measurement concern the potential difference between two electrodes, the distinction between mono- and bipolar recording, like that between "active" and "inactive" electrodes, is misleading and should be avoided.

Every electric dipole generates a magnetic field that is perpendicular to its electric field. Magnetoencephalography (MEG), unlike EEG, detects only dipole components that are tangential to the cranial surface and thus primarily measures the neural activity within the cortical sulci because of the way these axons are oriented. Unlike the electric field, the magnetic field is not distorted by the surrounding tissues, but its field strength diminishes more rapidly with distance from the source (inverse-cube law). Sources deep to the surface are thus more difficult to detect. Compared to EEG, MEG has the practical advantage that a rigorous placement of scalp electrodes is unnecessary. Nonetheless, the head must be kept fixed in relation to the sensors, and MEG may therefore be difficult to perform in psychiatric patients.

By virtue of the above-described properties, MEG is best considered a complementary technique to EEG that may be used to greatest advantage in combination with it. The joint application of these two techniques in psychiatric patients has, however, not yet been systematically studied.

Cerebral magnetic fields are analyzed with essentially the same methods as cerebral electric fields. MEG has a somewhat better spatial resolution for localization of the intracerebral sources than EEG (Cohen et al. 1990; Wikswo et al. 1993).

3 Quantitative Analysis of Cerebral Electrical Activity

3.1 Electroencephalography in the Frequency Domain

In the electroencephalographic tradition, information about cerebral processes is derived from the wave patterns of the EEG or ERP. A description of wave patterns was developed, primarily by neurologists, and it still possesses clinical validity for the detection of localized neurologic processes or of severe, generalized functional disturbances. In contrast, modern analytical methods enable quantification of the EEG in the frequency domain for descriptive and statistical purposes.

The digitized signal of each EEG channel can be converted by a fast Fourier transformation (FFT) into a set of power values (in μV^2) of its individual frequency components. The frequency resolution depends on the frequency at which the incoming signal is sampled. For example, with a sampling frequency of 128 MHz, power values can be obtained at 64 frequency points spaced 0.5 Hz apart, from 0 Hz to 32 Hz. For further analysis, these power values are summarized by average values in each of the classical frequency bands – delta, theta, alpha, and beta. The results of the FFT may be given either as absolute or as relative power values. The disadvantage of frequency or spectral analysis is its low temporal resolution, as it generally requires a data series that is at least 1 s long. Power measurement in the four frequency bands of the EEG has been used to investigate differences between patient groups, the effects of psychoactive drugs, and changes in brain activity induced by sensory stimuli. It is thus a valuable tool in the study of normal and pathological information processing as well as their hemispheric lateralization (Flor-Henry and Gruzelier 1983; Koukkou-Lehmann 1987).

Coherence analysis is used to investigate the relationship of electrical signals that are recorded simultaneously in different channels. This method involves a statistical estimation of the correlation of two signals in the frequency domain and is carried out as a pairwise comparison between two different channels at each frequency point or in each frequency band. Coherence is mathematically independent of the amplitude of the signal and is, in principle, inversely proportional to the distance between the two electrodes (French and Beaumont 1984). If one assumes that an increase in coherence in the frequency domain is a manifestation of coupled neural activity, this parameter may be interpreted as a measure of the functional relationship between two areas of the brain.

Digital filtering is used to enable measurement of the electrical activity in narrow frequency bands, which may be difficult or impossible with the unfiltered EEG. The major application of this method is in the study of the EEG in the so-called gamma band, which contains frequencies in the neighborhood of 40 Hz. Cognitive stimuli have been reported to evoke activity in the gamma band, and the relationship of this gamma response to evoked potentials has been studied. A distributed gamma system of functional relevance to cognitive processes has been postulated, by analogy to the 40-Hz action potentials of certain neurons as well as for other reasons (Basar-Eroglu et al. 1996).

The frequency characteristics of the resting EEG are not stationary (Lopes Da Silva et al. 1974). Changes can be measured quantitatively with temporal resolution in the 1-s range by segmentation of the spontaneous EEG activity, followed by analysis in the frequency domain. Studies involving autocorrelational analysis of the signals of individual channels (Barlow

et al. 1981) have not yet yielded findings of relevance to psychiatry.

Working in the frequency domain, it must be borne in mind that waveforms are not unique when measured with respect to reference electrodes. If recordings are taken from N channels, there are $N \times (N-1)/2$ possible distinct waveforms – thus, for example, 21 channels generate 210 possible waveforms. Conversion to a reference-independent mode (e.g. average reference) is to be preferred in all topographical analyses.

3.2 Spatial Analysis of Cerebral Electric Fields

In the study of widely distributed aggregate neural activity with unknown source localization and, from the neurologic viewpoint, only mild functional abnormality (as generally found in psychiatric disease), the analysis of the spatial configuration of the cerebral electric field has a particular importance. Its topographical alterations allow study of the chronology of the activation of spatially distributed groups of neurons, which cannot be performed with any other currently available imaging technique.

The information contained in a multichannel EEG or ERP recording can be viewed as a spatiotemporal series of instantaneous potential distributions from which the cerebral electric field can be reconstructed. The potential distributions on the scalp are represented in a two-dimensional, map-like projection of the electrode array, including peaks (positive values) and valleys (negative values), isopotential lines, and often color coding of amplitude ("brain mapping"; Lehmann 1971). The landscape map allows a clear visualization of topographical relationships. A change of reference changes only the baseline value (offset), while the use of an average reference removes spatial offset from the map without changing the landscape in any other way. Baseline corrections are not allowed, however, as they will distort the electric fields.

Not only potential distributions, but also FFT values (see above), the potential gradient (the first derivative of the distribution, i.e. the local steepness of the field), and current source density (CSD, the second derivative of the distribution) can be represented as landscape maps. Potential gradients and current source density both have the effect of a spatial high-pass filter, in which values obtained from electrodes at the edges of the array are lost. Potential differences between widely separated electrodes are suppressed, while those between neighboring electrodes are highlighted. The resulting maps are reference independent and give prominence to superficial cortical sources. Current source density, in particular, has been widely used, and various processing algorithms have been proposed (Nunez 1989).

A prerequisite for the valid interpretation of any landscape map, whether it depicts the distribution of the EEG, ERP, potential differences, potential gradients, or CSD or FFT values, is that the raw signal must be thoroughly checked for artifacts. Furthermore, it must be ensured that the anatomic–topological interpretation of the map is not merely trivial. In particular, the common practice of assuming that the neural sources lie directly under the maxima and minima of the landscape, on lines projected perpendicularly inward, is not correct.

The landscape maps of the spontaneous EEG and of cognitive ERP are usually simply configured, with one or at most two peaks and one valley. The isopotential lines generally form concentric circles around these extrema. For descriptive and statistical purposes, therefore, the field strength and topography of these landscapes may reasonably be summarized by a few local and global descriptors. The global field power (GFP) corresponds to the standard deviation of the measured potentials and is an index of the strength of the field as a whole. It can be used for the reference-independent determination of ERP components. A further, nonparametric index of field strength is the reference-independent amplitude, which is calculated as the difference between the highest and lowest values on the map. A major advantage of these reference-independent, global indices of field strength, compared to the traditional measures of amplitude at given electrode positions, is that they are largely independent of the topography of the field (Strik et al. 1994a).

The calculation of field topography descriptors is performed by projection of the electrode array onto a two-dimensional coordinate system. The coordinates of the extrema (maxima and minima) of the map, or of the mathematical centers of gravity of the positive and negative regions, constitute a quantitative measure of the field configuration that is independent of both amplitude and reference. Simple statistical tests involving these values may be used for the determination of topographical differences between maps. The "dissimilarity" of two maps is a global parameter of the difference between them and is mathematically related to a correlation coefficient (Lehmann 1987). This method allows amplitude-independent topographical comparisons and has proved to be robust, as well as being superior to multivariate tests at multiple electrode positions (Strik et al. 1994b).

In the topographical representation, the landscape maps of the spontaneous EEG typically show a periodic phase reversal with opposite polarity in the occipital and frontal regions. Earlier theories of "wave fronts" and "traveling waves" spreading across the cranial

surface could not be confirmed. The periodic background activity of the EEG may be regarded as the overall, tonic state (macrostate) in which smaller, more rapid alterations of the topographic field configuration (microstates) are embedded (Lehmann 1995). Macrostates are relatively stable for each individual and are partly genetically determined (Buchsbaum and Gershon 1984), while microstates vary over intervals of a fraction of a second (Lehmann et al. 1987).

A topographically oriented segmentation method for the study of these microstates was proposed by Lehmann and coworkers (1987). It was shown that microstates remain as stable field configurations for a duration of 50 ms to more than 1 s (mean, 144 ms; Strik and Lehmann 1993) and are distinct from rapid shifts of the field landscape. Durations in this range correspond well to those of the individual building blocks of cognitive processes that have been revealed by psychological experiments. Indeed, newer studies support the hypothesis of a relationship between microstates and conscious thought processes, as visual elements and linguistic/abstract thoughts were associated with differently configured microstates in a relaxed state (Lehmann 1995; Lehmann et al. 1998). Spatially oriented segmentation methods have also been applied to the determination of ERP components (Koenig and Lehmann 1996).

3.3 Localization of Neural Generators

Neural sources cannot be localized merely by projection from the recording electrode to the underlying cortical area, because the implicit assumption of a dipole lying on a vertical line between the recording and reference electrodes is not justified for any of the types of field that are relevant to psychiatry. From the physical viewpoint it is, of course, possible to calculate the field of an electric dipole; however, if we try to proceed in the other direction and rederive the localization and number of the electric sources from the field configuration, we find that they are not uniquely determined. This unavoidable mathematical limitation is known as the inversion problem.

The computation of a model dipole that accounts for the measured field up to a given accuracy (explained variance) must therefore be performed by means of iterative algorithms. Such a computation requires a number of assumptions about the shape of the skull, the surrounding media (skin, bone, meninges, cerebrospinal fluid), and the localization and number of the generators.

The natural dipoles of the brain are its neurons. Each computed source represents a center of gravity of neural activity and thus may well turn out to be located in an electrically inactive area, e.g. in the ventricular system. The greater the number of definitely valid constraints that can be placed on dipole source localization, symmetry, number, and so forth, the more reliable the dipole solution becomes from the physiologic viewpoint. Conversely, speculative constraints on the dipole model only increase the arbitrariness of the result (Fender 1987).

Thus only physiologically valid assumptions concerning the number, symmetry, and localization of dipole sources are permitted. Very limited information of this type is available for cerebral electric fields that are relevant to cognitive processes; consequently, the computed dipoles must be regarded as mathematical models, and their localizations cannot simply be equated with anatomical sites. New developments point to interesting ways of solving the source problem, in which sharpness of localization is sacrificed in favor of a data-driven solution that requires no prior assumptions regarding the number of dipoles (low-resolution electromagnetic tomography, LORETA; Pascual-Marqui et al. 1994).

In summary, the computation of dipole sources is a useful method of obtaining a quantitative description of a cerebral electric field in terms of six parameters (three spatial coordinates, two directional angles, and dipole strength). Dipole sources can be calculated for the spontaneous EEG, for ERP, and in the frequency domain (FFT approximation; Lehmann and Michel 1990). This method has found application in psychiatry (Michel et al. 1993; Dierks et al. 1995).

3.4 Other Modern Analytical Methods

3.4.1 *Dimensional Complexity*

Algorithms for computing the complexity of biological signals have been borrowed from the theoretical physics of nonlinear systems (chaos theory). Such procedures are based on the possibility of projecting the dynamics of the signal of a deterministic system onto a static attractor. The attractor is described by several parameters, including its dimension; a higher dimension indicates a higher complexity of the system. Dimension is thus also referred to as dimensional complexity and is computed as a correlational dimension (Grassberger and Procaccia 1983).

As a rule, the determination of this parameter requires a signal with a minimum number of data points, and it therefore cannot be used to characterize very short intervals of cerebral electric activity. In general, high-frequency patterns such as rapid eye movement (REM) sleep, waking EEG with the eyes open, and elevated arousal are associated with a

high-dimensional complexity, while complexity is lower for epileptic 3-Hz discharges, with the eyes closed, and in deep sleep (Röschke and Aldenhoff 1992; Babloyantz 1989).

For multichannel recordings, it is recommended that the number of channels be used as the "embedding dimension." In this way, the global correlational dimension of a series of cerebral electric maps can be calculated (Wackermann et al. 1993).

3.4.2 Multivariate Statistics and Neural Networks

With the aid of multivariate statistical methods, one can attempt to identify clinical subgroups on the basis of the parameters of the multichannel EEG. The neurometrics system (John et al. 1988) is the best-known example. In this type of procedure, discriminance analysis or similar methods are used to identify characteristic constellations of parameters in the EEG of patients with known diagnoses. The validity of the resulting patterns is then tested against the clinical diagnoses of a further, independent patient cohort. This is a matter of optimization of an expert system, which, however, cannot be definitively validated, because there is as yet no etiologic–pathogenetic classification of psychiatric diagnoses. This method is thus intrinsically unable to furnish new information regarding natural disease entities. Furthermore, its practical application is limited, because every change in diagnostic criteria requires a corresponding adaptation of the system, and its use as a simple means of diagnosis in the hands of nonpsychiatrists cannot be envisioned.

A further interesting application is the attempt to identify new patient subgroups on the basis of constellations of EEG parameters derived from principal component analysis (PCA) or cluster analysis. Although some of these subgroups include a high percentage of patients treated with neuroleptics, no clinical features relevant to psychiatric classification have been identified to date (John et al. 1994).

Neural networks are control or decision systems capable of learning. They have found application in statistics, machine control, adaptive signal processing, and pattern recognition (e.g. language). The name is taken from the neurophysiological tradition (Hebb 1949). Recently, it has sometimes been implied that these modern mathematical methods have made the biological foundations of conscious information processing "calculable." In fact, however, theories based on analogies between biological and mathematical neural networks are highly speculative, because realistic simulations of higher brain functions remain impossible. In practical terms, neural networks constitute a statistical method which, like PCA or discriminance analysis, can be used to optimize – in this case, by training – the separation of a multidimensional data set into previously specified groups (Arbib 1995).

4 Electroencephalography and Sleep

EEG remains the most sensitive method for the noninvasive measurement of transient changes in wakefulness. It plays an important role in the current understanding of sleep physiology and is the basis of classification systems for the stages of sleep. It can be used not only to document the presence of hypnagogic and hypnotic disorders, but also to obtain parameters of relevance to psychiatric disease, such as the time from falling asleep to the onset of the first dreaming stage (REM latency) or the absolute or proportional duration of the various sleep stages (e.g. deep sleep duration, REM density). The separation into stages is carried out on the basis of the wave pattern, either by visual inspection or by computer algorithm. The reader is referred to specialized texts for the classification and description of sleep stages (Rechtschaffen and Kales 1968; Schulz 1997).

All of the quantitative methods described in general in Sect. 3 above can be used to study the sleep EEG. The most important findings of sleep EEG studies involving psychiatric patients are described below in Sect. 7.

5 Event-Related Potentials and Their Components

ERP are obtained from the averaging of segments of the EEG that are temporally coupled to a specific event. Periodic activity that is not coupled to the event is eliminated by the averaging process, while the specific cerebral electric activity in response to the event, or in preparation for it, remains. This section contains a few examples with particular relevance to psychiatric disease, selected from among the many paradigms and components described to date. An overview of early evoked potentials can be found in Maurer (1993), and a thorough classification and description of ERP in Olbrich (1989). The nomenclature of ERP generally consists of an abbreviation for polarity according to the traditional system of referential recording (P, positive; N, negative) followed by the typical latency in milliseconds.

Among ERP of intermediate latency, P50 is of special psychiatric interest. This component diminishes in

healthy individuals upon repetition of the provoking auditory stimulus (click). Maximal suppression is reached by repeating the stimulus at an interval of 500 ms; with intervals of 8 s or more, the effect is lost. P50 is regarded as a reflection of the activity of an early sensory filtering channel that inhibits the neural response to irrelevant stimuli and thus restricts the incoming flood of sensory information. Evidence suggests that P50 is generated in the medial temporal lobe (Freedman et al. 1991).

Acoustic stimuli evoke an N100 component whose amplitude is proportional to the attention paid to the stimulus. This component is thus interpreted as a reflection of automatic stimulus processing and selective attention; it is regarded as an expression of the activity of the auditory cortex (Näätänen 1990). Increasing the stimulus intensity may result in an increase or a decrease of the N100 amplitude, depending on the subject. This intensity dependence is thought to be related to central serotonergic activity, as a high level of serotonergic activation is associated with a low N100 amplitude (Hegerl et al. 1996).

A small change of the duration, pitch, or intensity of an acoustic stimulus in the midst of an otherwise unvarying series leads to an increase in negativity at a latency of approximately 200 ms. This effect is known as mismatch negativity (MMN). In this paradigm, unlike the P300 paradigm, the subject does not direct his or her attention to the stimuli, but rather is given a distracting task to perform. This component is interpreted as a reflection of automatic perception and discrimination against the background of an "echoic" acoustic memory task (Näätänen 1990). The amplitude of the MMN increases with age (Woods 1992).

The best-known and best-studied late ERP component is P300, which occurs only when the stimulation involves a conscious mental process. For example, a typical P300 experiment concerns the recognition of a rare target stimulus against a background of meaningless stimuli ("oddball paradigms"). The amplitude increases with increasing rarity of the target stimulus. P300 can also be evoked by the omission of an expected stimulus.

In the acoustic modality, normal individuals generally display a center of gravity of the P300 field in the left hemisphere (Morstyn et al. 1983; Strik et al. 1993a), while in the visual modality there is a mild right hemispheric asymmetry (Alexander et al. 1995). The positive center of gravity lies farther forward when a motor response is suppressed than when it is carried out (Fallgatter and Strik 1996); in LORETA, this is explained by inhibitory functions of the frontal lobe (Strik et al. 1998).

The neural generators of P300 are still not known for certain. It is assumed that the temporal, parietal, and frontal lobes all contribute to this summed potential (Halgren 1986). Temporal lobe activity alone does not account for the potential (Johnson 1988). P300 latency increases after the 18th year of life (Goodin et al. 1978).

The N400 component, which arises only when a sentence ends with an inappropriate word (semantic incongruence), is of interest to cognitive science. This component is not present when sentence construction or spelling are faulty. It is a central negativity arising at a latency of approximately 400 ms. The location of its neural generators is not known with certainty.

Post-imperative negative variation (PINV) is a late ERP component that typically arises in normal individuals when the expected effect of a motor action fails to occur. It is regarded as a reflection of continuous cognitive processing (Pritchard 1986).

Contingent negative variation (CNV) arises before an expected sensory stimulus. In a typical experiment, two stimuli are presented with a fixed delay, usually of less than 2 s. The CNV occurs before the second stimulus in the form of a central negative potential lasting from 100 to 500 or more ms. This potential reflects the preparation of the brain for the incoming stimulus and is interpreted as an expression of the neural resources made available in this process (Rockstroh et al. 1989).

6 Psychopharmacology of Electroencephalography and Event-Related Potentials

The EEG reacts sensitively to psychotropic substances. Their mechanism of effect, dose–response and temporal response profiles, brain penetration, and bioequivalent dosing can all be investigated with quantitative EEG methods (Herrmann 1982; Saletu 1989). Because the resulting EEG changes show considerable interindividual differences, expert systems have been developed to distinguish psychoactive substances with antidepressant, neuroleptic, anxiolytic, and neurotropic effects (Itil et al. 1979).

In particular, benzodiazepines induce a characteristic beta activation with spindles at 14–16 Hz, as well as slow waves at higher doses (Friedman et al. 1992). In normal subjects, neuroleptic medications induce an increase of delta and theta activity, while alpha activity remains unchanged or is mildly reduced, and beta activity decreases occipitally and increases frontally (Fink 1974). Clozapine induces severe generalized slowing and, occasionally, spikes and spike-wave complexes, a finding that invites caution in raising the dose, but is not in itself a reason to discontinue the medication (Koukkou et al. 1979). Tricylic agents elevate delta and beta activity. The EEG changes produced by both neuroleptic agents and tricyclic

agents are dose dependent (Czobor and Volavka 1992). Mind-altering drugs generally induce an increase of high-frequency components in association with an increase in wakefulness (Fischhof et al. 1992), though not in a clearly dose-dependent fashion. Lithium treatment is often associated with major EEG changes, including slowing and increased amplitude of background activity, paroxysmal dysrhythmias, and occasionally hypersynchronous discharges (Helmchen and Kanowski 1971).

The influence of psychotropic substances on ERP components is best documented for P300. Centrally active sedatives such as alcohol, benzodiazepines, flupentixol, and anticholinergics lower the P300 amplitude. Cholinergics such as physostigmine, however, raise the P300 amplitude in normal subjects (Rösler et al. 1985; Picton 1992; Maurer et al. 1990). An elevation of amplitude without a change of latency was also seen in normal elderly subjects after the administration of the cholinergic substance pyritinol (Dierks et al. 1994). There is no single explanation for the effects of the dopamine agonist methylphenhydate, which raises the P300 amplitude in hyperactive children, but not in normal individuals (Klorman and Brumaghim 1991). If we consider these specific changes of P300 amplitude along with simultaneously measured cerebrospinal fluid levels of 3-methoxy-4-hydroxyphenylglycol (MHPG; the major metabolite of norepinephrine) and with psychometrically quantified changes of attention, we arrive at a unified interpretation of the P300 amplitude as a reflection of cortical arousal.

The P300 latency is increased in normal subjects by anticholinergics and by haloperidol. Haloperidol has no effect on P300 amplitude (Stanzione et al. 1990). In contrast, dopaminergic agonists such as L-dopa normalize the prolonged P300 latencies of patients with Parkinson's disease, but have no effect on P300 parameters in normal subjects.

7
Neurophysiologic Manifestations of Psychiatric Disease

7.1
Schizophrenias

Schizophrenic patients typically show an increased amplitude of both slow (delta, theta) and fast (beta) frequency components. In contrast, background alpha activity is reduced and slowed (Shagass 1987). Ocular artifact has been discussed as a possible explanation for these findings (Guenther et al. 1988), but several studies have failed to demonstrate the frontal accentuation of delta activity that is characteristic of ocular artifacts. An effect of neuroleptics cannot account for these findings either, because slow-wave activity is actually more pronounced in nontreated than in treated patients (Galderisi et al. 1991). The EEG of schizophrenic patients shows a lesser degree of modulation than that of normal controls; this property holds both for the spontaneous EEG and in the presence of visual stimuli and has been referred to as the "rigidity" of the schizophrenic EEG (Shagass 1987). The reactivity of the EEG normalizes upon remission from an acute schizophrenic episode, but to different extents in different frequency bands (Koukkou-Lehmann 1987). At the onset of disease, untreated patients have diminished reactivity, primarily of frequency and power in the alpha band. Alpha-band frequency reactivity normalizes in patients in stable remission who have been off medication for 3 months, but alpha-band power reactivity remains rigid. Alpha-band power reactivity has thus been proposed as a "trait correlate" of schizophrenia. The reactivity of the EEG has also been interpreted as an electrophysiologic manifestation of the reorganization of working memory in psychotic patients (Koukkou et al. 1995).

Single doses of neuroleptics change the EEG independently in a manner that correlates with their later therapeutic effect. Responders to pharmacotherapy show an increase in slow-frequency components (Herrmann and Winterer 1996; Gaebel et al. 1988). Seventeen of 18 responders and eight of ten nonresponders were correctly classified on the basis of their $alpha_1$ reactivity (7.7–9.5 Hz); responders reacted with an increase of $alpha_1$ activity, and nonresponders with a decrease (Galderisi et al. 1994). These findings support the hypothesis that pharmacotherapy is effective only in those schizophrenics whose EEG on neuroleptic medication reacts similarly to that of normal subjects.

The application of newer methods has revealed differences in the field configurations of the spontaneous EEG of normal subjects and schizophrenics. Patients who have never been treated manifest an increase of correlational dimension in anterior regions of their EEG recordings (Koukkou et al. 1993). The related finding of diminished coherence between prefrontal cortical areas under conditions of activation implies a functional uncoupling of these areas (Hoffman et al. 1991). Changes in orientation of the EEG microstates have been described on the basis of topographically oriented segmentation. The microstate configuration corresponds to that of normal subjects during concrete pictorial thought (Strik et al. 1995).

The deeper stages of sleep (i.e. non-REM or slow-wave stages) are shortened by approximately 50% in approximately 60% of schizophrenic patients, whether treated or untreated. This phenomenon is

not specific, however, as it is also found in healthy elderly persons as well as in depressed or demented patients (Keshavan et al. 1990; Fleming 1994). More recent studies of correlational dimension have shown a diminished complexity of the EEG signal during stage II and REM sleep. There is as yet no plausible explanation of these findings (Röschke and Aldenhoff 1993).

Evidence of changes in perceptual modalities can be seen as early as the intermediate ERP components. Repeated presentation of a simple acoustic stimulus leads to a diminution of the evoked P50 component in normal subjects, but not in schizophrenics (Adler et al. 1982; Judd et al. 1992). This has been interpreted as a manifestation of "sensory gating," i.e. regulation of the flow of sensory information through a hypothetical channel of limited capacity. The persistence of P50 in schizophrenics is regarded as a sign of hypervigilance, leading to a loss of the ability to suppress irrelevant external stimuli, and is said to be relatively specific to schizophrenia. Neuroleptic medications do, in fact, raise P50 amplitude generally, but do not alter the ratio of the responses to the warning and test stimuli. Only manic patients manifest a similar abnormality in the acute stage, which then disappears upon pharmacologic treatment and remission. This abnormality is said to be more common among relatives of schizophrenics than in the normal population (Freedman et al. 1991). The P50 response of schizophrenics normalizes after a brief period of deep sleep or after smoking a cigarette (Griffith et al. 1993; Adler et al. 1993).

The findings of recent studies of P300 in schizophrenics are among the more interesting developments in psychiatric neurophysiology. P300 amplitude has been known for many years to be lower in schizophrenics than in normal subjects, while a prolongation of P300 latency has not been consistently demonstrated. The reduction of amplitude cannot, however, be used as a diagnostic marker, because of its lack of specificity and a considerable overlap of values with those of normal subjects. An interesting new aspect came about with the description of topographic alterations in the form of an asymmetric left-hemispheric reduction of amplitude, with a maximum in the right hemisphere. Normal control groups showed the reverse (physiologic) asymmetry, with a maximum in the left hemisphere (Morstyn et al. 1983). This finding has not been described in other types of patients and is thus more specific than the reduction of amplitude.

Because of the inversion problem (see the above discussion of dipole analysis), the finding of a maximum in the right hemisphere cannot be taken as proof of a functional deficit in left temporal cortical areas. Indirect evidence from neuropsychologic and MRI studies is, however, consistent with this hypothesis (Heidrich and Strik 1997; McCarley et al. 1993). Consistent results have been obtained with visual hemifield stimulation according to an oddball paradigm: stimulation of the right hemifield is associated with prolonged P300 latency and diminished P300 amplitude (Galderisi et al. 1988).

Recent clinical studies indicate that these P300 changes have prognostic significance, as well as a relationship to diagnostic subcategories. Low amplitudes are significantly correlated with the social impairment caused by negative symptoms (Strik et al. 1993b). A cross-sectional study by Hergerl and coworkers revealed a higher frequency of tardive dyskinesia and a less favorable clinical course in patients with lower P300 amplitudes (Hegerl et al. 1995). In fact, a longitudinal study showed an association of low P300 amplitudes with poor social integration after a mean follow-up period of 2.4 years, which implies a possible prognostic significance for this parameter (Strik et al. 1996). In view of the known relationship of the P300 amplitude to attention (Heidrich and Strik 1997) and to the cerebrospinal fluid level of the major norepinephrine metabolite MHPG (Ford et al. 1994), it may be assumed that the P300 amplitude is modulated by the state of arousal of the central nervous system. If so, it would then be nonspecifically associated with the subject's readiness to perform a cognitive task. There is evidence that a corresponding phenomenon is at work in normal subjects as well: the P300 amplitude was found to be negatively correlated with a psychometric index of anhedonia (Simons 1982).

One successful application of P300 measurement has been found in the subclassification of the schizophrenias into cycloid psychoses and (proper) schizophrenias, according to the scheme of Leonhard (1986). It has been demonstrated, and replicated in several independent patient cohorts, that the P300 maximum lies in the right hemisphere only in patients who are schizophrenic in Leonhard's sense. P300 topography has been found to be normal in cycloid psychoses, even when the DSM-III-R criteria for schizophrenia are fulfilled. P300 amplitude, however, was recently found to be elevated in a cohort of psychiatric patients with cycloid psychoses (Strik et al. 1993a; Strik et al. 1997). It should be noted that Leonhard's distinction between cycloid psychoses and schizophrenias does not simply correspond to a grouping of schizophrenias into positive and negative types, as many subtypes of schizophrenia in the Leonhard scheme in fact have predominantly positive symptoms.

It is not yet known whether the elevation of P300 amplitude seen in cycloid psychoses regresses after complete remission and reintegration into everyday life. Other open questions concern the psychophysiological implications of P300 asymmetry

for the pathogenesis of schizophrenic symptoms. Language functions, which are highly lateralized to the left hemisphere in normal subjects, are of particular interest for the development of hypotheses for further study, as many central schizophrenic symptoms reflect a disturbance of particular aspects of cerebral language function, including expression (circumstantiality), conceptualization (disordered thinking), and perception (hallucinations of speech). Pathologic asymmetries have been described only when silent counting, i.e. the construction of imagined speech, was used as a control for attention, and not when a motor reaction was carried out; this provides a further indication of the important role of linguistic processes in P300 asymmetry.

A diminished amplitude of mismatch negativity has been found repeatedly in both treated and untreated schizophrenic patients. The magnitude of this diminution correlates, albeit weakly ($p = 0.4$), with the extent of negative symptoms. Mismatch negativity was normal, however, in a control group of patients with bipolar affective disorder (Catts et al. 1995). It should be added that practically all of the traditionally analyzed, cognitively influenced ERP components are diminished in amplitude among schizophrenics, so that the operation of a general modulating factor, rather than a disturbance of specific functions, must be postulated.

Similar limitations necessarily apply to the interpretation of findings regarding the N400 component, although the latter is, theoretically, a potential of great relevance to schizophrenia. The traditional waveform analyses performed to date have revealed inconsistent reductions of amplitude and/or prolongations of latency, analogous to the results obtained with other ERP components. There is evidence that these abnormalities are present only in a subgroup of schizophrenics and that the N400 amplitude is reduced only when the task does not require a decision (Andrews et al. 1993). There has been, as yet, no comprehensive topographic description of the N400 of schizophrenic patients. One may expect, in analogy to the recent findings of P300 studies, that the topography of N400 landscapes will turn out to be highly relevant to schizophrenic disorders.

CNV, like other ERP components, is reduced in amplitude in schizophrenic patients. There are contradictory reports of associations with particular symptoms. The reported finding of low amplitudes in floridly psychotic patients and normalization after clinical remission (Pritchard 1986) could not be replicated by other investigators (van den Bosch et al. 1988). A reduction of amplitude affecting predominantly the early components of the CNV over the vertex area has been described as typical for schizophrenic patients (Rockstroh et al. 1989).

Schizophrenics given a variety of stimulus–response tasks often spontaneously display a late negativity (PINV) that is seen in normal subjects only under certain experimental conditions. The topographical aspects of the distribution of electrical potential are correlated with negative symptoms (Eikmeier et al. 1993).

7.2 Affective Disorders

Even though there is no characteristic abnormality of the frequency pattern of the EEG in patients with affective disorders, studies of depressed patients have yielded evidence of an increased rigidity of alpha activity in psychotic depressions and an increased lability of alpha activity in neurotic depressions (Herrmann and Winterer 1996). The findings in psychotic depressions are analogous to the abnormalities typically seen in schizophrenic patients (see above). With spatially oriented segmentation of the spontaneous EEG, an elevated spatial variability was found, i.e. the cerebral electric field changed its configuration both more frequently per unit time and more extensively than in normal subjects. This finding has been thought to bear a relation to psychopathologically described properties of the cognitive strategies of depressed patients. Microstate topography in schizophrenics is, however, no different from that of normal control subjects (Strik et al. 1995).

A shortening of REM latency and elevation of REM density has been found in the sleep EEG of depressed patients, i.e. these patients fall significantly earlier into the first dreaming stage of sleep than control subjects, and they have briefer periods of deep sleep. This finding is quite robust but, unfortunately, nonspecific, as it is present in other psychiatric illnesses as well. Antidepressants suppress REM sleep, and the parameters of sleep normalize in many patients upon clinical remission. Surprisingly, no relationship was found between REM latency and the therapeutic efficacy of sleep deprivation treatment (Fleming 1994). Relatives of patients with sleep stage anomalies manifest this abnormality with a concordance of approximately 70%; REM latency has therefore been proposed as a marker of vulnerability to affective disorders. The association of short REM latency with an elevated rate of relapse, and the finding of early normalization among responders to amitriptyline, raised interest in the possible predictive value of this parameter, but these findings have not yet been sufficiently refined and validated to allow an application in clinical practice. Furthermore, the dependence of REM latency on the clinical state of affected patients seems to

contradict the notion that it is a useful marker of vulnerability to the disease.

A diminution of P300 amplitude less severe than that seen in schizophrenics has been described in severely depressed patients. In the present state of research, no clinical significance can be attached to this abnormality, which is assumed to be due to a lack of motivation and, indeed, disappears upon remission (Picton 1992). Systematic studies of P300 in manic patients are still rare. In a recently completed study, evidence for a frontal disinhibition has been found in manic patients, in contrast to the results in cycloid psychoses, which indicate a cerebral overreaction (Strik et al. 1998). The normal reduction of P50 amplitude upon repetition of the stimulus is absent in acutely manic patients, as in schizophrenics, but returns upon clinical remission. The CNV of depressed patients tends to show a diminution of amplitude that is negatively correlated with the severity of depression (Ashton et al. 1988). Timsit-Berthier, however, found a subgroup of depressed patients with elevated rather than diminished amplitudes. This subgroup also had a higher dopamine reactivity on apomorphine testing than the remainder of the cohort of depressed patients (Timsit-Berthier 1986).

7.3 Dementia

Features typical of dementia can be seen even on qualitative assessment of the EEG. An increase in theta and delta activity occurs in a generalized fashion in Alzheimer-type dementia, but focally in cerebrovascular dementias. Furthermore, a relative increase of alpha activity is found in frontal tracings, and there is a decreased reactivity of alpha activity upon eye opening or photic stimulation. These findings have been documented statistically with the aid of quantitative topographic FFT analysis (Dierks et al. 1991). Recent studies have shown a correlation between the increase in slow-wave activity and the severity of dementia. A frontal displacement of the center of gravity of alpha activity can be seen even in the early stages of Alzheimer-type dementia, and the extent of this abnormality correlates with the severity of dementia. There is evidence that functional assessment by means of EEG parameters correlates more closely with cognitive impairment than does regional cerebral blood flow (Müller et al. 1997). The dementias are thus a disease category in which EEG can supply clinically relevant information about the severity and nature of the disorder (Alzheimer-type versus multi-infarct dementia). EEG mapping allows a perspicuous representation of the abnormalities described (frontal displacement, focal versus global increase of slow-wave activity), provided that an experienced interpreter has ruled out the presence of significant artifact.

A diminution of P300 amplitude and a prolongation of P300 latency are typically found in patients with dementing illnesses. While a diminution of amplitude is nonspecific, a prolongation of latency is regarded as relatively characteristic of these processes of cognitive deterioration. In a meta-analysis, the sensitivity of this abnormality was found to vary from 13% to 80%, but its specificity (against a background of patients with general psychiatric illnesses) was nearly 90% (Goodin 1990). The sensitivity has been found to be higher in studies of more severe dementias. Of particular interest is the reported ability to distinguish the early stages of Alzheimer-type dementia from depressive pseudodementias, although the use of the P300 latency as an aid to differential diagnosis remains to be validated. P300 testing is of less value in the later stages of the disease, as many severely demented patients have a severe impairment of attention that makes such testing impossible.

7.4 Obsessive–Compulsive Disorder

Obsessive-compulsive patients given an acoustic oddball task were found to have an elevated N200 amplitude and a shortened P300 latency, but a normal P300 amplitude. While normal subjects had a prolongation of P300 latency that increased with the difficulty of the task, the patients did not show this effect. The elevation of N200 amplitude has been interpreted as a sign of elevated selective attention, and the shortening of P300 latency as a sign of accelerated information processing (Towey et al. 1990). In a more recent study, elevations of both N100 and P300 amplitudes were described, and the latter elevation was correlated with the severity of symptoms (Olbrich et al. 1996). There is as yet no explanation for these inconsistent results.

7.5 Anxiety Disorders

A reduction of alpha activity and a simultaneous increase of activity in both lower and higher frequency ranges have been described as characteristic of the EEG of patients with anxiety disorders. In anxious individuals or patients with chronic anxiety disorders, unlike normal subjects, alpha activity increases with cognitive activation, while the alpha blockade response is diminished, as are amplitude and frequency variability. At the same time, fast- and slow-wave activity decreases. Epileptic discharges have occasionally been

described as occurring during panic attacks, although it is not clear whether these may have been cases of comorbidity with two different diseases (Herrmann and Winterer 1996).

7.6 Personality Disorders

Individuals with personality disorders (Raine 1989) and normal extroverts (Cahill and Polich 1992) have an elevated P300 amplitude compared to control subjects, while normal adults with high psychometric values for anhedonia have a diminished amplitude (Simons 1982). A higher amplitude is interpreted as a reflection of elevated cortical arousal, of which risk-positive behavior (sensation seeking) is an epiphenomenon.

The N100 augmenting-reducing phenomenon in personality disorders has been extensively studied. In the visual modality, it has been shown that the N100 amplitude can be augmented by increasing the light intensity and that this augmentation is correlated with risk-positive behavior, extroversion, and impulsiveness; likewise, the opposite personality traits can be brought about by reducing the N100 amplitude (Pritchard 1986). In a manner analogous to the P300 findings, this phenomenon has been interpreted as the expression of a psychophysiologically based tendency to seek or to avoid excitatory stimuli.

7.7 Alcoholism

The consumption of moderate amounts of alcohol by healthy young men leads to a slowing of the EEG frequency spectrum (Ehlers et al. 1989). This effect was less marked in subjects who were alcohol dependent in a 10-year follow-up period than in subjects who did not become dependent on alcohol (Volavka et al. 1996). This result is in good accordance with the finding that a small intoxicating effect of alcohol is a predictor of later alcoholism (Schuckit 1994).

The P300 amplitude is diminished in alcoholics, and the P300 latency prolonged. This abnormality is more pronounced with acoustic than with visual stimulation. The reported diminution of P300 amplitude in relatives of alcoholics is of particular clinical and theoretical interest, although replication studies have not uniformly confirmed this finding (Picton 1992).

In both normal subjects and alcoholics, alcohol reduces the intensity dependence of the acoustic N1/P2 components. In consideration of the known effects of other drugs, this finding has been attributed to the serotonergic effect of alcohol (Hegerl et al. 1996).

8 Conclusions and Overview

Neurophysiologic testing is of particular importance in psychiatry because it allows a biological measurement of the activity of the intact brain on a timescale appropriate to the study of conscious mental processes. Nonetheless, the problem of anatomical-topological coordination of the events that are measured has yet to be satisfactorily solved. Furthermore, the sensitivity of these methods is still insufficient for the study of mental processes such as mental calculation, conscious stimulus discrimination, or semantic language processing, and their temporal resolution is not high enough to allow a description of the time course of perceptual and decision processes in the millisecond range.

Modern analytical methods and highly refined paradigms that activate well-defined brain functions while providing reasonable reference conditions will likely lead to a further expansion of our understanding of the concerted neuronal activity that is the basis of the highest functions of the human brain. The accumulated knowledge of the conditions and chronology of cognitive activity, the opportunities for practical application, and the high sensitivity to functional abnormalities will be invaluable for the development and testing of suitable activating conditions that will also meet the needs of modern, high-resolution functional imaging methods such as PET and fMRI.

Neuroanatomical and Neuropathological Basis of Mental Illness

Translator: E. Taub

1 Study of Brain Structure in Psychiatry

The role of neuropathology in the study of classical psychiatric diseases such as the schizophrenias, affective disorders, personality disorders, anxiety disorders, and obsessive-compulsive disorder was until recently highly controversial. Neuropathological findings have been largely impossible to demonstrate in psychiatric disease, except in the case of organic mental syndromes resulting from focal brain lesions or degenerative processes. A few structural abnormalities have been detected to date, but only with difficulty, with the aid of highly sophisticated techniques.

Neuropathological substrates for the schizophrenias and affective psychoses were long thought not to exist. Recent research, however, benefiting from statistical morphometric techniques and new histochemical techniques for postmortem analysis, as well as from in vivo techniques of structural and functional imaging, has revealed the presence of moderate abnormalities in certain brain areas in many patients. These macroscopic and histological abnormalities are not as extensive as those found in brain illnesses that are known to be organic; they are relatively inhomogeneous, both in type and in localization, and are found in only a subset of patients carrying the diagnosis of an "endogenous psychosis." Sophisticated statistical methods are often needed to demonstrate a difference between a group of psychiatric patients and a normal control group. There is generally considerable overlap between the two groups, and the morphologic parameters of many patients lie within the normal range. No pathognomonic abnormalities of brain tissue have yet been found that might be used for a reliable differential diagnosis of schizophrenic and affective disorders, as these are defined in the current systems of disease classification. The pathological findings in this area are thus of an entirely different nature from those familiar to us from the realm of neurology and cerebral degenerative disease.

Many studies of brain structure in schizophrenic patients have been performed to date, but the affective disorders have been the subject of almost no neuropathological studies, and of relatively few structural imaging studies. There have been no neuropathological studies at all to date of the so-called neuroses or personality disorders, which is not surprising, as it is commonly assumed that these result from psychosocial factors or variations of normal personality traits (although genetic factors may also be important). It is quite conceivable that some structural features of the brain may represent "vulnerability factors" for the latter class of disorders; no postmortem studies have yet been performed to provide evidence for or against this hypothesis.

There are several reasons why discrete, homogeneous neuropathological substrates for the named psychiatric disorders are so difficult to find. The first reason is that the schizophrenias and affective psychoses, unlike the classical organic mental disorders, are not unitary diseases but, rather, conventional diagnostic constructs, whose neurobiological causes may be as diverse as their clinical manifestations. In psychiatry as in internal medicine, a given constellation of signs and symptoms may result from one of multiple biological substrates that exert their effects through a final common pathway (as is true of fever or hypertension, for example).

It is also possible that the brains of many of these patients are entirely normal in structure, and that their mental illnesses are caused by reversible neurochemical disturbances or by stress-induced changes in neurotransmitter or neurohormonal systems. Another reason is that the histopathological substrates of the typical psychiatric diseases may be too subtle to be detected by the traditional qualitative methods of neuropathological research or that they may lie in brain areas or cell types that have not yet been investigated. The functional importance of the limbic system, for example, was not fully recognized until the 1950s (McLean 1952), and it has only recently become a major object of investigation in the neuropathology and pathophysiology of mental disorders. The neurotransmitter systems of the brain were discovered in the 1960s (Dahlström and Fuxe 1964), and the cell types containing neuropeptides 10 years later (for a review, see Nieuwenhuis 1985). There has been no systematic histopathological study of these cell types to date, despite their major relevance to the theory and pharmacology of mental diseases.

One possible technical reason for the slowness of progress in this area was the lack, until recently, of adequate neuropathological techniques. It was only after the introduction of immunohistochemistry and in situ hybridization that neuroglial subpopulations could be conveniently studied and observations regarding their function could be made (Table 1). These techniques were the first to add a functional dimension to the study of structural abnormalities, yielding important clues both to disease etiology (e.g. the expression of gene products) and to normal function (e.g. the characterization of inhibitory interneurons).

Another reason for the lagging interest in the neuropathology of mental illness is the conspicuous lack of success of neuropathological research on schizophrenia in the first half of the twentieth century. At that time, a dualistic attitude toward mind and

Table 1. New research techniques for postmortem study of the brain

Technique	Object under study
Stereology	Absolute cell number in a brain structure
Immunohistochemistry	Protein expression in brain sections
Western blot	Protein expression in brain homogenate
In situ hybridization	mRNA expression in brain sections
RT-PCR	mRNA expression in brain homogenate

RT-PCR, reverse transcription polymerase chain reaction.

brain was widespread among psychiatrists, in view of the prevailing lack of knowledge of many aspects of the central nervous system. Since then, however, modern brain research has yielded a great deal of insight into the functional architecture of the brain (Fig. 1).

A historical overview of neuropathological research in mental illness, documenting the gradual abandonment of the dualistic viewpoint, is provided in Tables 2 and 3.

The following discoveries stand out among all those that have led to an improved understanding of the neurobiology of psychotic syndromes:

- Hess, in 1949, discovered that elementary drives and emotions can be evoked by direct electrical stimulation of the diencephalon.
- McLean, in 1952, recognized the importance of the limbic system in the neural modulation of feelings and emotions.
- Dahlström and Fuxe, in 1964, localized the intracerebral neurotransmitters dopamine, norepinephrine, and serotonin.
- Jones and Powel, in 1970, described the neuroanatomical basis of the cortical integration and association of sensory input.
- The first integrated, multidimensional model of a mental symptom taking neurophysiological, psychological, ethological, and pharmacological aspects into account was proposed by Gray (for anxiety).

Finally, it must be noted that the introduction of computed tomography (CT) and magnetic resonance imaging (MRI), and the subsequent discoveries of structural abnormalities in psychiatric diseases (e.g. Johnstone et al. 1976), were a major stimulus to the performance of further studies of brain structure in this area. Since then, MRI has developed further and given rise to the two related techniques of magnetic resonance spectroscopy (MRS) and functional magnetic resonance imaging (fMRI), which yield information on brain biochemistry and functional activity, respectively, and help put the structural findings into a functional context.

2 Functional Neuroanatomical Concepts

2.1 The Limbic System and Mental Illness

The limbic system plays a central role in the neuropathology and pathophysiology of the schizophrenias, affective disorders, secondary psychoses, anxiety disorders, Alzheimer's disease, and the amnestic syndrome. The anatomy of the most important components of the limbic system is shown in Fig. 2. Information from the entire association cortex converges upon the limbic system, where it is then processed in coordination with other signals arising

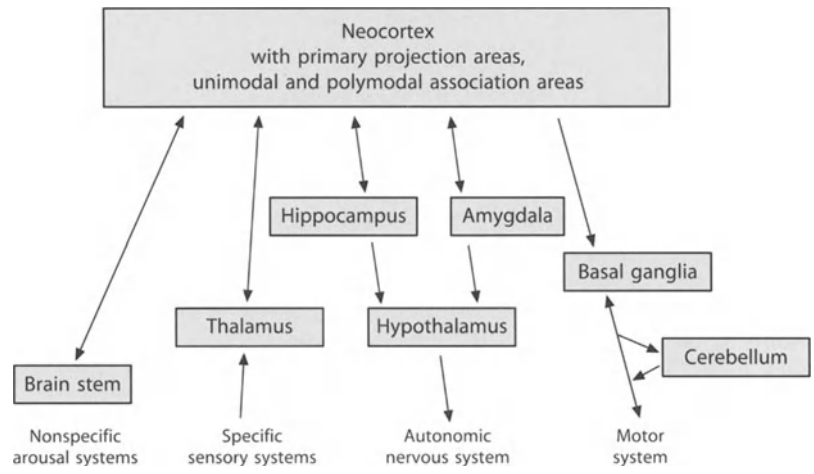

Fig. 1. Functional systems of the human brain

Table 2. Dates in the history of neuroanatomy and psychiatry

Year	Event
Sixth to fourth century B.C.	Presocratics: Democritus: thinking and perception have a material basis Hippocrates: epilepsy and psychoses are produced by irritation of the brain
Fourth century B.C.	Aristotle: the heart is the seat of reason and perception; the brain functions as a cooling organ and elaborates nasal mucus
Eighth century A.D.	Galen: discovery of the cerebral ventricles
1662	Descartes: the pineal gland as nexus of body and soul
Late eighteenth century	Gall: phrenology and cranioscopy Flourens: holistic vs. regionalistic views of the brain Psychiatry: somatic vs. physical concepts
1822	Bayle: description of progressive paralysis
1861	Broca: the case of Leborgne (motor aphasia)
1868	Harlow: the case of Phineas Gage (frontal brain syndrome)
1867	Griesinger: mental illnesses are brain illnesses
1874	Darwin: body and mind are both products of biological evolution
Approx. 1900	Cajal, Golgi, Nissl: the study of neurons (Nobel Prize 1906) Sherrington: the concept of the synapse Alzheimer: description of the neuropathological basis of the dementias, epilepsies, progressive paralysis, and psychoses Kraepelin: systematic classification of psychiatric disease Freud: psychoanalysis Pavlov, Thorndike: classical and operant conditioning, foundations of ethology and behavioral therapy
1949	Hess: intrahypothalamic stimulation (release of elementary drives and emotions by electrical stimulation of the brain)
1952	McLean: concept of the limbic system First International Congress of Neuropathology Introduction of antipsychotic neuroleptic drugs
1965	Dahlström and Fuxe: discovery of intracerebral neurotransmitter systems
1970	Jones and Powel: the neuroanatomical basis of cortical information processing
1975	Hughes and Kosterlitz: discovery of the endorphins (neuropeptide hormones)
Since approx. 1980	Structural and functional imaging of the brain by computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and single photon emission computed tomography (SPECT)
Since approx. 1990	Functional magnetic resonance imaging (fMRI) and magnetoencephalography (MEG)

from the brain stem. The central limbic structures form a ring ("limbus") around the corpus callosum on the medial surface of the cerebral hemisphere. The key limbic structures of the medial temporal lobe are sites of convergence for information from the entire higher association cortex. The hippocampus and amygdala project to the phylogenetically oldest parts of the brain stem and the septal nuclei. All of these pathways are bidirectional, i.e. the temporal limbic areas project back to the association cortex, and the septal nuclei and diencephalon project back to the hippocampus and amygdala. Structural and functional lesions at these sites may give rise to psychiatric syndromes.

The basic principles of cortical information processing will be discussed next, as a knowledge of these is indispensable for an understanding of the neurophysiological basis of psychiatric disease (see also Fig. 3).

All sensory information originates in the peripheral sensory organs, passes through specific sensory pathways (such as the visual, auditory, and somatosensory pathways), and then continues, through a thalamic relay, into the primary sensory cortical areas (visual cortex, auditory cortex, somatosensory cortex; see Fig. 3, *1a–c*). Sensory information then passes into the secondary, unimodal sensory association areas, which

Table 3. Historical aspects of neuropathological research on schizophrenia

Year	Research
Approx. 1900	Cortex (Kraepelin, Alzheimer, Nissl)
1930–1960	Thalamus, basal ganglia (C. and O. Vogt, Fünfgeld, Hopf, Hempel, Treff)
1927–1969	Pneumencephalography, ventricles (Jacobi and Winkler, Huber)
1952	First International Congress of Neuropathology in Rome "Schizophrenia is the graveyard of neuropathology" (Plum)
Approx. 1960–1976	Abandonment of neuropathological research on schizophrenia, dominance of psychoanalytic, biochemical, and social theories, antipsychiatry
1976–	Ventricular dilatation discovered by CT (e.g., Johnstone, Weinberger)
Since 1983	Morphometric postmortem studies of the dopaminergic system, limbic system, basal ganglia, thalamus (e.g., Bogerts, Pakkenberg, Benes)
Since 1984	Cytoarchitectural studies (e.g., Kovelman and Scheibel, Benes, Jakob and Beckmann, Falkai, Arnold)
Since 1989	MRI volumetry of the ventricular system, limbic system, cortex, thalamus (e.g., Suddath, Andreasen, Bogerts, Degreef)
Since 1990	Studies of cerebral structural asymmetry (e.g., Crow, Falkai, Bilder)
Since 1995	Immunohistological studies of cell types and cellular components

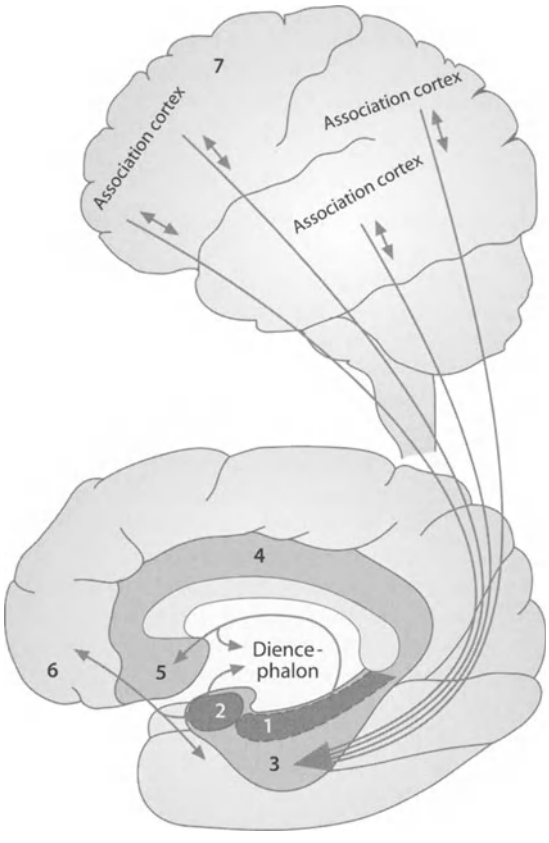

Fig. 2. Anatomical relationships of the limbic telencephalic structures and their most important fiber pathways. *1*, hippocampus; *2*, amygdala; *3*, parahippocampal and endorhinal cortex; *4*; cingulate gyrus; *5*, septum and posterior orbital cortex; *6*, mediobasal frontal lobe; 7, dorsolateral frontal cortex

are adjacent to the primary cortex (*2a–c*). In these unimodal association areas, incoming sense impressions are processed at a higher level of abstraction, so that their underlying properties become evident – this is the level at which pattern recognition occurs, so that words or spatial patterns, for example, can be discerned. "Associated information" of this type, generated in the unimodal association areas, then passes to the tertiary, polymodal cortical association areas of the frontal, parietal, and temporal lobes. In these neocortical areas, information derived from multiple sensory modalities (e.g. visual and auditory) converges onto single neurons. This fact is the neuroanatomical basis of the unitary nature of sensory perception, which comes about despite the segregation of peripheral sensory channels into different modalities. The tertiary association cortex projects further to supramodal cortical association regions in the prefrontal and temporal cortex, in which, on a still higher level, the incoming information is integrated and associated with previously acquired information (*3*).

After this cascade-like traversal of the unimodal, polymodal, and supramodal association cortices, all information finally converges upon the key limbic structures of the medial temporal lobe, the hippocampus and amygdala (*4*). The latter structures influence the activity of the hypothalamus (*5*), which controls the autonomic (sympathetic and parasympathetic) centers of the medulla (*6*). The relevant fiber pathways are shown in Fig. 3.

Fig. 3. The limbic structures play a crucial role in the filtering out of irrelevant information, or "sensory gating." They work in a coordinated fashion with the cortical sensory areas that lie proximal to them along the afferent pathway, comparing past and present incoming sensory data and evaluating these data for emotional relevance. Whatever information is emotionally relevant goes on to influence further brain activity, while superfluous information is deleted (Mesulam 1986; van Hoesen 1982; Swanson 1983; Gray 1982; Millner 1992).

In addition, the same central limbic structures of the temporal lobe stimulate or inhibit the activity of the hypothalamus through several pathways. The hypothalamus contains the neural generators of the drives and emotions, which constitute a phylogenetically ancient sphere of brain function (Palkovits and Zaborski 1979). Elementary drives such as aggression, flight, and sexuality, which may indeed be evoked by direct electrical stimulation in the area of the hypothalamus and septum (Hess 1949), are mediated by input to the hypothalamus arising from the amygdala and hippocampus and thus ultimately depend on information that the latter structures receive from the sensory association cortex.

The hypothalamus, in turn, exerts its effects on both parasympathetic and sympathetic functions through a long, descending autonomic pathway, the Edorsal longitudinal fasciculus. The latter delivers afferent input to the dorsal nucleus of the vagus, which provides parasympathetic innervation to almost the entire body, as well as to medullary sympathetic centers. The hypothalamus thus controls all aspects of peripheral autonomic function (Palkovits and Zaborski 1979; Nieuwenhuis 1985).

This completes the chain of sensory information processing, beginning at the sense organs and proceeding, by way of cortical association and integration areas, to further processing by the limbic system, activation or inhibition of the hypothalamus, and generation of peripheral sympathetic or parasympathetic reactions.

The dorsal longitudinal fasciculus, defined above as a fiber bundle connecting the limbic–hypothalamic system, which subserves emotion, to the lower medullary nuclei, which give rise to the parasympathetic and sympathetic outflow, is thus not only an important part of the regulating mechanism for endocrine secretion, but also, in a way, a locus of coupling between the psyche of the individual and his or her peripheral somatic responses. This tract may be considered a "psychosomatic pathway" that provides the anatomical substrate for the regulation of sympathetic and parasympathetic responses by higher cerebral processes.

2.2
The Environment and Brain Structure: Neuroplasticity

The neuropathological approach to the study of psychiatric disease makes exclusive use of reductionist strategies, through which the clinical manifestations of disease may be traced back to primary neurobiological disturbances. Nevertheless, it must be borne in mind that even an initially healthy brain may develop pathological neuroanatomical abnormalities as a result of exposure to a pathogenic psychosocial environment. Studies of brain plasticity have conclusively revealed that an abnormal constellation of environmental stimuli may lead to a lasting impairment of brain development, in both functional and structural terms. The appearance of irreversible changes of brain structure and function after sensory deprivation, particularly in the early phases of postnatal development, is an illustration of this phenomenon (Braun 1996).

In numerous deprivation studies carried out over the last 20 years, it has been shown that the development of cerebral structure and function depends not only on genetic factors, but also, to a large extent, on environmental influences (Singer 1991; Roth 1991; Fields and Nelson 1992). These findings apply to other brain systems as well. The following principles of

cerebral plasticity can be inferred from the results of such studies:

- The functional inactivation of brain systems by sensory deprivation in early postnatal critical developmental phases leads to irreversible, or only partly reversible, structural and functional damage.
- Brain systems that are underdeveloped as a result of previous deprivation and are then reactivated after the end of the critical phase can recover normal function only to a minimal extent or not at all. Conversely, brain systems that have developed normally in the presence of adequate stimulation and are then inactivated by deprivation after the end of the critical phase suffer only mild and reversible functional damage.
- The critical period, i.e. the period in which a cerebral system is vulnerable to irreversible damage as a result of functional deprivation, is different for each individual system. It is determined by the stage of postnatal development in which that system undergoes its genetically determined maturation and the corresponding functional abilities are acquired (e.g. the third to sixth postnatal week for binocular vision in primates).

Similar effects after early deprivation have been demonstrated at the receptor level for the corticosteroid and corticotropin-releasing hormone (CRH) system (for a review, see Aldenhoff 1997).

Deprivation studies have shown that complete recovery of a damaged cerebral system can no longer be achieved after the end of the critical period, when plasticity is severely limited. This explains the lack of effective therapies for mental disorders caused by massive early deprivation (Bogerts 1996). The subtle structural neuroanatomical defects often found in mentally ill patients may be thought of, in relation to brain plasticity, as the possible result of inadequate early sensory stimulation.

Neural plasticity is relevant to neuropsychiatric disease not only in the context of deprivation in early childhood, but also in the response to injury of the mature, normally developed brain. Both neuronal and oligodendroglial mechanisms are involved in the coordination of synaptic plasticity and axon regrowth that lead, if successful, to the restoration of normal function. A typical marker for neural plasticity is growth-associated protein 43 (GAP-43), a substance found in high concentration in synapses that has been shown to be important both in brain development and in the response to brain injury (Benowitz and Perrone-Bizzozero 1991). An autopsy study of schizophrenic patients revealed elevated GAP-43 immunoreactivity in the frontal cortex as well as a decreased concentration of the synaptic marker synaptophysin (Perrone-Bizzozero et al. 1996). This finding might be interpreted as reflecting an attempt by the brain to activate its reserve of plasticity in response to a previous down-regulation of synaptic activity.

3 Organic Mental Syndromes

3.1 Psychoses Resulting from Focal Brain Lesions

Lesions of the primary motor or sensory brain areas, or of the extrapyramidal motor system, cause neurological signs and symptoms, while disturbances of the higher association cortex or of the limbic system cause psychiatric signs and symptoms. In contrast, lesions of the simple unimodal cortical association areas, which occupy an intermediate anatomical and functional position between the primary sensory and motor cortices and the higher association cortex, are clinically manifest in the area of overlap between neurology and psychiatry (e.g. aphasia, apraxia, agnosia).

The frontal and temporal lobes consist predominantly of polymodal and supramodal association cortex. This explains why even large lesions in these areas, such as tumors, infections, trauma, infarcts, and degenerative changes, may not be associated with any motor or sensory neurological deficits (with the exception of anosmia caused by frontal tumors or trauma), while frontal and temporal syndromes typically do include a disturbance of higher cortical or limbic functioning.

Damage to the frontal lobe of any etiology may cause personality changes including loss of motivation, apathy, impairment of judgment, loss of anticipatory ability, social disinhibition or withdrawal, and psychomotor retardation.

Destruction of temporal limbic areas causes amnesia or psychotic manifestations. Total, bilateral hippocampal dysfunction renders the patient incapable of remembering new events, because the transition from short- to long-term memory is no longer possible. Bilateral lesions of the amygdala are clinically manifest as the Klüver-Bucy syndrome, which is characterized by the inability to assign an emotional value to sensory percepts, often in association with hypersexuality and diminished aggressiveness (Mesulam 1986).

Lesions of temporal limbic structures of lesser severity, such as the early stages of tumors and infections, are often associated with manifestations resembling those of schizophrenia. Viral infections with a high affinity for the medial temporal lobe, such as herpes simplex encephalitis or rabies, cause (in their early stages) severe emotional changes including anxiety, fearfulness, overreactions, aggressiveness or apathy, abnormal sexual behavior, delusions, and

Table 4. Distribution of brain lesions in schizophreniform psychoses

Localization	Brain injuries (%) (Hillbom 1951)	Brain tumors (%) (Davison and Bagley 1969)
Temporal lobe	40	35
Frontal lobe	23	19
Parietal lobe	14	–
Occipital lobe	8	2
Diencephalon	–	19
Cerebellum	–	6
Basal ganglia	–	1
Brain stem	–	3
Other areas	15	15

hallucinations (Greenwood et al. 1983). The same phenomena may be produced by trauma, tumors, or ischemia of the medial temporal lobe (Davison and Bagley 1969; Hillbom 1951) or by temporal lobe epilepsy (Slater et al. 1963), particularly when the focus is on the left side and the causative lesion is congenital (Flor-Henry 1969; Perez et al. 1984). Such affections of the limbic or paralimbic regions of the temporal or frontal lobes are often misdiagnosed, in their early stages, as schizophrenia or affective psychosis.

Table 4 provides an overview of the distribution into various brain areas of tumors and injuries that may give rise to schizophreniform psychoses. The frontal and temporal lobes are most often involved, i.e. those areas of the brain in which most of the limbic and paralimbic structures lie (including the hippocampus, parahippocampal cortex, amygdala, temporal pole, cingulate gyrus, and orbital cortex).

3.2 Alcoholic Brain Injury

The injurious effect of chronic alcoholism on brain tissue was described by Wernicke as early as 1881. The best known neuropathological sequela of alcoholism is Wernicke's encephalopathy, which is characterized by degenerative changes, gliosis, and small areas of hemorrhage, mainly in the diencephalon and midbrain. The diencephalic limbic structures bordering on the third ventricle and the cerebral aqueduct, which bear a close relation to the limbic telencephalon, are prominently involved, as is the cerebellum.

The clinical picture of the Wernicke-Korsakoff syndrome, consisting of amnesia, oculomotor dysfunction, ataxia, emotional blunting, and disorientation, is the result of alcoholic damage to the diencephalon, midbrain, and cerebellum. Other neuropathological changes occurring in chronic alcoholism include central pontine myelinolysis, Marchiafava syndrome, and fetal alcohol syndrome (for an overview, see Victor et al. 1989; Phillips et al. 1987; Mann and Widmann 1995).

Recent morphologic studies of the cerebellum in alcoholics revealed a significant diminution of the number of Purkinje cells and thinning of the molecular and granular cell layers. Cerebellar atrophy was seen in approximately half of the alcoholics examined. Alcohol alone can cause cerebellar damage; Wernicke's encephalopathy arises from the combination of alcohol toxicity with thiamine deficiency, a result of poor nutrition (Victor et al. 1989).

The cortical sulci and the cerebral ventricles are often found to be widened on CT and MRI scans of alcoholics (Mann et al. 1989). At the microscopic level, a diminished cell density in the frontal cortex and a diminished single-cell volume in the cingulate, motor, and temporal cortex can be observed. The cortical atrophy is reversible to some extent by prolonged abstinence (Mann and Widmann 1995), especially in younger individuals and those in whom the dependency was of brief duration. Nevertheless, the cerebellar and cerebral cortical cell loss, and the structural changes seen in the diencephalon and midbrain in Wernicke's encephalopathy, are irreversible.

The question of whether regular, but moderate alcohol intake causes brain injury is of great interest. The definition of moderate alcohol intake is largely relative, depending on sociocultural factors, but is usually taken, for scientific purposes, as 40–80 g of ethanol daily. An autopsy study of moderate drinkers revealed an insignificant trend toward cerebral atrophy and a significant degree of dendritic retraction of cortical neurons (Harper et al. 1988). The finding of a focal reduction of volume of the prefrontal cortex in alcoholics and in multiple-substance abusers is of interest (Liu et al. 1998) and has since been replicated. Volume loss appears to be restricted to this region and may have been present before the onset of alcohol abuse, i.e. it may not be an effect of alcohol toxicity.

3.3 Alzheimer's Disease

In view of the extensive literature on the neuropathological features of Alzheimer's disease, including several excellent reviews (Henderson and Henderson 1988; Maurer et al. 1990; Bauer 1994; Kurz 1995), we will not provide a detailed discussion here (see also Vol. 2, Part 2, Chaps. 5–7). We will, however, mention some recent advances that allow neuropathological staging of the disease and improved diagnosis with imaging techniques.

The two neuropathological hallmarks of Alzheimer's disease are the amyloid-containing senile plaques, which lie in the intracellular space, and the intraneuronal neurofibrillary tangles. Plaques and tangles are distributed differently in the brain. While plaques are ubiquitous in the cerebral cortex, tangles are found almost exclusively in the parahippocampal region in early stages of the disease. They then gradually spread to the hippocampus, the rest of the limbic and paralimbic cortex, and, finally, the entire brain, while remaining most numerous in the mesiotemporal limbic area (Braak and Braak 1991).

Plaques and tangles differ at the molecular level as well. The central, amyloid portion of plaques consists of aggregated β-A4 protein, which is formed by pathological cleavage of the amyloid precursor protein (APP), a protein encoded by a gene located on chromosome 21. The formation of plaques takes place over decades and precedes the clinical onset of disease by a long interval.

The major component of neurofibrillary tangles is τ protein (tau protein), whose normal function is thought to be in the stabilization of microtubules, an important substrate for intracellular transport within neurons. The pathological phosphorylation of τ protein results in the formation of neurofibrillary tangles and the disruption of neuronal intracellular transport.

The severity of dementia is more closely correlated with the spatial extent of neurofibrillary tangles than with the number of plaques.

The major site of pathologic changes in Alzheimer's disease is the medial temporal lobe, according to the findings of both MRI studies and histopathological studies (see also this volume, Part 1, Chap. 1). MRI revealed a reduction in overall brain volume by approximately 10% and a generalized widening of the cerebrospinal fluid spaces; the hippocampus–amygdala complex underwent the most extreme reduction in volume, by 30%–40% (Pantel et al. 1997). Several authors have estimated the sensitivity of hippocampal volume reduction as a diagnostic criterion for Alzheimer's disease at between 80% and 90% (Hampel et al. 1997).

Morphometric MRI techniques are thus useful tools for the differential diagnosis of Alzheimer's disease. Nuclear medical techniques are also highly useful for this purpose. Single photon emission computed tomography (SPECT) was initially performed mainly on patients with severe clinical manifestations, and these patients had correspondingly severe abnormalities on SPECT. More recently, however, patients with "milder" disease manifestations have been scanned, including patients who have just made their first visit to a psychiatrist or neurologist because of a newly evident memory deficit. Many of these patients, too, are found to have regional disturbances of cerebral blood flow and glucose utilization.

Extensive, symmetrical temporoparietal hypoperfusion may be considered a nearly pathognomonic finding of Alzheimer's disease and is seen in about one third of patients (the percentage depends on the patient group studied; Holman et al. 1992). Magnetic resonance spectroscopy seems to provide better differential diagnosis, allowing the provision of a diagnosis in between 70% and 80% of patients (see, e.g. Heun et al. 1997).

The fact that Alzheimer's disease originates in the limbic system accounts for the frequent presence not only of memory deficits, but also of emotional changes and delusions among its initial manifestations. These features may make the differential diagnosis of Alzheimer's disease from senile depressive syndromes, paranoid states, and late schizophrenias particularly difficult.

4 The Schizophrenias

4.1 Neuroanatomy: Present State of Knowledge

At the First International Congress of Neuropathology, which took place in Rome in 1952, the view prevailed that no specific neuropathological abnormalities were present in schizophrenic patients. Subsequently, research in this area remained at a standstill until the early 1980s (see Table 3), while psychodynamic and neurochemical theories of etiology attracted the most attention.

The introduction of CT in psychiatry led to a revival of interest in possible cerebral structural abnormalities in schizophrenic patients. All aspects of imaging studies in the schizophrenias are discussed in detail in Chap. 11 (this volume, Part 1). In 1976, Johnstone and colleagues were the first to show by CT that schizophrenics have, on average, wider cerebral ventricles than normal control subjects, thus confirming the findings of earlier, pneumoencephalographic studies (Huber 1957). The earlier studies had not gained full acceptance, because the risks associated with pneumoencephalography had made it impossible to study an adequate number of normal control subjects.

After these initial CT findings were reported (Johnstone et al. 1976), there followed numerous CT and, later, MRI studies of the internal and external cerebrospinal fluid spaces, and of other subcortical structures, in patients with schizophrenic psychosis. As reported in several meta-analyses of these studies, CT reveals a dilatation of the cerebral sulci and cerebral ventricles (mean third ventricular enlargement, approximately 30%) in 30%–50% of schizophrenics

(Raz 1993; Lewis 1990), while MRI reveals a reduction of volume of the entire brain (3%), of both temporal lobes (left 6%, right 9.5%), and of the amygdala–hippocampus complex on both sides (approximately 6% bilaterally) (Lawrie and Abukmeil 1998). The dilatation of the lateral ventricles seen on CT has been confirmed by MRI (Degreef et al. 1992b); according to the most recent meta-analysis, the magnitude of this dilatation is 44% on the left side and 36% on the right side (Lawrie and Abukmeil 1998).

Another meta-analysis yielded a value of 7% for volume reduction in the hippocampus, but no evidence of volume reduction in the amygdala (Nelson et al. 1998). Anatomical differentiation between the amygdala and the hippocampus is difficult in both CT and MRI; this fact may account for the divergent findings regarding amygdalar volume loss.

Nonetheless, there is now a consensus that the sulci of higher integration and association areas in the frontal and temporal lobes are preferentially dilated in schizophrenics. Even qualitative assessment of CT or MRI images of schizophrenic patients allows recognition of ventricular or sulcal dilatation in about half of the patients (Lieberman et al. 1992; Lawrie et al. 1997; Figs. 4, 5).

The findings of recent studies of brain structure in schizophrenia may be summarized as follows:

- Inhomogeneous abnormalities of brain structure
- Dilatation of the lateral ventricles and of the third ventricle
- Mild loss of brain tissue in limbic structures and in the thalamus
- Subtle abnormalities of higher cortical association areas
- Loss of cortical structural asymmetry
- Neuroleptic-induced enlargement of the basal ganglia
- Lack of progression of tissue loss in the limbic system
- Correlation between the extent of ventricular dilatation and an unfavorable disease course

The use of quantitative rating scales (such as that of Smith et al. 1997) is helpful in the assessment of large numbers of CT or MRI images within reasonable time constraints. An especially economical feature of such scales is that they limit the necessary number of measurements to just a few important locations.

4.2 Evidence for Possible Etiologies

In addition to these abundantly replicated findings of dilatation of the internal and external cerebrospinal fluid spaces, major focuses of current interest include studies of limbic structures, the thalamus, the cerebral cortical architecture, and the basal ganglia. A further current topic is the finding of an abnormal alteration of the cortical asymmetry pattern in schizophrenia.

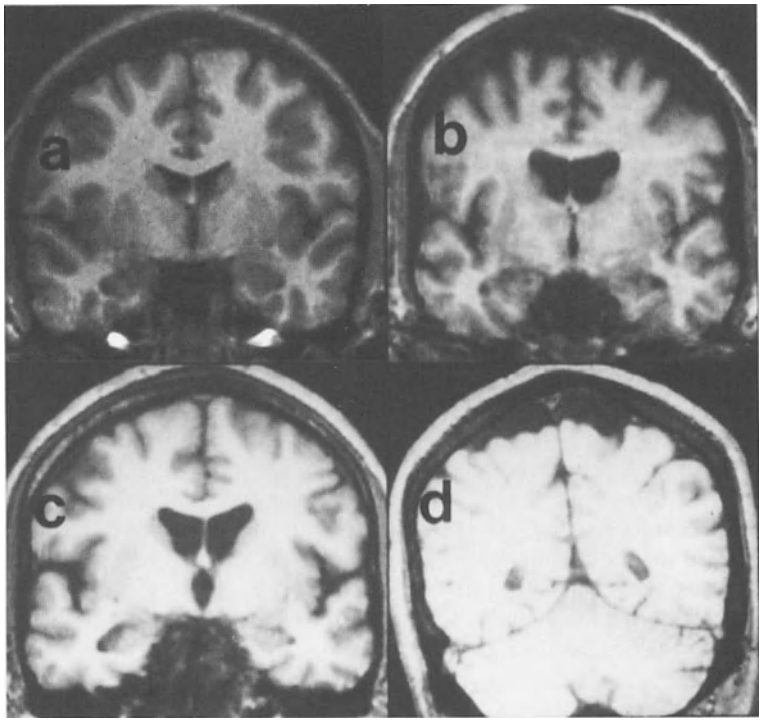

Fig. 4. Coronal magnetic resonance imaging (MRI) sections of **a** a mentally healthy individual, **b,c** two schizophrenic patients of similar ages, with lateral ventricular dilatation (**b**) and a combined dilatation of the lateral ventricles and the third ventricle (c), and **d** a schizophrenic patient with dilatation of the parietal cerebrospinal fluid space

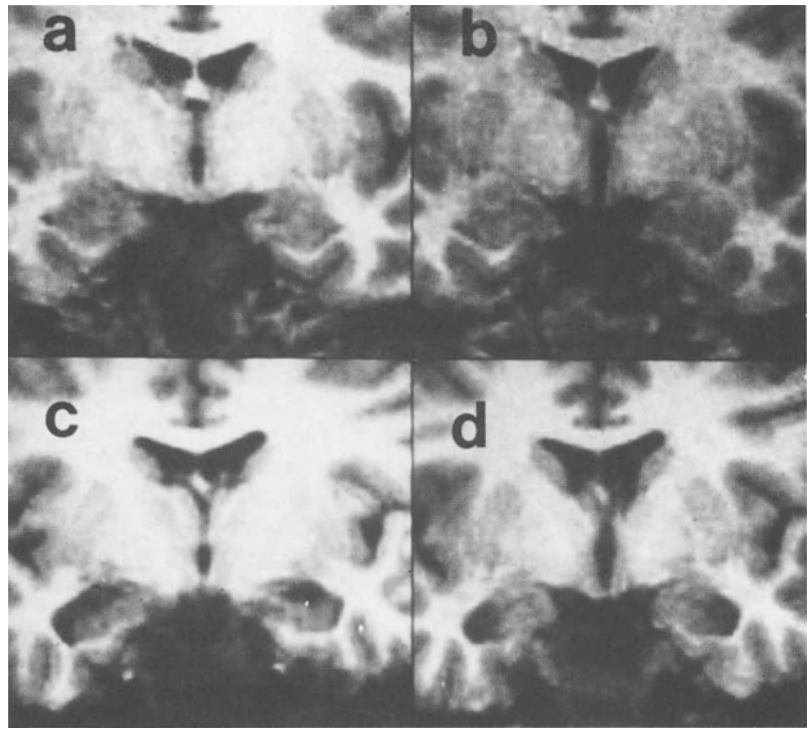

Fig. 5a–d. Coronal, T2-weighted magnetic resonance imaging (MRI) sections through the anterior hippocampus. **a,b** Two consecutive sections showing normal anatomy. **c,d** The same anatomical planes in an age-matched schizophrenic patient with dilatation of the temporal horns and hippocampal hypoplasia

Approximately 50 neuropathological or MRI studies of the limbic structures have been published in the last 10 years (for reviews, see Bachus and Kleinman 1996; Bogerts 1993, 1995; Bogerts and Lieberman 1993; Shapiro 1993; Travis and Kerwin 1997; Nelson et al. 1998; see also Vol. 3, Part 1, Chap. 6). Most of these studies revealed subtle structural defects in limbic areas, including volume loss, cell loss, and cytoarchitectural changes or abnormal cellular configurations in the hippocampus, parahippocampal cortex, amygdala, cingulate gyrus, septum, and orbital frontal cortex. Pathological abnormalities have also been reported in the thalamus and cerebellum, which are closely related to the limbic system (Pakkenberg 1990; Katsetos et al. 1997).

The anterior nucleus of the thalamus (which is a component of the limbic system) and the medial dorsal nucleus of the thalamus appear to be particularly affected by the disease process. In the anterior nucleus, a selective reduction of the number of parvalbumin-containing neurons (inhibitory projection neurons) by approximately 40% has been demonstrated (Danos et al. 1998). Significant cellular losses were also found previously in the medial dorsal nucleus (Pakkenberg 1990). Tissue loss was demonstrated in the thalamic periventricular gray area (Lesch and Bogerts 1984). The finding of reduction in the overall thalamic volume has since been confirmed by MRI (Andreasen et al. 1994).

The presence of schizophreniform symptoms in patients with organic lesions of the limbic system has long led to the suspicion that some of the functional disturbances of schizophrenic patients may be able to be localized to the limbic system, particularly to the medial temporal lobe (Bogerts 1997). As discussed above, the key limbic structures of this area are central sites of convergence for information from the higher cortical association areas of the frontal, temporal, and parietal lobes (see Figs. 1, 2). They play a crucial role in the analysis of situational context, in the filtering of stimuli, and in the comparison of past with present experience. These structures may be regarded as the highest cortical integration and association areas of the brain, and simultaneously as mediators between neocortical cognitive activity and the phylogenetically older neural responses of the septal–hypothalamic–brain stem axis.

It is thus entirely plausible that structural and functional disturbances in temporal limbic areas may lead to a dissociation of higher cognitive processes from elementary emotional modes of response. Bleuler regarded this uncoupling of cognition and emotion as the basic functional disturbance in the schizophrenias.

In addition to limbic structural and functional disturbances, there are many indications of prefrontal cortical disturbance in schizophrenics (Weinberger 1987; Goldman-Rakic 1994). As there is a close connection between the medial temporal lobe and the prefrontal cortex, it is not surprising that prefrontal dysfunction and hippocampal pathology may be described in the same patient. In pairs of monozygotic

twins of whom only one had been diagnosed as having schizophrenia, it was shown that the schizophrenic twins had a significant inverse correlation between hippocampal volume and prefrontal activation by the Wisconsin Card-Sorting Test (Weinberger et al. 1994). The conclusion was drawn that prefrontal cortical function is controlled, at least in part, by the hippocampus.

There is increasing evidence that more widespread loss of cortical volume occurs in schizophrenics, beyond the changes seen in temporal limbic areas. Several CT and MRI studies (Harvey et al. 1993; Raz 1993; Schlaepfer et al. 1994; Ross and Pearlson 1996) have revealed volume loss in polymodal association cortex (dorsolateral prefrontal cortex, inferior parietal lobule, and superior temporal gyrus), but not in occipital or sensorimotor cortex. This volume loss in the polymodal association cortex appears to be specific to schizophrenia, as it has not been found in patients with affective psychoses. This finding supports the hypothesis that not only limbic functioning, but also the functioning of higher cortical association areas is disturbed in schizophrenia.

Several other studies have shown that macroscopic parameters of the brain are also reduced in schizophrenia to a modest extent. A reduction in brain volume by approximately 3%, a reduction in anteroposterior diameter, and a generalized dilatation of the external cerebrospinal fluid space have repeatedly been described (Bogerts 1995).

The pattern of loss of brain substance among schizophrenics is inhomogeneous: some patients have pathological abnormalities mainly in the limbic system and others in the association cortex, while in other patients ventricular dilatation is the most prominent finding. In any case, structural changes in the temporal limbic system and the closely related polymodal association cortex seem to play a major role in the pathophysiology of this disease, as well as of secondary schizophreniform psychoses in patients with organic brain diseases (Ross and Pearlson 1996).

Cerebral structural abnormalities in schizophrenia are summarized at the end of Sect. 4.1. The following findings may be considered supportive evidence for the hypothesis of a disturbance of early brain development in schizophrenics:

- Lack of gliosis in limbic and cortical structures
- Cytoarchitectural changes in temporal and frontal cortex
- Frequent occurrence of cavum septi pellucidi
- Absence of the normal cortical structural asymmetry
- Lack of correlation between structural abnormalities and duration of illness
- Lack of progression of structural abnormalities in follow-up studies

4.3 Clinical Correlates of Structural Abnormalities

Most authors agree that the ventricular dilatation and hippocampal volume loss seen in schizophrenia are not progressive; their severity does not correlate with the duration of the disease, and they do not change over time in follow-up studies, except for the normal effect of aging. These findings seem inconsistent with a progressive, degenerative disease of the brain, but are compatible with hypoplasia acquired early in life (Weinberger 1987; Bogerts 1991; McCarley et al. 1996). On the other hand, there is increasing evidence that cortical pathology in schizophrenia may be progressive (Waddington 1993; Zipurski et al. 1994; DeLisi et al. 1997) (Table 5).

Cytoarchitectural changes in limbic and prefrontal cortex are also important evidence for a disorder of

Table 5. Computed tomography (CT) and magnetic resonance imaging (MRI) follow-up studies in schizophrenic psychoses

Reference	Method	Parameters	Progression
Nasrallah et al. (1986)	CT	VBR	No
Bogerts et al. (1987)	CT	Superior portion of left insular cistern	Yes
Illowsky et al. (1988)	CT	VBR	No
Vita et al. (1988)	CT	VBR	No
Sponheim et al. (1991)	CT	VBR, frontal horns of the lateral ventricles, third ventricle	No
Kemali et al. (1989)	CT	VBR	Yes
Woods et al. (1990)	CT	VBR	Yes
DeLisi et al. (1997)	MRI	Temporal lobes, corpus callosum, lateral ventricles	Yes
Zipurski et al. (1994)	MRI	Temporal lobes	Yes

The parameters were specifically chosen for investigation at the outset of the study or were found to be significantly altered. VBR, ventricle to brain ratio.

early brain development, even though the initial reports of aberrant cell migration in the parahippocampal region (Jakob and Beckmann 1986; Arnold et al. 1991) were criticized on methodological grounds (Falkai et al. 1988a,b; Heinsen et al. 1996; Akil and Lewis 1997; Krimer et al. 1997; Bernstein et al. 1998a). Reports of an abnormal configuration and distribution of neurons in the hippocampus and in cingulate, frontal, and temporal cortex, and in the neighboring subcortical white matter zones (Benes and Bird 1987; Akbarian et al. 1996; Jönsson et al. 1997; Luts et al. 1998), reinforce previous evidence of abnormal cytoarchitecture in schizophrenics and provide further support for the hypothesis of a disturbance of brain development; yet another piece of evidence is the reportedly increased prevalence of cavum septi pellucidi among schizophrenics (Degreef et al. 1992a; Kwon et al. 1998).

Most controlled autopsy studies revealed no evidence of significant gliosis (Falkai et al. 1999). An elevated glial cell density (i.e. gliosis) is present in progressive brain diseases such as Alzheimer's disease and is easily demonstrated by neuropathological techniques. Schizophrenic patients certainly do not have this type of abnormality, but slowly progressive encephalopathies must be mentioned here in the differential diagnosis. Taken together, the histological findings in schizophrenia suggest a disorder of brain development, which possibly triggers another, secondary process in cortical structures (Woods et al. 1996).

Genetic factors play an important role in the etiology and pathogenesis of schizophrenic psychoses (see, e.g. Maier and Schwab 1998), while concordance rates of schizophrenic illnesses in monozygotic twins are no higher than 50%, which implies that environmental factors are important as well. The risk of developing schizophrenia is twice as high in the presence of perinatal complications, according to a recent meta-analysis (Geddes and Lawrie 1995). A prospective study of children at risk revealed that the extent of abnormalities on CT was significantly correlated with genetic risk factors and the presence of perinatal complications (Cannon et al. 1993). Interestingly, perinatal complications were found to be the single important determinant of ventriculomegaly, while cortical sulcal dilatation was a product of both perinatal complications and genetic risk factors (Cannon et al. 1993).

Ventriculomegaly and limbic atrophy cannot be regarded as sequelae of neuroleptic treatment or as secondary effects of the disease. No CT, MRI, or autopsy study to date has shown an association between the duration of therapy and the structural abnormalities found in these brain regions. Despite the sometimes very pronounced clinical manifestations of neuroleptic-induced tardive dyskinesias, no study to date, including well-controlled autopsy studies, has revealed an association of these with localized histopathological changes, e.g. in the basal ganglia (Bogerts 1995; Marsh et al. 1994).

Increased volume of the basal ganglia in chronic schizophrenia is a quite remarkable and repeatedly replicated finding (Chakos et al. 1994; Keshavan et al. 1994; Meshul et al. 1996), surprising because neuropathological processes do not, as a rule, lead to an enlargement of neural tissue. A study in which MRI scanning was performed on schizophrenics at the onset of the illness and 18 months later provides a possible explanation for this finding: the caudate nucleus was significantly larger on the follow-up scans, and the extent of enlargement was correlated with the cumulative dose of neuroleptic medication.

The increased size of the caudate nucleus was attributed to the disinhibitory effect of neuroleptics on the basal ganglia (blockage of the inhibitory effect of dopamine), leading to an overuse hypertrophy of striatal neurons (Chakos et al. 1994). A recent longitudinal MRI study revealed that the superior temporal gyrus is of lower volume in untreated schizophrenics than in normal controls, but that this difference disappeared completely after 1 year of neuroleptic treatment (Keshavan et al. 1998). This finding is clearly in need of replication. The authors explain it by postulating that prolonged overactivity of the dopaminergic system leads to a reversible injury of cortical cells that regresses under neuroleptic treatment. This argument seems plausible, as neuroleptics are known to block apoptosis.

4.4 Use of Structural Findings in Differential Diagnosis and Assessment of the Response to Therapy

Three to 10% of unselected patients with psychotic disorders, in whom the general physical and neurological examinations are unremarkable, are found to have brain lesions on structural imaging (Lewis 1995; Falkai 1996). These are usually clinically irrelevant incidental findings, such as arachnoid cysts (Fig. 6) or septal cysts (Fig. 7), although tumors or subdural hematomata are also occasionally found.

Clear criteria for when structural imaging is indicated are sparse in the literature (e.g. Weinberger 1984). Thorough structural imaging should certainly not be omitted in patients with atypical disease manifestations or atypical progression.

There is some controversy in the literature over the usefulness of structural imaging for differential diagnosis and the prediction of therapeutic response and disease course. A meta-analysis of 33 CT and MRI studies was performed to determine how well structural parameters such as the "ventricle to brain ratio"

Fig. 6. A cyst in the right temporal lobe in a 33-year-old man

(VBR, an index of ventriculomegaly), the width of the sulci, third ventricular width, and others could be used to predict the short-term response to neuroleptic therapy (Friedman et al. 1992). Although the findings were remarkably heterogeneous, no single parameter with predictive value could be identified. Our own study confirmed this finding with respect to the cerebral ventricles. We did find a significant difference between responders and nonresponders in the mean value of other parameters relating to the frontal interhemispheric fissure, the temporobasal portion of the insular cistern, the inferior horn, and frontal asymmetry, but these parameters could not be used to obtain a reliable differential diagnosis in the individual case (Falkai et al. 1993; Falkai and Bogerts 1994). This finding points to a dilatation of the cerebrospinal fluid space that is most marked in the area of the polymodal association cortex.

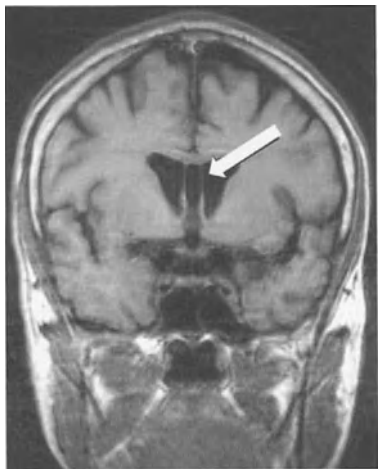

Fig. 7. Verga's ventricle in a 47-year-old man

The predictive value of structural parameters for long-term prognosis is different from that for short-term therapeutic response. Ventricular dilatation is a good predictor of long-term therapeutic success and of disease outcome (Lieberman et al. 1992; Raz 1993; van Os et al. 1995). There is also a highly significant correlation between ventricular dilatation and premorbid social adaptation (van Os et al. 1995): the wider the ventricles, the worse the patient's premorbid social adaptation, and the less favorable the long-term course of the illness.

4.5 Interpretation of Structural Findings in the Brain

The question of whether the brains of schizophrenics are more or less symmetrical than normal has attracted increasing attention recently (Crow 1990, 1993). It has been found repeatedly that the normal asymmetry of the frontal lobes (right larger than left) and of the occipital lobes (left larger than right) is not present in schizophrenics (Bilder et al. 1994; Falkai et al. 1995). This finding may be specific to schizophrenia: Falkai et al. (1995) found the normal asymmetries in patients with affective disorders and neuroses.

In addition to these frontal and occipital asymmetries, the human brain has still more marked asymmetry of other structures, including the temporal plane and the sylvian fissure. Human anatomic variability probably accounts for the contradictory results of recent studies (Rossi et al. 1992; Kleinschmidt et al. 1994; Frangou et al. 1997; for a detailed discussion, see Vol. 3, Part 1, Chap. 5).

Thus far, we have discussed a subtle dilatation of the internal and external cerebrospinal fluid spaces, structural defects in the temporal limbic area, enlargement of the basal ganglia, and absence of the normal asymmetry of the frontal and occipital lobes as recognized categories of cerebral structural abnormality in chronic schizophrenics. Because cerebral asymmetry begins to develop even before birth, the latter finding strongly supports the hypothesis of a prenatal disorder of cerebral development (as do the cytoarchitectural changes and the lack of correlation between structural abnormalities and the duration of disease).

The heterogeneity of these cerebral structural abnormalities among schizophrenics reflects the biological and clinical heterogeneity of the disease. No clear and replicable link has been found to date between the individual types of structural anomaly and the subtypes of clinical psychopathology. One possible exception is the correlation between dilatation of the cerebrospinal fluid space in the left temporal region and positive schizophrenic manifestations (Degreef et al. 1992b).

Dilatation of the lateral ventricles and of the third ventricle, dilatation of the cortical sulci, and abnormal structural findings in the limbic system are the best documented morphological abnormalities in schizophrenics. Furthermore, losses of brain substance in cortical association areas have been described repeatedly. Structural abnormalities in polymodal cortical association areas and the absence of the normal asymmetry of the frontal and occipital lobes have been demonstrated to date only in schizophrenics, but not in patients with affective psychoses or neuroses; these abnormalities thus possess a degree of specificity for schizophrenia.

The results of recent structural studies imply that the schizophrenias are diseases of the entire brain in which the limbic regions, and the cortical association areas most closely related to them in function, are especially severely affected.

The majority of the neuropathological findings, as well as the findings of CT and MRI studies, imply that the ventricular dilatation and limbic structural defects of schizophrenics are static, i.e. not progressive. Studies revealing an association between cortical volume loss and the duration of illness suggest that a second disease process may be at work. As the subcortical abnormalities, at least, seem to be static, they can be used to explain neither the variable course of illness, nor the typical onset of disease manifestations in early adulthood. These abnormalities should thus be regarded as vulnerability factors, which, along with other factors (psychosocial, biochemical, and nonspecific stressors), render the individual more likely to develop the disease.

5 Affective Illnesses

5.1 Histopathological Studies

In contrast to the abundance of neuropathological studies of schizophrenia that have been published since the end of the nineteenth century, there has been relatively little interest in the neuropathological investigation of patients with affective psychoses, and this remains so today. Perhaps the prevailing dualistic view of mind and body made investigators less likely to consider the possibility of organic processes operating in the emotional sphere than in the realm of cognition and perception, which is so prominently affected by schizophrenia (see also Vol. 3, Part 1, Chap. 6).

Two extensive reviews of the world literature (Jeste 1988; Bogerts and Lieberman 1993) turned up only 15 neuropathological studies of the temporal limbic areas, cerebellum, and basal ganglia in patients with affective disorders. In most of these studies, the brains of depressed or cyclothymic patients were used as control cases for the investigation of the neuropathology of schizophrenia. The number of patients in all of these studies was small (five or less), and the qualitative methods used were generally inadequate to yield significant findings in the absence of quantitative, statistical analysis. These methodologically flawed studies yielded no replicable conclusions.

The neurotransmitter-containing cell groups of the brain stem are known to be important in the pharmacology of the affective psychoses, but their histopathology has nevertheless not been investigated in any study of depressive or cyclothymic patients published to date. The situation is similar for the septal–hypothalamic area as well as for the amygdala and other limbic structures, even though the role of these structures in the modulation of elementary drives and emotions, as well as circadian rhythms and endocrine function, has long been recognized (Ketter et al. 1996; Grasby and Bench 1997). It was recently shown, with the aid of immunohistochemical methods, that depressed patients have an increased number of CRF-containing neurons in the paraventricular nucleus of the hypothalamus; this finding is clearly related to the hypercortisolism found in this patient group (Raadsheer et al. 1994). Immunohistochemical methods further revealed a reduced number of nitrous oxide synthase-containing neurons in the hypothalamus, which is perhaps related to an abnormality of endocrine regulation associated with depression (Bernstein et al. 1998b).

5.2 Structural Imaging Techniques

Structural imaging techniques have revealed several abnormalities in the brains of patients suffering from affective disorders (see also this volume, Part 1, Chap. 11). A considerable number of CT and MRI studies have documented the width of the internal and external cerebrospinal fluid spaces as well as the volumes of cortical and subcortical structures. Subtle widening of the cerebral ventricles seems to be present not only in patients with senile depression, but also in some patients with uni- and bipolar affective disorders, even though intergroup comparisons reveal less marked differences than in the case of schizophrenia (for reviews, see Wurthmann et al. 1995; Soares and Mann 1997; Grasby and Bench 1997). Most studies have revealed no dilatation of the cortical sulci in cyclothymic patients. Direct comparisons of the external cerebrospinal fluid spaces of schizophrenics and patients with affective disorders revealed that the

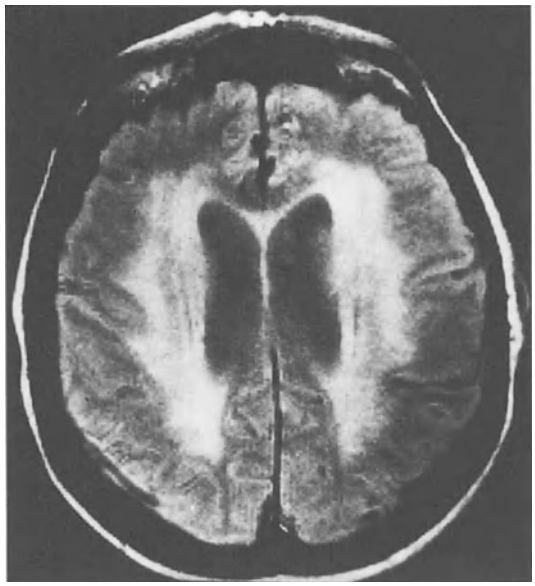

Fig. 8. White-matter lesions in a patient with affective psychosis

supramodal cortical association areas are affected in the former, but not in the latter (Harvey et al. 1993; Schlaepfer et al. 1994). This may explain why patients with affective disorders are less likely to have profound cognitive disturbances than schizophrenics.

The most frequently replicated structural finding in the brains of patients with both uni- and bipolar affective disorders is the increased prevalence of signal-intense areas in the cerebral white matter (Fig. 8).

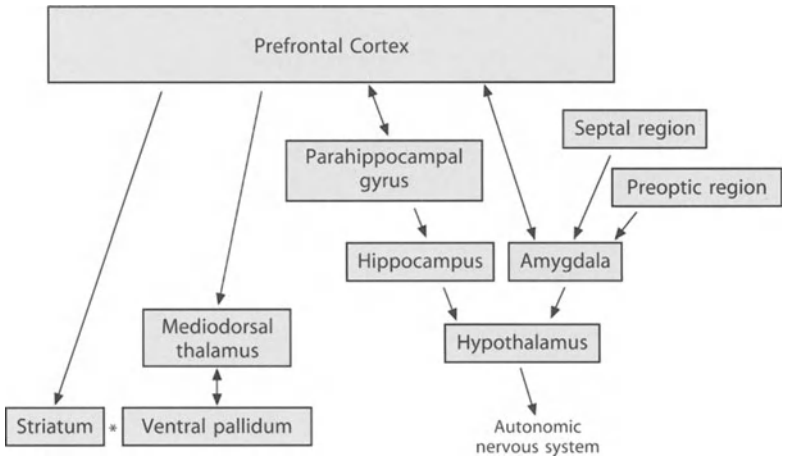
White matter lesions are particularly common in elderly depressed patients compared to age-matched controls, and this is true to a statistically significant extent even after possible vascular causes have been excluded (Soares and Mann 1997; Grasby and Bench 1997). The histological nature of these lesions and their pathophysiological significance are still unknown.

In many other areas of the brain, however, there is a dichotomy between the structural findings of unipolar depression and of bipolar affective disorder. Patients with unipolar depression have diminished volume of the frontal lobe, the cerebellum, and the striatum, while patients with bipolar affective disorder have dilatation of the third ventricle and diminished volume of the cerebellum and temporal lobes. Furthermore, a diminished volume of the basal ganglia of unipolar depressives (caudate, putamen, and nucleus accumbens) has been found in several studies (Soares and Mann 1997).

Among all components of the basal ganglia, its limbic component, the nucleus accumbens, appears to be particularly affected (Baumann et al. 1999). The observation that cerebrovascular accidents involving the basal ganglia often give rise to depressive manifestations is further evidence that the basal ganglia are functionally important not only in motor control, but also in the neural modulation of affect (Herrmann et al. 1993). The key structures of the limbic system involved in the processes of emotion and memory are depicted in Fig. 9.

The dichotomous MRI findings in the two types of affective disorder imply that they have different neurobiological causes. A further finding of interest is that the third ventricle and the frontal and temporal cerebrospinal fluid spaces are widened in patients carrying the diagnosis of endogenous depression (according to ICD-9), but not in neurotic depressives, who have a lifelong susceptibility to depression (Baumann et al. 1997). This finding is an argument against removing the distinction between neurotic and endogenous depressive syndromes, as was done in DSM-IV and ICD-10, as well as a demonstration, on the level of brain structure, of the variable contribu-

Fig. 9. Key structures involved in emotion and memor



tions of psychogenesis and organogenesis to the etiology of affective disorders.

6 Outlook

Recent discoveries in the functional neuroanatomy of the brain, particularly concerning the stages of cortical information processing and the role of the limbic system, have added considerably to our understanding of the neurobiology of psychiatric disease. Especially important findings have been made with respect to the telencephalic limbic structures of the medial temporal lobe, which, by virtue of their anatomic connections, play a mediating role between the neocortex and the brain stem, and thus also between higher cognitive processes and phylogenetically ancient emotions.

If we simplistically divide the brain into primary and higher areas of sensory information processing, then we may conclude from the classic neuropathological studies and the more recent studies of brain structure in psychotic patients that injuries of the primary sensory and motor cortical areas cause neurological manifestations, while disturbances of the higher cortical integration and association areas of the frontal lobes, temporal lobes, and limbic system cause psychiatric syndromes. Pathological abnormalities of the latter brain areas play a central role in organic mental syndromes (including Alzheimer's disease and symptomatic psychoses) and also in those forms of psychoses that were, until recently, termed "endogenous." In Wernicke-Korsakow syndrome, structures of the limbic diencephalon and midbrain are particularly affected, while in affective psychoses the limbic portions of the basal ganglia also appear to be disturbed. Disturbances of memory and cognition, abnormal interpretation of reality, and the dissociation of cognition and emotion that typifies psychosis are all produced by dysfunction of higher cortical areas and of the limbic system.

The neuropathological study of the schizophrenias is still in an early phase, and that of the affective psychoses still more so; nonetheless, considerable progress has been made in recent years, a happy contrast to the failure of neurobiological research on psychosis in the first half of the twentieth century. Most of the currently available studies have revealed moderately extensive, yet statistically significant and replicable losses of volume in areas subjected to gross measurement. Future investigators will have to perform more detailed histological and cytological analyses of these areas, and of neural systems and neuronal cell types that have so far been studied inadequately, or not at all, despite their theoretical relevance to the genesis of psychotic syndromes.

The neuropathological findings in schizophrenia, and probably also in the affective disorders, should be viewed as vulnerability factors for psychiatric disease. It remains entirely unknown what other, nonstructural biological factors (perhaps such as age and stress) might determine the course of psychiatric illness in a patient made vulnerable by a previous structural injury to the brain. If this question were answered, the prospects for effective therapy would be dramatically improved.

Brain Imaging in Psychiatry

Translator: E. Taub

1 Introduction

Modern in vivo brain imaging, made possible by the major advances in radiology and nuclear medicine over the course of the twentieth century, has led to the formulation of new concepts of brain function and enabled the identification of specific pathological changes in diseases of the central nervous system. For much of its history, the study of brain function depended exclusively on postmortem examination of brain lesions and on the findings of electrophysiological tests. Early maps of brain function were often speculative and based on highly mechanistic assumptions. This approach could yield no more than a rudimentary conception of the modular organization of the brain.

The earliest means of imaging brain structures in vivo were the plain skull X-ray and, somewhat later, pneumoencephalography. The latter was the first technique used to study the relationship between brain parenchyma and ventricular size in various psychiatric disorders.

In the second half of the twentieth century, a first step toward in vivo functional imaging was taken with the introduction of particle emission tomography, which enabled the study of blood flow, metabolism, and specific neurochemical aspects of brain function. The decisive breakthrough for modern functional imaging came with the development of computerized reconstruction algorithms for radiologic and emission-tomographic data. Magnetic resonance tomography, introduced shortly thereafter, was a further addition to the wide range of structural and functional imaging modalities available to neuroscientists and clinicians.

This chapter will provide an overview of computed tomography (CT), magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT), positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS). Its primary objective is to describe the major current research strategies in this field. The basic capabilities of each imaging modality and some representative results will be presented and discussed.

An imaging technique, in the broadest possible sense, is any technique that enables a spatial representation of structural or functional data. As virtually any data set obtained from the brain can be displayed as an image, such methods as quantitative electroencephalography (qEEG), event-related potentials (ERP), and magnetoencephalography (MEG) might also be referred to as imaging techniques. These will not be included in the present chapter; the reader is referred to Chap. 9 (this volume, Part 1) for a discussion. Brain imaging studies relating to substance abuse will also be discussed in a separate chapter (Vol. 3, Part 2, Chap. 22).

2 Structural Imaging: Computed Tomography and Magnetic Resonance Imaging

2.1 Technical Principles

Before modern radiologic techniques were available, pneumoencephalography provided no more than an indirect means of estimating the size of some brain structures in vivo. In this technique, air was introduced into the ventricular system by way of a lumbar puncture. This was both invasive and very unpleasant for the patient. CT was one of the first radiologic techniques to provide exact quantitative information about brain structures. It is noninvasive and, aside from radiation exposure, carries no risk to the patient.

X-rays are emitted by a point source rotating around the head, traverse the brain, and are received by a detector on the other side. The attenuation of the beam by the tissue is measured for a large number of trajectories through the brain. These data are then used to calculate the spatial distribution of the attenuating structures, which is usually displayed as a two-dimensional, gray-scaled image.

MRI is based on the fact that atomic nuclei with an odd number of nucleons (i.e., protons and neutrons) act as electrically charged spinning tops, thereby generating a magnetic field. These atomic nuclei align themselves either parallel or antiparallel to a strong, externally applied magnetic field, while simultaneously rotating about their axes ("precessing") at a specific frequency independent of field strength – the Larmor frequency. An externally applied radiofrequency (RF) pulse causes the nuclei to deviate from their original orientation. When the pulse is removed, the nuclei return to their original orientation. This so-called relaxation is accompanied by the emission of an RF signal, which can be detected by appropriately placed detector coils. In order to localize the source of the emitted signal, the RF pulse is applied repeatedly with systematic variation of frequency- and phase-encoding gradients. The data obtained are then converted by Fourier transformation to an image data matrix, which can be represented in the form of two-dimensional, gray-scaled MRI images.

This technique returns three elements of data for each location in imaging space: the two relaxation

times, T_1 and T_2, and the proton density. T_1 is the time constant for the return of the nuclei to their original orientation, while T_2 is the time constant for the loss of phase coherence in the transverse direction.

Gray matter and white matter are easily distinguished in T_1-weighted images, while T_2-weighted images provide a sharper contrast between brain parenchyma and cerebrospinal fluid (Buschong 1996).

2.2 Findings

Schizophrenia

The association of schizophrenia with ventricular dilatation was first suggested by pneumoencephalographic studies and later firmly established using CT (Andreasen et al. 1990b; Jones et al. 1994). This finding implied that at least some psychiatric disorders may be the result of structural abnormalities. The detected abnormalities were small, however, and there was considerable overlap between the schizophrenic patients and the normal control subjects.

MRI has recently enabled the performance of more sensitive and more detailed studies, which will largely form the topic of the present discussion.

The finding of lateral ventricular dilatation was replicated in many MRI studies (Chua and McKenna 1995). The quantitative measure commonly used, the ventricle–brain ratio (VBR), has been found to be elevated in schizophrenics, reflecting an increase in ventricular size at the expense of brain parenchyma. Ventricular dilatation is reportedly associated with both negative (Andreasen et al. 1990a; Gur et al. 1994) and positive (A.H. Young et al. 1991) symptoms of schizophrenia.

Ventricular dilatation and diffuse cerebral atrophy were found to be related to the severity of symptoms, as measured on the Brief Psychiatric Rating Scale (BPRS) (A.H. Young et al. 1991), but the extent of ventricular dilatation seems not to be correlated with the duration of illness (Hoffman et al. 1991; A.H. Young et al. 1991). It may be concluded that brain atrophy is not merely a consequence of the established disease process, but is rather the result of pathogenetic factors that are present at the onset of the disease or even before it. Later prospective studies did show, however, that progressive structural changes occur in the brain over the course of the illness. Progressive volume loss of both cerebral hemispheres, of the right cerebellar hemisphere, and of portions of the corpus callosum have been described (DeLisi et al. 1997a).

Direct measurements have revealed that the normally present asymmetry of the temporal plane (the left side is larger than the right) is less marked in schizophrenic patients than in normal controls (Petty et al. 1995). In pairs of schizophrenic twins, horizontal sylvian fissure asymmetry was found to be more highly correlated within pairs than across pairs, which implies that this structural brain abnormality has a genetic basis (DeLisi et al. 1997b).

Other structural imaging studies have documented an extensive loss of gray matter volume in schizophrenics which is not merely confined to the temporal lobes (Schlaepfer et al. 1994). Schizophrenics have been found to have significantly smaller frontal lobes (Andreasen et al. 1986) as well as a smaller corpus callosum (Woodruff et al. 1993) and an enlargement of the basal ganglia (Hokama et al. 1995).

Normal aging and a variety of demographic variables, including social class, intelligence, and education, are known to be correlated to varying degrees with overall brain size and with the size of individual brain structures (Pearlson et al. 1989; Andreasen et al. 1993). Thus the proper selection of control groups for patient studies must take these variables into account.

Structural abnormalities may be directly related to neuropsychological deficits. A significant correlation has been found between cognitive measures of prefrontal function and the size of the dorsolateral prefrontal cortex (DLPFC), especially in the left hemisphere (Seidman et al. 1994). The results of imaging studies suggest that structural damage to the frontal lobes may account, at least in part, for the cognitive deficits seen in schizophrenia. Studies performed to date also indicate that atrophy may be more marked in patients resistant to neuroleptic therapy (Lawrie et al. 1997).

Affective Disorders

Structural abnormalities of the brain have also been described in patients with both unipolar and bipolar depression. An increased VBR and other manifestations of cerebral atrophy have been found (Videbech 1997). A reduction of the volume of the basal ganglia was found among patients with unipolar, but not bipolar depression. The VBR and the width of the third ventricle were significantly correlated with scores on various rating scales for the severity of depression (Schlegel et al. 1989b; Krishnan et al. 1992). In addition to these findings, patients with affective disorders were found to have subcortical hyperintense signal abnormalities on MRI more frequently than controls (Dupont et al. 1990). In general, findings of cerebral structural abnormalities are less consistent in the affective disorders than in schizophrenia. Measures of volume loss, such as the VBR, are diagnostically nonspecific, as they are found both in schizophrenic patients and in patients with affective disorders.

Dementia

CT and MRI have revealed structural abnormalities in Alzheimer's disease (AD) including cerebral atrophy with widening of the cortical sulci, ventricular dilatation, and deep white-matter lesions with periventricular distribution (Faulstich 1991). MRI has further revealed a particularly severe atrophy of mesial temporal areas (Murphy et al. 1993), including the amygdala–hippocampus complex (Heun et al. 1997a). Brain atrophy is found early in the course of the disease process, and its extent is correlated with the severity of cognitive impairment (Kesslak et al. 1991; Pearlson et al. 1992).

The presence of a large number of hyperintense white-matter lesions, particularly in periventricular areas, is characteristic of dementia of vascular origin, rather than Alzheimer's disease (Erkinjuntti 1987). In this regard, however, there is considerable overlap between demented patients and normal controls, as also between patients with different subtypes of dementia, so that a reliable differential diagnosis generally cannot be made in this way in individual cases.

Other Diseases

A significant difference between the VBR of patients with obsessive-compulsive disorder (OCD) and that of normal controls was reported in CT studies (Behar et al. 1984). Subsequent MRI studies provided evidence of lateral asymmetry, with a larger-sized caudate nucleus on the right side (Calabrese et al. 1993), but failed to confirm a difference in VBR between OCD patients and normal controls (Kellner et al. 1991). The application of structural imaging to OCD is thus a good illustration of the fact that early findings may fail to be replicated when newer, more advanced imaging techniques become available.

There are similar problems regarding the findings of structural abnormalities in schizophrenia, particularly when the differences between groups are small and there is considerable overlap with the normal population. It was noted in a review of the literature (Van Horn and McManus 1992) that the year of publication of studies in this field is significantly negatively correlated with the strength of the effects reported in them. It may be inferred that methodological difficulties account in no small part for this unfortunate situation.

Nonetheless, the advent of modern tomographic techniques has brought about a major resurgence of interest in structural imaging as a tool in psychiatric research. These new methods were the first to enable a correlation of structural changes with psychopathological descriptors, neuropsychological performance parameters, and genetic aspects of various psychiatric disorders.

3
Functional Imaging

The use of short-lived radionuclides to create radiolabeled tracer substances was the key factor in the development of functional imaging. A tracer is a compound that has been "labeled" by the replacement of one or more atoms with a radioactive isotope. The tracer is normally injected into a peripheral blood vessel and transported by the bloodstream into the brain. The tracer has the same biologic activity as the original unlabeled substance; once in the brain, it either binds to specific receptors or becomes concentrated at specific sites through other neurochemical processes. The quantity and distribution of radioactivity in the brain are then measured by the methods described below and displayed as an image.

Although the initial experience of in vivo brain imaging with radiotracers was gained as long ago as the 1950s, the major technical breakthrough in this field – the use of spatial reconstruction algorithms demanding large amounts of computing power – necessarily awaited the development of sufficiently fast computers decades later.

3.1
Positron Emission Tomography

3.1.1 Technical Principles

In PET, unstable positron emitters are used to mark various chemical compounds. When a positron is emitted by one of these radionuclides, it travels a short distance and then collides with an electron, whereupon both the positron and the electron are annihilated and two photons (gamma rays), each with 511 keV of energy, are emitted in opposite directions (i.e., 180° apart). Because the two photons are emitted simultaneously, the site of their production (very near the site of the positron emitter) can be determined by means of a coincidence detector. The output of the coincidence detector is picked up by scintillation crystals and then digitized, and a computerized reconstruction algorithm is used to generate an image.

Positron emitters are normally characterized by short half-lives, and they must therefore be produced in a cyclotron in the immediate vicinity of the PET scanner. As practically all biologically important molecules contain oxygen, carbon, or nitrogen, the short-lived radioisotopes ^{15}O, ^{11}C, and ^{13}N can be used to mark molecules without altering their chemical structure. Because they are short-lived, the patients are exposed to only small amounts of radiation, and studies can be conveniently repeated. Other

Table 1. Commonly used positron emitters for positron emission tomography (PET) studies in psychiatry

	Half-life (min)
^{11}C	20.4
^{13}N	10.0
^{15}O	2.1
^{18}F	109.8
^{75}Br	99.0
^{76}Br	972.0

radioisotopes in use, such as ^{18}F, ^{75}Br, and ^{76}Br, have longer half-lives (Table 1).

Positron emitters and detectors were used to study brain tumors as early as the 1950s. One of the first positron cameras, developed at the Brookhaven National Laboratory in New York, contained an array of ring detectors (Robertson et al. 1973). The steady improvement of PET technology in recent years has led to spatial resolutions as low as 4 mm, depending on the specific tracers and devices used. The theoretical limit of spatial resolution for PET is given by the distance traveled by positrons before their annihilation. This distance is approximately 2 mm for ^{11}C.

Two basic strategies are used in PET functional imaging studies. The first involves the measurement of cerebral blood flow (CBF) or metabolism. The second involves the use of a radiotracer with known specificity for a particular neurotransmitter system. The tracer binds to a site that may be a receptor, a transporter, a neurotransmitter, or a neurotransmitter precursor. PET may be used to measure the in vivo distribution and affinity constants of both pre- and postsynaptic neurotransmitter receptors.

[^{18}F]Fluorodeoxyglucose ([^{18}F]FDG) is the preferred tracer substance for the measurement of cerebral energy metabolism, expressed as the regional cerebral metabolic rate for glucose (rCMRglc). This method has been shown to have a high intrasubject reproducibility (Bartlett et al. 1991a). [^{18}F]FDG is transported across the blood–brain barrier in both directions by the same transporter as unmarked glucose. [^{18}F]FDG also undergoes the same initial metabolic step as glucose, namely 6-phosphorylation. Unlike glucose metabolism, however, the metabolism of [^{18}F]FDG stops at this stage (i.e., as [^{18}F]FDG-6-phosphate).

After 35 min, most of the radioactivity is trapped within the cell in the form of [^{18}F]FDG-6-phosphate, and the amount of radioactivity remains roughly constant for a further 30 min. Tomographic images are obtained during this period to determine the distribution of the positron emitter in the brain. Mathematical algorithms incorporating various correction factors, including the plasma concentration of [^{18}F]FDG, are used to generate a pictorial representation of metabolic activity (Sokoloff et al. 1977; Huang et al. 1980).

When interpreting these data, it should be borne in mind that a given value of regional glucose metabolism does not directly imply any specific functional state of the neurons in the vicinity. Metabolic rates determined with [^{18}F]FDG primarily represent the metabolic activity in nerve terminals, which are rich in mitochondria. Since neurons and neurotransmitters may have either excitatory or inhibitory functions, heightened metabolic activity in a given area may be consistent with either an increase or a decrease of overall information processing in that area.

[^{15}O]H_2O is the preferred tracer substance for the measurement of regional cerebral blood flow (rCBF) with PET. Because the half-life of ^{15}O is much shorter than that of ^{18}F, use of this tracer allows the repetition of studies at short intervals to demonstrate cognitive activation or short-acting pharmacologic effects. ^{18}F, in contrast, is more suitable for the study of relatively stable mental states and longer-lasting clinical pharmacologic effects.

PET and SPECT also have an important application in the study of neuroreceptor pharmacology, including the study of interactions between neurotransmitter systems. In recent years, many radioligands have been developed that are specific for individual receptor types. Radioligands for use in PET receptor studies vary in a number of important technical properties, including tracer pharmacokinetics, reversibility of binding, selectivity, nonspecific binding, and metabolic stability.

Imaging techniques for the study of neuroreceptor systems were first used primarily to study the dopaminergic system. In recent years, ligands have been developed that allow the study of many aspects of this system. One of the first ligands used to study the D_2 receptor system was [^{11}C]*N*-methylspiperone (NMSP) (Wagner et al. 1983). This ligand binds preferentially to D_2 receptors, but also has a high affinity for 5-HT_2 serotonergic receptors. Further ligands for the study of D_2 receptors include [^{76}Br]bromospiperone (Maziere et al. 1985) and [^{11}C]raclopride (Farde et al. 1985), as well as [^{18}F]NMSP.

Ligands successfully used to image the dopamine transporter include [^{11}C]nomifensine (Aquilonius et al. 1987), [^{11}C]WIN35,428 (Bennett et al. 1995), [^{11}C]cocaine (Volkow et al. 1992; Bennett et al. 1995), [^{11}C]methylphenidate (Volkow et al. 1995), and [^{11}C]β-CIT (Farde et al. 1994). The concentration and distribution of the dopamine-metabolizing enzyme monoamine oxidase B (MAO-B) have been studied with the ^{11}C-labeled irreversible enzyme inhibitors

[^{11}C]clorgyline and [^{11}C]L-deprenyl (Bench et al. 1991). Different aspects of presynaptic dopaminergic function have been studied with the radiotracer [^{18}F]fluorodopa (Leenders et al. 1986; Kuwabara et al. 1993).

A number of other neurotransmitter and receptor systems have also been studied by PET. 5-HT_2 receptors may be studied with the radiotracers [^{11}C]setoperone (Blin et al. 1990) and [^{11}C]altanserin (Sadzot et al. 1995). Most of the radiotracers currently available for the study of the serotonergic system have low affinity and low selectivity and are thus of limited usefulness. Newer serotonergic radiotracers, such as [^{11}C]MDL100907 (Lundkvist et al. 1996), may help resolve this problem. For the study of 5-HT_{1A} receptors, ligands such as WAY-100635 appear promising (Pike et al. 1996). The radiotracer [^{11}C]5-hydroxytryptophan has been used to study the function of presynaptic serotonergic nerve terminals (Agren et al. 1991). The radiolabeled benzodiazepine antagonist [^{11}C]flumazenil has been used for quantitative study of benzodiazepine receptors (Frey et al. 1991).

Functional imaging may also be used to study the influence of drugs or neuropsychological tasks on the metabolic and neurochemical processes of the brain. The dynamic response to such challenges may be studied by measuring the regional metabolic rate (rCMRglc) or the regional blood flow (rCBF), as well as by measuring changes in receptor occupancy by means of endogenous ligands (Schlösser et al. 1996).

PET studies incorporating various neuropsychological tasks have enabled the construction of a map of the brain with regard to cognitive function, both in normal subjects and in various patient populations. The typical experimental design of a [^{15}O]H_2O study of regional blood flow involves several alternating epochs of baseline and activation scanning. Scans acquired at baseline and during activation are separately averaged, and a *t* test is performed at each volume element (voxel) to determine whether statistically significant regional activation has occurred. The *t* values are then color coded, and the resulting functional image can be superimposed on a corresponding anatomical image (MRI or CT).

In a further extension of this approach, the predicted response over the time of the activation study is used as a reference function. The observed activation in each voxel over time is correlated with the predicted response function, and the resulting correlation coefficients are displayed as a statistical map. Modern statistical approaches, such as statistical parametric mapping (SPM), involve statistical assessment of signal strength and of the spatial extent of activation, while appropriate corrections are made for multiple comparisons (Friston et al. 1991, 1996). Extensive reviews of the methodological aspects and findings of activation studies with PET and fMRI have been provided by Roland (1993) and by Frackowiak et al. (1997).

3.1.2 Imaging of Metabolism and Blood Flow

A few representative findings of PET studies will be discussed in this and the following section. The distinction between so-called baseline studies and studies performed under the influence of various pharmacologic and neuropsychological manipulations will be kept in mind.

In metabolic PET studies, cognitive tasks are often used to ensure a constant mental state during scanning (Buchsbaum et al. 1992a). The naturally occurring fluctuations of alertness and general mental state are eliminated by the specification of a given state (i.e., the state of performing the given task). Cognitive tasks used in this way serve a normalizing function rather than providing a specific activation of cognitive processes. They are, as a rule, not part of the object under study in such experiments and are applied not only during "activation" but also during the "baseline" component of the study. The term "baseline" should not, therefore, be considered synonymous with "resting state."

Schizophrenia

Many PET studies have been performed concerning the metabolic activity or regional blood flow of the frontal cortex of schizophrenic patients, but their results are, in part, inconsistent. A "hypofrontal" pattern was found by a number of investigators (e.g., Williamson 1987; Andreasen 1988; Buchsbaum et al. 1992a), but this finding could not be replicated by others (Gur and Gur 1995). It should be noted that these studies differ widely in their design, case selection, medication status of patients, and definition of the cerebral region of interest and are thus not easy to compare with one another.

In general, however, it seems unlikely that pharmacotherapy is the sole cause of hypofrontality, as PET studies have shown that drug-free or drug-naive patients also have reduced activity in the prefrontal cortex (Andreasen et al. 1997).

Hypofrontality also seems to be characteristic of chronically ill patients and patients with predominantly negative symptoms (Volkow et al. 1987). Further discoveries concerning metabolic abnormalities in psychotic patients were made with the aid of pharmacologic model substances, as will be discussed further below.

In a study of neuroleptic-naive patients, Andreasen et al. (1997) found a reduction of rCBF not only in the prefrontal cortex (lateral, orbital, and medial), but also in inferior temporal and parietal cortical areas.

This finding suggests that the neural basis for schizophrenia involves widespread dysfunction of cortical systems.

These and similar findings imply that an analysis of functional connectivity should be more profitable than mere isolated analysis of regional changes in rCBF and rCMRglc. The view gradually took hold that an alteration of the overall metabolic pattern, rather than locally restricted alterations, was likely to be the pathophysiological correlate of psychiatric diseases and subsyndromes. It was demonstrated, for example, that various subsyndromes of schizophrenia, including psychomotor slowing, disorganization, and reality distortion, could be distinguished by their characteristic metabolic patterns (Liddle et al. 1992).

As mentioned above, in studies involving the performance of a neuropsychological task, a defined state of activation is compared with the baseline state within a single experiment. It is assumed that the difference between the two states reflects the performance of a specific function by the brain, such as word-finding or working memory (Friston 1992). A word-finding task (i.e., a test of "verbal fluency") has been found to be associated with a comparable activation of the left prefrontal cortex (among other areas) in both schizophrenic and normal control subjects. The schizophrenics, however, did not have a reduction of blood flow in the left superior temporal cortex, as was found in the normal controls. According to the authors of this study, this finding indicates a disturbance of the functional connectivity between the frontal and temporal cortex of schizophrenic patients (Frith et al. 1995).

In addition to the various types of activation paradigm we have discussed, PET may also be used to study the patterns of activation associated with spontaneously occurring psychopathological symptoms. It has been shown, by means of an event-related study design, that active auditory hallucinations in schizophrenic patients are associated with an activation of the subcortical nuclei, limbic structures (particularly the hippocampus), and paralimbic regions as well as of the orbitofrontal cortex. These findings are consistent with the speculation that auditory hallucinations may be generated, or at least modulated, by deep-seated brain structures, while the specific content of a hallucination may depend on the particular neocortical region activated during it (Silbersweig et al. 1995).

Studies of alterations in cerebral metabolism caused by treatment with various neuroleptics have yielded partly inconsistent results. This may be due to differences in treatment regimens or other factors causing heterogeneity in the patient groups studied. The finding of elevated metabolic activity in the striatum during treatment with typical neuroleptics, such as haloperidol, has been replicated repeatedly (Volkow et al. 1986; Bartlett et al. 1991b; Holcomb et al. 1996).

An elevation of metabolic activity in the basal ganglia was also demonstrated after subchronic treatment with the atypical neuroleptic clozapine (Buchsbaum et al. 1992b). On the other hand, reduced neocortical activity, particularly in the frontal lobes, was found after treatment with haloperidol (Bartlett et al. 1991b; Holcomb et al. 1996). In a direct comparison of patients taking either fluphenazine or clozapine, both groups had a reduction of overall cortical glucose metabolism. The use of either medication resulted in a reduction of rCMRglc in the superior prefrontal cortex and an elevation of rCMRglc in the limbic cortex. Fluphenazine use simultaneously increased the rCMRglc subcortically and in the lateral portions of the temporal lobes, while clozapine use reduced metabolic activity in the inferior prefrontal cortex (Cohen et al. 1997).

These results suggest that typical and atypical neuroleptics exert their effects in overlapping brain areas. Both substance classes seem to be associated with an elevation of subcortical metabolism, particularly in the basal ganglia, and with varying degrees of reduction of neocortical metabolism, predominantly in the frontal lobes. With regard to treatment response, it has been shown that an increased metabolic rate in the right putamen and a decreased metabolic rate in the caudate nucleus are associated with clinical improvement after neuroleptic treatment (Buchsbaum et al. 1987). Responders to haloperidol treatment were found to have had a lower metabolic rate in the striatum before beginning treatment (Buchsbaum et al. 1992c); the same was found for patients responding to clozapine (Buchsbaum et al. 1992b). An acute haloperidol challenge was found to cause a significant drop in absolute glucose metabolism in cortical areas, thalamus, and cerebellum in schizophrenics who responded to neuroleptic treatment as compared to nonresponders. This finding implies that pharmacologic challenge paradigms might be used to predict the response to therapy (Bartlett et al. 1998).

The application of pharmacologic model substances is an innovative method for the study of cerebral metabolism and blood flow in schizophrenia and related psychotic disorders. It is well known that phencyclidine (PCP) and other *N*-methyl-D-aspartate (NMDA) antagonists may evoke symptoms resembling the positive and negative symptoms of schizophrenia in normal subjects. The PCP analogue ketamine, when given to normal subjects, was found to evoke mild psychotic symptoms that were accompanied by a focal increase of metabolic activity in the prefrontal cortex (Breier et al. 1997a).

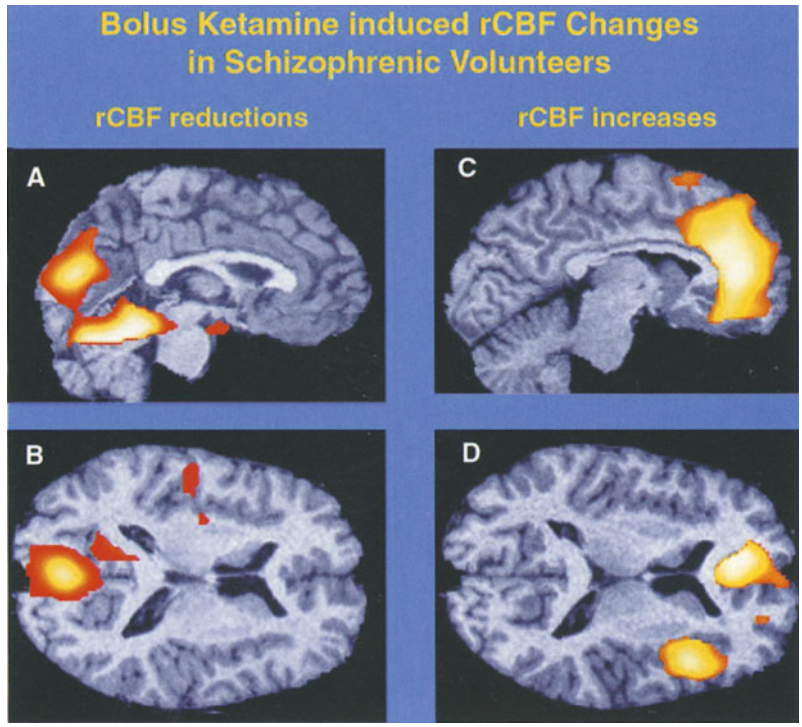

Fig. 1. Horizontal and sagittal images of the areas of significantly altered regional blood flow, as determined by $[^{15}O]H_2O$ positron emission tomography (PET), in five schizophrenic patients, before and 6 min after bolus administration of ketamine. **A,B** Enhanced regional cerebral blood flow (rCBF); **C,D** diminished rCBF. (After Lahti et al. 1995)

When given to schizophrenic patients, ketamine produced an activation of psychotic symptoms in tandem with a distinct pattern of alteration of rCBF, as determined by PET (Lahti et al. 1995). The results of $[^{15}O]H_2O$ PET scans of five schizophrenic patients before and 6 min after bolus administration of ketamine are shown in Fig. 1. Areas of significant change are color coded and superimposed on anatomical MRI images. As may be seen in these statistical parametric images, there is an enhancement of local rCBF in the anterior portion of the cingulate gyrus and in the inferomedial prefrontal cortex (A,B). In contrast, areas of diminished rCBF are shown (C,D); such areas are recognizable in the visual cortex and in the right hippocampus. These findings support the conclusion that the prefrontal cortex and limbic structures participate in the generation of NMDA receptor-mediated psychotic states.

The effect of the hallucinogen psilocybin, a 5-HT_2 and 5-HT_1 agonist, on regional glucose metabolism was studied in normal subjects using $[^{18}F]$FDG-PET. The findings are shown in Fig. 2 (color coded). The regional metabolic rate for glucose is shown under baseline conditions (*left*) and after a psilocybin challenge (*right*). Oral administration of psilocybin led to a global increase in rCMRglc that was most pronounced in the medial frontal (FRM), lateral frontal (FRL), and medial temporal cortex (TEMPORAL) and in the anterior portion of the cingulate gyrus (CGA). Subcortical structures, including the caudate nucleus, putamen, and thalamus, had a smaller increase in rCMRglc than the cortical areas mentioned.

These findings show that excessive activation of 5-HT receptors leads to a hyperfrontal metabolic pattern that is clearly distinct from the hypofrontality described in schizophrenic patients. The severity of the psilocybin-induced psychotic symptoms in normal subjects was correlated with the extent of the metabolic alteration (Vollenweider et al. 1997).

The studies cited regarding ketamine and psilocybin provide evidence that acute psychotic states are associated with a transient hyperfrontal metabolic pattern. In contrast, a hypofrontal pattern is described in schizophrenics.

The modulating effect of dopaminergic, serotonergic, and cholinergic pharmacological challenges on cognitive brain activation was investigated in a series of studies. Significant results were found in studies involving a combination of pharmacological and neuropsychological interventions. The effect of the muscarinic cholinergic antagonist scopolamine on CBF was studied by $[^{15}O]H_2O$-PET in normal subjects during performance of a memory task. The application of scopolamine was found to result in a widespread diminution of activation in the prefrontal cortex bilaterally as well as in the anterior cingulate region (Grasby et al. 1995).

Drug-naive schizophrenic patients were studied with $[^{15}O]H_2O$-PET before and after administration of the dopamine agonist apomorphine in conjunction with a

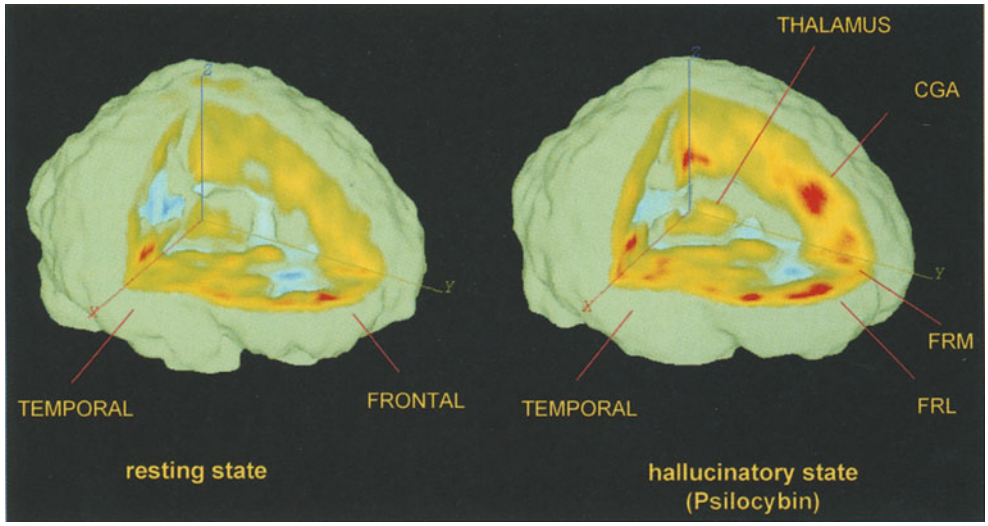

Fig. 2. Fluorodeoxyglucose ([^{18}F]FDG) positron emission tomography (PET) images under baseline conditions (*left*) and after psilocybin challenge (*right*). *CGA*, cingulate gyrus; *FRM*, medial frontal cortex; *FRL*, lateral frontal cortex. (After Vollenweider et al. 1997)

word-finding task. When no drug was given, schizophrenics had a relative reduction of activation of the anterior portion of the cingulate gyrus as compared to the normal controls. After the administration of apomorphine, however, the patient group showed an increased activation of the anterior portion of the cingulate gyrus that was, in fact, more pronounced than that of the normal controls (Dolan et al. 1995). These findings suggest that faulty dopaminergic regulation in the anterior portion of the cingulate gyrus is a feature of schizophrenia.

Affective Disorders

Baseline studies with [^{18}F]FDG- or [^{15}O]H_2O-PET in affective disorders revealed a reduction in either rCMRglc or rCBF in the inferior and superior frontal as well as the temporal and parietal cortex (Baxter et al. 1989; Hurwitz et al. 1990; Martinot et al. 1990; Bench et al. 1992; Drevets et al. 1992). There is increasing evidence for involvement of the anterior portion of the cingulate gyrus in depression. Decreased rCBF in this area was found in a direct comparison of depressed and normal subjects (Bench et al. 1993). Mayberg et al. (1997) found that the rCMRglc in the anterior portion of the cingulate gyrus of depressed patients differed in responders and nonresponders to antidepressant therapy: this area was hypometabolic in nonresponders, but hypermetabolic in responders. This finding is illustrated in color-coded fashion in Fig. 3.

A study of patients with bipolar and unipolar depression and a positive family history revealed a reduction in rCBF in the prefrontal cortex ventral to the genu of the corpus callosum. Lower CBF was, however, partly accounted for by a diminution of the volume of this area, which was revealed by an MRI study performed in parallel (Drevets et al. 1997).

In an [^{18}F]FDG study, administration of the serotonin releaser and reuptake inhibitor fenfluramine to

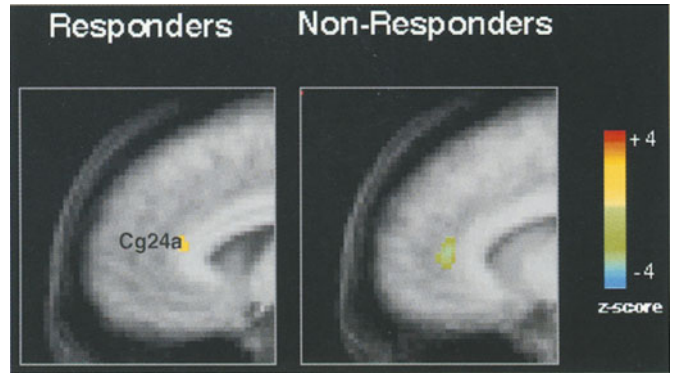

Fig. 3. Fluorodeoxyglucose ([^{18}F]FDG) positron emission tomography (PET). Statistical representation of differences in glucose metabolism in the rostral portion of the cingulate gyrus (Brodmann area 24a) in depressed patients who responded (*left*) or did not respond (*right*) to treatment with an antidepressant. (After Mayberg et al. 1997)

normal subjects caused a significant increase in rCMRglc, particularly in the left frontal and temporoparietal cortex, while rCMRglc was diminished in the right prefrontal cortex and elsewhere. In contrast, depressed patients showed no significant changes after fenfluramine administration, and their response pattern thus resembled that of normal subjects without a pharmacological challenge (Mann et al. 1996). This result supports the hypothesis of reduced serotonergic transmission in depression.

The induction of a sad mood brought about an increase in rCBF in the inferior orbitofrontal cortex of normal subjects (Pardo et al. 1993). The same result was found in another study regardless of whether a depressed or an elevated mood had been induced (Baker et al. 1997). In general, it may be concluded that higher-order functional neural networks responsible for the processing of emotional information are predominantly located in the anterior portion of the cingulate area and in the inferior frontal gyri (George et al. 1993). Activation during a word-finding task was diminished by either an elevated or a depressed mood throughout the left prefrontal, premotor, and cingulate cortex and in the thalamus, in association with an impairment of cognitive performance (Baker et al. 1997). This suggests that cognitive ability is linked to mood; indeed, cognitive distortion during depressive episodes is frequently observed in clinical practice. In sum, studies of normal subjects have yielded valuable information about the anatomical and functional substrates of emotional stimuli. The studies cited here provide a basis for further research in this area.

PET has also been used to study the effects of antidepressants on cerebral metabolism. Ten weeks of treatment with sertraline, a selective serotonin reuptake inhibitor (SSRI), led to increased activity in the middle frontal gyrus. In drug-naive depressed patients, this region exhibited reduced activity in comparison to temporal and some occipital areas. Other areas whose activity differed between depressed and control subjects (including the medial portion of the frontal lobe, the cingulate gyrus, and the thalamus) displayed a normalization of metabolism after sertraline treatment (Buchsbaum et al. 1997). These findings suggest that antidepressant therapy can reverse a depression-related reduction in cerebral metabolism.

Anxiety Disorders and Obsessive-Compulsive Disorder

In a PET study of patients with generalized anxiety disorder required to perform an active viewing task, the administration of benzodiazepines resulted in diffuse reduction of the absolute metabolic rate in cortical regions, the limbic system, and the basal ganglia (Wu et al. 1991). Nonetheless, this did not represent a normalization of the rCMRglc pattern present before benzodiazepine administration. The clinical effectiveness of benzodiazepines seems not to be associated with complete normalization of pathologically altered cerebral metabolism.

Baxter et al. (1987) carried out extensive studies of metabolic alterations in OCD patients before and after treatment. Two studies of untreated OCD patients revealed a significant elevation of glucose metabolism in the cerebral hemispheres, the heads of the caudate nuclei, and the orbital gyri in comparison to normal subjects. Responders to either pharmacotherapy or behavioral therapy were found to have a diminished rCMRglc in the head of the caudate nucleus relative to the ipsilateral hemisphere (Baxter et al. 1992). In another study, OCD patients had a significantly elevated rCMRglc compared to normal subjects in the cingulate gyrus, thalamus, and lentiform nucleus (putamen–pallidum complex). Improvement of OCD symptoms by SSRI treatment was associated with a significant reduction in rCMRglc in the cingulate gyrus (Perani et al. 1995). In summary, OCD is associated with a hyperactivity of specific neural circuits, which may be modulated or normalized by successful pharmacologic or behavioral therapy.

A number of symptom-provocation paradigms have been used to study anxiety disorders. While initial studies of patients with simple phobia revealed no association of induced anxiety with measured changes in rCBF (Mountz et al. 1989), later studies clearly showed that rCBF alters with anxiety: patients with simple phobia in whom phobic symptoms had been induced had significant elevations of rCBF in the anterior cingulate gyrus, the insula, the anterior temporal, postcentral, and orbitofrontal cortex, and the thalamus as compared with the nonanxious control state (Rauch et al. 1995). These findings indicate that paralimbic structures participate in the pathogenesis of simple phobia.

The amygdala seems to play an important role in the processing of emotional, anxiety-arousing information. The visual processing of anxious facial expressions by normal subjects is associated with significant activation of the amygdala (George et al. 1993).

The recall of traumatic events by patients with posttraumatic stress disorder has been reported to be associated with an elevation of rCBF (compared to the symptom-free control state) in right-sided limbic and paralimbic areas as well as in visual areas (Rauch et al. 1996).

Dementia

Alzheimer's disease and the associated neuropsychological deficits have been the subject of intensive study using PET. Imaging studies of brain metabolism in Alzheimer's disease consistently show a reduction in neocortical metabolism, particularly in the prefrontal, temporal, and parietal association cortex (Frackowiak

1989; Smith et al. 1992). Except in the early stages of the disease, both hemispheres are usually involved, though sometimes asymmetrically. The severity of dementia is primarily correlated with the extent of reduction of the temporoparietal rCMRglc (Herholz 1995).

In contrast, the typical pattern of altered glucose metabolism in vascular dementia consists of scattered focal cortical and subcortical areas of hypometabolism (Mielke et al. 1996). Functional imaging, like structural imaging, leaves a residual uncertainty in the differential diagnosis of Alzheimer's disease from vascular and other types of dementia (Tedeschi et al. 1995; Brooks 1996).

Three months of treatment with the cholinesterase inhibitor tacrine were shown, in a PET study, to result in an increase in rCMRglc (Nordberg et al. 1992).

The modulation of cholinergic transmitter systems in patients with Alzheimer's disease leads to altered performance on memory tasks, including those involving working memory. Physostigmine, a short-acting cholinesterase inhibitor, was found to improve performance of a working memory task while simultaneously reducing rCBF in the right middle frontal gyrus, an area thought to be involved in working memory. The authors of this study propose, as an explanation of this finding, that enhancement of cholinergic transmission may improve the efficiency of working memory and thereby reduce the effort required to perform a given task (Furey et al. 1997).

3.1.3 *Imaging of Specific Neurotransmitter Systems*

Studies of Drug-Binding Sites

In studies of the receptor binding profile of neuroleptic agents, PET is used to measure the displacement of a receptor-specific radioligand by the applied, nonlabeled drug. With the aid of this technique, it was found that a normally effective dose of a typical neuroleptic (such as 2–6 mg haloperidol) results in a 65%–89% occupancy of putaminal D_2 receptors (Farde et al. 1989). This finding implies that a high-dose treatment strategy would not be expected to increase receptor occupancy significantly.

PET studies of the atypical neuroleptic clozapine revealed a significantly lower D_2 receptor occupancy than with typical neuroleptics (Farde et al. 1992). However, even at relatively low doses of clozapine (125–250 mg/day), more than 80% of the 5-HT_2 receptors were found to be occupied. This finding supports the hypothesis that the atypical clinical effects of clozapine are largely produced by 5-HT_2 receptor antagonism (Nordström et al. 1993). A relatively high 5-HT_2 receptor occupancy has also been found for other atypical neuroleptics and seems to be a characteristic property of these agents. For example, a PET study using the radiolabeled 5-HT_2 ligand [^{18}F]setoperone in normal subjects showed that ziprasidone, an atypical neuroleptic, is a highly potent blocker of 5-HT_2 receptors (Fischman et al. 1996). Seven hours after normal subjects received a single dose of olanzapine, the D_2 receptor occupancy was 59%–63%, and, after 9.5 h, the 5-HT_2 receptor occupancy was 74%–92% (Nyberg et al. 1997).

The preclinical and clinical evaluation of the pharmacokinetic and pharmacodynamic properties of new drugs will certainly be an important future application of PET in psychiatry.

Schizophrenia

When D_2 receptor ligands became available for use in PET studies, scientific attention focused on the question of specific differences in receptor density (B_{max}) and affinity (K_D) among patients with different neuropsychiatric disorders. Initial studies in untreated schizophrenics yielded inconsistent findings. Wong and colleagues at Johns Hopkins repeatedly reported an increased density (B_{max}) of D_2 receptors in these patients compared with normal controls (Wong et al. 1986c; Tune et al. 1993).

These findings could not be replicated, however, by Farde and colleagues (1987) of the Karolinska Institute or by other groups, and the excitement they had initially aroused was considerably dulled. A number of possible explanations for these discrepant findings were subsequently discussed (Andreasen et al. 1988).

In their initial studies, the Karolinska group used [^{11}C]raclopride, a highly specific substituted benzamide, as the radioligand for the D_2 receptor. [^{11}C]Raclopride competes with endogenous dopamine for postsynaptic D_2 receptor sites (Wong et al. 1986a,b; Seeman et al. 1989), while [^{11}C]NMSP is less sensitive to the influence of endogenous dopamine (L.T. Young et al. 1991; Volkow et al. 1994).

A further difference between these two ligands, demonstrated by an in vitro study, is that [^{11}C]NMSP has a higher affinity for D_4 dopaminergic receptors than [^{11}C]raclopride. An autopsy study of the brains of schizophrenic patients revealed increased D_4 receptor density (Seeman et al. 1993). Ligand differences could thus at least partly account for the conflicting results of the PET studies.

Unfortunately, however, the reported differences in receptor density between schizophrenic patients and normal controls could not be replicated even in a study (Nordström et al. 1995) using the same radioligand that had been used in the original study by Wong et al. (1986c), i.e., [^{11}C]NMSP. Likewise, no quantitative alteration of striatal D_2 receptor density was found in studies using the ligands [^{76}Br]bromospiperone (Maziere et al. 1985) and [^{76}Br]bromolisuride (Martinot et al. 1991).

The effort to find an alteration of receptor density in schizophrenic patients tended to obscure other issues, as receptor density is merely one aspect of neurochemical regulatory processes. In view of the physiological ability of neurochemical processes to adapt to internal and external stimuli, B_{max} and K_D are probably variable both in normal individuals as in patients. Alterations in these parameters seem to reflect the general adaptive capability of the system rather than any specific pathophysiologic process.

In a recent PET study of normal subjects using [^{11}C]raclopride, a statistically significant interindividual variation was found in B_{max}, but not in K_D (Farde et al. 1995). This finding supports the hypothesis of interindividual variability of dopaminergic tone.

Other PET studies using [^{11}C]raclopride have demonstrated both short- and long-term stability of D_2 receptor binding parameters in individual subjects (Volkow et al. 1993; Schlösser et al. 1998a). This stability is, however, limited by effects of aging, which have been described for numerous pre- and postsynaptic binding and reuptake sites (Wang et al. 1996).

It has been consistently shown that [^{11}C]raclopride PET is sufficiently sensitive to detect changes in endogenous dopamine resulting from pharmacological intervention. Amphetamine, for example, has been found to lower the binding potential of [^{11}C]raclopride, presumably because of increased release of endogenous dopamine.

A clinical study using this activation paradigm revealed that amphetamine induces a significantly greater reduction of specific striatal [^{11}C]raclopride binding in schizophrenic patients than in normal control subjects (Breier et al. 1997b). Similar findings had been obtained earlier in a SPECT study with [^{123}I]iodobenzamide (IBZM) based on a similar amphetamine challenge paradigm (Laruelle et al. 1996).

These data provided the first direct, in vivo confirmation of the hypothesis of an amphetamine-induced elevation of synaptic dopamine concentration in schizophrenia. They further imply a dopaminergic hyperresponsivity in schizophrenics as compared to normal controls.

After more than a decade of PET studies using specific radiotracers for different neurotransmitter systems, the interactions of these systems are now drawing more attention. Earlier studies of this topic were performed on nonhuman primates (Dewey et al. 1992, 1993). A pharmacological study in healthy men revealed a significant reduction in specific striatal [^{11}C]raclopride binding after the acute administration of fenfluramine, a serotonin releaser and reuptake inhibitor. This finding confirms that serotonin stimulates the dopaminergic system and elevates the intrasynaptic dopamine concentration (Smith et al. 1997).

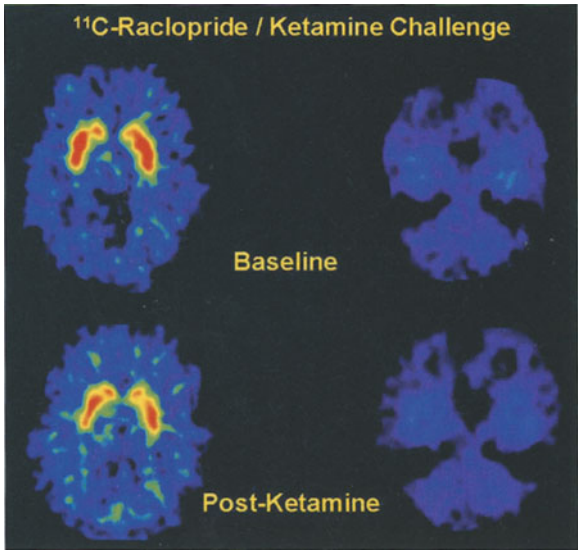

Fig. 4. ^{11}C-raclopride positron emission tomography (PET) images of a normal subject before (*top*) and after (*bottom*) the intravenous administration of ketamine. (After Smith et al. 1998)

The glutamatergic–dopaminergic axis was studied in an analogous fashion after acute administration of the NMDA antagonist ketamine. In Fig. 4, representative [^{11}C]raclopride PET images of a normal subject before and after the acute administration of ketamine are shown. The observed bilateral reduction of [^{11}C]raclopride binding in the basal ganglia is the result of increased release of endogenous dopamine (Smith et al. 1998).

This finding may be relevant to the pathophysiology of the psychotomimetic activity of ketamine, which may be mediated by transient alterations in the dopaminergic system. Future study designs will extend these paradigms to the patient population and thereby enable the investigation of neurotransmitter interactions in various diseases and forms of treatment.

Aside from the controversial discussion of D_2 receptor changes in schizophrenia, other receptor systems, too, have been the target of specific radiotracer binding studies. A study with the D_1 receptor ligand [^{11}C]Sch23390 revealed no difference in striatal binding between schizophrenic patients and normal controls. In the prefrontal cortex, however, ligand binding to D_1 receptors was reduced in schizophrenic patients as compared to the controls. The extent of this reduction was correlated with the severity of negative symptoms and with impairment of performance on the Wisconsin Card Sorting Test, which is used to assess deficits of frontal and other related brain functions. The authors of this study suggest that dysfunction of the D_1 receptor system in

the prefrontal cortex may contribute to the negative symptoms and cognitive deficits seen in schizophrenia (Okubo et al. 1997).

Presynaptic dopaminergic function is another focus of interest in schizophrenia research. Initial studies with [^{18}F]fluorodopa demonstrated a higher fluorodopa influx constant (K_i) in the caudate nucleus of schizophrenic patients than in normal controls (Hietala et al. 1995). In a more recent study, however, K_i did not differ significantly between schizophrenics and controls (Dao-Castellana et al. 1997). The latter study did reveal a higher variability of [^{18}F]fluorodopa uptake values among schizophrenics, which suggests a heterogeneity of presynaptic dopaminergic functional states in schizophrenia.

Affective Disorders

PET neurotransmitter studies have yielded less consistent results for the affective disorders than for schizophrenia, partly because suitable radiotracers for the relevant neurotransmitter systems are lacking. [^{11}C]NMSP, [^{18}F]setoperone, and [^{18}F]altanserine, among other compounds, have been used as 5-HT$_2$ ligands, but their low specificity limited their value for PET studies. In a group of depressed patients studied with [^{18}F]altanserine PET, a significantly lower uptake of the tracer was found, especially in the posterolateral orbitofrontal cortex and the anterior portion of the right insula. There was, however, no correlation between the extent of tracer uptake and the severity of depression (Biver et al. 1997).

As for presynaptic aspects of neurotransmitter systems in depression, a study of patients with unipolar depression revealed a diminished uptake of [^{11}C]5-HT and [^{11}C]L-dopa across the blood–brain barrier. Increased utilization of [^{11}C]5-HT, but not of [^{11}C]L-dopa, was detected in the inferior portion of the medial prefrontal cortex, particularly on the left side. The authors of this study interpret these findings as a reflection of increased serotonin synthesis in this area, possibly as a local compensatory mechanism in the context of a generalized serotonergic hypometabolism (Agren and Reibring 1994).

Dementia

Patients with Alzheimer's disease were found to have a decreased density of nicotinic acetylcholine receptors in a PET study using the radiotracer [^{11}C]nicotine (Nordberg et al. 1990). This finding confirms previous observations from autopsy studies. As for the dopaminergic system, a significant correlation was found between cognitive performance, as measured by the Mini-Mental Status Test, and uptake values (K_i) of [^{18}F]fluorodopa. The last result implies that progression of Alzheimer's disease is associated with increasing impairment of dopaminergic metabolism (Itoh et al. 1994).

The question of whether regional specific decreases in cerebral metabolism in Alzheimer's disease are due to local neuron loss or to a decrease in synaptic activity was addressed by a study of the accumulation of [^{11}C]methionine in protein structure in vivo. No significant decrease was found in the incorporation of [^{11}C]methionine into protein in the temporoparietal and frontal cortex. In the same group of patients, [^{18}F]FDG-PET revealed a 45% decrease in temporoparietal glucose metabolism. It thus seems that decreased synaptic activity plays a larger role than neuron loss in explaining the decrease in cerebral metabolism.

It was demonstrated in one study that treatment with the cholinesterase inhibitor tacrine led to increased uptake of [^{11}C]nicotine into brain tissue, which implies that cholinesterase inhibitor treatment can restore nicotinic cholinergic function. This finding was accompanied by an increase in the local rCMRglc as well as by an improvement in neuropsychological performance parameters (Nordberg et al. 1992, 1997).

In summary, the findings of specific neurotransmitter studies imply that different functional systems may be involved in the pathogenesis of Alzheimer's disease. Further, it seems that a specific pharmacotherapeutic intervention may partially restore both the impaired cholinergic transmission and the reduced cerebral metabolism of this disease.

3.2 Single Photon Emission Computed Tomography

3.2.1 Technical Principles

SPECT is based on the use of proton-rich radionuclides that have the ability to capture an electron, whereupon one of their protons is transformed into a neutron. The daughter nucleus generated by this process then decays further and emits a single photon (i.e., a particle of light or, in equivalent terms, a packet of gamma radiation). The gamma radiation emitted by the commonly used isotopes ^{99m}Tc and ^{123}I is sufficiently intense to traverse the body for external detection.

A collimator is positioned between the radiation source and the scintillation detectors so that only photons with parallel trajectories can reach the detectors. These detectors are either arrayed in several detector heads that rotate around the patient or else directly integrated into a ring detector. After the amount of radiation in many individual trajectories is measured, the distribution of the radiotracer can be calculated with suitable mathematical algorithms. Intra-arterially injected or inhaled ^{133}Xe was used as a radiotracer in many earlier studies, in which fixed

external radiation detectors were used. The spatial resolution of this technique was relatively poor, and low-lying areas of the brain could not be studied with it. The development of rotating gamma cameras was a major technical improvement. Currently available SPECT scanners provide a spatial resolution of 6–8 mm.

SPECT has the major advantage of not requiring a cyclotron at the site of the scanner, which spares the attendant costs of cyclotron installation and maintenance and of on-site radiochemistry. SPECT cameras are therefore in more widespread clinical use than PET systems. The tracers used in SPECT have relatively long half-lives and may thus be delivered from the site of synthesis to the SPECT scanner site, as is usually done with ^{123}I, if they are not synthesized at the scanner site itself, as is usually done with ^{99m}Tc.

Despite the progressive improvement of both the spatial resolution and the sensitivity of scanner systems, absolute quantification with SPECT remains problematic. A number of factors limit the sensitivity of the method. The photons relevant to SPECT possess a lower energy (80–160 keV) than those detected in PET (511 keV) and are thus more subject to attenuation, and the collimator eliminates a large number of photons. Because only a single photon is emitted, coincidence detection (as in PET) has no application to SPECT, which further limits its spatial resolution. The problems of correcting for scattering and attenuation, too, have been only partially solved to date.

One of the most commonly used radioligands for SPECT studies of rCBF and presynaptic metabolic activity is ^{99m}Tc-hexamethyl propyleneamine oxime (HMPAO). This tracer rapidly crosses the blood–brain barrier, is then transformed into a hydrophilic metabolite, and enters the cells. The tracer remains stable intracellularly for several hours, so that scanning may take place at any time within several hours after the injection.

A number of specific SPECT tracers are available for different neurotransmitter systems for both pre- and postsynaptic sites of transmitter activity. Some of the more important ligands are [^{123}I]IBZM for D_2 and D_3 receptors, [^{123}I]iomazenil for the benzodiazepine receptor, and [^{123}I]β-CIT for the serotonin, dopamine, and noradrenaline transporter (Bartenstein and Koepp 1995; Schlösser and Schlegel 1995; Schlösser et al. 1997). Two other ligands for the D_2 receptor are [^{123}I]IBF and [^{123}I]epidepride. The latter has markedly higher affinity for striatal D_2 receptors than [^{123}I]IBZM (Kornhuber et al. 1995) and is therefore not suitable for challenge studies in which the ligand competes for receptor sites with the endogenous neurotransmitter. Nonetheless, its higher affinity makes [^{123}I]epidepride suitable for the study of extrastriatal D_2 receptors (Kuikka et al. 1997).

Because absolute quantification was hardly possible until recently, semiquantitative methods were developed that were sufficient for many research questions. The so-called ratio approach and the analysis of radiotracer uptake and washout curves were the most commonly used methods for semiquantitative determination of the receptor binding parameters B_{max} and K_D.

In the ratio approach, the uptake of a radiotracer in a receptor-rich target region is compared with its uptake in a reference region that, ideally, contains no, or negligibly few, receptors of the type under study. In the case of [^{123}I]IBZM, the striatum is the target region and the cerebellum or specific cortical regions are used as the reference region. The striatal-to-cerebellar uptake ratio provides a means of estimating the occupancy of striatal D_2 receptors. The receptor occupancy by a drug is calculated from the change in this ratio before and after its administration.

By studying uptake and washout curves, the time to maximum uptake, and the washout rate, after the administration of a drug can be determined and the values of these parameters can be compared to those obtained without the drug. Continuous infusion of the radiotracer at a constant rate by means of a suitable perfusion device has been used successfully to maintain stable levels of striatal and occipital activity (Laruelle et al. 1994). The main advantage of the continuous infusion method is the reduction of variability in cortical uptake due to alterations in blood flow.

3.2.2 *Imaging of Blood Flow*

A number of research questions have been addressed in comparable ways with both PET and SPECT. To avoid redundancy, we shall largely confine the following discussion to results that were not already mentioned in the section above on PET.

Schizophrenia

Despite the technical limitations discussed above, the ^{133}Xe method allowed fundamental observations to be made concerning cortical activation during normal and pathologically altered states of cerebral function. Ingvar and Franzen (1974), using this method, made the important discovery that frontal cortical blood flow is relatively reduced in schizophrenic patients; the shorthand term "hypofrontality" expresses this finding. It was later found, again using the ^{133}Xe method, that schizophrenic patients who performed poorly on the Wisconsin Card Sorting Test had a lower degree of activation in the dorsolateral prefrontal cortex (DLPFC) than normal control subjects (Weinberger et al. 1986). A similar finding of deficient frontal activation in schizophrenics was made in a SPECT

study involving the Tower of London task (Andreasen et al. 1992). The tasks used in these two studies both rely on an intact working memory, and the observed results are in accord with the reported impairment of working memory in schizophrenia.

A ^{99m}Tc-HMPAO-SPECT study of untreated patients with acute schizophrenia revealed patterns of both hyper- and hypoperfusion, depending on the predominant form of psychopathology. Scores on a rating scale for formal thought disorders and grandiosity were positively correlated with bifrontal and bitemporal rCBF, while scores for delusional ideas, hallucinations, and suspiciousness were negatively correlated with rCBF in bifrontal and left temporal cortex as well as in the cingulate gyrus and the left thalamus. Stereotyped ideas were negatively correlated with left frontal, temporal, and parietal rCBF (Sabri et al. 1997).

Affective Disorders

^{99m}Tc-HMPAO-SPECT studies support the hypothesis of diminished metabolic activity in the frontal, temporal, and parietal cortex in depression. The severity of depressive symptoms was negatively correlated with regional uptake parameters (Schlegel et al. 1989a). Although a direct comparison is difficult because of differences in data acquisition and analysis, the results of the ^{99m}Tc-HMPAO-SPECT studies generally agree with those of the PET studies.

Anxiety Disorders

SPECT has been used successfully to study alterations of regional cerebral blood flow in various anxiety disorders. The results confirm and complement those obtained in PET studies.

It was shown, with use of the ^{133}Xe inhalation method, that patients with panic disorder have either a mild increase or a decrease in hemispheric blood flow after the induction of a panic attack by lactate infusion. In contrast, lactate infusion resulted in a significant increase in hemispheric blood flow both in normal control subjects and in patients with panic disorder who did not experience a panic attack after the infusion (Stewart et al. 1988).

In OCD patients, too, ^{99m}Tc-HMPAO-SPECT has revealed a hyperfrontal metabolic pattern. Treatment with the SSRI fluoxetine reversed this hypofrontality, while (despite contrasting PET findings) the metabolic rate in the basal ganglia was unchanged (Hoehn-Saric et al. 1991).

Dementia

^{99m}Tc-HMPAO-SPECT studies of Alzheimer's disease quite consistently reveal a temporoparietal perfusion deficit (Lang et al. 1990). Data on sensitivity and specificity make clear that the discriminating ability of SPECT improves with increasing severity of dementia. Alzheimer's disease could be diagnosed with 90% specificity on the basis of the SPECT perfusion pattern, while the sensitivity of SPECT varied from 42% to 79% depending on the severity of the disease (Claus et al. 1994). Modern pattern recognition algorithms, e.g., with the aid of artificial neural networks, seem to be superior to classical statistical approaches in the analysis of perfusion patterns of patients with Alzheimer's disease (Page et al. 1996).

Vascular dementia and the so-called pseudodementia of depression are important alternative diagnoses to Alzheimer-type dementia. The temporoparietal hypoperfusion pattern revealed by SPECT scan in most patients with Alzheimer's disease (discussed above) was also seen in other types of dementia and thus cannot be regarded as specific for Alzheimer's disease (Masterman et al. 1997). Patients with vascular dementia, however, often had a higher uptake in anterior parietal regions than patients with Alzheimer's disease.

Patients with relatively higher posterior temporal perfusion and frontal reduction in rCBF or rCMRglc may reportedly be more likely to suffer from depressive pseudodementia than from Alzheimer's disease (Curran et al. 1993). Once again, it must be emphasized that SPECT and PET do not currently provide a reliable diagnosis in individual cases, because there is considerable overlap between groups.

3.2.3 Imaging of Specific Neurotransmitter Systems

Schizophrenia

Like the D_2 receptor ligands used in PET studies, [^{123}I]IBZM competes with endogenous dopamine for binding to the postsynaptic D_2 receptor. An acute challenge with the dopamine releaser amphetamine caused a significantly greater increase in the [^{123}I]IBZM binding potential in schizophrenic patients than in normal controls, presumably because more endogenous dopamine was released in schizophrenic patients. There was simultaneous development of psychotic positive symptoms. These findings, depicted in Fig. 5, suggest that schizophrenic patients are more sensitive to the dopamine-releasing effect of amphetamine, which in turn may be due to a pathologically altered responsiveness of dopaminergic neurons in this disease (Laruelle et al. 1996).

Central benzodiazepine receptors were studied in schizophrenic patients with the aid of the benzodiazepine receptor ligand [^{123}I]iomazenil. No overall differences in benzodiazepine receptor binding were found between schizophrenic patients and normal control subjects. There were, however, significant correlations between the severity of schizophrenic symptoms and [^{123}I]iomazenil binding in the limbic cortex: positive symptoms were negatively correlated with benzodiazepine receptor binding in the left

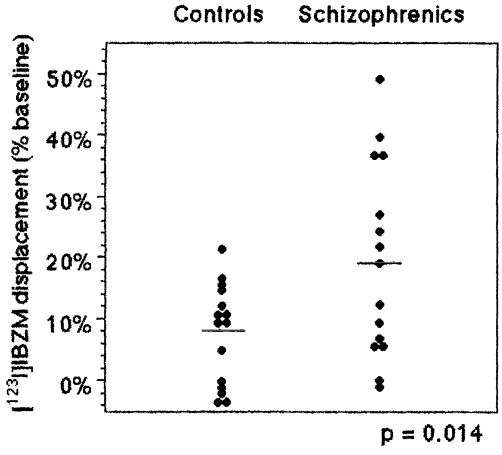

Fig. 5. Relative decrease in striatal [^{123}I]iodobenzamide (IBZM) binding after the acute administration of amphetamine to schizophrenic patients and control subjects, expressed as a percentage of the initial value. (After Laruelle et al. 1996)

medial temporal cortex, while negative symptoms were inversely related to benzodiazepine receptor binding in medial frontal areas. These results suggest that a reduction in inhibitory GABAergic tone contributes to the generation of schizophrenic symptoms (Busatto et al. 1997b).

Affective Disorders

Depressive patients were shown to have a diminished uptake of the 5-HT_2 antagonist [^{123}I]ketanserin in the parietal cortex, as well as a lateral asymmetry favoring the right side in the inferior frontal area, in comparison to normal controls. This finding suggests that alterations in the 5-HT_2 receptor system may play a role in the pathogenesis of depression (D'haenen et al. 1992).

Anxiety Disorders

Patients with panic disorder were found to have a lower [^{123}I]iomazenil uptake in frontal, occipital, and temporal cortex than patients with epilepsy (Schlegel et al. 1994). Another study of patients with panic disorder revealed an elevated right-to-left ratio of the uptake of the benzodiazepine receptor ligand in the middle and inferior frontal gyri (Kuikka et al. 1995).

The results described up to this point were obtained with the aid of semiquantitative techniques for the determination of [^{123}I]iomazenil uptake and thus might conceivably be due to alterations in rCBF rather than to specific benzodiazepine receptor effects. A study by Kaschka et al. (1995) provided evidence that this is so, to some extent. On the assumption that iomazenil uptake values 10 min after tracer injection largely represent perfusion-related effects, while the values after 90 min reflect specific ligand binding properties, the ratio of uptake values at these two times was used to correct semiquantitatively for perfusion-related tracer uptake. Even after this correction was made, patients with panic disorder were still found to have a hypoactivity in the left lateral temporal cortex.

Dementia

Patients clinically judged to have probable mild Alzheimer's disease were found to have reduced binding of the muscarinic acetylcholine receptor ligand [^{123}I]4-iododexetimide in temporal and temporoparietal cortical areas (Claus et al. 1997). This finding implies that the density of muscarinic acetylcholine receptors in these areas is decreased.

Chronic administration of scopolamine resulted in an increased uptake of the muscarinic acetylcholine receptor ligand [^{123}I]QNB in patients with Alzheimer's disease, but a decreased uptake of the same ligand in a control group of nondemented elderly subjects. Patients with Alzheimer's disease thus seem to be especially sensitive to chronic cholinergic blockade (Sunderland et al. 1995).

3.3 Functional Magnetic Resonance Imaging

3.3.1 Technical Principles

In recent years, fMRI has played an increasingly large role in the study of regional blood flow and neural activity. Focal changes in neural activity lead to focal changes in perfusion, blood oxygenation, and metabolism. The technique of fMRI exploits these changes to study brain activation during the performance of behavioral or neuropsychological tasks. The noninvasiveness of the technique, the absence of radiation exposure, and the ability to perform studies on widely available clinical scanners all contribute to the growing popularity of fMRI

Most fMRI studies at present use a method known as blood oxygenation level-dependent (BOLD) contrast. Perfusion studies have revealed that cerebral activation induces a local increase in oxygen delivery that actually exceeds the local metabolic demand (Fox and Raichle 1986). Increased oxygenation leads to a higher concentration of diamagnetic oxyhemoglobin and to a lower concentration of paramagnetic deoxyhemoglobin in the activated area. As a result, field inhomogeneity is decreased, and the local T_2*-weighted MR signal becomes stronger.

Rapid imaging sequences are favored because they enable high temporal resolution and reduction of motion artifact. The principle underlying echo-planar imaging (EPI) is that all of the desired information in the spatial frequency domain can be measured after a single RF pulse. The advantages of EPI include high

speed of acquisition (times as short as 50 ms) and high signal-to-noise ratio. The best spatial resolution that can be achieved at present with EPI using BOLD contrast is on the order of 1 × 1 mm in plane, with a slice thickness of 3 mm. The technical quality of such images is steadily improving as new scanners are being developed.

Multislice EPI fMRI of the whole brain with good spatial resolution can be performed in a few seconds. The signal-to-noise ratio can be improved further by the use of magnets stronger than 1.5 T. Scanners incorporating such strong magnets are not yet in widespread use. Further technical problems limiting the applicability of fMRI in clinical studies include field inhomogeneity and temperature gradients, which are increasingly troublesome as the field strength increases.

Fast fMRI techniques enable single images to be acquired practically as snapshots, in which motion artifact is not a significant problem. Nonetheless, there is still an artifact arising from movement in between image acquisitions, and technical measures are still necessary to limit the size of this artifact. Physical head immobilizers, such as head-holders, are used as well as computer algorithms that correct for movement (Woods et al. 1992).

Not only motion artifact, but also physiological artifacts – arising from respiration, heartbeats, and cerebral pulsations, among other sources – must be taken into account in the interpretation of fMRI data. There is as yet no fully satisfactory solution to the problem of signals arising from blood flow in large vessels such as cerebral veins. Microvascular changes related to neural activity occur at the site of activation, but altered blood flow in veins draining the site of activation might induce signal changes at other locations as well (Segebarth et al. 1994). Approaches to a solution of this problem include the use of more or less specific signal thresholds and of angiographic sequences for the subtraction of vascular signals.

The observed signal changes in fMRI activation studies at 1.5 T generally lie in the range of 1%–5%. A large number of images are obtained in rapid sequence so that activation paradigms can be carried out, which, as in PET, consist of alternating blocks of behavioral or neuropsychological tasks. In addition to this type of block design, it is now possible to study the hemodynamic correlates of single sensory or cognitive events. This technique is known as "event-related fMRI" (Rosen et al. 1998).

It should be noted that neither emission-tomographic techniques nor fMRI detect neural activity directly. Both approaches are used to measure correlates of neural activity that normally follow neural activation after a certain temporal delay. PET is characterized by relatively low temporal latency, with acquisition times on the order of 40 s to several minutes for a single image. Single fMRI images may be acquired in a considerably shorter time (currently about 50 ms).

MEG and EEG studies have shown that neural activity returns to its starting value 300–800 ms after the end of the activating stimulus. The hemodynamic response persists, however, for as long as 9 s (Bandettini et al. 1993). Thus the temporal resolution of fMRI appears to be limited more by the nature of the hemodynamic response curve itself than by technical aspects. This fact, in turn, implies the necessity of exact modeling of the underlying hemodynamic response function, as can now be done with the aid of suitable statistical techniques.

3.3.2 Findings in Normal Subjects

In recent years, functional activation imaging has been used to study motor, sensory, and higher association areas of the brain. Because of the absence of radiation exposure, fMRI is an ideally suitable technique for functional brain mapping. Reliable paradigms have been developed for the study of various functional modalities. In the following sections, we will present a few representative examples, in several modalities, among the many paradigms that have been used to date.

Language Processing

Studies using language activation paradigms have yielded new information regarding the neural networks underlying language processing. The cerebral areas that participate in language processing seem to extend considerably beyond the "classical" areas of Broca and Wernicke into frontal, temporal, and parietal cortex (Hinke et al. 1993; Imperato et al. 1994).

Initial fMRI studies seemed to support the hypothesis of sex differences in language processing, e.g., on the phonological level (Shaywitz et al. 1995). More recently, however, more sensitive studies failed to confirm the existence of such differences (Frost et al. 1997; Schlösser et al. 1998b). Figure 6 shows the results of an fMRI study using a word-finding task as its activation paradigm; areas in which the signal was increased during performance of the task are indicated. In this right-handed male subject, the left frontal and parietal cortex are seen to be activated.

Working Memory

Various tasks have been used as activation paradigms for the study, by fMRI, of brain areas involved in working memory.

The sequential letters task or, as it is also known, the *n*-back task is one of the most common activation paradigms for the study of various components of

Fig. 6. Functional magnetic resonance imaging (fMRI) study using a word-finding task as the activation paradigm in a healthy right-handed male subject. Areas of increased signal during the activating condition are shown. (Data from Schlösser et al. 1998b)

working memory, having been used in many different studies, including imaging studies (Cohen et al. 1994). One version of this task involves a series of sequences of letters. In the 0-back condition, the subject is told to press a button each time a previously defined letter appears. In the 2-back condition, the subject must press the button whenever a letter appears that previously appeared two letters back, and so forth. The 2-back condition, when compared with the 0-back condition, was found to be associated with activation of the frontal and parietal association cortices (among other effects). Furthermore, when the demand on working memory was systematically altered by switching to the 1-back or 3-back condition, an increase in activation was found that depended on the degree of demand placed on working memory (Braver et al. 1997).

Further variations of applied neuropsychological paradigms allow the delineation of individual components of working memory and associated sensory processes. It was shown, with the aid of visual working memory tasks, that occipitotemporal areas respond only transiently to visual stimuli, in accordance with their primary role in the processing of sensory information. Prefrontal areas, in contrast, are continually activated over the entire period of information acquisition. This finding accords with their major attributed role in working memory (Courtney et al. 1997).

Long-Term Memory

fMRI has also been used to study long-term memory. In vivo studies have shown that the hippocampus and other medial temporal structures are involved in the processes of encoding and storage of information in long-term memory. During the encoding of novel images, statistically significant increases in the fMRI signal were seen bilaterally in the posterior portion of the hippocampus, in the parahippocampal gyrus, and in the lingual and fusiform gyri (Stern et al. 1996). Other studies have shown that the frontal cortex also participates in the encoding and recall of information stored in long-term memory (Busatto et al. 1997a).

Emotional Processing

fMRI is also suitable for the study of brain activation in connection with emotional processing. The left amygdala was found to be activated by the induction of either a sad or a happy mood, as had been found in an earlier PET study (Schneider et al. 1997).

3.3.3 Patient Studies

Schizophrenia

fMRI studies of schizophrenia focused at first on the primary sensory and motor cortices. Renshaw et al. (1994) used fMRI to study alterations in regional neural activity induced by visual stimulation. The mean change in signal intensity in the primary visual cortex was significantly higher in schizophrenic patients than in normal control subjects. The reason for this difference was unclear; an abnormality of the cerebral vasculature in schizophrenic patients was suggested as a possible explanation (Cohen et al. 1995). Schizophrenic patients were further found to have a lower than normal activation of both the sensorimotor cortex and supplementary motor areas during the performance of a finger-to-thumb opposition task (Schröder et al. 1995). Another study using the same task revealed no difference in the motor cortex of schizophrenic and control subjects (Buckley et al. 1997).

After these relatively simple studies of unimodal cortical areas, higher cognitive functions, too, were increasingly studied.

Studies of schizophrenic patients have repeatedly revealed multiple neuropsychological abnormalities,

particularly in the area of working memory. While performing the 2-back task described above, schizophrenic patients had a significantly lower degree of activation of the prefrontal cortex than normal control subjects (Callicott et al. 1998). In another study using the Wisconsin Card Sorting Test, schizophrenic patients were found to have a lower degree of activation in the right frontal lobe, and a higher degree of activation in the left temporal lobe, than normal control subjects (Volz et al. 1997a).

Word-finding tasks activate widely distributed neural networks and seem particularly suitable for the study of a number of patient groups. During such a task, schizophrenic patients had a significantly weaker left frontal activation, but a significantly stronger left temporal activation, than normal control subjects (Yurgelun-Todd et al. 1996). A more recent study, again using a word-finding task, revealed weaker left prefrontal activation and a reduced response in the left parietal cortex of schizophrenics as compared to normal control subjects (Curtis et al. 1998).

These findings all point to a diminution, in schizophrenics, of the frontal cortical activation associated with working memory and language processing and are thus in accordance with the findings of PET activation studies. Meanwhile, other functionally related areas also seem to be involved in the pathophysiology of schizophrenia.

Obsessive–Compulsive Disorder

The use of individually tailored provocative paradigms to induce obsessive–compulsive symptoms in patients with OCD was found, in an fMRI study, to produce an activation of various brain areas, including the medial orbitofrontal, lateral frontal, and anterior temporal cortices as well as the anterior portion of the cingulate gyrus. The caudate nucleus and the amygdala were also activated. Normal control subjects, in contrast, had no significant alteration of fMRI signal in response to these stimuli (Breiter and Rauch 1996; Breiter et al. 1996). These findings indicate a pathological overactivation of frontostriatal circuits in OCD and are thus consistent with the findings of earlier metabolic PET studies.

Pharmacological Modulation of the fMRI Signal

Preliminary fMRI studies have been performed concerning alterations of the cerebral activation pattern by the administration of drugs. In one such study, patients with narcolepsy were scanned during continuous presentation of periodic auditory and visual stimuli, before and after the administration of amphetamine. Amphetamine reduced the sensory-evoked activation of normal control subjects, while, in the narcoleptics, an increased activation was seen in the primary sensory cortex and the sensory association cortex (Howard et al. 1996). This finding demonstrates that drug challenge studies with fMRI are feasible. Similar study designs are likely to be used increasingly in the future.

fMRI is potentially a powerful tool for the study of cognitive activation in normal subjects and in patients with psychiatric diseases. This technique is likely to be used for many different applications in the future.

3.4 Magnetic Resonance Spectroscopy

3.4.1 Technical Principles

MRS enables the in vivo study of specific chemical substances and processes, including membrane components and substrates of energy metabolism, neurotransmitter metabolism, and the metabolism of pharmacologic agents.

The technical principles of MRS are essentially the same as those of MRI. As discussed above, each type of atomic nucleus resonates at a specific frequency. When the atomic nuclei reorient themselves along the axis of the static magnetic field, they emit a signal at their specific resonance frequency, which contributes to the generation of an MR signal. Regardless of the characteristics of the applied external gradient, however, not all of the atomic nuclei of a given type resonate at exactly the same frequency. This is because the local magnetic field experienced by each nucleus is slightly perturbed by its chemical microenvironment. This slight deviation of the resonance frequency is known as chemical shift. While MRI and fMRI make no special use of this additional frequency information, MRS resolves the full range of different resonance frequencies in the form of a spectrum. The power of MRS to resolve slightly different frequencies is a function of the strength of the applied magnetic field. A highly homogeneous field of at least 1.5 T is generally necessary to achieve adequate resolution in the frequency domain for the detection of differences in chemical composition.

The MRS techniques most commonly applied in psychiatric research are ^{1}H- and ^{31}P-spectroscopy. ^{1}H-Spectroscopy provides a chemical spectrum including peaks corresponding to *N*-acetyl aspartate (NAA), creatine (Cr), phosphocreatine (PCr), choline (Cho), *myo*-inositol (mIns), glutamine, glutamate, aspartate, γ-aminobutyric acid (GABA), and lactate. NAA is considered to be a marker of neuronal integrity, although the precise function of this substance is not yet completely understood (Tsai and Coyle 1995). Because the signal produced by these molecules is embedded in a signal arising from a very large number of water molecules, special techniques must be used to suppress the water signal.

^{31}P-Spectroscopy enables the detection of cerebral membrane phospholipids and high-energy phosphates. The phosphate spectrum contains peaks corresponding to adenosine triphosphate (ATP, β-ATP, and α-ATP), phosphocreatine (PCr), phosphodiesters (PDE), phosphomonoesters (PME), and inorganic phosphate (P_i). The PME and PDE peaks are considered to be indicators of membrane synthesis, and low values of the PME to PDE ratio are considered to be a manifestation of a low rate of phospholipid synthesis.

Other nuclei of importance to MRS for psychiatric research are ^{7}Li, ^{13}P, and ^{19}P.

3.4.2 Findings

Schizophrenia

A decreased level of PME and P_i and an increased level of ATP and PDE were found in the dorsolateral prefrontal cortex of drug-naive, first-episode schizophrenic patients (Pettegrew et al. 1991). A more recent study revealed a significantly diminished level of PME in the frontal regions of schizophrenic patients who had high scores on negative symptom rating scales (Shioiri et al. 1994). These findings suggest reduced synthesis and/or increased degradation of membrane phospholipids. Another study, however, showed a lower level of PDE in schizophrenic patients than in normal control subjects (Volz et al. 1997b). These contradictory findings may perhaps be explained by differences in MRS techniques and localization methods.

An ^{1}H-MRS study of schizophrenic patients revealed a decreased concentration of NAA in the frontal lobes (Buckley et al. 1994). Bertolino et al. (1996) found significantly decreased NAA to Cr and NAA to Cho ratios bilaterally in the hippocampus and dorsolateral prefrontal cortex of schizophrenic patients; there were no significant changes in the Cho to Cr, NAA to Cr, or NAA to Cho ratios in any of the other regions tested. Thus a lower NAA concentration was found exclusively in two areas that have been repeatedly implicated in the pathogenesis of schizophrenia. The regional distribution of metabolites obtained in this study is depicted in Fig. 7. In another study, the anterior portion of the cingulate gyrus also had a significantly lower NAA concentration in schizophrenic patients than in normal control subjects (Deicken et al. 1997). In addition, increased levels of glutamate were found in the medial prefrontal cortex and in the anterior portion of the cingulate gyrus. The authors of this last study interpret their findings as evidence of dysfunction of the glutamatergic system, because glutamine is the immediate precursor of glutamate in its synthetic pathway (Bartha et al. 1997).

In schizophrenic patients, memory functions were found to be closely related to creatine concentration in the temporal lobes, but not in the frontal lobes – a pattern of distribution different from that seen in normal control subjects. These findings suggest that disturbances of memory in schizophrenic patients may be associated with a specific abnormal pattern of temporal lobe metabolism (Buckley et al. 1994).

The basal ganglionic NAA to Cho ratio was found to be significantly reduced bilaterally in schizophrenic patients. This finding suggests that there is neuronal dysfunction in subcortical structures as well (Fujimoto et al. 1996).

Affective Disorders

^{31}P-MRS studies provided evidence of alterations of membrane metabolism and high-energy phosphate metabolism in patients with affective disorders. The PME level was elevated in patients in either the manic or the depressive phase of a bipolar I disorder and depressed in the same patients in the euthymic state. Bipolar II patients, in contrast, had reduced PCr values both during disease episodes and in the euthymic state (Kato et al. 1994b). The observed abnormalities had no correlation with the cerebral concentration of ^{7}Li, which was simultaneously determined by MRS (Kato et al. 1993b). ^{1}H-MRS revealed an elevated Cho to (Cr+PCr) ratio in the left basal ganglia of bipolar patients in the euthymic state, which may be interpreted as evidence of cell membrane damage in bipolar disorders (Kato et al. 1996b).

Anxiety Disorders

In a ^{31}P-MRS study, patients suffering from panic disorders were found to have a slightly decreased concentration of inorganic phosphate and a significant asymmetry (left side greater than right) of PCr concentration in the frontal cortex. Abnormalities of phosphorus metabolism in frontal cortex are thus possibly a feature of panic disorders (Shioiri et al. 1996b).

Dementia

MRS studies reveal that the early stages of Alzheimer's disease are associated with increased concentrations of cerebral PME. Later in the course of the disease, PDE and PCr concentrations increase (Pettegrew et al. 1988, 1994). The increase in PME may reflect alterations of membrane metabolism, while the increase in PDE and PCr indicates the presence of neuronal degeneration. Recent studies indicate an increase in the PME to PDE ratio by approximately 50%. Nonetheless, no differences of absolute PME or PDE concentration between schizophrenic patients and normal control subjects could be found (Gonzalez et al. 1996).

A lower NAA concentration in the temporal and frontal cortex of Alzheimer's disease patients, as compared to healthy age-matched control subjects, has been described (Parnetti et al. 1997). This decreased NAA concentration was significantly correlated with

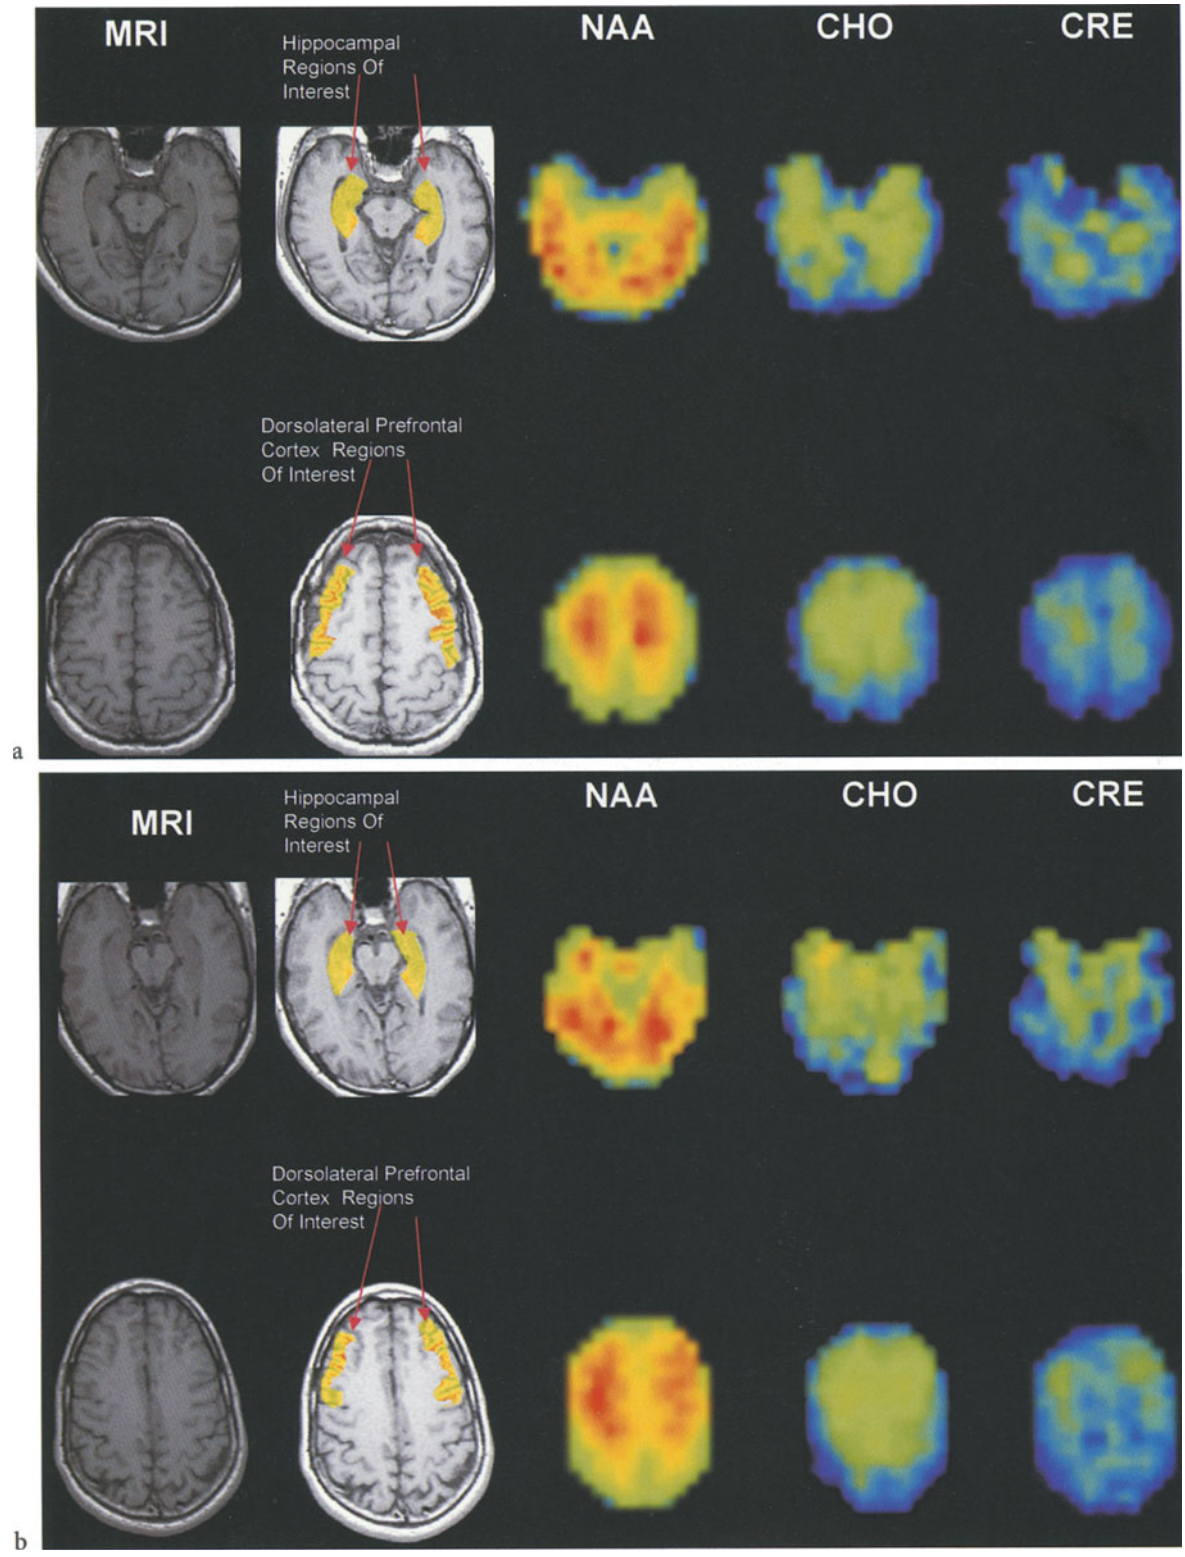

Fig. 7a–c. Studies using ^{1}H-magnetic resonance spectroscopy (MRS) in schizophrenic patients and normal control subjects. (After Bertolino et al. 1996). **a,b** Metabolite signal intensity of compounds containing *N*-acetyl aspartate (*NAA*), compounds containing choline (*CHO*), and creatine/phosphocreatine (*CRE*) in **a** a schizophrenic patient and **b** a normal control subject. Fig. 7c

the extent of these patients' cognitive disturbance (Heun et al. 1997b; Parnetti et al. 1997). Elevated concentrations of *myo*-inositol, which were also revealed by an ^{1}H-MRS study of patients with Alzheimer's disease, may reflect changes in the polyphosphate second messenger system (Miller et al. 1993).

Treatment Studies

With the aid of ^{7}Li-MRS, it has been shown that the concentration of lithium in the brain is approximately half that in serum (Kato et al. 1993a). It was also shown in bipolar patients in the manic phase that the response to lithium treatment is more closely correlated to the brain concentration than to the serum concentration of lithium (Kato et al. 1994a). Furthermore, the occurrence of tremor was also found to be correlated to the brain lithium concentration (Kato et al. 1996a).

^{19}F has also been used in MRS studies for the determination of brain concentrations of various fluorine-containing drugs, such as fluvoxamine. Nonetheless, no clear relationship of these concentrations to the treatment response of psychiatrically ill patients has yet been established (Strauss et al. 1997).

MRS has, further, enabled the study of the effect of pharmacologic interventions on biochemical processes in the brain. Thus a positive correlation was found between the chlorpromazine equivalent dose of a neuroleptic treatment and the measured NAA concentration in the basal ganglia of schizophrenic patients. There was, at the same time, a negative correlation between the neuroleptic dose and the Cho to NAA ratio (Shioiri et al. 1996a).

The results presented here illustrate the special ability of MRS to probe various biochemical systems in vivo without prior injection of a tracer substance. The further development of MRS and its application to the study of psychiatric disease and, possibly, to the monitoring of treatment with psychotropic drugs

depend largely on the stability of the technique. At present, the intertest reliability of MRS still seems to be in need of improvement; in contrast, the intertest reliability of metabolic and neuroreceptor PET studies is now considered adequate (Marshall et al. 1996; Bertolino et al. 1998). This residual methodological uncertainty must be taken into account, particularly in view of the partially conflicting findings of MRS studies.

4 Prospects

Functional imaging is a new approach to the study of psychiatric diseases and the pathophysiologic processes that underlie them. The deeper understanding of these diseases thus acquired should enable the development of new biological concepts and innovative treatments. In the future, the classical nosology of psychiatric disease may perhaps be replaced, at least in part, by a functional classification.

Future research involving functional imaging with PET and fMRI will likely move increasingly in the direction of determining the role played by functional networks and their connectivity in the genesis of psychopathological abnormalities. The application of in vivo challenge paradigms may further lead to the establishment of dose–response relationships relating to the functional interaction of multiple neurotransmitter systems.

The various methods described in this chapter will, in future, be integrated into multimodal imaging systems in which anatomical, functional–metabolic, and specific neurochemical information will be displayed simultaneously. The monitoring of therapeutic interventions and the study of neuropsychological performance ability by means of functional imaging will be of major clinical utility.

It is also becoming evident that the fields of psychiatry and neurology are moving closer together with respect to the questions they pose and the methods they use to answer them, particularly the modern methods of functional imaging described in this chapter. Both clinical medicine and scientific research will benefit from this new, integrated neuropsychiatric approach.

CHAPTER 12

U. Baumann, M. Perrez

Psychology and Its Relevance to Psychiatry

Translator: E. Taub

1 Introduction

1.1 Psychology as a Science

There is no single definition of psychology, but the definitions given by various authors tend to make use of similar terms. Gray (1994, p. 3), for example, defines psychology as "the science of behavior and the mind." "Behavior" here refers to observable actions, while "mind" subsumes perception, memory, motivation, emotion, and so forth. Among German-speakers, psychology is often defined as the science of "Erleben" (experience) and "Verhalten" (behavior), which accords well with the American definitions. The science of psychology thus comprises a large number of subfields, of which the study of the mentally ill patient is but one.

There is a consensus among scientific psychologists that psychology is an *empirical* science (Baumann 1995; Perrez 1991), i.e. a discipline that draws its conclusions from experience, in which experimentation is particularly important and has been so from as early as the nineteenth century (for the history of psychology, see Evans et al. 1992; Ash and Geuter 1985). Psychology is considered to be partly a basic science and partly an applied science (Herrmann 1976).

The discoveries of those branches of psychology that are primarily basic science, such as general psychology, allow a better understanding of the mechanisms and principles that regulate human behavior and that underlie changes in behavior in both the normal and the pathologic situation. Such knowledge is necessary for the understanding of normal and pathologic processes (etiology and pathogenesis). The technical knowledge obtained from the applied-science subfields of psychology, such as clinical psychology, provides a rational basis for the application of methods of treatment by establishing the results that various methods are likely to achieve under various conditions (Perrez 1991, 1998b). Such knowledge is indispensable for therapy, and especially for prevention; it is fundamental to methods of both assessment and psychotherapy.

Only a small subset of the actual and potential contributions of psychology to psychiatry can be discussed in this chapter. Particular subfields will be dealt with separately in other parts of this text (for example, see Vol. 1, Part 1, Chaps. 13, 14). Individual findings will not be discussed in detail here, as this chapter aims to concentrate on more fundamental aspects.

1.2 The Science of Psychology and Its Relation to Other Fields

The scientific study of humans can be separated into basic categories, each of which concerns data collected on a different level (Seidenstücker and Baumann 1987): the biologic/somatic, the psychic/psychological, the social, and the ecological level. The use of expressions such as social psychology, psychophysiology, and psychosomatics shows that psychology attempts to link the psychic data level with other data levels. According to the German Scientific Council (Wissenschaftsrat 1983), psychology occupies a position between the social sciences and humanities, the natural and biological sciences, and medicine and is thus intrinsically multimodal and multidisciplinary. The analysis of the relation between the psychic data level and the biologic/somatic data level is relevant to the mind–body problem, for which philosophers have made various attempts at an ontological or epistemological solution.

In accordance with the complementarity principle enunciated by Fahrenberg (1981), we assume that the somatic and psychic levels of description in human science complement one another, even though each level possesses its own category systems, theoretical foundations, and basic methodologies (for the emergence concept, see Bunge 1984). We thus reject ontological reductionism and recognize that the discipline of psychology plays an important, independent role in the analysis of behavior, by addressing the entire range of topics lying between the social and biological levels.

1.3 Clinical Psychology and Psychiatry

Among all of the subspecialities of psychology, clinical psychology bears an especially close relation to psychiatry (for an overview, see Baumann and Perrez 1998a). Baumann and Perrez (1998b, p. 4) provide the following definition of clinical psychology: "Clinical psychology is the subfield of psychology that deals with psychic disorders and the psychic aspects of somatic disorders." The topics addressed by clinical psychology include fundamental issues (scientific/theoretical, ethical, and conceptual questions), epidemiology, classification, diagnosis, etiology, and analysis of perpetuating factors as well as interventions such as prevention, psychotherapy, rehabilitation, health care, and evaluation (Baumann and Perrez 1998a; for the history of clinical psychology, see Routh 1994; Walker 1991).

From the foregoing list it is clear that clinical psychology overlaps substantially with psychiatry. From the scientific point of view, both clinical psychology and psychiatry deal with psychic disorders; in other words, they differ little on a fundamental level, even though they have different emphases with regard to the area of study; psychiatry tends to stress the somatic level of description, and clinical psychology the psychic level. There are, nonetheless, significant and legally mandated differences between psychologists and psychiatrists in terms of their professional training and clinical practice.

Other border areas to psychiatry, besides clinical psychology, include health psychology, behavioral medicine, and medical psychology. Health psychology (see Schwarzer 1997) is understood by its practitioners as being oriented toward the prevention of somatic disorders and the preservation of health. It is also partly concerned with questions of treatment and rehabilitation. Behavioral medicine also overlaps with psychiatry (Blanchard 1992), inasmuch as it constitutes an interdisciplinary approach to the study and treatment of (primarily) somatic disorders. It involves psychologists, physicians, and scientists from other disciplines. The term "medical psychology" refers to psychology as a subject of instruction for physicians. Research in medical psychology mainly concerns physician–patient interaction and the situation of the patient (Schwenkmezger and Schmidt 1994).

2 Fundamental Methods

2.1 General Observations

Alongside the subject-oriented subspecialities discussed above, a further central subspeciality of basic psychology is that of methodology in psychological research. This subspeciality deals with questions such as the construction of theories, the planning of experiments, and the statistical assessment of results (Breakwell et al. 1995). The basic principles of psychological methodology require further specification in two respects when applied to particular situations in clinical psychology and psychiatry (Baumann 1991):

1. The particular concerns of clinical psychology and psychiatry require a content-based adaptation of methodological postulates to the specific problem at hand. For example, general methodology requires that all experiments have a control group; the nature of the control group in a particular experiment (e.g. placebo control group) must be decided on the basis of a field-specific methodology (see, e.g. Kazdin 1994; Sher and Trull 1996).
2. Particular research methods may be of greater or lesser value at different stages in the course of the research effort. For example, single case studies are useful in phase I medication trials, but of no value in phase III, in which comprehensive, multicenter studies are required.

The methodology of research in psychology has also given a strong impulse to psychiatry, making contributions not only to the planning of experimental research, but also to assessment (see Sect. 5) and to the evaluation of interventions and concepts of care (see Sect. 6.4). As an illustration of the discussion of method in psychology, which is also of importance to psychiatry, the following sections will deal with two general framework concepts: field versus laboratory research, and multimodality. There is not enough space to discuss further topics in detail.

2.2 Field Versus Laboratory Research

In psychological methodology, a distinction is often drawn between laboratory and field research (Breakwell et al. 1995). Laboratory research is prototypically viewed as an artificially constructed approach and equated with the performance of hypothesis-testing experiments, while field research is viewed as a correlative approach, with an emphasis on naturally occurring phenomena. Recent methodology (Patry 1982) views this dichotomy, and the associated criticisms of particular methods, as superfluous and untenable. According to Paltry (1982), research methods may be characterized as "natural" or "artificial" with respect to each of at least three criteria, namely, the setting of the investigation, the treatment given (independent variable), and the behavior investigated (dependent variable).

Artificially constructed methods have dominated psychological research up to the present, both in the laboratory and in the field. Because the artificiality of a method bears on the generalizability of the research findings, the naturalness or artificiality of the method used in any research study must be taken into account in the interpretation of its conclusions. In our opinion, too much research in clinical psychology and psychiatry falls into the category of artificial, with respect not only to setting, but also to the dependent variables used (often based on questionnaires or interviews). The conclusions of such studies are even less reliable because, frequently, only retrospective data are

obtained. A narrow focusing of research methods on artificial conditions appears problematic for a science that considers itself to be empirical; it is imperative that natural conditions be used as well (see Sect. 5.3). Studies performed under natural conditions are complementary, rather than alternative, to studies with artificial parameters.

2.3 Multimodality as a Fundamental Principle

The principle of multimodality is a central tenet of research in clinical psychology and in psychiatry (Seidenstücker and Baumann 1987). Multimodality means that a multi- rather than univariate approach is used, in which variation is possible in each of several individual categories. The following categories may be distinguished:

- *Data level* (basic categories of observation): Biologic/somatic, psychic/psychological, social, ecological (see above).
- *Data source* (informant): The proband him- or herself, other people (e.g. people bearing some relationship to the proband, trained judges, therapists, institutionally collected data), data from instruments or apparatus. When self-assessment and external assessment yield different results, the disagreement is not merely due to inaccuracies of method. Rather, self-assessment and external assessment are fundamentally different means of obtaining access to the individual, and they are informative to different extents in different areas. External assessment should not be considered more objective than self-assessment; the two variants are of equal theoretical value.
- *Data-gathering techniques* (see Sect. 5.2).
- *Constructs*: There is no generally accepted taxonomy of constructs in psychology; in each individual case, a reasonable choice of construct is made on the basis of the current status of research. Complex global constructs incorporating data from several different areas are specific to the clinical field (see Laireiter et al. 1994). These global constructs (social adaptation, social integration) primarily represent an attempt to characterize patients on the social level, but also frequently include indicators on the biological, psychic, and ecological levels (e.g. state of health, coping, and quality of residence, respectively) and are thus multimodal constructs. The construct of quality of life is similar to these global constructs, and to social adaptation in particular (Bullinger 1996; see also Vol. 1, Part 2, Chap. 7).

Multimodality is a general framework concept and does not provide specific details of the proper selection of data-gathering techniques in concrete, individual cases. This may lead to difficulties in interpretation (Seidenstücker and Baumann 1987); several simultaneously investigated data modalities will not necessarily yield matching results at a single point in time or in their overall course. There is no definitive solution to this problem, but difficulties in interpretation can be alleviated somewhat if the selection of data modalities is directed by particular hypotheses and theories. Furthermore, method studies such as "multitrait multimethod analysis" are necessary to elucidate complex relationships empirically.

3 Fundamental Concepts: Personality

3.1 Objectives of the Study of Personality

A further subspeciality of psychology that is relevant to psychiatric research is the study of personality. In this subspeciality, psychology provides theories for the general understanding of different types of people. These theories are important in psychiatry because an understanding of normal experience and behavior is a necessary prerequisite for the assessment of psychic disorders (Baumann 1993; Becker 1996; Butcher and Rouse 1996). The concepts of the psychology of personality are particularly important for the understanding not only of personality disorders, but also of the premorbid personality (Watson and Clark 1994; von Zerssen 1996).

The dimensions of person, personality characteristics, and situation (or time) are important sources of variation for the study of personality. As far as the dimensions of person and characteristics are concerned, two viewpoints can be distinguished:

- The analysis of the covariation of characteristics gives rise to traits or, in the clinical sector, to syndromes.
- The analysis of the covariation of persons, on the other hand, gives rise to typologies or, in the clinical sector, to diagnoses.

While the trait approach has supplanted the typological approach in the psychology of personality, we find that the typological approach dominates in psychiatry, because of the manner in which diagnoses are made; the trait, or syndrome, approach has a long tradition in psychiatry, but has receded into the background in the last few years because of the dominance of the ICD and DSM diagnostic systems.

3.2 Different Approaches to Personality

Concepts of personality may be classified into groups of related theories. Some of these concepts that are or were applied in psychiatry, either implicitly or explicitly, will be discussed here (Asendorpf 1996; Amelang and Bartussek 1997; Wiggins and Pincus 1992).

The psychodynamic approaches stress intrapsychic aspects, particularly motivation. The psychoanalytic concepts of personality (compare Freud), which are fundamental to psychoanalytic theories of etiology and treatment, are prototypical of psychodynamic approaches. Psychodynamic approaches often originate in the clinical setting and then are generalized to apply to the field of normal experience and behavior. From the viewpoint of empirical personality research, psychoanalytic personality concepts, in particular, have not received adequate empirical confirmation. The concept of motivation, however, has proved to be very fruitful, as has that of defense mechanisms. The latter has been developed further in coping research (Lazarus 1991; Perrez and Reicherts 1992) and in new concepts of defense strategies, such as vigilance and cognitive avoidance (Krohne 1996).

The trait approach has become extremely widespread in personality psychology since the 1930s (e.g. Guilford, Eysenck, and Cattell; see Amelang and Bartussek 1997). In this approach, behavior is said to be determined by persistent features of personality ("traits") that are largely independent of situational factors. Since the 1980s, integrative efforts have increasingly been made with regard to the temperamental factors, culminating in the concept of the "big five factors" (Wiggins and Pincus 1992). Extraversion, neuroticism, agreeableness, conscientiousness, and openness were postulated as overriding entities. Integrative approaches may also be found in intelligence research, where a few basic dimensions have been postulated (Carroll 1993). Integrative efforts are to be applauded, but they do not make up for the drawbacks of the trait approach, particularly its neglect of situational factors (see Butcher and Rouse 1996). Trait concepts also occur in the other kinds of theories discussed here, e.g. psychodynamic theories (where "orality" and other traits play a role) and cognitive approaches (compare "locus of control," control beliefs). Traits such as "hardness," social supportiveness, and hostility are also discussed among the factors that may protect against or predispose to psychic and somatic illnesses.

Behavioral approaches stress observable behavior, which is conditioned by the environment or by situational factors (see, e.g. Thorndike, Dollard, and Miller; also see Amelang and Bartussek 1997). The laws of the psychology of learning, as they apply to conditioning, operant learning, and model learning, are central to such approaches. These approaches have given a major impetus not only to interventional treatment (behavioral therapy), but also to the understanding of the origins of behavioral disturbances (Perrez and Zbinden 1996; Westmeyer 1995). Behavior-theory personality constructs serve as intermediate variables between environmental factors and learning processes and include, among others, conditionability (or introversion, according to Eysenck; see Amelang and Bartussek 1997) as a temporally stable personality trait, which, when it assumes extreme values, may result in either hyper- or hypoadaptability (dysthymic disorders or sociopathy). A further trait is the differential capacity for "delay of reinforcement," which is relevant to operant conditioning (Mischel 1983) and has been studied particularly with regard to the etiology of delinquent behavior. A further development of classical behavioral approaches may be seen in the cognitive concepts to be discussed below, which extensively incorporate concepts of learning theory as well as other concepts.

Internal processes that manifest themselves in planning, goal-setting, personal constructs, values (e.g. reinforcer preferences), self-regulating systems, and so on are important components of cognitive and information-processing approaches (see, e.g. Kelly, Rotter, Mischel, and Kanfer; also see Amelang and Bartussek 1997). These approaches are a major extension of the behavioral approach, by which behavioral therapy in the narrow sense is further developed into cognitive behavioral therapy. In information-processing approaches, cognitive theories are made more precise and given added depth.

According to humanistic and existential approaches, the most important avenue to the understanding of a person is his or her individuality, as stressed by Frankl, Maslow, and Rogers, among others; the central concepts here are those of the self and of self-regulating abilities (Buss 1995). This conceptual approach has found major resonance, particularly in humanistic psychotherapy. Its development has been, in part, in a direction away from empirical research; phenomenological, hermeneutic conceptual categories are preferred.

The advantages of several different approaches may be summed up under the heading "interactionism" (e.g. Magnusson 1990). Actual experience and behavior are the product of a dynamic interaction between internal processes and external factors. A given person does not enter a given situation as a tabula rasa, but rather brings to it his or her own stable framework conditions (traits). In the theoretical formulation of complex concepts of this type, the individual operationalizations have mostly been realized only for partial

aspects. Interactionalist approaches require a complex consideration of personality, situation, and environment.

All biopsychological models to date have been formulated primarily on the psychic data level. Despite numerous studies with interesting findings, there is still no convincing biopsychological concept of personality (see Zuckermann 1991; Fahrenberg 1996). Such concepts are indispensable not only for personality research, but also for the collaborative interaction of psychology and psychiatry. In addition, models of personality that delineate the range of normal states and the clinical spectrum with equal precision are necessary for research in the clinical sector. Most models of personality are formulated as "normal psychology" and can be applied to psychic disorders only as extreme variants, without differentiating adequately among the distinct disorders. Eysenck's concept (see Amelang and Bartussek 1997) is an exception; it postulates the dimensions of extraversion, neuroticism, and psychoticism as constructs allowing a consideration of both normality and various clinical disorders. The construct of psychoticism is, however, not as well elaborated as neuroticism, and the distinction between neuroticism and psychoticism has become problematic, as neurosis has been eliminated from both the DSM-IV and the ICD-10 diagnostic systems.

4 Etiology of Psychic Disorders and Factors that Perpetuate Them

4.1 Multiple-Phase Model

With respect to the generation of psychic disorders, clinical psychology distinguishes between their etiology, or initial cause, and the factors that perpetuate them. Several distinct phases in the development of psychic disorders have been described (Shepherd 1987; Baumann and Perrez 1998c), in each of which specific factors, including psychological factors, are at work:

1. *Pre- and perinatal phase*: Genetic, intrauterine, and perinatal influences are included here. The sum of all factors occurring during this phase is often subsumed under the term "predisposition."
2. *Socialization or developmental phase*: This phase includes those factors that come into play over the course of the individual's life. Great importance has often been attributed to early childhood influences, in line with psychoanalytic theory. The current understanding of development as a lifelong process implies, however, that later factors are also significant. The influence of socialization moderates the individual's predisposition and determines his or her vulnerability to psychic disorders in general or to specific psychic disorders.
3. *Phase immediately prior to the onset of the disorder*: It is assumed that the onset of a number of disorders may be brought about by critical life events, traumata, etc., among other factors (compare stress research).
4. *Phase after the onset of the disorder*: This fourth phase corresponds roughly to the medical concept of pathogenesis. In clinical psychology, the current intrapsychic and social conditions that perpetuate the disorder are considered to be the most important factors at work in this phase.

While an understanding of the first three phases is primarily important for the prevention of psychic disorders, an understanding of the fourth phase is particularly relevant to their treatment. An understanding of the perpetuating conditions includes disorder-specific mechanisms, which may be intrapsychic, social, or both.

As an example, we may consider depressive disorders, whose onset may be triggered by an experience of loss. We may assume that an individual may be more vulnerable to a depressive reaction because of predisposing factors and socialization factors. This can only be a working hypothesis, as these factors cannot be reconstructed exactly in the concrete case, and the etiology in this sense must remain unknown. A more secure understanding of the triggering factors can be gained, however, by analysis of the experience of loss and the corresponding functional mechanisms of the depressive reaction. Thus certain modalities of control belief (e.g. belief of external control) and certain forms of causal attribution (attribution of failure to self) may be important elements in the depressive functional mode. Even if these elements are not the etiology of depression, they are nevertheless conditioning factors whose modification is of therapeutic importance.

4.2 Models of Causation

The models of causation underlying clinical psychology are no different, in principle, from those of medicine. A multicausal, deterministic or probabilistic cause-and-effect structure is assumed, in which biological, psychological, social, and ecological factors (see Sect. 2.3) may influence psychosomatic processes. The historical/genetic type of explanation, which reconstructs a disorder as the result of a developmental

process, plays a central role in etiology. The stages of this development represent a series of prior dispositions on the one hand and newly occurring events on the other.

With regard to psychophysical aspects, it is possible in some groups of disorders that biological processes bring about psychic conditions, just as psychic conditions and processes may affect neurobiological processes. Causal chains often cannot be exactly defined, whether they span the somatic and psychic data levels or remain within the psychic data level itself. Psychic factors may be the cause, precondition, prodrome, symptom, accompaniment, or result of a disorder (consider, for example, the interpretation of depressive disorder by means of the concept of learned helplessness; Baumann and Perrez 1998a). Experiments with individuals with psychic disorders often fail to reveal the causal chain; longitudinal studies are necessary. Psychology, in collaboration with psychiatry, must develop precise experimental protocols that can optimally investigate the causal mechanisms at work.

4.3 Socialization Theories

Psychoanalysis was long considered the prototype of a socialization theory. The psychoanalytic theories of etiology were a major impulse to the field, but, because of their exclusive nature, failed to achieve empirical confirmation (see Ernst and von Luckner 1985). The psychoanalytic conceptions of bonding theory, which constitute an interactionistic developmental psychology of early childhood (mother–child interaction), have proved to be of greater significance (see also Vol. 1, Part 1, Chap. 22). The study of bonding initiated by Bowlby has yielded fruitful hypotheses about the consequences of inadequate bonding, and of separation, for the genesis of depressive and other disorders (Jones et al. 1997).

Another socialization concept of developmental psychology that is useful in the study of the genesis of psychic disorders is Havinghurst's concept of developmental tasks (Perrez 1998a). Here, development is understood as a sequence of more or less demanding readaptational or developmental tasks, which are experienced as phase-specific disturbances of equilibrium. These tasks are predetermined in a more or less obligatory fashion by the individual's development or by culture. They represent phases of high vulnerability; inadequate performance of a task raises the risk of failure to perform the next task in the sequence. Thus an inadequate performance of the first developmental task – bonding – can impair performance of the next developmental task – the infant's exploration of its immediate environment.

4.4 Learning Theories and Theories of Information Processing

Two traditions of psychological research have yielded valuable contributions to the improved understanding of the generation and perpetuation of psychic disorders: the study of learning and the concepts of information processing. The tradition of the study of learning began in Russia with the Pavlov school, which analyzed the disorganization of behavior by the conditioning of antagonistic inhibitory and excitatory processes. In the United States, Dollard, Meyer, Masserman, and Miller studied the neuroses through animal experiments, starting in the late 1930s. There exists today an extensive corpus of knowledge derived from the psychology of learning (see Perrez and Zbinden 1996): classical conditioning (e.g. the generation of anxiety disorders), operant conditioning (e.g. the generation of certain depressive disorders through the loss of reinforcement and control), and model learning (e.g. the acquisition of aggressive behavior) (for more on this subject, see Vol. 1, Part 1, Chap. 14).

Information-processing approaches (see also Sect. 3.2) are centered on the ascertainment of characteristics or present determinants of psychic disorders, with the emphasis to date on depressive and anxiety disorders (see Ehlers and Lüer 1996). Experimental findings on the relationship between mood and memory, for example, imply that depressive patients are more likely to report negative experiences, although they have not necessarily had such experiences more frequently than others. The concepts of information processing have also proved useful in the study of schizophrenic disorders.

The future development of psychological theories of etiology may be expected to link developmental aspects with behavioral aspects and those of cognitive psychology. Above all, multimodal theories of etiology are required, which will connect psychological findings with biological parameters (compare the approaches of psychoendocrinology and psychoimmunology).

5 Assessment

5.1 Objectives of Assessment in Clinical Psychology

Psychological assessment involves questions reaching over the individual disciplines of psychology (e.g. Jäger and Petermann 1995). In specific disciplines, however, specific problems occur. In this section, we shall discuss some of the aspects of assessment in

clinical psychology (see Stieglitz and Baumann 1994; Maruish 1994).

In medicine, assessment is often equated with the provision of a diagnosis, but in psychology this is but one of several objectives. According to Perrez (1985), assessment in clinical psychology has several distinct functions, with regard not only to individuals, but also to interpersonal systems (partners, families, groups, and organizations) (Reinecker-Hecht and Baumann 1998):

1. *Description*: The description of the present condition and of its alterations forms a basis for the other functions of assessment (e.g. classification); many different assessment procedures are available.
2. *Classification*: Descriptions of large numbers of individual patients may be used in the clinical field to construct systems of classification (e.g. ICD-10, DSM-IV), which often rely upon criteria derived from structured, standardized interviews.
3. *Explanation*: Assessment in clinical psychology may help to explain a disorder (see Sect. 4), particularly with regard to the factors that perpetuate it.
4. *Prognosis*: Assessment in clinical psychology helps to predict the future course of psychic disorders with or without intervention. The prognostication of the course of a disorder after intervention involves an estimate of the probability of success of treatment (compare predictor analysis).
5. *Evaluation*: In the clinical sector, both individual therapeutic approaches (see Baumann and Reinecker-Hecht 1998) and care models (compare quality assurance; Haug and Stieglitz 1995; see also Vol. 1, Part 2, Chap. 12) must be evaluated by means of psychological data-gathering techniques.

German-speaking psychologists use the term *Diagnostik* ("diagnostics") as the equivalent of the English "assessment," and *Verhaltensdiagnostik* as the equivalent of "behavioral assessment."

5.2 Data-Gathering Techniques in Psychology

A number of quite different classification schemes have been suggested for the systematization of data-gathering techniques in psychology, but none of them have achieved general recognition. These techniques are thus usually classified along pragmatic lines (see, e.g. Baumann and Stieglitz 1994). Psychological tests have proved to be an especially important group of techniques (e.g. Rost 1996; Lienert and Raatz 1994). Tests are characterized by the following: standardization (i.e. fixed rules) with respect to their performance, grading, and interpretation; the acquisition of random samples of behavior as evidence for the traits of the subject tested; the measurement (quantification) of traits; and the presence of evaluative criteria such as objectivity, reliability, validity, and norms (Jäger and Petermann 1995).

Although psychological tests are the most rigorous type of technique in clinical psychology, the diagnostic interview is very often used in practice (Wittchen et al. 1994). The diagnostic interview is a means not only of gathering information, but also of providing counseling and treatment.

Various data-gathering techniques and measurement instruments are used to acquire data on the psychic and social levels; these cannot be discussed here individually (see, e.g. AMDP and CIPS 1990; CIPS 1996; Stieglitz and Baumann 1994; Westhoff 1993). Most data-gathering techniques, particularly psychological tests, are intended for use in assessment of the individual. A further group of techniques deals with interindividual systems (such as social networks, partners, families) from the point of view of the individual ("egocentric approach," e.g. family atmosphere as viewed by the child). In fact, only a minority of techniques are intended to be systemic, i.e. to cover all elements of a system and their mutual relationships (e.g. cooperative problem-solving in the family; Cierpka 1996).

A new, particularly important group of techniques known as field assessment represent a complementary approach to classical assessment (see Sect. 2.2). In field assessment, both the data-gathering situation and the observed behavior are in a natural setting (see Perrez 1994; Fahrenberg 1994; Laireiter and Thiele 1995). Field assessment fulfills the objectives of assessment listed in Sect. 5.1. The various techniques of field assessment differ from one another in several parameters, of which the following are most important:

- *Data source*: Self-observation or external observation, automatic recording
- *Data level*: somatic, psychic, social, ecological level
- *Method of recording*: paper and pencil (compare the classical diary), audio/videotape, computer
- *Data sampling*: interval contingent (e.g. at predetermined times), event contingent (e.g. after stress, after contact), signal contingent (upon hearing a signal tone)
- *Temporal separation* between event and recording: immediate, delayed (retrospective)
- *Systems of reference* for the results of field assessment: empirical norms, ideal criteria, intrapersonal before-and-after comparisons.

The diary is the oldest technique of field assessment. It is relatively unstructured in its traditional form and can be of considerable clinical use in the generation of hypotheses as well as for exploratory purposes. More highly structured paper-and-pencil techniques include observation questionnaires or books, which contain

precise instructions about the modalities of observation (including the time of observation, which may be determined by a timer; de Vries 1992).

These paper-and-pencil techniques, however, are gradually being replaced by computerized techniques (pocket or palm-top computers; Fahrenberg and Myrtek 1997), which have a number of advantages. One advantage is that the computerized techniques reduce the latency interval between the actual experience or behavior and its diagnostic recording. The improved organization of the conditions of observation, the opportunity for branched questioning, and the greater evaluative complexity of the data are all further advantages. Electronic data storage makes the data directly transferable to other computers. Furthermore, the computer provides psychologically relevant information about the behavior of the person under assessment, e.g. with respect to the exactness with which he or she follows the instructions for observation. Not only can the computer give the auditory signal for the time of observation, but it can also record when the observation is actually made. Depending on the goals of assessment, the users can define behavioral protocols according to a temporal or event-based sampling plan, by which different types of data (e.g. motives of behavior, behavior, mood) can be obtained in different contexts (e.g. the evaluation of panic attacks, stressful experiences, contact structures, family stresses; Fahrenberg and Myrtek 1997).

In summary, computerized field assessment yields new possibilities for data collection that go far beyond what was previously feasible. These techniques are useful particularly for external assessment of both in- and outpatients, as well as for outpatient self-assessment; they have only a limited application to self-assessment in the hospital setting.

6 Intervention

6.1 Intervention in Clinical Psychology

Various forms of intervention may be used to produce changes in experience and behavior. In somatic medicine, medical, surgical, and physiotherapeutic forms of intervention occupy the foreground. Psychological intervention is a further form that finds application in educational, occupational, and clinical settings. The clinical psychology-based interventions of relevance to psychiatry (Bergin and Garfield 1994) are characterized primarily by the specificity of their methods (Perrez and Baumann 1998a), which are localized to the psychic level, i.e. that of experience and behavior. Typical psychological methods are the interview (e.g. interpretation, confrontation) or the application of behavioral elements (e.g. role-playing, confrontation with reality). What interventions in clinical psychology have in common is not the etiology of the disorders for which they are applied, or their objectives, but rather their methods. These interventions may thus be directed toward somatic characteristics as well.

Further determinants of interventions in clinical psychology which do not apply equally to all methods are their functions (prevention, treatment, rehabilitation), goal orientation, theoretical background (particularly psychological theories), verification of effectiveness, and professional realization (Perrez and Baumann 1998a). These methods of intervention are directed not only toward individuals with disordered functioning (e.g. memory disturbances) or disordered functional patterns (e.g. depressive symptoms), but also toward interpersonal systems such as couples and families (e.g. partner conflicts).

Depressive disorders may serve as an example for the way disordered functioning may be influenced by intervention. These disorders manifest themselves by loss of interest, loss of activities, feelings of worthlessness, guilt feelings, etc. Cognitive behavior-therapy approaches (see Hautzinger and de Jong-Meyer 1996) attempt to affect the psychic components of depressive disorders selectively and systematically through the use of psychological methods. The therapeutic arrangement consists, among other things, in the organization of learning processes that recreate the motivation to participate in gratifying activities and consolidate the quality and frequency of leisure and professional activities (e.g. through reinforcement schemes). Furthermore, cognitive components are selectively influenced that motivate the individual to increase his or her level of activity, promote gratifying emotions, enable appropriate causal attributions, etc. Self-confidence training is used to modify the individual's self-image. The various elements of therapy are thus systematically integrated and do not simply constitute an agglomeration of single aspects.

Clinical-psychology methods of intervention are traditionally largely restricted to the treatment of psychic disorders (e.g. Van Hasselt and Hersen 1994; Bellack and Hersen 1990). In the last 20 years, they have been increasingly applied to somatic disease as well (Sweet et al. 1991).

6.2 Psychotherapy

The traditional conception of psychotherapy covers the subset of interventional methods in clinical psychology

that are used for the treatment of disordered functional patterns (syndromes) and disordered interpersonal systems in the presence of psychic disturbances (Freedheim 1992). The various forms of psychotherapy display a similarity of structure (Perrez and Baumann 1998b):

1. Introductory phase, with thorough assessment and establishment of indications
2. Construction of the therapeutic relationship, which enables role-structuring and the formation of a therapeutic alliance
3. Realization of therapeutic learning
4. Evaluation of the therapeutic process

Behavioral therapy occupies a special position in psychotherapy because of its particularly close connection to scientific psychology (Baumann 1996). Classical behavioral therapy was primarily based on the theory of learning. In the early 1970s, new currents took on importance, such as the social-cognitive learning theory of Banduras (model-based learning) and the cognitive approach of Beck. There is no single definition of behavioral therapy. The characterization by Franks and Wilson (1975; compare Margraf and Lieb 1995) is often cited with approval; this characterization stresses the close relation of behavioral therapy to scientific psychology, especially regarding the application of principles of experimental and social psychology and the systematic evaluation of the effectiveness of treatment.

More than any other method of psychotherapy, behavioral therapy retains as a central element its orientation toward empirical psychology (Margraf and Lieb 1995). Current behavioral therapy still places an emphasis on learning psychology, but also makes use of other subdisciplines (e.g. cognitive, emotional, and social psychology).

Behavioral therapy has become an overarching term for a multitude of diverse methods that are also of major importance in psychiatry (e.g. Bellack and Hersen 1993; Margraf 1996). Behavioral therapy includes very diverse types of intervention and has proved its value remarkably well in multiple evaluative studies (see Sect. 6.5). Behavioral therapy is particularly helpful in psychiatry because of its focus on concrete behavior.

6.3 Combined Approaches in Psychotherapy

Although behavioral therapy is well established and has been thoroughly evaluated, it has nonetheless been criticized from a psychological viewpoint. Behavioral therapy has only partly fulfilled its basic aim of being founded on the entirety of empirical psychology, and in its structural development it has partly become an independent school of psychotherapy, with the associated drawbacks (Baumann 1996). A less school-dependent and more overarching concept of psychotherapy is required in order to provide the necessary depth. Combined approaches may be listed under the following headings (see Norcross 1995):

- *Integration*: This refers to a theoretically based combination of different approaches (e.g. behavioral therapy and psychoanalysis).
- *Eclecticism*: The effective elements of diverse approaches are applied, without regard to their theoretical compatibility.
- *Common, general, nonspecific factors*: These related terms have been used in a pejorative sense ("nonspecific factors as placebo effect") and in an explanatory sense ("nonspecific factors are responsible for the absence of differential findings"). Recently, the term "general factors" has been used to refer to important dimensions (central postulates) that should be realized in all forms of psychotherapy (Weinberger 1995; Grawe 1995, 1998).

6.4 Evaluation

The evaluation of individual therapeutic approaches and systems of care is especially important in the interventional sector (Baumann and Reinecker-Hecht 1998). Behavioral therapy has given a major impulse to the evaluation of therapeutic approaches, while the evaluation of systems of care and questions of quality assurance (Haug and Stieglitz 1995) have only recently received major attention in psychology.

Effectiveness is a central element of scientifically based forms of intervention (Perrez and Baumann 1998a). It should, however, be remembered (Baumann 1997) that the effectiveness construct has multiple components, so that we cannot speak of *the* effectiveness of a method of treatment. Effectiveness must be specified with respect to the following points, among others:

- Data level, data source, constructs (see Sect. 2.3)
- Level of abstraction of the therapeutic objectives (theoretical concepts, concepts of disposition and observation; Perrez and Baumann 1998a)
- Time of evaluation (during or at the end of therapy or at the time of catamnesis)

Given these multiple aspects of effectiveness, it is hardly surprising that there is sometimes controversy over the effectiveness of psychotherapeutic techniques.

Alongside the evaluation of effectiveness of psychotherapeutic methods by individual studies, the

meta-analysis of groups of studies has risen in importance in the last 15 years (Smith et al. 1980; Lipsey and Wilson 1993; Grawe et al. 1994). Meta-analyses attempt to evaluate the available literature systematically by means of so-called strengths of effect (for the advantages and disadvantages of meta-analyses, see e.g. Grawe et al. 1994). Meta-analyses in the narrow sense provide an important contribution to the evaluation of the effectiveness of psychotherapy, but an evaluation cannot rest on such meta-analyses alone (see Vol. 1, Part 2, Chap. 10). These primarily provide descriptions, but can also detect differences in the effectiveness of different forms of therapy. The evaluation of differences, however, like all statistical questions, depends on the particular conventions used (e.g. α-risk).

A normative approach to evaluation going beyond meta-analyses has been recommended by the American Psychological Association (Task Force APA 1993). A catalogue of criteria was created for well-founded interventional techniques, which can be drawn upon as a raster for the evaluation of individual forms of intervention. The Task Force acknowledged the arbitrariness of the criteria chosen, but justified their selection on the basis of expert knowledge and provided a list of psychotherapeutic techniques that satisfy the given criteria. Such lists must, of course, be tested and updated continually, so that "seals of approval" will not be awarded in an uncontrolled fashion.

As the discussions of the approach used by Grawe et al. (1994) reveal, the question of evaluation is central for intervention and remains unsettled in psychotherapy in many of its aspects. Further discussions of this question can profit greatly from a consideration of methodology in psychology.

7 Overview

The discussion in this chapter reveals that psychology can provide major contributions to psychiatry, both through an understanding of psychological methods and through psychological theories. Unless a reductionist position is assumed ("all psychic phenomena are ultimately biologically based and thus biologically explicable"), which we consider unacceptable, psychiatry will always be dependent upon psychology for such major contributions. To what extent this transfer of knowledge can actually be realized depends on the efforts undertaken by both sides. Psychology and psychiatry must make a commitment to multimodal thinking and must acquire competence in diverse modalities if communication between them is to take place. For psychology, this implies a deeper consideration of the modern biological concepts of psychiatry; psychiatry, on the other hand, must take adequate account of phenomena on the psychic level, despite its strong biological orientation. Dialogue with the individual patient can only occur on the psychic level. This perspective must, therefore, be optimized for the benefit of those who suffer from psychic disorders.

G. Goldenberg

Neuropsychology of Memory and the Central Executive

Translator: S. Davison

1 Introduction

This chapter concentrates on current developments in two areas of neuropsychology that are of particular relevance in understanding psychiatric syndromes: disorders of memory and disorders of the central executive control of cognitive and emotional function. Both areas are strongly interlinked. The chapter begins with the description of a model of human memory that is integrated by the central executive. On the basis of this model, clinical aspects of relevant disorders are described and new approaches to their explanation presented for discussion.

2 A Neuropsychological Model of Human Memory

In the field of neuropsychology, the lay concept of "memory" is actually separated into several different memory functions (Tulving 1985; Baddeley 1990; Squire et al. 1993). In order to describe and distinguish these different functions, neuropsychologists construct models. These models are supposed to explain observed behaviour and bridge the gap between behaviour and neuronal function. However, they are, and always will be, theoretical constructs, whose contents and classification will remain the subject of heated debate and constant evolution (Goldenberg 1996).

Traditionally, a distinction is made between a primary type of memory, which serves to hold information in the short term, and a secondary type of memory, in which information is stored in the long term. While primary memory has a restricted capacity, secondary memory, in principle, has no restrictions on its capacity. The contents of primary memory are directly present in the conscious mind, whereas the contents of the secondary memory first have to be retrieved in order to enter consciousness.

Primary and secondary memory are also known as short-term and long-term memory, respectively. In the model presented below, primary memory will be referred to as working memory. Secondary memory will be subdivided into episodic and semantic memory.

2.1 Working Memory

Information held in primary memory can be processed cognitively. Primary memory can therefore be thought of as working memory. Theories about working memory postulate that it is comprised of specialised subsystems and a central executive.

The verbal subsystem of working memory holds verbal information, i.e. mainly words and digits, whereas the visuospatial subsystem stores visual and spatial information in the short term. The central executive is needed when information held within both subsystems needs to be processed simultaneously, such as when planning several moves ahead in a chess game. The central executive also co-ordinates the activities of the two subsystems when they are attending to several competing flows of information, such as when reading while also listening to the radio.

In the aforementioned example of the chess game, the planning ahead of possible combinations of moves is not an end in itself. It may serve to find a way out of a tricky situation or at least to lead to a decision about the next move. This example clearly demonstrates that problems are solved and decisions made about future behaviour in working memory.

It can therefore be seen that the central executive of the working memory is also a higher controlling authority of thoughts and behaviour. This aspect of the central executive will be discussed in more detail in the second part of this chapter.

2.2 Episodic and Semantic Memory

Within secondary memory, a distinction is made between episodic and semantic memory. Episodic memory contains memories of individual, time- and place-specific memories of discrete events. In contrast, semantic memory stores general knowledge whose validity is not restricted to individual episodes. We are often not aware of how and when such knowledge was acquired. The contents of episodic and semantic memory are closely linked to one another. During storage of an incident in episodic memory, individual incidents will be related to general knowledge and interpreted in this light. When the incident is retrieved, missing details will be plausibly filled in using general knowledge.

Most of the information that is taken up into episodic and semantic memory is initially labile and can still be forgotten. Really long-lasting storage requires a consolidation process that can last over several years. It can generally be assumed that information that has survived for about 5 years will be retained for the rest of one's life.

The retrieval of contents from episodic and semantic memory stores is co-ordinated and checked by the central executive. The central executive is particularly important for properly ordering and for checking the plausibility of the contents of episodic memory.

2.3
Explicit and Implicit Knowledge

Episodic and semantic memory share the fact that information retrieved from them enters conscious awareness. It is not only the retrieved information, but also the act of retrieval itself that is conscious. Episodic and semantic memory, as forms of explicit or declarative memory, have therefore been distinguished from implicit, non-declarative or procedural memory. These latter terms bring together a series of learning capacities and acquired skills that are used without being consciously sought and retrieved. Sometimes there is not even any conscious access to the contents. Pre-school children, for example, already have implicit knowledge of grammar rules, but this is only manifest in the fact that they build grammatically correct sentences. The children would be unable to state explicitly the rules that govern their sentence construction. In addition, motor skills such as skiing or playing the piano are only truly mastered when their rules have passed from explicit to procedural knowledge and can give rise to the behaviour in question without a detour via conscious retrieval.

3
Memory Disorders in Brain Lesions

3.1
Disorders of Working Memory

When one of the subsystems of the working memory fails, the capacity to retain the relevant information is reduced. The loss of function is manifest even in very easy tasks that do not require any intervention from the central executive. Such a task for the verbal subsystem is the digit span, where a patient has to repeat a sequence of digits immediately after they are presented to him or her. A parallel task for the visuospatial system is the block span, where a sequence of spatial locations have to be reproduced immediately after presentation. Significant reductions in performance on these simple memory tasks are usually linked to further disorders in processing the corresponding information: the digit span with aphasia, and the block span with visuospatial disorders.

If the central executive of working memory fails or is impaired, the simple span capacities are preserved, as they only require the short-term storage, and not the simultaneous processing of the information. However, such patients have difficulties with tests which require information to be simultaneously held and manipulated. An example of such a test is the Paced Auditory Serial Addition Test (Gronwall and Wrightson 1981), in which a patient hears numbers in quick succession and, on hearing each number, must answer with the sum of that number and the preceding one.

3.2
Anterograde and Retrograde Memory Disorders

Disorders of explicit long-term memory may be anterograde or retrograde. Anterograde disorders affect the ability to take new contents into long-term memory and to consolidate them there permanently. Retrograde memory disorders, on the other hand, consist of the loss of memories that were permanently stored and retrievable before the onset of the disorder. Retrograde memory disorders may be restricted in time, only affecting the memory contents that were still in the consolidation phase at the onset of the disorder, or they may be extensive and affect memories that had previously been stored permanently and had been retrievable for many years (Hodges 1995).

3.3
Amnesic Syndrome

Brain damage can cause an amnesic syndrome. The amnesic syndrome is characterised by a selective impairment of the acquisition and consolidation of new information into episodic and semantic memory. Primary memory and implicit learning capacity are preserved.

The amnesic syndrome is always associated with a time-restricted retrograde memory deficit that may stretch back from a few minutes to a few years. On the other hand, the retrieval of memory contents that were already permanently consolidated remains unharmed.

The anterograde memory impairment is seldom global. In the case of incomplete amnesias, the learning of new information is not impossible, but is slow and patchy. In some cases, memory may even appear normal if recall is tested soon after the acquisition of information. However, rapid forgetting over only a few days demonstrates the defective consolidation process. The impairment in the ability to retain information in memory may be specific to particular types of material, either mainly verbal or mainly non-verbal (Milner 1971).

In clinical practice and in everyday life, the lack of acquisition of new information in episodic memory is more noticeable and dramatic initially than the faulty storage in semantic memory.

The inability to store ongoing events in episodic memory can lead to loss of orientation in time and place. The fact that new learning in semantic memory

is also impaired may only become noticeable when patients try to return to training or study.

3.4 Confabulation

Neuropsychological syndromes are characterised by the fact that they are seldom "pure". This is because the causes of brain damage are rarely restricted to exactly those structures which are responsible for one particular neuropsychological function. The amnesic syndrome occurs particularly commonly in association with simultaneous impairment of the central executive. When this occurs, not only is the consolidation of new material faulty, but so are the mechanisms for systematic retrieval of existing information and for monitoring plausibility.

Confabulation may ensue. Patients do not search systematically for the correct answers to questions. Instead they give the first answer that comes to mind, without checking its plausibility. If the material is only being stored poorly from the outset, then the symptoms of the actual memory impairment will be exacerbated by the impairment of the retrieval mechanisms. However, the degree of confabulation depends less on the extent of memory impairment itself than on the extent of the accompanying impairment of executive functions (Fischer et al. 1995).

3.5 Extensive Retrograde Amnesia

Extensive retrograde memory disorders extend beyond time-limited retrograde amnesias and affect materials that were acquired and consolidated many years previously. They are an area that has been actively debated and researched for some years in the field of neuropsychology (Warrington and McCarthy 1988; Hodges 1995). They may affect episodic or semantic memory.

3.5.1 Retrograde Disorders of Autobiographical Memory

Episodic memory is usually referred to as autobiographical memory when discussed in connection with extensive retrograde memory impairment. Extensive retrograde impairment of autobiographical memory has been studied and analysed most extensively in alcoholic Korsakoff's syndrome.

In Korsakoff's syndrome, the memory gaps extend back over many years. However, they show a time gradient, with relative sparing of more remote memories. Serious anterograde memory impairment always accompanies the extensive retrograde impairment. It was therefore suggested that the apparent retrograde memory impairment might come about as a result of an anterograde memory impairment which worsens over years, hindering the learning of new information, such that the apparently "lost" past memories are never properly stored in the first place. However, convincing evidence to the contrary was provided by the observation of a patient who had written an autobiography shortly before the onset of Korsakoff's syndrome (Butters and Cermak 1986). In comparison with the written autobiography, it was evident that there was complete retrograde memory loss for the preceding 10 years. Beyond that, the impairment decreased with increasing remoteness of the memory, but nonetheless extended back over 50 years. The patient had therefore clearly lost access to memories that were previously stored and accessible.

It is a matter of controversy whether extensive impairment of autobiographical memory can occur in the absence of anterograde memory impairment. In the first instance, this combination would suggest a psychogenic amnesia or a feigned deficit. In the case of patients with "identity loss", who no longer know what they are called or who they are, this assumption is seldom called into question (Kopelman et al. 1994). Recently, however, several cases have been reported following head and brain injury where there was minimal or no anterogorade memory impairment but there was severe and extensive retrograde impairment of autobiographical memory, and investigators could find no psychiatric symptoms or motives for simulation (Kapur 1993). The fact that several patients with focal retrograde disorders of autobiographical memory occurring in isolation had lesions in the same parts of the brain has also been put forward as evidence for a possible organic aetiology for such disorders (see below).

Another unresolved question is whether extensive retrograde amnesia can selectively affect either autobiographical memory or semantic memory (Hodges and McCarthy 1993; De Renzi et al. 1987). Selective loss of autobiographical memory might be simulated because the reconstruction of one-off autobiographical events makes greater demands on the central executive than the retrieval of general semantic knowledge. Disorders of the central executive may therefore lead to apparently selective loss of autobiographical memory. This relationship appears particularly convincing when the retrograde impairment of autobiographical memory manifests itself less as a complete loss of memory and more as a confabulatory mixing and mistaking of memories (Hodges and McCarthy 1993). On the other hand, patients have also been described in whom retrieval of autobiographical events was better preserved than was that of general semantic

knowledge (De Renzi et al. 1987). This would suggest that autobiographical memories and general knowledge may in fact have different cerebral substrates.

3.5.2 Retrograde Disorders of Semantic Memory

Patients with extensive retrograde impairment of semantic memory lose access to knowledge that was previously self-evident to them. This loss of knowledge affects linguistic functioning. Spontaneous speech may be devoid of content and filled with set phrases. Disorders of word finding and naming mistakes become apparent when trying to name objects. As far as misnaming of objects is concerned, it is typical for generic categories to be preserved while differentiation within particular categories is lost. Thus a patient may call all four-legged animals horses. It hardly ever occurs, however, that a horse is mistaken for a type of fruit or vice versa. In addition, if the names of objects are provided and patients are asked to describe their characteristics, they cannot always answer. They have particular difficulty in describing those characteristics that distinguish a particular specimen in a given category from other specimens in the same category. On the other hand, knowledge of the qualities that are common to the whole category is retained. If they are asked about the characteristics of a peach, patients know that, like most fruits, peaches are round and juicy, but they do not know that their skin is velvety and they have large stones. Impairment of semantic memory is therefore more likely to manifest itself as an impoverishment and lack of differentiation of knowledge than as a complete loss of knowledge of particular things (Warrington 1975).

3.5.3 Category-Specific Disorders of Semantic Memory

Extensive retrograde impairment of semantic memory may be category specific (Warrington and McCarthy 1987; Gainotti et al. 1995). A series of patients were described who had lost knowledge of natural things such as animals, fruits and vegetables but had well-preserved knowledge about man-made things such as tools and items of furniture.

The opposite problem, i.e. preserved knowledge of natural things and missing knowledge about man-made things, has only been described in very few cases. All except one (Sacchett and Humphreys 1992) of the affected patients had severe aphasias which prevented all but a very limited examination of their semantic memory.

The differentiation between man-made and natural things describes only very approximately which types of knowledge are retained and which are lost in these patients. For example, patients who have lost knowledge about natural things often retain the ability to distinguish body parts, even though these are naturally occurring things. A plausible explanation for the pattern of the gaps in knowledge is that particular types of knowledge about the individual attributes of things are linked together (Warrington and McCarthy 1987). For example, one type of knowledge specifies the visual appearance of objects, whereas another type of knowledge specifies the motor actions and functions that are associated with them. The theory is therefore that examples from the category of naturally occurring objects are distinguished by differences in their appearance and rarely by differences in their function. An apple is distinguished from a pear by its curvature and not by its function as an edible fruit or by the motor action of eating it. In contrast, man-made things have differing functions and are associated with different motor actions. A pair of pliers is used differently from a hammer. Differences in appearance are largely determined by the different functions and uses: the head of the hammer has to be firmly attached to the shaft so that the force of the blow can be transmitted to the nail, whereas the pliers have to have a joint such that the jaws can close around the nail. Body parts likewise have specific and distinct functions which determine their shape: the nose has openings to draw in air, and the hand has fingers to grasp with. Category-specific deficits can therefore occur in which either knowledge about appearances or knowledge about functions is selectively lost. Categories of objects are affected to a greater or lesser extent by the deficit, depending on how important that type of knowledge is for distinguishing between different examples within that category. The loss of knowledge about appearances would tend particularly to affect natural things, whereas the loss of knowledge about function and usage would tend particularly to affect man-made objects and body parts.

The idea that semantic memory is composed of subsystems which each hold information about only one aspect or property of objects is supported by observations of patients who have selectively lost their knowledge about the appearance of objects while retaining knowledge about the non-visual properties of the same objects (Goldenberg 1993). In the same way, the failure of patients with apraxia to use tools properly has been interpreted as being caused by a selective loss of the knowledge about the correct use of objects and tools (De Renzi and Luchelli 1988; Goldenberg and Hagmann 1998).

Despite some methodological shortcomings (Gaffan and Heywood 1993), these observations present a coherent and convincing picture. It follows that semantic memory consists of a network in which similar types of information about particular

characteristics of things are linked together. When the knowledge is retrieved, the related components are simultaneously activated. If only individual parts of the network are damaged, then knowledge is lost selectively for individual categories of objects or for individual properties of things.

4
Anatomical Basis of Memory Disorders

Technical advances in the last 10 years have led to an enormous expansion and refinement of the depiction of the anatomical basis of psychological functions and their disorders. The impressive images that are publicised and the popularity which they enjoy should not, however, be allowed to obscure the fact that the mapping of psychological functions onto anatomical locations remains an uncertain enterprise.

The uncertainty arises from the fact that psychological functions are theoretical functions that can only be inferred by interpreting the data that are actually observed. Even when the anatomical findings themselves are accurate and reliable, relating them to particular psychological functions remains a matter of interpretation and controversy. Nevertheless, it is precisely these attempts to discover and verify such relationships that form the essence of and also the fascination of neuropsychology.

4.1
Cerebral Substrate of Working Memory

The measurement of cerebral blood flow in healthy subjects undertaking tasks which require the short-term storage of verbal or visuospatial material provides a clear and credible picture of the cerebral basis of working memory. The short-term storage of verbal information activates pre-motor and temporo-occipital speech areas of the left hemisphere in a similar way to speech. This is attributed to the fact that the active retention of verbal memory within working memory occurs through inner speech (Paulesu et al. 1993). In contrast, visuospatial tasks activate predominantly right brain regions, namely the frontal and parieto-occipital cortices (Jonides et al. 1993). However, if the information to be held relates to the appearance of objects rather than to their spatial relationships, the activity shifts from the right to the left parietal lobe with additional activation of the left temporo-occipital region (Smith et al. 1995). The anatomy of the central executive of working memory will be discussed in the last section of this chapter.

4.2
Amnesic Syndrome

The localisation of the structures which are responsible for the uptake and consolidation of information in declarative long-term memory have mainly been deduced from the examination of lesions in patients with the amnesic syndrome. It is clear from this work that these memory functions rely on the integrity of the limbic structures which surround the third ventricle on the inner surface of the cerebral hemispheres.

Within the limbic system, there are three strategic locations in which lesions typically give rise to an amnesic syndrome: the hipppocampal formation, the thalamus and the basal forebrain. The core symptoms of the amnesic syndrome should be the same for lesions in all three regions, but because of their differing anatomical relationships, each may have differing accompanying symptoms.

Lesions of the basal forebrain can also affect the frontal lobes and are then often associated with confabulation (Fischer et al. 1995). Lesions of the thalamus form the basis for Korsakoff's syndrome, which is likewise associated with confabulation and with extensive impairment of autobiographical memory. These connections are understandable if we accept that confabulation and extensive impairment of autobiographical memory occur as a result of insufficient central executive control of retrieval from long-term memory. The central executive depends largely on the function of frontal cortical areas and frontobasal lesions thus lead directly to disorders of the central executive. Thalamic lesions may conceivably interrupt the connection of the frontal lobes to the limbic system and with it the central executive's access to the memory store (Hodges and McCarthy 1993).

The hippocampal formation borders on the neocortical areas of the temporal lobe. Lesions of the temporal neocortex can cause extensive retrograde memory deficits (see Sect. 4.3). In addition, the hippocampal formation lies close to the amygdala, which plays an important role in the regulation of emotions. However, it has not yet been conclusively established which symptoms may be attributed to damage of the amygdala in humans (Aggleton 1993; Young et al. 1995).

Bilateral damage to the limbic system is necessary for global amnesia, while unilateral lesions lead to material-specific memory impairment. Verbal material is affected predominantly by left-sided lesions, and non-verbal material by right-sided lesions. However, the consequences of left-sided lesions are on the whole more marked than those of purely right-sided lesions. The few patients in which it has been suggested that unilateral lesions may have led to a transient global

amnesia have all without exception had left-sided brain lesions (Goldenberg 1995a).

4.3
Extensive Retrograde Impairment of Semantic Memory

The cases of category-specific deficits of semantic memory that were mentioned above have provided a fairly consistent picture of the anatomical basis of semantic memory (Gainotti et al. 1995). They suggest that the left hemisphere is more important than the right for nearly all types of knowledge. Unilateral left brain lesions can be sufficient to cause retrograde deficits of semantic memory. This asymmetry is seen irrespective of whether the knowledge is tested through speech or pictures (Gainotti et al. 1983; Goldenberg 1995b). Temporal lobe lesions form the basis of deficits specific to knowledge about living things, whereby the lateral parts of the inferior and middle temporal gyri may be important. On the other hand, all patients with a loss of knowledge about man-made things have had suprasylvian lesions. These lesions were very extensive and affected the frontal lobes, parietal lobes and the perisylvian speech area. In keeping with the extensive nature of the lesions nearly all patients had severe aphasias.

Isolated deficits in knowledge about the appearance of things have been described following lesions of the temporo-occipital gyri at the base of the left hemisphere (Goldenberg 1993), whereas apraxias with deficits in the knowledge about the correct use of objects have been linked to left suprasylvian areas (Basso et al. 1985). These areas are bordered on one side by the areas responsible for category-specific deficits and on the other side by both visual and motor cortices. Such topographical relationships lend plausibility to the hypothesis mentioned above that similar types of information are linked in semantic memory.

Studies of cerebral blood flow in healthy subjects concur in this respect with clinical findings. Activation during animal recognition is concentrated in the inferior temporal lobe, whereas during the recognition of tools it extends over the sylvian fissure into the parietal or frontal lobe (Damasio et al. 1996; Perani et al. 1995). Visual mental imagery activates left occipital and temporo-occipital areas (Farah 1989; Goldenberg 1993; D'Esposito et al. 1997).

4.4
Extensive Retrograde Deficits of Autobiographical Memory

Extensive autobiographical memory deficits following thalamic lesions have already been mentioned. These are associated with an anterograde amnesia and are best understood as a disorder of the systematic retrieval of available autobiographical memories. Extensive bilateral temporal damage, such as that seen after herpes simplex encephalitis, destroys not only semantic memory but also remote autobiographical memory.

It is less clear what forms the anatomical substrate of selective deficits of autobiographical memory. Such deficits might be caused by right lesions of the fronto-temporal cortex (Markowitsch et al. 1993; O'Connor et al. 1992). However, patients have been described in which no clear lesions can be detected.

4.5
Memory Disorders in the Degenerative Dementias

The combination of an amnesic syndrome with extensive retrograde memory impairment is particularly characteristic of dementia of the Alzheimer type. This fits well with the theory that the temporal lobe plays a key role in memory function, because the pathological changes in Alzheimer's disease appear to extend from the entorhinal cortex on the medial side of the temporal lobe to the hippocampus on one side and laterally into the neocortex on the other side (Braak and Braak 1991).

It appears that, in the early stages of the disease, the retrograde impairment of semantic memory affects natural things to a greater extent than man-made one (Silveri et al. 1991). This finding is compatible with the predominantly temporal location of the degenerative changes.

5
Disorders of the Central Executive

The disorders described in this section are traditionally referred to as the "frontal lobe syndrome". This term does not, however, fit well with the logic of neuropsychology. Neuropsychological method consists first of relating observed behaviours to psychological functions and then seeking the neurological substrate of such functions. The term "frontal lobe syndrome" suggests a direct relationship between behaviour and the neurological substrate. On the assumption that the disturbed functions are best described as those of the central executive, the term "dysexecutive syndrome" has gained acceptance in recent years (Baddeley 1996; Shallice 1988).

The central executive has already been discussed in an earlier section in relation to memory function. It is postulated that the same central executive that

co-ordinates working memory also co-ordinates and oversees other cognitive functions, namely emotional reactions and social behaviour. This theory is not without its problems. It can lead to the central executive being equipped with omnipotence and omniscience and thus becoming a "mind within the mind" or a homunculus. With some exaggeration, it could be suggested that the indivisible and inexplicable soul hides in the central executive from the attacks of neuropsychological analysis (see Baddeley 1996).

Faulty central executive function is assumed to cause a variety of neuropsychological symptoms. In the first instance, these can be divided into two categories: disorders of cognitive problem-solving and disorders of emotions and social behaviour.

5.1 Disorders of Problem-Solving

The central executive has to intervene when problems and obstacles interrupt routine activities, thereby calling for forward planning, the weighing up of alternative actions and rational decision-making. If the central executive fails, patients may continue their routine activities without recognising that any problem exists. If patients seek solutions to problems, they fail to take all the alternatives into consideration. They stick to previous ways of solving problems and make rash decisions without consideration of the consequences and also sometimes in violation of previously given rules.

Studies of the dysexecutive syndrome using psychological tests aim largely to demonstrate the cognitive problem-solving deficits. Several types of task are used for this purpose (von Cramon and Matthes-von Cramon 1993).

Sorting tests require a series of stimuli to be classified and sorted according to as many different criteria as possible. For example, coloured tiles of varying size, thickness and shape may be sorted by colour, size, thickness or shape. In order to find the similarities between the stimuli, the patient has to be able to abstract from the visible differences. Sorting tests therefore require both the ability to abstract and flexibility of thought. Tests aimed specifically at flexibility of thought are those in which the sorting criteria are learned over several attempts and then changed. If the central executive fails, then habitual reactions are not successfully inhibited.

So-called fluency tests examine the fluency of the production of ideas. For example, patients are asked to give as many words as they can think of beginning with a particular letter, to produce as many graphical figures as they can, or to name as many uses for a particular object such as a brick within a specified time. A further variation of the fluency test is the random generation test (Baddeley 1966; Spatt and Goldenberg 1993). In this test, patients are required to produce digits or letters in a random order. This apparently trivial exercise makes great demands on the central executive. The human mind cannot throw a dice. The human mind can only produce the digits or letters by using strategies (e.g. in ascending order or steps of two). If a strategy is employed for too long, then a predictable sequence of letters or digits results. In order to simulate chance, each strategy must be used for only a short time. The central executive must monitor for uninterrupted strategies and change them.

Perseveration appears as a central symptom of disorders of the central executive in both sorting and fluency tests; patients stick to previously selected answers and strategies. Perseveration may appear after an interval during which another answer was given.

A further line of investigation consists of administering planning exercises in which patients are confronted with complex problems and have to seek a solution. The problems may consist of mental puzzles in which counters or balls have to be moved from one position to another in accordance with particular rules. These games require patients to plan several moves ahead, and the final position can only be reached via a circuitous route. Another possibility is to present patients with tasks that involve planning activities similar to those encountered in daily life, such as the drawing up of a timetable in which a series of things to do have to be co-ordinated in the optimal way. The disturbance of executive control function manifests itself in these tasks as rash actions, inadequate consideration of all circumstances and the breaking of rules.

All cognitive "frontal tests" share the fact that patients receive clear instructions as to what they have to do; that patients have to concentrate fully on the task at hand; and that they are protected in the test situation from outside distractions.

The abilities required for such tests, namely abstraction, production of ideas, flexibility of thought and forward planning, are strongly reminiscent of a description of intelligence. In fact, a high correlation was found in normal subjects between results on frontal tests and culturally fair intelligence tests (Duncan et al. 1996).

5.2 Disorders of Behaviour

The consequences of disordered control of emotional and social behaviour do not lend themselves easily to systematic classification, especially as some produce apparently conflicting symptoms. Increased

"environmental dependency" may be manifest in differing levels of severity. Extreme and impressive manifestations are "utilisation behaviour" and "imitation behaviour".

The term "utilisation behaviour" describes the tendency to pick up objects within easy reach and use them, even when their use is inappropriate at that moment. For example, if a rubber stamp and a piece of paper are lying on a table, the paper will get stamped all over. Milder manifestations which lie at the boundary to normality are the tendency to play with objects that are lying around, such as match boxes or pencils.

In the case of imitation behaviour, patients mimic the actions of those facing them without being asked to, and sometimes in contravention of the rules of social conduct. Echolalia, the constant repetition of the last few words of the person one is talking to, belongs in this category.

Increased distractibility is a further symptom of so-called environmental dependency. It is difficult for patients to tune out irrelevant environmental stimuli and they attend to them, sometimes abandoning their original behavioural goal. Even patients who can resist this temptation complain that they are easily distracted by irrelevant environmental stimuli and are hindered in their activity.

Poor impulse control, manifest as unbridled outbursts of aggressive or sexual behaviour, is a symptom of failure of the central executive that has particularly serious social consequences. Pathological outbursts of anger may be precipitated by trivial things. Sometimes patients are able to recognise in retrospect that the precipitant was ridiculous and the anger out of proportion. At the time, however, they are incapable of controlling their behaviour. Inadequate control over sexual impulses may be manifest in socially unacceptable attempts to seek sex or, in extreme cases, as excessive masturbation.

Rash behaviour refers above all to the behaviour involved in solving cognitive problems. It is a matter of opinion whether this is classed as a cognitive or a behaviour disorder. When patients are confronted with problems they do not think through the consequences of several possible solutions. Instead they decide overhastily to take the first behavioural option they can think of. As a result of this rash behaviour, problem-solving is stopped before it has really begun and the need to solve a problem is not even recognised and assessed accordingly.

Rule-breaking as a type of error seen in frontal lobe tests has already been discussed. In such tests, patients must follow rules that are given to them at the time of the test but that otherwise have no general application. Patients may, however, break social rules that they have been familiar with for many years. Such rules exist, for example, for engaging in conversations. When patients disregard them, they do not let the other person get a word in; they do not take notice of objections; they talk round questions; and bring up topics that are not appropriate for the other person they are with or the situation they are in. Disregard for social rules relating to good manners and hierarchy is experienced by others as over-familiarity.

Flattening of affect and egocentric behaviour are subtle symptoms which may only be noticed by the closest relatives, but that nonetheless have particularly severe consequences because of their effect on interpersonal relationships. The patients appear coarse and show little sympathy for those closest to them. In conflicts they are egocentric and concentrate exclusively on their own interest or misfortune. It appears as though they are incapable of simultaneously taking into consideration their own opinions and feelings as well as those of other people.

The central executive is needed to initiate behaviour in the absence of an external impetus as well as to see behaviour through in the absence of external reinforcement. If the central executive fails, then lack of drive results. Patients do not start any activities for themselves. Instead, they wait for instructions and requests. Behaviours that have been started are broken off in the face of small difficulties. Patients make no long-term plans and do not actively contemplate the future.

Placidity (from the Latin *placidus*, meaning calm, peaceful) is related to lack of drive, but the two are not identical and do not necessarily occur in association with one another. Some patients with disorders of the central executive are excessively peaceable and contented. Remarkably, some patients experience this change as positive and rationalise it to the effect that the stroke of fate that was the brain damage has actually helped them to achieve peace with themselves and the world. It can be that relatives also see the change as advantageous if patients engaged in aggressive behaviour before their brain injury.

6 Dissociation of Different Aspects of Central Executive Deficit

It is an unresolved question whether the central executive represents a unified function or whether a whole series of controlling authorities and functions, related to one another to a greater or lesser extent, are hidden within this construct. To answer this question, it is essential to know whether different aspects of the disorders of executive control can occur independently of one another. Dissociation of the different aspects of the disorder of executive control would go against the idea of a unified central executive.

Clinical experience tends to support a division into several executive control functions that are independent of each other. The results of frontal lobe tests do not permit any conclusive predictions of behavioural disturbance. There are patients who manage normally on theoretical problem-solving tests but who founder in everyday life (Shallice and Burgess 1991; Saver and Damasio 1991). On the other hand, there are patients who fail on frontal tests but whose emotional and social behaviour in everyday life, at least according to clinical impression, are largely unremarkable. Patients with Parkinson's disease, for example, fall into this group (Goldenberg et al. 1990).

Below we present three theoretical approaches which attempt to explain the dissociation of cognitive problem-solving deficits and disorders of emotional and social behaviour. However, it must be borne in mind when assessing these theories that the assumption that the functions are not associated with one another is based on clinical impression and individual observations that are more or less anecdotal. It has not been systematically researched to date.

Two of the approaches presented are based directly on anatomical observations and equate the function of the central executive with that of the frontal lobes. In particular, they refer to the pre-frontal cortex, which occupies the anterior portion of the frontal lobe.

6.1 Integration and Inhibition

One anatomically based approach distinguishes two functions of the central executive which are each assigned to different sections of the pre-frontal cortex: one holds and integrates information in working memory, while the other prevents irrelevant information from entering working memory (Fuster 1989). This differentiation of the two functions is based mainly on experiments on apes who have parts of their frontal lobes removed.

Apes with dorsolateral frontal lesions fail to react to a stimulus after a delay when they are required to do so. Their difficulty appears be the holding of the association between the stimulus and the response in working memory. Primates with orbitofrontal lesions, on the other hand, have particular difficulties when the relationship between stimulus and response is constantly changed. They cannot prevent a previously learned association from influencing their reactions. The failure of the animals can be attributed to an inability to shield the working memory from irrelevant and distracting information.

Parallels can be drawn between the findings of these animal experiments and the clinical manifestations of impaired central executive functions in humans.

Frontal lobe tests call mainly for the storing and processing of information in working memory, whereas the control of everyday behaviour and emotions calls mainly for the suppression of irrelevant and digressive information and actions. Frontal tests are administered in a structured and distraction-free environment, whereas in everyday life, behaviour has to be controlled in unstructured situations and under the influence of environmental stimuli. Everyday life therefore calls more on the ability to shield from irrelevant stimuli and to inhibit digressive reactions than does the test situation. Conversely, the demands placed by frontal tests on the storing and comprehensive integration of information are probably greater than the requirements for controlling socially acceptable behaviour in everyday situations. The significance of this difference between "laboratory" and "life" in the manifestations of central executive deficits is demonstrated by patients who are able to perform without hesitation in problem-solving tests, but who behave unsystematically, perform rash and irrelevant actions and break rules when they have to plan and carry out real activities outside laboratory situations (Shallice and Burgess 1991). The observation mentioned earlier that patients with Parkinson's syndrome fail on frontal tests but are not conspicuous in everyday life for their chaotic behaviour or rule-breaking may also be an indication that everyday behaviour is better preserved than problem-solving in a laboratory.

6.2 Cognitive Planning and Behavioural Control

A further approach, based directly on anatomical observations, differentiates between the cognitive capacity of the central executive and its ability to intervene in the control of emotional reactions and behaviour. It is assumed that the latter abilities relate to the integrity of the orbitofrontal cortex and its connection to the limbic system. Saver and Damasio (1991) showed that a patient who had suffered a complete social decline as a result of "sociopathy" caused by brain damage, was not only able to complete cognitive problem-solving tests perfectly, but was also able to provide highly moral and socially acceptable solutions to theoretical cases of social conflict. The central executive was obviously able to plan and assess actions and their consequences, but could not carry this judgement over into real behaviour.

In a further study, Damasio et al. (1990) studied psycho-galvanic skin responses in this patient and five further patients with orbitofrontal lesions. The patients were shown pictures of catastrophes, maimings and nudity under two sets of conditions: once without

further instructions and once with the request that they describe their feelings on seeing the pictures. Whereas both normal controls and patients with non-frontal brain damage produced a psycho-galvanic response in both sets of conditions, the patients with frontal lobe damage showed a restricted response in the second set of conditions where they had to describe their feelings.

Damasio constructs a far-reaching theoretical speculation from these findings. He postulates that emotional reactions are the means whereby the prefrontal cortex is able to communicate biologically important decisions swiftly and effectively to the rest of the brain and translate them into appropriate behaviour (Damasio 1994). The anatomical basis for this behavioural control is the connection of the prefrontal cortex to the limbic system. This connection requires the integrity of the orbitofrontal cortex. The psycho-galvanic skin response is interpreted as the outward sign of emotional reactions that are controlled by the prefrontal cortex. Its loss in patients with orbitofrontal lesions means therefore that the pre-frontal cortex has lost access to emotions and thereby to effective control of behaviour. However, if we believe the experiment that forms the basis for this speculation, the challenge of describing one's own feelings is enough to suggest that the competence of the central executive is restored.

6.3
Control of Behaviour as a Dual Cognitive Task

The third approach presented here seeks an explanation at the level of psychological functioning without relating it directly to anatomical structures. It is postulated that the co-ordination of two simultaneous activities places a particularly large burden on the central executive. The control of emotional and social behaviour can be seen as just such a dual task. In order to control behaviour and emotions in everyday life, the information, demands and stimuli coming from the environment must be processed. Simultaneously, one's emotional reactions to the stimuli and one's behaviour must be observed, judged and controlled. This dual task overloads the central executive of working memory. The inability to supervise two activities simultaneously affects dual cognitive tasks as much as it does behavioural control. However, the impairment in dual cognitive task performance can only be demonstrated in specialised test situations, whereas the impairment of behavioural control has dramatic repercussions on patients' everyday lives.

The relationship between dual cognitive tasks and control of behaviour was examined in two studies by an English research group (Baddeley 1996; Alderman 1996). The ability to carry out two tasks simultaneously was examined using a combination of two very easy exercises, namely a tracking exercise and the repetition of sequences of digits. The ability to combine the two exercises was measured by assessing the drop in performance when the exercises were combined, compared with when the exercises carried out individually. In one study, this measure showed a far greater relationship with an assessment of behavioural disorder in brain-damaged patients than did a series of other frontal lobe tests. A further study looked at the effectiveness of behaviour modification techniques in patients with disturbed behaviour following brain injury (Alderman 1996). A few patients benefited from the therapy, whereas others were not able to bring their behaviour under control. The patients who were considered "non-responders" differed from the "responders" in their dramatic drop in performance on the dual-task experiment mentioned previously, but hardly differed at all in their performance in other frontal lobe tests. The authors inferred that these patients were incapable of simultaneously monitoring their own behaviour and the social sanctions it gave rise to, and therefore the therapeutic feedback was not able to exert any influence over their behaviour.

The assumption that behavioural control is a dual task and that the management of dual tasks is a particularly difficult and error-prone task for the central executive does not, however, explain the fact that there are patients who do badly in cognitive problem-solving tests but who nonetheless behave in socially appropriate ways. If the supervision of dual tasks places particularly large demands on the central executive, then all patients exhibiting any symptoms of impaired central executive function should show impairment in the supervision of dual tasks. By the same token, they should all exhibit disorders of behaviour. In order to explain the lack of association, it would be necessary to assume that the supervision of dual tasks can be impaired or preserved independently of the other tasks of the central executive. This assumption is supported by the fact that many studies have failed to demonstrate one clear impairment in dual cognitive tasks in patients with Parkinson's disease (Goldenberg 1990; Brown and Marsden 1991; Robertson et al. 1996).

There is, however, another possible explanation for the observation that some patients have problem-solving difficulties with otherwise good control of their behaviour. It is possible that the lack of behavioural impairment is only apparent. For example, patients with Parkinson's disease may in fact display poor impulse control and egocentricity, but this is considered by relatives as less important than the obvious motor symptoms; or the relatives excuse the poor impulse control and egocentricity as natural age-related changes. In any case, there are no systematic studies of putative behavioural disorders in these patients.

7
Anatomy of the Central Executive

Disorders of the central executive are frequently associated with lesions of the frontal lobes. Both animal experiments and clinical findings suggest that different kinds of lesions within the frontal lobes can damage different aspects of the central executive. In addition, disorders of the central executive can also be caused by lesions that do not lie in the frontal lobes.

7.1
Frontal Lobe Areas

Three areas of the frontal lobes are particularly relevant for disorders of the central executive: the dorsolateral pre-frontal cortex, the orbital pre-frontal cortex and the cingulate gyrus. Lesions in these three areas can be related to three different aspects of impairment of executive function.

Dorsolateral lesions lead to the severest deficits in cognitive problem-solving tasks. Selective behaviour disorders with preserved problem-solving are seen almost exclusively following orbitofrontal lesions. Lesions of the cingulate gyrus are particularly significant for lack of drive and placidity.

However, clinical experience shows that attributing symptoms to particular locations in the frontal lobes is more difficult than it is in other areas of the brain. Clinical cases are well known where extensive frontal lobe lesions were present in the absence of any noticeable effects on cognition or behaviour and, vice versa, where severe deficits did not correspond to any substrate on imaging.

Naturally, lesions may cross the boundaries between the three portions of the frontal lobe. The resulting combination of the different aspects of impairment of central executive function may lead either to symptoms potentiating one another or dampening one another. Thus disregard for rules, poor impulse control and increased distractibility in response to environmental stimuli may all worsen problem-solving ability and performance on frontal lobe tests. On the other hand, placidity and lack of drive may conceal the existing poor impulse control and egocentricity.

7.2
Laterality of Frontal Lobe Lesions

Localising symptoms in the frontal lobes differs from that in other parts of the brain in that differences between right- and left-sided frontal lobe lesions are less significant. In the case of dorsolateral lesions, it can be shown, using appropriate tests, that right-sided lesions may be more likely to interfere with the fluent production of graphic patterns or drawings and with the retention and processing of visuospatial information. On the other hand, left-sided lesions may be more likely to affect the fluency of speech and the storage and processing of verbal information. In addition, the effects of right- and left-sided frontal lesions on social behaviour and cognitive ability should differ. In lesions that are otherwise in exactly the same location in the frontal lobes, disturbed social behaviour and disregard for rules are more prominent in right-sided lesions, and difficulties in exercises which call for problem-solving and cognitive flexibility are more prominent in left-sided lesions.

7.3
Central Executive Deficits in Non-frontal Lobe Lesions

Impairment of central executive function is a clinical diagnosis which can and should be made independently of the location of the damage. In fact, such impairment is not necessarily associated with frontal lesions. Similar disorders can arise as a result of lesions that do not affect the frontal lobes at all. It is an unresolved question whether, in these cases, the central executive deficits arise because the connection to and from the frontal cortex has been interrupted or whether in fact the neuronal substrate of the central executive includes areas of brain outside the frontal lobes.

Impaired performance on frontal lobe tests is the most striking neuropsychological finding in the subcortical dementias which occur as a result of multiple white matter lesions, such as those seen in progressive supranuclear palsy, lacunar state and multiple sclerosis (Albert et al. 1974). "Frontal" cognitive impairment is also seen in patients with Parkinson's disease who show no other signs of dementia whatsoever (Goldenberg et al. 1990; Dubois et al. 1991). Even healthy normal individuals show decreased flexibility of thinking and inadequate planning ability on frontal lobe tests when they are tested after sleep deprivation (Horne 1988). Likewise, patients with schizophrenic disorders perform badly on frontal lobe tests. Moreover, they also show behavioural disorders such as affective flattening and apathy which resemble the sequelae of frontal lobe lesions (Weinberger 1988; Frith 1992). These symptoms are associated with memory and other cognitive deficits (Dunkley and Rogers 1994; McKenna et al. 1995).

It is a matter of debate whether a central executive disorder can be regarded as causing psychosis (Frith 1992; David 1992). It has been suggested that poor executive control of perception, thinking and affect

may lead to delusions, hallucinations and thought disorder. This idea is tempting, but not rigorous in its logic. It is reminiscent of the principle of political accountability; following a serious crime, the resignation of the Home Secretary is called for because the police were not able to prevent the crime. However, this is far from meaning that the Minister is suspected of having committed the crime him- or herself. The co-occurrence of psychosis with impairment of the central executive and of memory and other cognitive functions (Dunkley and Rogers 1994; McKenna et al. 1995) can be explained, without falling into any logical traps, as different manifestations of the same brain disease.

8 Conclusions

The neuropsychological study of schizophrenia is a growing field for the exchange of ideas and collaborative working between psychiatrists and neurologists. Psychiatric research overlaps with neurological research insofar as it is concerned with the study of the psychological manifestations of brain diseases. Neuropsychology brings methods and ways of thinking to the study of psychiatric disorders that were developed first and foremost from experience with patients with circumscribed, anatomically defined brain lesions. Alongside the emphasis on the cerebral localisation of psychological functions, the theoretical model-oriented analysis of psychological phenomena is a defining characteristic of the neuropsychological approach.

Neuropsychology starts from models of normal psychological functions and their disorders and tries to derive falsifiable hypotheses from these models and test them. The application of these methods to the study of dementias, psychotic disorders and affective disorders presents a challenge to neuropsychology and hopefully will serve to enrich psychiatry (Halligan and Marshall 1996).

Behavioural Psychology

Translator: S. Johnson

1 Definitions and Development of Theoretical Concepts

Learning and behaviour are fundamental concepts in psychology and are part of the theoretical framework on which aetiological models of various psychological disorders are based (see this volume, Part 1, Chap. 12). This has wide implications for psychological treatments in these disorders. Learning can be defined as change in behaviour based on experience (Correll 1987). Learning can occur both by trial and error and through insights gained in the course of structured processes. Behaviour refers to actual actions, which are driven by physiological processes, cognitive judgements and also motivational and emotional factors. The study of behaviour needs to take into account the full range of factors which modify it. Description and explanation of learning processes are based on the theoretical assumption that people develop theoretical concepts inductively on the basis of experiments.

At the end of the nineteenth century, Thorndike (1878–1958) set out the foundations for behavioural psychology in his treatises about the association between sensory impressions and impulses to act. His observations laid the foundation for stimulus-response psychology (see Bower and Hilgard 1983). Two models of learning are fundamental to this type of psychology: classical and operant conditioning. The Russian physiologist and Nobel prize-winner Pavlov (1849–1936) worked in the tradition known as "reflexology" and demonstrated through experiments with dogs the formation of associations between different stimuli (classical conditioning). Building on these results, the emphasis in Skinner's (1904–1990) experiments is on investigation of the connections between behavioural responses and their consequences (operant conditioning).

More recent extensions of learning theory have involved greater investigation of the mediating processes between learning and behaviour, such as motivational factors and level of performance in attention, memory and imitation. For example, these are among the concepts which form the basis of the theory of observational or social learning (Bandura 1977; Miller and Dollard 1941; Mowrer 1960). Social learning theory is based on the observation that changes in behaviour result from observing the behaviour of others. Seligman's learned helplessness model (Seligman 1975) demonstrates the influence of cognitive processes on learning processes. According to this model, experiencing uncontrollable aversive stimuli leads to passive behaviour, which is also displayed in subsequent controllable situations.

In the course of the past century, theoretical concepts explaining human behaviour have been developed on the basis of a multitude of experimental investigations. Beginning from simple stimulus-response patterns, various modulating factors have been added to the models so that they now incorporate complex patterns of behaviour such as systematic, methodical actions and problem-solving (see Ehlers 1996; Perrez and Zbinden 1996; Reinecker 1987). In this chapter, we will give a brief account of the fundamental paradigms in behavioural psychology and will describe how they have been used as a basis for models of the aetiology of psychiatric disorders and for methods of treatment.

2 Theoretical Concepts

2.1 Classical Conditioning

The concept on which classical conditioning is based is the association of pairs of stimuli. Such association formation was successfully demonstrated by Pavlov (1928) using an animal experimental model (Pavlov's dog). Classical conditioning can be encapsulated as a process through which, after repeated presentation of an unconditioned stimulus (UCS) together with a neutral stimulus, the subject – in the original instance an experimental animal – that the previously neutral stimulus is a marker of the UCS. As a result of this learning process, the previously neutral stimulus becomes a conditioned stimulus and the previously unconditioned response can be triggered by the conditioned stimulus (conditioned response).

This process may be clarified by comparison with the conditioning of immune responses (Buske-Kirschbaum et al. 1992). Under experimental conditions, a sherbet sweet (conditioned stimulus) was placed on the tongue of healthy subjects just before intravenous administration of adrenaline (unconditioned stimulus). After four combined presentations of the sherbet sweet and the adrenaline injection (unconditioned stimulus), at the fifth time point the increase in natural killer cell activity (unconditioned response) normally associated with adrenaline administration (unconditioned stimulus) could be achieved solely through the conditioned stimulus (increase in natural killer cell activity has become a conditioned response) (Fig. 1). This conditioning experiment demonstrates that an originally physiological process is clearly susceptible to influence from a psychological learning process. With this conditioning experiment, it could be demonstrated that an originally physiological process could clearly

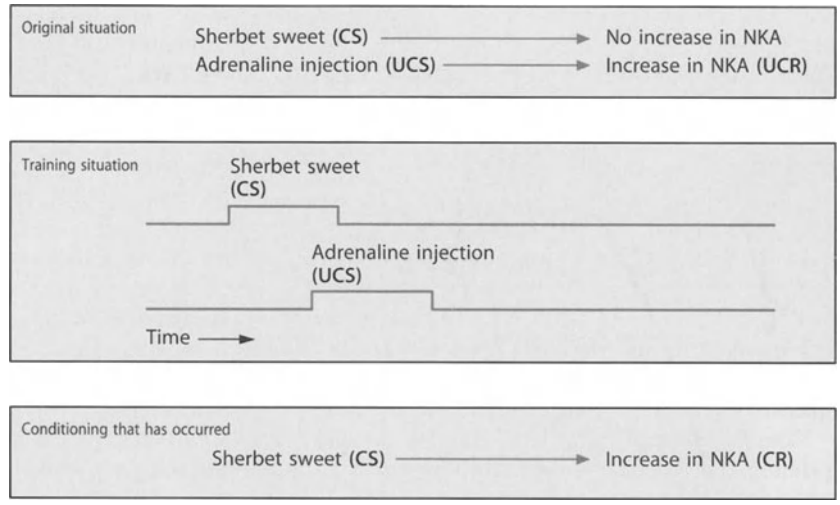

Fig. 1. Classical condition in relation to the example of natural killer cell activity

be influenced through the psychological process of learning.

The formation of conditioned responses is influenced by the motivational, cognitive and dispositional characteristics of the individual. In addition, temporal proximity between the conditioned and unconditioned stimuli is also a requirement for conditioning. Finally, the qualities of the stimuli themselves need to be taken into account. "Neutral" stimuli which already lead by themselves to clear unconditioned responses are very much less suitable for successful conditioning than stimuli not already associated with responses.

Once a successful association has been formed between a neutral and an unconditioned response, the conditioned response fades out (extinction) if the conditioned stimulus is repeatedly presented on its own. Interestingly, after this extinction phase, the conditioned response may nevertheless reappear at a further presentation of the conditioned stimulus (spontaneous return). This phenomenon should be noted, as an anxiety response which appeared to have been eliminated (e.g. through treatment of anxiety) may reappear to the patient's understandable consternation (see Schonecke 1996).

Further characteristic processes in classical conditioning are generalisation of stimuli, stimulus discrimination and higher-order conditioning. A conditioned response may be triggered not only by the conditioned stimulus, but also by another stimulus which resembles it (generalisation). In a patient with anxiety, a physiological response (e.g. sweating, increase in pulse rate) may be triggered only in lifts at the start of the illness. However, as the disorder advances, tunnels, escalators or aeroplanes (situations from which an immediate escape is not possible) may also trigger the conditioned response.

Discrimination is a process which complements generalisation; not every stimulus which resembles the conditioned stimulus triggers the conditioned response. Higher-order conditioning is the term applied to the observation that, where a stable association already exists between a conditioned and an unconditioned stimulus, the first conditioned stimulus may function as an unconditioned stimulus for a second conditioned stimulus. For example, the verbalisation of the first conditioned stimulus can become a second conditioned stimulus. For someone with a snake phobia, the word snake may trigger a conditioned response, even if he or she neither actually sees a snake (first conditioned stimulus) nor is bitten by one (unconditioned stimulus; see Reinecker 1987).

2.2 Operant Conditioning

The concept of operant or instrumental conditioning is based on Skinner's (1938) observations that while many of an organism's responses are triggered by stimuli, a variety of behaviours without observable stimuli are also displayed. The term "operant behaviour" was applied by Skinner to such behaviour, as the likelihood that it will be displayed is influenced by its consequences. Where the consequences lead to a behaviour subsequently occurring more frequently, positive reinforcement has taken place, whereas if it occurs less frequently, the behaviour has been punished. Strategies for increasing or reducing a behaviour can be derived from its positive and negative consequences. A behaviour can be increased through positive reinforcement (e.g. praise) or through discontinuation of a negative consequence (withdrawal of a punishment, also called negative reinforcement). Reduction of behaviour may be achieved through a negative consequence (punishment) or removal of a positive consequence (e.g. removing positive

Table 1. Promotion and reduction of a behaviour through operant conditioning

Promotion of a behaviour	Reduction of a behaviour
Positive reinforcement	Punishment through an aversive stimulus
Removal of an aversive stimulus (negative reinforcement)	Punishment through removal of a pleasant stimulus

conditions). The four forms of operant learning based on different reinforcers (negative or positive consequences of behaviour) are summarised in Table 1.

Consequences of behaviour may be divided into primary and secondary reinforcers. The first of these satisfy basic drives (e.g. food, sexual activity), while the second relate to conditioned (social or material) reinforcers. If a variety of consequences follow the behaviour, the likelihood of the behaviour being displayed again will be influenced most by the consequences with the closest temporal relationship to it and the greatest intensity. In experimental conditions, the reinforcement of a particular response may follow an interval schedule, occurring either after a fixed interval or after an interval of variable duration has elapsed. In ratio schedules, reinforcement occurs after a certain number of responses, with the number of responses to be made before reinforcement either fixed or variable (Skinner 1938, 1953). In real-life situations, reinforcement of behaviour usually follows variable schedules of reinforcement. A behaviour which is no longer reinforced is eventually extinguished. Responses prove to be particularly resistant to extinction if they have been conditioned through a combination of variable ratio and variable interval schedules (Ferster and Skinner 1957).

Complex patterns of behaviour are learned through shaping, i.e. through division of the behaviour into its constituent elements. Each element within the desired pattern is individually reinforced, and once all the elements have been successfully learned, reinforcement is provided only for successful combination of all of them (see Wippich 1984).

Miller's research group has shown through animal experiments that operant conditioning also applies to physiological forms of activity. For example, electric stimulation of the reward centre in the central nervous system (CNS) or punishment using electrical shocks can lead to increases or decreases in blood pressure (DiCara and Miller 1968a) or pulse rate (DiCara and Miller 1968b) in curarised rats. The target behaviour was achieved in these experiments by progressively increasing the degree of change in pulse or blood pressure required to trigger reinforcement. Even though these results could not be clearly replicated in later experiments (see Köhler 1995), the work of Miller and colleagues laid the foundations for research on biofeedback (on this subject, see Rau 1996; Rief et al. 1996).

The outstanding nature of Skinner's achievement in the description of human behaviour is evident from the techniques for functional analysis of complex behaviour which were derived from it. However, his model does not take account of the mediating processes between learning and manifest behaviour. In Skinner's view, behaviour is malleable and, if appropriate training is given, virtually every person is capable of achieving an acceptable performance in virtually every form of behaviour (see Bower and Hilgard 1983). Psychological concepts such as personality traits, insight, attribution, intrinsic motivation or motivation provided by external incentives (see below) play no part in the explanation of human behaviour following Skinner's principles. However, these concepts have been taken into account in the further development of the learning paradigms outlined above. To illustrate these further developments, we will now discuss observational learning as an example of a social learning theory and the concept of learned helplessness as an example of a cognitive theory.

2.3 Observational Learning

In many situations in life, learning can be shown to occur through imitation of the behaviour of others. In contrast to conditioned or operant learning processes, in the observational learning model (also referred to as imitative learning, vicarious learning, modelling, identification or social learning), cognitive and social aspects of the learning process are explicitly taken into account. From the theories of Bandura (1969, 1977), four components or elements may be identified in observational learning:

1. In order for a behaviour to be learnt by imitation, targeted attention from the observer is required (attention process).
2. The observed behaviour is coded in the memory as a stimulus event, symbolically represented and stored until the imitative behaviour takes place (retention process).
3. Assuming that a behaviour has been adequately observed and cognitively represented, in many cases particular motor abilities will be required for it to be imitated successfully (reproduction process).
4. Anticipation of positive reinforcement for the behaviour influences the likelihood that imitation will actually take place (motivational process).

The learning process is promoted where the model is attractive to the observer, but also similar enough to the

observer's own model so that imitation lies within his or her capabilities, i.e. the observer needs to be competent to carry out the behaviour (see Spada et al. 1990).

Social learning is directly linked to the principles of developmental psychology, in that observational learning is a basis for development of a capacity for self-regulation in human behaviour. According to Bandura (1976), there are three phases in development of this capacity. In the first phase, ways of behaving are adopted through observational learning. In the second phase, people in an individual's social environment react to these forms of behaviour as described in the operant conditioning model, with either positive or negative consequences. As a result, the individual forms expectations about future consequences of the behaviour. In the third phase, the behaviour is either continued or abandoned on the basis of these internalised expectations.

An individual's hypotheses about the consequences of actions can be influenced not only by his or her own experiences but also by the experiences of others communicated to the individual verbally. The learned helplessness model shows how assumptions about the consequences of actions (causal attributions) can lead to disturbances of behaviour.

2.4 Learned Helplessness

The concept of learned helplessness originates from the animal and human experiments of Seligman and colleagues (Hiroto and Seligman 1975; Overmier and Seligman 1967; Seligman and Hager 1975; Seligman and Maier 1967). In the human studies, the experimental means of producing helplessness involved two conditions. In the first condition, the subjects were subjected to an aversive stimulus which, regardless of their actions, they could not escape (uncontrollable and unavoidable negative situation). In the second condition, they were again subjected to a negative situation, but this situation could be terminated by a simple response (the negative situation is controllable and avoidable). Subjects who had previously experienced the first condition showed the poorest performance in learning how to end the aversive stimulus. The experience of a negative situation being uncontrollable (helplessness) leads in later controllable situations to passive behaviour. The subjects show no motivation for active coping with the situation because they have formed unfavourable assumptions about their own strategies for action when subjected to stress (Fig. 2).

According to Abramson et al. (1978), three dimensions can be distinguished in attributional styles: internal versus external, specific versus global and stable versus variable. Individuals' assessments of a helplessness-generating situation in relation to these dimensions indicate the extent of learned helplessness. Three questions may be used to indicate the nature of these assessments (see Davison and Neale 1996):

1. Does the failure have personal (internal) or environmental (external) causes?
2. Is this an instance of a specific or a general (global) inability to avoid failure?

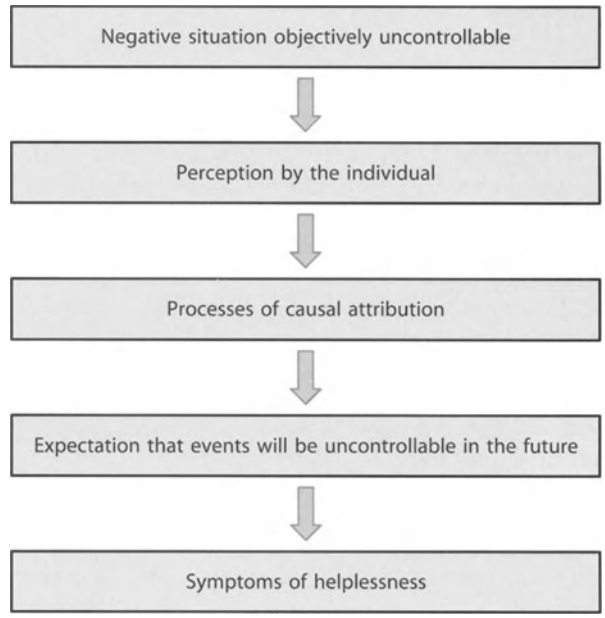

Fig. 2. Model assumptions regarding learned helplessness in humans

3. Is the failure to be seen as a transient (variable) or a lasting (stable) problem?

The least favourable combination is where the attribution made is internal, global and stable, resulting in a marked feeling of helplessness. Overmier (1988, p. 240 ff.) identifies frustration, fear, disturbances of concentration, disturbances of motor coordination, loss of appetite, raised levels of cortisol, reduced noradrenaline response, gastric ulcerations and an increased susceptibility to illness as characteristic psychological and physiological effects of learned helplessness.

Thus, according to the learned helplessness model, learning experiences can lead to the development of certain styles of attribution and emotion which are unfavourable for the individual. These are accompanied both by physiological dysfunctions and by a passive style of coping with future situations. In cases with poorer outcomes, learning experiences lead to deviations from physical and psychological homeostasis and thus to pathological states (see Overmier and Hellhammer 1988). If we accept this principle that illness may develop through learning, then presumably the inverse also applies, i.e. pathological conditions may be alleviated by changing learning experiences. In the following, we will discuss the contribution of behavioural psychology both to causal explanation and to treatment of a selection of disorder types.

3 Influence of Behavioural Psychology on Models of the Aetiology of Abnormal Behaviour and on Its Treatment

3.1 Aetiology

Concepts from behavioural psychology regarding the basis of psychological characteristics are applied with the aim of understanding the (abnormal) behaviour of a patient in terms of his or her individual responses to various situations. According to Hautzinger (1996, p. 36), individual behaviour is influenced by social learning history, situational conditions (stimuli) and the consequences of the behaviour. Thus three dimensions need to be taken into account as determinants both of healthy behaviour and of behaviours characteristic of psychological disorders:

1. Characteristics of the situation (circumstances which make it easier or more difficult to achieve a goal)
2. Characteristics of the individual (physiological characteristics, attitudes and experiences, behavioural characteristics, such as cognitive and motor skills), which lead to particular responses to the situational conditions
3. Short- and long-term consequences of the behaviour (positive or negative effects)

In a range of psychiatric and psychosomatic illnesses, detailed analysis of the patient's behaviour allows a variety of statements to be made about the disorder's origin and the treatment required.

Depending on the particular illness, behavioural principles allow explanation of part of the range of behavioural abnormalities observed. This may be understood by considering schizophrenic illnesses, drug dependence or somatoform disorders. In aspects of behaviour such as secondary gain from illness, reinforcement of the symptom behaviour also plays a decisive role. In the following, the value of learning psychology principles will be illustrated using depressive illness and anxiety disorders as examples. While the contribution of behavioural psychology in depressive illnesses needs to be placed in context of the overall framework of causal elements, concepts from learning theory are the main basis for effective treatment of anxiety.

Hautzinger and de Jong-Meyer (1990), reviewing the current status of research on depression, argue that the heterogeneity of depressive illnesses means that a satisfactory explanatory model needs to encompass multiple causes. In addition to biological factors, social, personality-related and behavioural aspects influence the occurrence and maintenance of the illness. Current research suggests that one of the explanations of depressive behaviour is in terms of an emotional state of hopelessness and a loss of or shortage of positive reinforcers.

Extending the theory of learned helplessness described above, Abramson et al. (1989) propose that the origin of some forms of depressive illness lies in hopelessness. This emotional state results from learning experiences and the cognitive judgements made subsequent to these. The assumptions are as follows: (a) desirable events do not occur, (b) unwanted events do occur and (c) this situation cannot be altered. According to the theory of learned helplessness, hopeless humans show a passive coping style in situations experienced subjectively as stressful and almost inevitably ascribe negative consequences to such situations. A general reduction in level of activity constitutes a form of passive coping.

Lewinsohn et al. (1984) established through observation of the behaviour of depressive individuals that these people obtain fewer positive reinforcers for their behaviour than non-depressive individuals in similar situations. Because of this lack of positive reinforcement, behaviours stop being manifested, resulting in a

reduction in level of activity. Because of their limited activity, these individuals obtain still fewer positive reinforcers, so that behaviours which might be favourable to mood are reduced still more. Lewinsohn's principles are much more a description of the maintaining factors for depressive behaviour than of its original causes.

Behavioural assumptions about the origins of anxiety disorders are the basis for the two-factor theory of the development of anxiety and avoidance put forward by Mowrer (1947). According to this model, there are likely to be some innate associations between particular pain–fear stimuli and pain–fear responses. If a neutral stimulus precedes such a stimulus–response pair once or more than once, then following the principle of classical conditioning, this neutral stimulus itself becomes a trigger for the pain–fear response. This response is followed by particular motor actions, which lead to a reduction in the pain–fear response. In future pain–fear responses, these actions are therefore more likely to occur, as, according to the operant conditioning model, reinforcement has been obtained in the form of avoidance of negative consequences. In order to understand the development of anxiety as a pathological condition, two assumptions behind this theory need to be made explicit (see Krohne 1982):

1. The conditioned pain–fear response can be differentiated from the unconditioned one, in that the actual pain component is missing. The conditioned response represents an anticipatory response based on expectation of a pain–fear response. On the basis of this distinction, Mowrer (1940) designates the conditioned response an anxiety response.
2. In contrast to the extinction principle for conditioned responses, anxiety responses show a high level of resistance to extinction. On the basis of animal experimental findings, Solomon and Wynne (1953) describe the development in several stages of "self-protection against anxiety". With repeated presentation of a conditioned stimulus, the time latency between presentation of the conditioned stimulus and the operationally conditioned avoidance behaviour becomes shorter and shorter. Because of the longer latency time between the conditioned stimulus and the conditioned response, this classically conditioned anxiety response can no longer occur. As this stimulus–response association does not occur, it can also not be extinguished, so that the intensity of the potential anxiety response remains unaltered. Thus individuals react so swiftly to a danger signal that they escape before they can really feel disturbed by it.

The specificity of the stimuli that trigger phobic behaviour can be explained through the concept of physiological preparedness for an anxiety response. This principle accounts for the fact that particular stimuli (e.g. spiders, rats, cats) are more likely to lead to anxiety behaviour than other stimuli (e.g. butterflies). In experimental investigations of stimulus specificity (hman et al. 1985; McNally 1987), it has been shown that in classical conditioning the conditioned response can be obtained to neutral stimuli with the same intensity as with a more uncomfortable stimulus (pictures of snakes), but that the extinction phase is clearly more prolonged with the uncomfortable than with the neutral stimuli. Finally, animal experiments have demonstrated that phobic behaviour can also be produced by learning from models (observational conditioning) (Mineka et al. 1984).

While the two-factor theory of anxiety is invoked to explain a variety of forms of anxiety disorder, the literature also contains critical discussions of the overall value of the theory in explaining the genesis of disorders (see Ehlers and Margraf 1990). For example, in relation to the development of post-traumatic stress disorder, there has been debate about whether a single episode of trauma ("one-trial learning") can really lead to such extensive psychological disturbances as intrusive thoughts, dissociative episodes of flashbacks or hypervigilance (see DSM-IV; Saß et al. 1996). In defence of the behavioural explanatory model, Quirk (1985) observes that the single appearance of a stimulus–response association certainly can lead to successful learning provided the connection is simple and the latent period short. This applies especially to a life-threatening situation, which is characterised by particular endocrinological features and a natural anxiety reaction. Although for ethical reasons, no experimental evidence has been obtained regarding these principles, Steil and Ehlers (1996) state that, whatever model is used to explain the occurrence of post-traumatic stress disorder, avoidance of stimuli associated with the trauma has a decisive role in maintaining this disorder.

Another reason for criticising the conditioning model of the aetiology of anxiety disorders is that for a significant proportion of patients, phobias or generalised anxiety disorders develop without any evidence of an initial triggering event. The reasons for this may lie either in real absence of a triggering situation or in limited ability to recall an unspectacular event associated with the first appearance of anxiety.

This can be illustrated by an example. An agoraphobic patient reported that the unpleasant physical sensations which characterise her anxiety disorder first appeared around 8 years before the time of assessment. At the time, she was attending a lecture in a large auditorium. No psychological stresses or other remarkable characteristics were associated with this situation. Only with exploration of her activities prior

to being in this situation did it emerge that around 2 h before going to the lecture, the patient had voluntarily given blood. On previous questioning, the patient had never mentioned this blood-taking, as she had not made a causal connection between this event and the dizziness, nausea and shortness of breath she experienced in the lecture theatre.

It should certainly not be concluded on the basis of a single case study that a patient with anxiety only needs to be questioned for long enough for a connection between physical and psychological discomfort and a corresponding triggering situation to be found. However, in evaluating models of anxiety disorders based on behavioural psychology, it is important not to lose sight of the importance of high-quality and extensive exploration.

Finally, there is evidence that, in addition to learning experiences, the development of an anxiety disorder is influenced by predisposing variables. These variables include lack of self-confidence (Bates 1990), cognitions, e.g. about the uncontrollability of a situation (Barlow 1988) or the "fear of fear" (Goldstein and Chambless 1978), and also as a genetically determined instability of the autonomic nervous system (Gabbay 1992). The original two-factor theory of the acquisition of anxiety and avoidance therefore needs to be extended in considering an individual's anxiety disorder to take into account personality, cognitive, physiological and genetic variables.

3.2 Treatment

Many individual methods of altering behaviour have been developed by a variety of therapists, based on the behavioural psychology theories described in Sect. 2 above. These procedures are collectively known as behaviour therapy (see Wolpe and Lazarus 1966). There are wide variations among procedures in behaviour therapy in their specificity and range of applications. Thus positive reinforcement of behaviours which promote a reduction in symptoms, for example, is used in a great variety of disorders (Blöschl 1996), whereas waking programmes are designed specifically for the treatment of enuresis (see Grosse 1993).

Behaviour therapy methods constitute an element within an overall treatment plan. While use of specific, partially standardised treatment procedures results in a clear structuring of the treatment session, the personal influence of the therapist is still of decisive importance for the success of therapy. Producing motivation for behavioural change is achieved less by applying the right techniques than by the therapist genuinely becoming involved with the client's overall welfare and being able to show the potentially negative consequences of maladaptive behaviours and to propose alternative behavioural strategies (Goldfried and Davison 1979, p. 43).

The techniques shown in Table 2 are derived directly from behavioural psychology theories.

Table 2. Behaviour therapy methods derived from learning psychology theories (based on Reinecker 1991, p. 132)

Type of technique	Method
Techniques of stimulus control	Systematic desensitisation Graded exposure Exposure and response prevention Introduction of a delay between stimulus and response Anxiety management training Flooding Paradoxical injunction
Techniques of control of consequences	Selective reinforcement of desirable responses Cue exposure Contingency contracting Token economies Aversive techniques Time out
Observational learning techniques	Observational learning in vivo Covert observational learning Provision of role models
Techniques for self-regulation	Self-monitoring Self-control Contingency control Setting up of contracts

The techniques of stimulus control enable the patient to develop a capacity for avoiding situations which are potentially problematic for him or her. The best-known technique of this kind is probably confrontation management. In techniques involving control of consequences of behaviour, selective reinforcement is used to minimise the problem behaviour and maximise the goal behaviour. The techniques of observational learning are used particularly in group sessions, e.g. in improving social skills. In relation to this, the therapist has substantial significance as a model. The aim of self-control techniques is to make the patient aware of particular ways of behaving through self-observation. Symptom management protocols are a frequently used application of self-observation. More extensive descriptions of specific techniques used in behaviour therapy can be found in the work of Linden and Hautzinger (1996) and Margraf (1996). To illustrate the management of specific clinical disorders, we will now describe a selection of techniques which are in use for the management of depressive illnesses and anxiety disorders.

3.2.1 Depression

In the behavioural treatment of depression, the main effective method based on the principles described in Sect. 3 is a systematic programme of increasing social and physical activity (a primary behavioural technique), together with modification of negative attributions and patterns of thinking (primary cognitive techniques, see Beck et al. 1992).

The first step in building up activity involves observation of activity; on this foundation, an agreement is made with the patient on a gradual increase in activities. All activities shown following this are positively reinforced and quality and quantity of activities are gradually built up. The experience of initiating actions themselves has a lasting positive impact on patients, and this generally has a positive influence on the overall course of treatment. Lack of interpersonal skills may be an obstacle to engaging in social activities. If this is so, role plays or training in communication skills may be used to modify problematic ways of behaving (see Ullrich and Ullrich de Muynck 1996).

The effectiveness of cognitive-behavioural treatment of depressive illnesses has been convincingly demonstrated in controlled trials (see Hautzinger 1993; Hollon et al. 1993).

3.2.2 Anxiety Disorders

In behavioural techniques for the treatment of anxiety, whatever subtype of anxiety disorder is present, the aim is repeated exposure of the patient to the imagined or actual anxiety-provoking stimuli. According to Birbaumer and Schmidt (1996, p. 660), such exposure to the anxiety-provoking stimulus leads to loosening of the associational link between the conditioned and the unconditioned anxiety stimuli, as the negative consequences fail to appear. At the level of cortical and subcortical processes, treatment leads to extinction of those memory connections which were associated with excessive arousal at the beginning of treatment.

Exposure treatments can be divided into prolonged exposure in the imagination, prolonged exposure in vivo and flooding. In the first two of these procedures, the patient is exposed to the anxiety-provoking situations in a graded way, either in the imagination or in reality. In flooding, the patient is immediately confronted with the situation which provokes the most severe anxiety. Accompanying exposure techniques, anxiety management techniques are used, including relaxation techniques, breathing exercises, distraction techniques, social skills training and protection against stress using positive self-instruction, self-observation and self-strengthening. The complaints of patients with a range of anxiety disorders have been alleviated by this combination of exposure and anxiety management (see Becker 1995; Ehlers and Margraf 1990; Foa et al. 1991; Steil and Ehlers 1996).

4 Outlook

In this chapter, we have discussed the central theoretical concepts in behavioural psychology. These theories form the basis for psychological explanations of behaviour. The precise analysis of human behaviour on behavioural psychological principles allows conclusions to be drawn about the causes of abnormal behaviour and is thus particularly important for aetiological deliberations regarding psychiatric disorders (such as behavioural disorders in childhood, schizophrenic illnesses, substance dependence, eating disorders, somatoform disorders and psychosomatic illnesses).

For many psychiatric illnesses, it is now widely accepted that a variety of factors have proven influences on illness development and maintenance. Taking depressive illnesses and anxiety disorders as an example, it has been shown that, in addition to biological factors, learning processes and ways of behaving that result from these influence the origin of illness. For both illnesses, behavioural treatment methods, combined with cognitive restructuring techniques, are the treatment of choice for patients who participate actively in treatment. It needs to be

emphasised that this description by way of an example of aetiological concepts and forms of treatment derived from learning psychology represents only a small excerpt from the large number of empirically grounded explanatory and treatment concepts for psychiatric and psychosomatic illnesses, and the significance of these approaches for the welfare of the patient should not be underestimated.

In future clinical research based on learning psychology, it is important that these concepts should not only be referred to when explaining psychiatric and psychosomatic illnesses, but also that they should be taken into account in the maintaining conditions for physical illnesses. In the area of care, behavioural therapy treatment procedures are to be assessed as especially effective (Grawe et al. 1994). Even so, on the grounds of health politics, the effectiveness of short-term treatments should be demonstrated more convincingly through cost-effectiveness studies. Longitudinal studies (outcomes at 1 and more years) should further be used to examine the long-term effectiveness of psychotherapeutic measures.

Sociology and Psychiatry

Translator: E. Taub

1 Introduction

The usual generic classification of the empirical sciences distinguishes the natural sciences (and, in medicine, the biological sciences) from the social, behavioral, cognitive, and cultural sciences. Economics, political science, sociology, and psychology are usually counted among the social and behavioral sciences. Sociology is that area of the social sciences concerned with the structural characteristics and developmental dynamics of human societies and socialization processes. Sociology shares certain characteristic features with all other scientific disciplines:

1. It possesses a specific set of concepts and methods with which a portion of the real world can be systematically described.
2. It contains a cumulative body of knowledge built up over decades by research work carried out in many countries on the basis of these concepts and methods.
3. It provides a number of more or less well-tested, generalizable theories by means of which societal phenomena can be explained.

Sociology arose historically out of the twofold revolution – both industrial and political (democratization) – that took place in the late eighteenth and early nineteenth centuries and was, perhaps, the most significant societal change of all times. The "crisis science" of sociology assumed the tasks of interpreting the new societal dynamics (e.g. classes and stratification, social mobility, urbanization, change in family structure) that had emerged after the collapse of the traditional social order and of making its own, informed contribution to the process of societal development.

Two aspects of the historical development of sociology are particularly significant in the context of this chapter. First, in the last 150 years, sociology has proved particularly susceptible to exploitation on behalf of normative sociopolitical programs, whether "progressive" or "conservative." Such coupling of scientific work with sociopolitical activity has split the discipline unproductively into camps and slowed its progress by blocking the development of cumulative paradigms. Political involvement has also made the process of professionalization more difficult and injured the reputation of sociology as a free and independent scientific field.

Second, since its early days as a scientific discipline, sociology has been divided into a number of subdisciplines, the so-called hyphenated sociologies. These have enriched the mother discipline – "general sociology" – in some ways, but have led mainly to a heterogeneity of theoretical approaches that now characterizes sociology as a whole. In the main, each subdiscipline is concerned with an individual aspect of society or an individual major function of social systems in developed societies, such as education, labor, economy, law, and health. The subdiscipline concerned with societal aspects of health and disease has developed historically into medical sociology (lately also called health sociology), and a major part of this subdiscipline deals with psychiatric topics (psychiatric sociology) (Cockerham 1997; Mechanic 1978; Siegrist 1995).

2 Psychiatric Sociology in Retrospect

The first epoch-making research publication in psychiatric sociology appeared just over 100 years ago: Emile Durkheim's study of societal influences on suicidal behavior in 1897 (Durkheim 1951). To explain the remarkable differences in suicide rates among different religious and occupational groups, Durkheim examined the hypothesis that the loss of binding social norms and institutions, and the lack of representation of societal values and patterns of thought in situations of crisis, very likely generates feelings of desperation that may end in suicidal behavior. On the basis of this idea, Durkheim developed a typology of suicidal behavior, in which the egoistic and anomic types of suicide are considered characteristic of modern societies. Durkheim's concept of anomie prepared the way for later psychiatric sociology. His major innovation lay in the decision to analyze suicidal behavior as a societal fact, rather than as a product of individual motivation. In methodological terms, he applied so-called ecological analysis to this problem, using aggregate rather than individual data.

Using similar methods, Faris and Dunham (1939), in the United States, demonstrated a relationship between markers of disadvantaged socioeconomic status and high rates of psychiatric disease. The classic studies in psychiatric sociology, however, were not carried out until the late 1950s and early 1960s. These included the analysis of the social component of treated psychiatric disease in New Haven by Hollingshead and Redlich (1958) (the lower the social status, the more severe the diagnosed illness), the Midtown Manhattan study (Srole et al. 1962), and the Stirling County Study (Leighton et al. 1963). The latter two studies provided a test of various sociological explanatory approaches, including a more refined concept of social anomie and sociocultural disintegration, and were the first to examine the role of critical life experiences and the significance of cumulative psychosocial stress in a life-cycle perspective. Two further studies should be mentioned in this

context: Kornhauser's analysis of the influence of occupational stress on mental health (Kornhauser 1965), and Brenner's time-series analyses of the relation between economic crises and rates of mental illness and psychiatric hospitalization (Brenner 1973).

A second line of development of this sociological subdiscipline, which has had considerably more practical impact, concerns the analysis of medical practice in psychiatry and the critical study of what happens during psychiatric hospitalization. In evaluating the achievements of earlier research today, we must be aware that institutional psychiatry was in a desolate condition before the introduction of effective medications and the coming of the reform movement in health policy, with its emphasis on deinstitutionalization. The unsparing sociological analysis of the psychiatric hospital as a "total institution" (Goffman 1961) and the convincing demonstration of "hospitalism" in chronic patients (Brown 1959) had an important signal effect on the formation of the social and community psychiatry movement of the 1960s and early 1970s. The same is true of the exemplary assessment studies of the course of illness of schizophrenic patients in a new model of care (Pasamanick et al. 1967).

The sociological analysis of the provision of psychiatric diagnoses was just as consequential in its ability to reveal deficiencies in medical practice, even though the conclusions drawn were excessively generalized. Researchers including Goffman (1963) and Scheff (1966) demonstrated the major effects of psychiatric diagnoses on the social identity of patients (stigmatization) and the negative course of social differentiation and exclusion. This work rested on theories of symbolic interactionism and on the theorem proposed by Thomas ("If a person defines a situation as real, then the consequences of that definition are also real"; Thomas 1965). The negative effects on patients were even more serious in that diagnoses were often provided without the requisite degree of care and nosological validity. Thus Scheff's analysis, for example, showed that psychiatrists (like other physicians), when faced with diagnostic uncertainty, tend to follow the rule that it is better to diagnose a healthy person as sick than to declare a sick person healthy – and this despite the very serious consequences of such a diagnosis. The far-reaching effects of this diagnostic principle were first made clear by Rosenhan's shocking report, published in the journal Science in 1973 (Rosenhan 1973). A group of pseudopatients, trained to dissimulate symptoms of insanity, were diagnosed as schizophrenic and committed to psychiatric institutions. Even though they resumed fully normal behavior immediately after hospitalization, they uniformly failed (with one exception) to convince the treating psychiatrists of the incorrectness of their original diagnosis.

This report and others lent credence to the psychiatrist Thomas Szasz' early, far-reaching and mordant critique of what he called "The Myth of Mental Illness" (Szasz 1960). He claimed that psychiatric diagnoses function primarily as metaphors for problems that are not rooted in biological psychopathology, but are rather essentially moral and social in nature.

Two aspects of this critique will be considered here. At the time Szasz' book was written, there were only very few etiologically well-founded psychiatric diagnoses, as indeed there are today, while the modern, standardized nosologic classification had not yet been widely put into practice. Because of this diagnostic near-vacuum, and the growing trend toward the "social disciplinization" and "medicalization" of deviant behavior, psychiatrists had considerable latitude in the assignment of diagnoses; there was thus considerable potential for abuse and for diagnostic errors fraught with serious consequences. A further and still current problem is that of "subdiagnostic" morbidity, e.g. in the area of depressive symptoms and anxiety disorders, and with it the problem of locating the border between mental health and illness. In fact, societal value judgments as well as economic interests exert a strong influence on physicians' determination of the threshold level that separates mere impairment of well-being from morbid functional disturbance.

In summary, psychiatric sociology went through a remarkable efflorescence in the relatively short period between 1955 and 1975, mainly in the United States and the United Kingdom, and had a major impact on health policy. It contributed to a society-wide reconsideration of the role of the physician and of diagnostic decision processes and provided an empirical foundation for some of the major ideas of new movements in social and community psychiatry. On the methodological and theoretical levels, it provided new evaluative approaches and explanatory concepts, particularly in the area of social epidemiology and follow-up studies. It may well be asked, therefore, why these fruitful developments had no comparable sequels in the two decades from the mid-1970s to the present.

3 Recent Developments

3.1 Social Determinants of Mental Illness

After the failure of empirically untenable attempts to ascribe the origin of mental illness mainly or exclusively to societal reaction processes (so-called labeling theory; for a critical account, see Robins 1975) or to disturbed interpersonal relationship patterns (Bateson

et al. 1956), a theoretically and methodologically sophisticated interdisciplinary approach gained prominence in psychiatric sociology, largely through the efforts of the British sociologist George W. Brown. He developed a comprehensive evaluative technique for the assessment of critical life events and chronic difficulties and thus gave empirical social research a new importance in psychiatry (Brown and Harris 1989). Furthermore, his group succeeded in identifying specific social determinants of affective disorders ("major depressions") in a research effort spanning 20 years (Brown and Harris 1978; Brown et al. 1990; Bifulco and Brown 1996).

The empirically supported model of affective disorders maintains that critical life events and chronic difficulties are most likely to lead to intense experiences of emotional distress, and possibly to depressive episodes, when the affected individual possesses certain vulnerability factors. The most important factors are the lack of a confidant who can provide emotional support and negative self-esteem. These two factors, when combined, lead to inappropriate coping behavior (primarily self-blaming and general helplessness). They not only reinforce each other (persons with negative self-esteem tend to blame themselves and often lose the support of those close to them), but also often share a common origin in the life history of the individual, as negative self-esteem is significantly more common among people who lost a parent in early life.

Brown's group obtained an impressive confirmation of this model in a longitudinal study of 353 women, all of them mothers living with at least one dependent child under unfavorable conditions. The occurrence of depression was best predicted by a model incorporating the two vulnerability factors mentioned, as well as negative coping style in the face of experienced social stresses. A total of 69% of women in the psychosocial high-risk group developed depression, as compared with only 9% in the group that had experienced little or no psychosocial stress (Bifulco and Brown 1996). These findings are all the more convincing, now that basic research on the physiology of stress has revealed a close relationship between emotional distress and dysregulation of the hypothalamic-pituitary-adrenal axis, in which an increased synthesis of corticotropin-releasing factor plays a major role (Axelrod and Reisine 1984).

The hypothesis that psychosocial factors influence the occurrence of depressive illnesses (particularly in women) has since been confirmed by other research groups (Bebbington et al. 1984; Parry 1986; for an overview, see Geyer 1998), but no such influence has been found for the second major group of mental illnesses, the schizophrenias. Rather, research has revealed the operation of social selection processes as a consequence of illness. This concept received solid support from an impressive longitudinal study of more than 4900 young adults in Israel (Dohrenwend et al. 1992).

The explanatory ability of sociological models in relation to the occurrence of mental illness goes further beyond the research results just cited. The past few years have witnessed intensive study of the role of morbid chronic stress in working life. Two theoretical approaches are most prominent: the so-called demand-control model, and the effort-reward imbalance model.

The demand-control model posits that occupations that place high quantitative demands (e.g. time pressure) on workers, and simultaneously offer little opportunity for control and decision-making, have long-term pathogenic effects (Karasek and Theorell 1990). In contrast, the model of effort-reward imbalance identifies chronic stress as a consequence of the lack of reciprocity between high cost spent and reward received; the model considers not only situational aspects, but also personal, intrapsychic processes, in particular a specific pattern of coping with demands termed "overcommitment" (Siegrist 1996). The model distinguishes three types of reward: wages/salary, esteem, and career opportunities/job security.

The two models were recently prospectively tested in the Whitehall II study, in which some 10,000 civil servants in London participated. The work-related stresses assessed upon each subject's entrance into the study were related to onset of psychiatric disorder over a mean period of 5.3 years, as determined by repeated administration of the General Health Questionnaire. Men who had initially suffered from effort-reward imbalance were found to be 2.6 times more likely to develop new mental illness, while the corresponding relative risk for women was 1.7. Both effects remained significant after controlling for age, socioeconomic status, and initial state of mental health (Stansfeld et al. 1999). Weaker independent effects were found for the variable "high demand" of the demand-control model, while a high level of control and good support in the workplace exerted a protective effect (also see Borrill 1996).

On the basis of these findings, we may presume that sociological research incorporating theory-driven, standardized methods of evaluation, similar to those successfully applied to chronic degenerative illnesses and cardiovascular illnesses (Bosma et al. 1998; Siegrist 1998; Theorell and Karasek 1996), can be profitably pursued in psychiatry.

3.2 Social Influences on Coping and the Course of Mental Illness

The present state of knowledge of the origins of major mental disorders, especially the schizophrenias

(Batesonet al. 1956), seems to leave little room for explanatory models derived from the social sciences, as the endogenous processes of neurotransmitter dysregulation are recognized to play a dominant etiologic role (for a summary, see Gaebel and Wölwer 1996). The situation is different, however, as regards the course of mental illnesses and the coping strategies used once they are manifest. Studies of the socioeconomic and psychosocial condition of the mentally ill after release from hospital have clearly shown that the dynamic interaction of the disease manifestations with the coping behavior of the patient and people close to him or her has a major influence on the further course of the illness and the patient's quality of life. Selected studies of the course of illness in schizophrenic patients will be used to illustrate this point briefly.

Deficiencies in social skills, such as a disturbance of nonverbal-empathic patterns of interaction and a reduced drive for the initiation of social contacts, leading to total social withdrawal in extreme cases, have been described as characteristic of the premorbid phase of schizophrenia (Goldstein et al. 1992). These deficiencies become especially important, however, in the further course of the illness, because they can reduce social competence and thereby increase the risk of a relapse. Negative styles of family interaction described by the "expressed emotions" concept (Leff and Vaughen 1984), i.e. either a disapproving style or one of extreme emotional engagement, leading to excessive solicitousness, increase the risk of relapse, at least partly because they permanently interfere with the patient's self-initiated social-communicative activities, whose proper "dosage" only he or she can determine (Kavanagh 1992).

A recent longitudinal study from Sweden is also of interest. Patients who succeed in actively seeking social support and who wish to overcome their social isolation have a markedly better prognosis than those who are satisfied with relatively undemanding interpersonal relationships (Hultman et al. 1997). Such patients have particularly severe anhedonia related to a disturbance of the dopaminergic mesolimbic-mesocortical system (see Blanchard et al. 1994).

The socioeconomic consequences of an unfavorable dynamic interaction of disease manifestations, coping strategies, and further course of illness are often severe and exacerbate the intrapsychic and interpersonal stresses already present. A comprehensive German follow-up study of more than 300 schizophrenics showed that 60% of them were single at a mean age of 35, more than half lived alone or with their parents, and one third were socially very isolated. Half of the patients became prematurely unemployed, and, after 2 years of observation, a progressive long-term economic impoverishment was observable in two thirds of the study cohort (Müller et al. 1998).

The findings just discussed are highly relevant to the design of sociotherapeutic measures, which make up an important part of an integrated treatment plan. Such measures include behavior-therapy approaches to employment, to the improvement of social skills, and to the learning of appropriate responses to illness (including actively seeking help and avoiding stressful situations), as well as systemic interventions such as family therapy and occupational rehabilitation.

The methodological and conceptual contributions of sociology and psychology to interdisciplinary studies of disease course and therapy will also be increasingly important in the future. One of the special challenges in this area is a valid operationalization of the self-assessment of mentally ill patients, several components of which are important in course-of-illness research as predictors or criterion variables (e.g. assessment of satisfaction, level of demand, understanding of illness, and social role functioning). Furthermore, the current, highly refined understanding of psychopathology will have to be complemented by a similarly differentiated assessment of social handicaps. The theoretical and methodological approaches of symbolic interactionism and phenomenological sociology may be of assistance here, as well as the more recent microsociological approaches.

3.3 Sociological Evaluation Research in Psychiatry

Sociological evaluation research in the health sector was developed in the United States in the 1960s (Suchman 1967) and provides an empirical evaluation of the structures, processes, and outcomes of medical care. It is concerned both with the analysis of in- and outpatient care, including epidemiologic determination of the number of individuals requiring treatment, and with the assessment of specific therapeutic interventions by means of clinical studies with extended outcome criteria. Sociological evaluation research in psychiatry to date has mainly been devoted to the analysis of in- and outpatient treatment methods and system-determined "patient careers" (referral processes). The resulting findings provide an estimation of the quality and efficiency of the current system of care and may thus yield useful ideas for improvement, including far-reaching innovations such as organizational models for the optimal integration of in- and outpatient care, decentralization measures involving "case management," and multiprofessional teamwork concepts in near-home care (Goldberg and Huxley 1980; Üstün and Sartorius 1995). Evaluation research in medical care is also increasingly expected to provide empirically founded arguments for rational health policy with

regard to the setting of priorities and the allocation of resources (Mechanic 1996).

Outcome evaluation research in psychiatry, in the narrow sense, has been undertaken on a large scale only very recently, understandably in health systems where economic constraints make it necessary to justify the expense of intervention. As in other medical specialties, the conviction that treatments should be maximally "evidence based" has not yet taken firm root in psychiatry. Efforts to promote this concept have run into a number of difficulties, including the limited current knowledge concerning effective treatments, the variability of courses of illness, multiple confounding factors in the manner of care and coping strategies, and, finally, the methodological problem of a valid and reliable determination of the patient's disease history and current status. These problems can be overcome only by giving adequate attention to the assessment of the treatment process itself, and not only of its outcome, because the quality of care and the organizational framework within which it is provided exert a major effect on the adequacy of coping and the course of illness.

The methodological advances and empirical findings of sociological evaluation research thus take their place in psychiatry alongside conventional clinical studies and health-economic analyses of treatment outcome.

4 Concluding Observations

The foregoing makes clear that sociology has not only directed its critical attention to the concept of mental illness and the role of the psychiatrist, thereby contributing to progress in the field, but has also, as an interdisciplinary science, made important empirical and methodological contributions to psychiatric research. These contributions may be roughly divided into three major areas, as described above: etiology; disease course and coping; and the results of treatment. We should not, however, overlook the fact that psychiatric sociology has not yet attained an appropriate level of professionalization, even in the countries where it is most widely practiced.

We will not analyze here to what extent the inadequate professionalization of psychiatric sociology is due to professional politics in sociology or to the paradigm of biological psychiatry that has acquired major economic importance over the last 20 years. There is reason for cautious optimism in the current increased effort to incorporate psychiatry into social-science aspects of public health research, whose aim is to study the health and illness of entire populations, and thereby determine the need for medical care and the development measures necessary for its provision (Schwartz et al. 1998).

There are promising developments, too, in basic research in biological psychiatry, where the vulnerability-stress model of mental illness is being further refined. Connections are being made between new discoveries of biopsychological and neurophysiological stress research on one hand and neurological and pharmacological basic research into the origins of mental illness on the other, including the interdisciplinary study of the progression of neurogenerative diseases afflicting the elderly. Thus Liu et al. (1996), for example, present novel strategies for research in Alzheimer's disease and Parkinson's disease, aimed at elucidating the possible synergistic effects of endogenous oxidative damage and stress-induced neurohumoral activation.

We may yet hope that avenues of successful interdisciplinary cooperation and knowledge transfer will be found, so that a theoretically and methodologically sound psychiatric sociology can assume its rightful place and continue to assist in the development of patient-centered, need-oriented, and effective psychiatric care.

CHAPTER

16

M. Knapp

Economic Evaluation of Mental Health Care

Dr. Annette Donath made enormous contributions to the writing of this chapter and, but for various protocol considerations beyond her and my control, would have been a co-author. Dr. Thomas Becker and Klaudia Werth made very helpful comments on the penultimate draft of the manuscript. My thanks to them all. Some parts of this chapter are necessarily summary accounts of issues, methods or examples dealt with in more detail elsewhere (Knapp 1995).

1 Introduction

There has long been recognition of the enormous and persistent personal and social consequences of mental illness. The chronicity of disorders such as schizophrenia and dementia, and the long-term if lower-level debilitation of depression and many neuroses, have substantial impacts on cognition, health, functioning and quality of life. They can leave many sufferers and their families with constrained, deprived, often devastated lives. The care of people with mental health problems in hospital or in community settings, support for their families and the treatment of symptoms as well as clinical and social sequelae generate considerable costs for health care, social services and other agencies. Directly or indirectly, there are also cost burdens for sufferers and their families. The consequences of mental illness, in other words, can be far-reaching and expensive.

The high costs of treatment and support have generated interest in, and demand for, economic evaluations of alternative policies and practices. Although this interest (or *concern*) is relatively new in most countries, it is fairly pervasive in that many treatment modes are now the subject of economic research. It would be accurate to say that, in *all* countries of the developed world, there is widespread recognition of the need for economic insights to inform health care policies and intervention strategies, although controversy abounds as to the influence that cost considerations should have in individual treatment decisions. The growing recognition of the relevance of economics and the controversy this can engender are clearly evident from experience in countries such as Germany, the United States and the United Kingdom.

The humane demands of the German government's expert enquiry on psychiatry, Psychiatrie *Enquête*, reported in 1975, influenced the structural developments of mental health care for more than two decades (Deutscher Bundestag 1975). The *Enquête* found over-reliance on hospital-based care, few community-based services and a separation between psychiatry and general health care which often hampered the provision of good-quality treatment. The key principles recommended were to provide services for rehabilitation; to promote equal rights for somatic and mental illness; to introduce community-based, decentralised and comprehensive care for all patients; and to create active coordination and collaboration between all mental health care services. A later report, based on a comprehensive research project, *Modellprogramm des Bundes und der Länder*, made further recommendations for the organisation of community mental health care, including patient-oriented cooperation between services (Empfehlungen der Expertenkommission 1988). While it was possible to implement psychiatric reform at a time of relatively high prosperity among the various funds or sponsors, a second and ultimately dominant force appeared with the growing need for cost controls, resulting in two major health care reforms enacted by the German government in 1989 (the *Gesundheitsreformgesetz*, GRG; the Health Care Reform Act) and 1993 (the *Gesundheitstrukturgesetz*, GSG; the Health Care Structure Act). The dominant system of pursuing an expenditure-orientated income policy turned to the pursuit of an income-orientated expenditure policy. As we shall see, these developments are associated with changes to the economic structure of mental health care in Germany and clearly generate numerous demands for economic evaluations and perspectives.

Legislative reforms and other system changes in other countries have also brought about some marked changes to the balance of economic power within mental health care systems and have simultaneously generated a range of demands for economic analysis. In the United States, for example, concerns have been expressed about limitations on clinical practices imposed by certain forms of "managed care". As we shall see later, managed care has introduced a variety of arrangements – from benefit limits and cost sharing to case management – with, among other aims, the intention of reducing the costs of treating health problems. Arguably, the balance of power – clinical and economic – has shifted from the clinician (and the provider side of the market generally) to the insurance company or the state. Among the consequences has been an upsurge in the expressed needs for economic information and insights, but at exactly the time when (and in exactly the context where) many clinicians have become rather worried about constraints on their clinical freedom.

In the United Kingdom, the advent of the so-called internal market following major parliamentary legislation in 1990 brought the most fundamental changes to the health care system for more than 40 years. The previously bureaucratic or hierarchical decision-making structure was transformed into a public sector quasi-market, with most clinicians employed as providers, but primary care general practitioners acting as both providers of services and as purchasers within the "market." A new economic agenda was set by this market-inspired structure, albeit one that is still almost completely dominated by the public sector. The quite legitimate and very sensible growth in the demand for economic data – on the costs of treatment, the economic and other benefits, the incentives and

motivations which propel inter-agency relations, the structures and forces inherent within expenditure decisions and programmes – has thus been associated (at least by some people) with the politically loaded move from a welfare state model of health care to a form of health market. It was anticipated that "the money would follow the patients", tilting the balance of power towards service users and purchasers.

Many other countries have recently experienced health care reforms, although perhaps not as extensive in their scope (Klein 1995), and across the world there have, of course, been quite substantial developments in treatment approaches and modes. Each of these many changes poses questions about the role of economics: What, for example, has prompted this interest in the economics of mental illness? Where does the need for economic evaluation stem from? What modes of economic evaluation have been developed? And how have they been deployed? These are the core issues addressed in this chapter, starting with discussion of the needs and expressed demands for economic insights and then turning to the supply response: the main modes of economic evaluation and how they are conducted. Examples of completed mental health economics evaluations are then presented. The concluding section takes stock of the current and potential contributions of economics in psychiatry. A glossary of terms is provided in the Appendix.

2 Needs and Demands for Economics

2.1 Scarcity

What are the underlying needs for economic insights, and how do these manifest themselves in expressed demands for economic evaluation? Economics starts with recognition of the widespread prevalence of scarcity: there are too few resources relative to needs or demands. One should be careful not to overplay the scarcity argument or to use it as a convenient justification for unpopular forms of rationing (Light 1997), but only a fool would fail to recognise the endemic problem of scarcity. In many countries, there are shortages of psychiatrists, clinical psychologists, social workers and medication relative to the assessed needs and/or expressed wants of the population. In some parts of Britain, there are currently serious shortages of acute psychiatric in-patient beds (Johnson et al. 1997). Very rarely will individual and societal demands for health care be met fully by available supplies. In the face of scarcity, choices must be made between alternative uses of available services and resources.

Economics has given particular emphasis to understanding how such choices can be made. Indeed, as we now argue, the aim of economics in this context is to describe, evaluate, understand and guide the workings of health care systems so as to improve the efficiency with which health and other services are produced and distributed and to ensure the equitable funding of mental health services and their targeting on needs. These two criteria underpin the different modes of evaluation.

2.2 Efficiency and Equity

Efficiency and equity (justice) are examined in economic evaluations, either singly or in combination. Component criteria are effectiveness and economy (Fig. 1).

Economy is the saving of resources, and its pursuit requires detailed costs data, but the impact of lower spending upon patients or families (the outcomes of treatment) is not examined within this criterion. Effectiveness is the other side of the coin: it is conventionally defined in terms of improvements to patient and family health and quality of life, but it is also an incomplete criterion, for it pays no regard to costs. There are of course many well-developed and widely tested instruments to measure effectiveness, covering psychopathology (including measures related to specific aspects of a disorder), social and personal functioning, family and peer-group relations, and so on. Economic evaluations can (and generally *should*) base their effectiveness measures on such instruments, but a steadily increasing number are also including unidimensional ("utility") measures of users' and others' direct valuations of care processes or outcomes (see Sect. 3).

The criterion of efficiency combines the resource (cost) and effectiveness (outcome) dimensions. The pursuit of efficiency could mean reducing the cost of achieving a given level of effectiveness or improving the volume and quality of outcomes achieved with fixed budgets. Efficiency must not be used as a euphemism or excuse for "cutback", because it can sometimes be promoted by spending more, not less. Examples of efficiency-inspired evaluations will be provided later in the chapter. Efficiency is sometimes (and usually most helpfully) examined in combination with the fourth criterion of equity (justice). Allocating budgets or services so as to achieve a more equitable (fairer) distribution of access to treatments and/or a more equitable achievement of levels of health or quality of life are common aims of most health care systems. Targeting services on needs is an example of adopting an equity criterion, although even this has

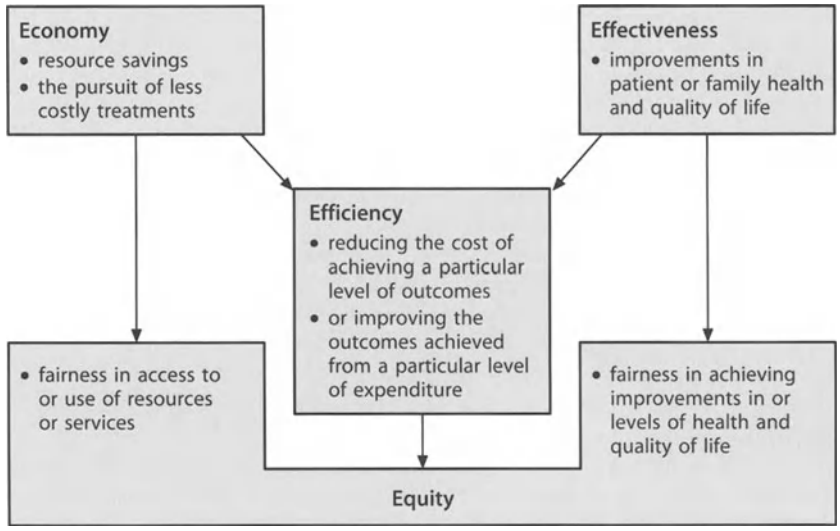

Fig. 1. Evaluative criteria

efficiency implications and interpretations, which illustrates the inter-connectedness of these important concepts and objectives.

2.3 Pressures of Growing Need

A number of factors are combining to increase the pressures of scarcity in mental health care systems, including those listed in Fig. 2. These underlying sources of scarcity, which can thus be called latent needs for economics, have fed into a number of expressed demands (manifest needs).

2.3.1 Growing Prevalence of Mental Illness

Many of the growing pressures on health and social care resources are especially important in mental health care, including the realisation that prevalence rates are higher than previously recognised and the concern that the proportion of identified need which is treated appropriately remains comparatively low. Unless there is an increase in resources, narrowing the difference between the true or underlying prevalence rate and the *treated* prevalence rate necessarily puts additional pressures on general practitioners, psychiatrists, pharmacy budget holders and others.

For example, affective disorders often go unrecognised and untreated. In the United Kingdom, the government and the main professional bodies have supported the Defeat Depression campaign – to raise awareness of the illness, among other things – even though success will undoubtedly further stretch available clinical time and budgets (at least in the short term). At the same time, health service budget holders and clinical decision makers are facing pressures from pharmaceutical companies and lobbyists to encourage wider utilisation of the selective serotonin reuptake inhibitors (SSRIs), whose market prices are much higher than those of the conventional tricyclic antidepressants (TCAs). Internationally, the apparently rising prevalence of depression in childhood and adolescence is causing further concern (Klerman and

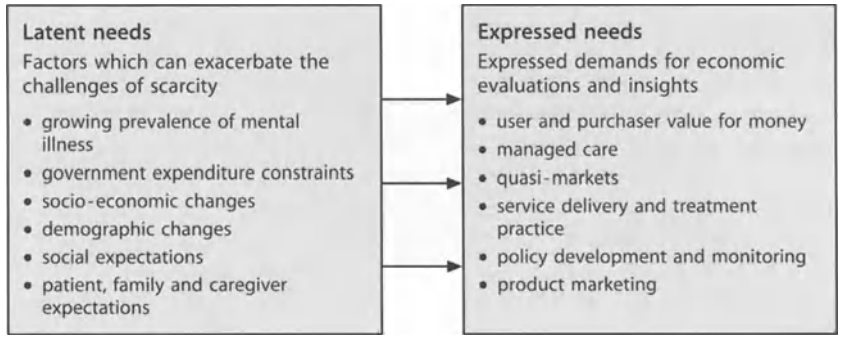

Fig. 2. Needs and demands for economics. (From Knapp 1997a)

Weissman 1989; Diekstra 1995). The biggest change in every country is the growing prevalence of Alzheimer's disease and other age-related dementias, which are already posing major resource allocation questions for national governments.

In Germany, the number of hospitalisations related to psychiatric diseases increased by 83% between 1980 and 1993, and the total number of hospital days increased by 40% over the same period. Even with the shortening of the duration of hospitalisation by about a quarter in the 1980s (Wissenschaftliches Institut der Ortskrankenkassen 1986), psychiatric patients still lead other specialties when it comes to mean duration of hospital stay (28 days in 1993; AOK-Bundesverband 1996), and mean length of stay has not shortened in recent years (Rössler and Salize 1994). This might be indicative of growth in treated prevalence (Rössler et al. 1996).

2.3.2 Government Expenditure Constraints

Growing underlying prevalence rates and the gap between underlying and treated prevalence stem in part from economic and socio-demographic trends. In countries in which a large proportion of health care is funded out of national or local taxation, the calls for economic evaluations to guide resource allocation are usually louder when the economy and/or public expenditure are under pressure. Pressures of this kind can be seen in Germany today. To understand how the current round of public expenditure cuts in Germany affects mental health care and perhaps to tease out some of the factors which have contributed to the scarcity of resources, we need to analyse the organisational and funding structures. The mixed economy of mental health care in Germany is a system of interdependent sectors:

- In-patient care and day-patient units (active psychiatric treatment) are financed by insurance companies (sickness funds).
- Custodial care is funded by patients (from their income and capital) and their relatives, complemented by funding from local authorities (*Sozialhilfeträger*).
- Out-patient medical treatment is provided by (freelance or private) psychiatrists and a few out-patient departments at psychiatric hospitals and is funded by the sickness funds.
- Most other out-patient care is not funded by health insurance but by social services agencies of local authorities (*Sozialhilfeträger*). This includes staffed hostels, sheltered homes, work rehabilitation or supported employment, drop-ins and socio-psychiatric services.
- Some work rehabilitation schemes are funded from the national insurance against unemployment (*gesetzliche Arbeitslosenversicherung*) and the pension scheme (*gesetzliche Rentenversicherung*).

The system is steered by regular negotiations between physicians' (Kassenärztliche Vereinigung, KV, i.e. the association of statutory health insurance physicians) and insurers' associations about the allocation of resources for ambulatory care, public planning for the hospitals and competition between pharmaceutical companies (both price and quality competition). One of the problems of this sectoral structure is a chronic lack of incentives both for cross-sector savings and for intra-agency savings (e.g. by shifting from in-patient to out-patient care). The GSG 1993 made doctors partly responsible for the quality of prescribed pharmaceuticals, which was apparently followed by a sharp decline in total expenditure on pharmaceuticals. As a consequence, the number of referrals to specialists and hospitals increased, as primary care physicians tried to shift the budgetary burden of complex and expensive cases. There is always the danger with these kinds of funding arrangements that they encourage supply-led decisions (fitting patients into available services) rather than needs-led decisions (shaping service responses to meet individual needs). There are also few incentives for coordinated action between different funding bodies.

Although government expenditure decisions have enormous implications for the level of available resources and the scarcity constraints faced by clinicians, it would be wrong to see scarcity as some kind of government plot or to believe that difficult resource allocation decisions could be obviated simply by spending more and more money.

2.3.3 Broader Socio-economic Changes

Increasing prevalence rates have been linked to cultural, social and economic changes. National suicide rates, for example, have been linked to rates for divorce, employment, homicide, female labour force participation, alcohol consumption and church membership, as well as demography (World Health Organization 1982; Diekstra 1995). Children in low-income families are more likely to have one or more psychiatric disorders, including conduct disorder, in later years (Offord et al. 1992). A high rate of unemployment (which is now the reality in all European countries) not only makes it harder for people with psychiatric problems to find jobs, but also increases the tax burden for the (smaller) number of people who are in employment. These are just some of the

direct economic impacts on scarcity. One of the most challenging changes for national and regional governments is population ageing. Between 1990 and 2000, the number of people aged 65–74 in Germany will have grown by around 40%. Pension payments will rise to around 18% of the gross domestic product by 2035, while pension contributions – on current trends – will remain at around 8% (The Economist 1996). The number of elderly people with dementia could increase by 50% (Beske and Kern 1995). This ageing of the population will inevitably mean some diversion of resources towards the support of elderly people, and away from younger age-groups. It could also mean increased tax burdens or higher insurance premiums for the (relatively smaller) working population.

2.3.4 Social Expectations

For a variety of reasons, the general public holds increasingly high expectations of its doctors and its health care services. There are other public concerns. The popular media in the United Kingdom, for example, have fanned concerns about seriously mentally ill people being discharged from in-patient settings to community care. These concerns have foundation, for there has been a catalogue of violent incidents in the United Kingdom perpetrated by people with psychoses, many of whom have not received adequate treatment (see, e.g. Ritchie et al. 1994), but rarely do the media report patient deaths associated with neuroleptic drugs or detention of people in secure settings when they no longer need to be there (Sayce 1995), nor do they publish many "good news" stories about successful treatments.

Patients and families (and other caregivers) are potentially important lobbyists for more and better services. The social stigma of mental illness is probably lower now than for a long time, and family pressures for higher standards of care or treatment are probably higher. The effect of new pharmacological developments on patient and family expectations can already be seen, for example, in relation to clozapine and fluoxetine: patients and families expect to have access to these new (and higher-priced) drugs partly because conventional treatments have failed (for them) and partly simply because they are new. In the circumstances, it is understandable if families question clinical or budgetary decisions which deny them access to particular drugs or courses of psychological therapy. In a study of prescription patterns for psychiatric disorders among general practitioners in Berlin, differences between the Eastern and the Western parts of the city were clear. The critical view of benzodiazepines held by the public was leading to a decrease in prescriptions of these drugs, but was correlated with a parallel increase in prescriptions of antidepressants, neuroleptics and psychotherapies (Heinrich et al. 1989; Linden and Gothe 1993).

A number of self-help groups have been formed by family members or caregivers, some of them in Germany represented by the federal organisation *Bundesverband der Angehörigen psychisch Kranker e.V.* By disseminating information on new treatment schemes, these groups can raise expectations and perhaps influence physicians' decisions. In 1992, a group of former psychiatric patients founded their own association, the *Bundesverband Psychiatrieerfahrener e.V.*, to help patients (who they call people "experienced in psychiatry") organise local groups and so defend their rights as patients. In cooperation with the *Deutsche Gesellschaft für soziale Psychiatrie*, these groups lobby to bring about further structural improvements for prevention and rehabilitation. In fact, with the GRG and the GSG, quality assurance has become a mandatory part of the health care system, and the patient perspective is an important part of outcome evaluation within quality assurance programmes. In social psychiatry research, of course, subjective patient and family criteria for the evaluation of care are of increasing interest and relevance (Priebe 1994; Lehman 1996).

2.4 Pressure of Demand for Economic Evaluations

The trends and changes summarised above generate what we might call the "latent" demands for economic data and evaluations; they explain the build-up of pressures on available resources. They are pervasive and cumulative. After a time, these latent demands are liable to become manifest: they change from underlying trends into real and expressed needs for economic insights and interpretations (Fig. 2). What triggers this change is not altogether clear, but it is associated with the recognition that economics can offer conceptual frameworks, relevant data and interpretations which can – in combination with other perspectives and data – inform, analyse and (ultimately) ease choices in the face of resource scarcity.

2.4.1 User and Purchaser Value for Money

The most fundamental concern of patients and their families is that the treatments they receive should be effective at alleviating the symptoms and/or compensating for the disabilities associated with mental illness. This, too, is the primary concern of the psychiatrist, psychotherapist, social worker or other

health care professional. However, in neither case is effectiveness likely to be the *only* concern. If patients or families are directly bearing some of the treatment cost, through co-payments in insurance-based systems or user charges in public health systems, what they pay could certainly influence what they decide to use (Brand et al. 1977; Frank and McGuire 1996). For example, the raising of co-payments and the reduction of coverage between 1978 and 1983 for U.S. federal employees and their dependents insured by Blue Cross and Blue Shield lowered both out-patient and in-patient mental health service use by children and adolescents (Padgett et al. 1993). Even when patients and families bear none of the direct costs, there could be indirect costs associated with particular treatments which could influence take-up and compliance (McPhillips and Sensky 1997). The influences of resource considerations on clinicians' decisions are discussed below.

2.4.2 Managed Care

Scarcity implies the need for choice, in particular, choice as to how available services are to be rationed between competing needs. Can these allocations be left to market forces? The moral legitimacy and efficiency of markets for health care services have been widely and heatedly debated. However, it is rare for the treatment of serious mental illness to be left exclusively to open market forces, where patients or their families must purchase treatments from profit-seeking providers, and there are numerous market intermediaries – private and social insurance schemes, brokerage, charities, and so on – and of course many governments operate "safety net" schemes to cover the pool of individuals (typically the chronically ill and low paid) without any other access to effective treatments. Need and ability to pay are often inversely correlated, and most mentally ill people have insufficient insurance coverage (Rössler and Salize 1994).

Mental health care markets are characterised by numerous difficulties. Prevailing incentive structures have been argued to lead to over-provision of certain services (especially in-patient care) and inefficient resource allocation. Other difficulties can arise because patients and families are poorly informed about their health status, health needs and the means to eradicate them. Professionals (psychologists, psychiatrists and others) act as their agents, but can patients and families judge the quality or monitor the effects of a professional's efforts? Professional self-interest or corporate profit margins may lead to negligence, in the form of failure to give proper attention to a patient, or to skimp, where professionals deliberately undertreat so as to save time or expense (Maynard et al. 1986).

"Managed care" has been the response in some insurance-based health care systems. For example, the main reason for the growth of managed care in the United States was that the health care costs falling to employers and other payers were increasing rapidly (Dorwart 1990; Frank et al. 1991). Limits were put on benefits, cost sharing was introduced and case management was promoted (Unützer and Tischler 1996). Managed care clearly raises the demand for reliable cost and cost-effectiveness evidence and, in so doing, raises practical and ethical issues, particularly around the influence which cost does and should have on clinical decision-making (Geraty et al. 1992; Sabin 1994).

This same link is evident in Germany. The German social insurance system has had to cope with a strong increase in demands for expenditure while facing a permanent decrease of revenues. In a system where health insurance coverage is financed by specific contributions calculated on the basis of gross monthly income, the overall deficit can be partly explained by reduced income from unemployed people. The two health care reforms – the GRG in 1989 regulating ambulatory care and the pharmaceutical sector, and the GSG in 1993 regulating hospital care and competition between the insurance companies – set in place current mechanisms to guide expenditure. The series of cost control interventions began in 1983 with the imposition of a "negative" pharmaceutical list, covering drugs for which the patient paid the full price (Hoffmeyer 1994). The list was further extended in 1989. Reference prices were introduced in 1989 and a drug budget for office-based physicians in 1993. To create better transparency, the standard daily rate for hospitalisations – until recently based on a mixed calculation including costs of care, hotel costs and medical treatment – was defined as a variable rate based on the hotel costs, specific rates for the different wards, *Fallpauschalen* (lump sum per patient) and *Sonderentgelten* (additional payments for specific medical services or assessments). Funding changes which are currently pending include capitation for office-based physicians, dependent on the subject area and the number of patients per practice, and more independence for the insurance companies in defining their services.

Discussion of managed care in Germany has focused on whether high-standard care with lower costs can be achieved by any of the following measures: better communication and cooperation between players in the health care system, particularly between primary and secondary care; elimination of duplication of effort and activity; incentives to encourage players to work together; quality assurance and standardised medical

practice; and provision of total health care for individual patients. In the recently introduced competition between insurance companies, insurers will not succeed in offering different contribution rates because of the *Risikostrukturausgleich* (risk-based fiscal equalisation, i.e. a system to balance out the expenditure and revenues among the individual regional health insurance companies; the amount to be transferred is calculated according to the individual "risk" of the insured, i.e. income, sex, age, number of family members who do not have to pay contributions), and they are unlikely to compete in terms of the range of provision because of consolidated financing mechanisms, but they probably *will* compete in terms of the structure of care they can offer. Encouraged by changes in the law, the major insurance companies have started evaluating new structural models of health care. Two pilot projects, based in Berlin and Baden-Württemberg, pursue similar strategies to managed care: both models – "networked practices" (combined budgets) and the *Hausarztmodell* (increased primary care) – have been developed to strengthen the out-patient sector by improving information flows between individual practices and funds. However, there are complications in Germany because of the different methods of funding and provision; the high level of government involvement; fragmented, uncoordinated health care delivery; and lack of, or prohibited access to, data on patient needs and outcomes.

2.4.3 Quasi-Markets

Expressed demands for economic evidence can also be seen in those countries which are moving away from a "socialised", welfare state or publicly dominated health care system to a mixed economy of market-like arrangements. A recent example is provided by the U.K. National Health Service (NHS), which moved from a "command and control" hierarchy to a set of internal or quasi-markets following the 1990 NHS and Community Care Act. It was intended that patterns of provision and use would be determined locally and – in principle – with greater opportunities for patient influence (for an excellent review, see Klein 1995). In this U.K. context, "managed care" developments have a somewhat different meaning and raise rather different issues both for the professional and the care system. Economic data are needed to inform, structure and monitor the contracts drawn up between purchasers and providers of services. In fact, cost awareness has been seen as an ethical duty for doctors in the British NHS for some time; a much-quoted British Medical Association (1988) statement, for example, included the principle that "it is the doctor's ethical duty to use the most economic and efficacious treatment available."

2.4.4 Service Delivery and Practice

The growth of forms of managed care in the United States, structural changes in Germany and the separation of public sector purchasers and providers in the United Kingdom offer examples of how economic considerations have entered the clinical domain at the practice level. One reaction to such constraints is to complain about and campaign against the collection and dissemination of economic evidence and to argue that a doctor's ethical duty is to achieve the greatest possible health gain for patients.

A more constructive and realistic view is to recognise that the scarce skills of general practitioners, psychiatrists and other mental health professionals should be used to best effect, and achieving that means taking account of the resource consequences of clinical decisions. In turn, this means gathering evidence on how available resources are deployed and with what effects. In other words, there is justifiably a practice-level need for economics. Part of that justification is in fact the argument that it would be unethical to take decisions without cognisance of the cost consequences, as to do so is potentially to waste scarce resources which might be better deployed so as to improve the health and quality of life of patients by greater amounts. Such pragmatic action does not mean that psychiatrists and others should not be lobbying for higher levels of government or other expenditure, but there is still a need to recognise the value of practice-level utilisation so as to make more effective and cost-effective use of those resources currently committed to the field.

In the United Kingdom today, for example, and also in countries such as Sweden, Canada, Australia and the United States, new treatments, new care settings and new ways of organising service systems must demonstrate not only their effectiveness in improving patient health and quality of life, but also their cost-effectiveness (see Sect. 2.4.6). In these countries, many of the major new practice innovations of recent years have been subjected to economic as well as clinical and social evaluation. Clinical decision-makers – and also case managers and keyworkers in social welfare settings – understand that they will be in a stronger position to make more effective placements and/or to offer better advice to their patients and families if they possess reliable data on needs, outcomes, costs and the links between them. The rapid growth of support for evidence-based medicine has had its economic dimension, as evidenced by the first mental health output from the Cochrane Collaboration on family interventions (Mari and Streiner 1996).

2.4.5 Policy Development and Monitoring

Cost-effectiveness demands at a macro-level in Germany are associated with the development and monitoring of both government policy and fund givers (*Leistungsträger*) policy. Governments and *Leistungsträger* require information about the resources needed nationally to care for people with mental health problems and the targeting of services on needs.

Recent changes, sometimes sweeping reforms, to health care systems in a number of European countries have been driven by concerns about rising costs, unknown outcomes, wide variations in assessment methods and treatment modes, inequitable allocations and perverse incentives. Health economics research which meets broader policy demands can therefore hope to inform and assist policy makers by uncovering the behaviours, constraints and motivating forces of different agencies or individuals. For example, there are evaluations under way in the United Kingdom which are looking at the new primary care arrangements (primary care groups), the move from hospital-based to community-based care systems and the prevalence of psychiatric problems among the growing number of homeless people. The illustrative studies in Sect. 5 offer further examples of policy-relevant economics research.

2.4.6 Product Marketing

A final source of expressed demand for cost-effectiveness and other economic evaluations is the pharmaceutical industry. Insurance companies, governments and individual pharmacy budget-holders are concerned about the rising prices of medications, especially with the arrival of the SSRIs and atypical antipsychotics. They want to know whether these high-priced medicines can be justified by resource savings from reduced hospitalisation and lower long-term costs and/or by improved patient outcomes (see Sect. 5).

At the same time, pharmaceutical companies naturally want to promote their products in both economic and clinical terms. Regulatory and funding bodies in some countries want similar evidence. In Australia, evidence of economic analysis is required before a new product can be accepted for government subsidy (Commonwealth of Australia 1990), and there are national guidelines and provincial regulations concerning the economic evaluation of new pharmaceutical products in Canada (Drummond 1992). Increasing attention to cost-effectiveness arguments (but without formal guidelines) can be seen in Italy and the United Kingdom. The same kinds of questions need to be asked of psychotherapy (Tillett 1996), but psychological therapies generally lack "product champions" to fight their corner, which might disadvantage them vis-à-vis pharmacological interventions if governments, purchasing authorities or clinicians become more cost-conscious.

3 Economic Evaluations

3.1 The Supply Response

The response from economists to these latent needs and expressed demands for economic evidence has been relatively limited. There are still comparatively few completed economic evaluations outside the United States, although many such evaluations are now under way in Europe. There are many reasons for this low supply response: a lack of mental health expertise and interest among economists, a dearth of suitable and relevant data, a lack of incentives for service providers and purchasers to seek economic insights, and few moves by clinical research teams to recruit an economist or add an economic dimension. There has also been the problem that policy-makers or decision-makers at various tiers in key agencies do not believe or recognise economic problems as being researchable or, by contrast, that they are so anxious to acquire cost data that they grasp unselectively at the first evidence that comes along, no matter how poor the quality (Knapp 1997b). As policy-makers have become more discerning, the problem has been that the supply of health economics expertise has not been able to keep pace with the demand.

3.2 Modes of Evaluation

The three most useful modes of economic evaluation are cost-effectiveness (CEA), cost-benefit (CBA) and cost-utility analyses (CUA) (Table 1; for a full account of principles, see Drummond et al. 1987; for an account of these evaluative modes in mental health applications, see Kavanagh and Stewart 1995). These modes have some common elements, but differ in two main respects: they measure outcomes differently, and consequently they address slightly different policy or practice questions. Other evaluative types are cost-offset and cost-minimisation analyses, but these do not measure outcomes in terms of the impacts on patients or families, and thus are (generally) less helpful.

CEA is concerned with ensuring that resources allocated to the mental health sector are used to

Table 1. Modes of economic evaluation

Mode of evaluation	Cost measurement	Outcome measurement
Cost-minimisation, cost-offset	Comprehensive	Not measured
Cost-effectiveness	Comprehensive	Clinical scales
Cost-benefit	Comprehensive	Monetary values
Cost-utility	Comprehensive	Utility (e.g. QALYs)

QALY, quality-adjusted life-years.

maximum effect. It is usually employed to help decision-makers choose between alternative interventions available to or aimed at specific population groups: If two treatments are of equal cost, which option has the greater effectiveness from a given budget? Or if two options have been found to be equally beneficial in terms of health outcomes (say), which is less costly? A CEA seeks to measure costs comprehensively (see Sect. 4) and measures outcomes along the dimensions usually distinguished by clinical researchers – such as symptomatology, behaviour, social role functioning, social networks, quality of life – and using the same clinical scales.

CBA seeks to show whether a particular course of action, such as a mental health treatment programme, is socially worthwhile. All costs and benefits are valued in the same units – usually monetary units – and can thus be directly compared: if benefits exceed costs, the evaluation would recommend the policy or project, and vice versa. The simple comparison of "costs incurred" with "costs saved" is not a CBA but what economists now call a "cost-offset analysis". Conducting proper cost-benefit analyses is particularly difficult because some very valid outcome indicators are not easily expressed in monetary terms. Recent methodological developments have sought direct measures of the values placed on outcomes (or care processes) by patients, families or others, perhaps using either willingness-to-pay methods (McGuire et al. 1988) or conjoint analysis (Ryan 1996).

The newest mode of economic evaluation, CUA, is similar to CEA with the important exception that it measures and then values the impact of an intervention as well as the cost of achieving that improvement. The value of health improvement from a treatment is measured in conflated units of "utility", in contrast to CBA, which uses monetary values. CUAs avoid the potential ambiguities with multi-dimensional outcomes in CEAs and can be applied to choices across a range of policies or practices for different target groups. Most progress with CUAs appears to have been made in health economics, where the most common value measure is the quality-adjusted life-year (QALY), which seeks to measure both the number of life-years gained following a health care intervention and the quality of those life-years (see below). Interesting alternatives are the disability-adjusted life-year (DALY) measure, pioneered by the World Bank (1993), and healthy year equivalents (HYEs; Mehrez and Gafni 1989).

These different modes of evaluation have a common aim in their approach to cost measurement. If a societal perspective is adopted, which is usually the case, this common aim is to range widely across all direct and indirect costs, no matter to what agencies or individuals they fall. The main evaluative modes obviously differ with respect to their measurement of outcomes. CEAs can rely on clinical outcome scales – which can make it easier to conduct an economic evaluation, especially if it is alongside a clinical trial – but cannot provide such powerful or widely applicable answers as CBAs or CUAs (Knapp 1995).

4 How to Conduct an Economic Evaluation

Generally, and for ease of execution, an economic evaluation should have the same broad design (criteria for eligibility, intervention modes, quasi-experimental approach, sample sizes) as the design chosen for the main research evaluation. It should employ the same data collection points and should span a similar period of time. There are unlikely to be strong reasons for adopting a different design in relation to each of these methodological considerations, except for sample size. In order to achieve enough power to test some economic hypotheses, a larger sample might be required, but currently there is little evidence upon which to base this argument (Gray et al. 1997).

It is helpful to distinguish six main stages to an economic evaluation:

1. Defining the alternative treatments or services to be evaluated
2. Identifying (listing) the costs and outcomes to be covered by the evaluation

3. Quantifying and valuing the costs and outcomes for each alternative
4. Comparing costs and outcomes between alternatives
5. Conducting sensitivity analyses and perhaps qualifying or revising findings
6. Examining the distributional implications and drawing conclusions

These stages are described in more detail in Knapp (1984) and in Knapp and Beecham (1996).

The first task in any evaluation – economic or clinical – must be to clarify the question to be addressed: What is the purpose of the study? All evaluations are comparative, whether they compare two or more alternative policies or modes of intervention, two or more groups of people or localities, or a single group of people before and after an intervention. It is obviously imperative from the outset that the alternatives being compared are agreed. At this point, therefore, the decision has to be taken as to the mode of evaluation to be employed.

The second evaluative stage is to draw up a comprehensive list of all relevant costs (regardless of the source of funding) and of all relevant outcomes or dimensions of effectiveness (and not just those relating directly to the mental health of the patient). These comprehensive lists are needed even if it is expected that some dimensions need not be measured (because a narrower perspective is to be adopted and/or because it is simply unnecessary to collect more data than can be used) or might subsequently prove impossible to measure in practice. In this way, the full breadth of the possible resource and effectiveness impacts of the alternative treatments can be drawn to the attention of decision-makers, agencies in service delivery networks, researchers and others, even if there are no data for some of those impacts. For example, very few completed evaluations have been able to obtain adequate measures of the costs borne by families, yet a substantial number of mentally ill people are financially dependent on their families (Bundesministerium für Jugend, Familie, Frauen und Gesundheit 1986).

The third stage in an economic evaluation is the measurement or quantification of each of the costs and outcomes. On the outcome or effectiveness side of the evaluation, the research task will clearly depend on the evaluative technique to be employed. Clinical scales for assessing outcomes are discussed in other chapters of this volume and would form the basis of a CEA. If a CBA is to be undertaken, these effects or outcomes would also need to be valued in monetary terms. We have already noted how difficult it would be to attach monetary values to most mental health outcomes, although some studies have used employment earnings as a (single and generally inadequate) benefit indicator. In a CUA, a single, uni-dimensional indicator of "utility" would need to be constructed. The most commonly used such measure is the QALY, but the instruments currently used for QALY assessment and comparison across specialties and diagnostic groups are largely irrelevant for mental health research (Chisholm et al. 1997). Recent advances in research on people with schizophrenia might eventually help (Revicki et al. 1996).

Cost measurement is probably easier, but unfortunately still not straightforward. Cost measures are most usefully based on service utilisation data obtained for each sample member. Service utilisation data can be collected using an instrument such as the Client Service Receipt Inventory (CSRI) (Beecham and Knapp 1992). Costs are then attached to each service or element of support in turn, using the best available estimates of long-run marginal opportunity cost. In this procedure, "marginal" refers to the addition to total cost attributable to the inclusion of one more user, and "opportunity cost" refers to the opportunities forgone by not using a resource in its best alternative use, which is the conventional economics definition. The short-run average revenue cost plus appropriately measured capital and overhead elements is usually likely to be close enough to the long-run marginal cost for most services, and it is conventionally taken as the cost estimate for empirical work in economic evaluations. (In the United Kingdom, there is an excellent annual compendium of many such unit cost measures, ranging across the most important services; Netten and Dennett 1997.)

The fourth stage is to compare the costs and outcomes. Comparisons between the alternatives being evaluated are made in relation to both costs and outcomes after whatever summation is possible. (In cost-benefit studies, the costs of a treatment or policy can be compared directly with its benefits, and cost-benefit differences or ratios can then be compared between alternative treatments or policies to see which offers the greatest net benefits to the health service or to society.) Difficulties can arise when costs and outcomes are distributed over time in different patterns: for example, costs may be incurred early, but outcomes may not accrue until rather later. The usual procedure is to discount future costs and outcomes back to a present value before making comparisons, using a suitable procedure to weight future costs and outcomes less highly than current costs and outcomes.

Most commonly in a CEA, average costs are calculated for each of the samples and compared with the outcomes. The option with the lowest cost per given level of outcome is then deemed to be the most desirable on the grounds of efficiency in the use of resources. Some CEAs rely on a single (dominant) outcome – perhaps the mortality rate or a measure of

the improvement in positive symptoms – but psychiatrists have generally found it more relevant (as a guide to policy or practice) to use multi-dimensional outcome measures. This rules out the use of a simple ratio measure to indicate comparative efficiency: reductionism could well misdirect decision-making. Complications will then arise if there is improvement along some outcome dimensions but deterioration along others. Complications will also arise if the cost and outcome comparisons point to different preferred solutions: treatment A may be more effective than treatment B, but also more expensive. In these circumstances, the role of the economic evaluator is to present all relevant findings to those policy-makers or practitioners whose task it is to make decisions. In turn, they will need to weigh up the clinical, social or political importance of those findings.

The fifth stage is to examine how sensitive the findings are to the assumptions that inevitably have to be made in the course of any evaluation. For example, costs may have been estimated with some error, or outcomes may have been weighted on the basis of one particular, but not generalisable perspective. Assumptions and perspectives should therefore be altered to see whether the conclusions change. This fifth stage thus provides the opportunity to check the assumptions made in all previous calculations to allow for possible error or bias.

The last stage is to draw conclusions from the evaluation. If, as is usually the case, the primary purpose of an economic evaluation is to examine efficiency, this final stage should also explore to what extent the distribution of the burden of costs and the enjoyment of outcomes which would follow if each of the alternative treatments or services were implemented is equitable or fair. One treatment may be the more cost-effective (efficient) of two alternatives, but it may leave patients or their families bearing a much higher cost burden. If this treatment were to be more widely adopted, it might therefore be necessary to find a way to compensate patients and families for their extra costs, not only for reasons of fairness but because these costs may create a disincentive for them to continue with treatment.

5
Examples of Economic Evaluations

The main types of economic evaluation will now be illustrated by describing a small number of completed studies. In principle, economic evaluations could address a wide range of questions about mental health policy and practice, but to keep the discussion manageable the section will focus on just two topics: (1) antidepressant drug therapies and (2) community care as an alternative to hospital treatment. Together, these allow us to look at each of the different evaluative modes and different research designs.

5.1
Antidepressant Drug Therapy

The treatment of depression has changed quite markedly since the launch of the first SSRI (fluoxetine) in Belgium in 1986. Since then, other SSRIs have been developed and marketed, usually at a price which is considerably higher than the typical prices of the TCAs. Two of the most pressing questions in the treatment of depression currently therefore concern relative effectiveness and cost. Are the higher prices of the SSRIs outweighed by either improved symptoms or better quality of life for patients or their caregivers? And are the overall treatment and support costs reduced either now or in the future? Neither question is easy to answer, yet without answers it would be premature either to support or to block the wider use of the new drugs on economic grounds (Hotopf et al. 1996). A new treatment mode should not necessarily have to demonstrate that it is less costly than alternative treatments in order to be cost-effective, but it must demonstrate that any increase in costs (compared to its closest alternative) is at least matched by increased effectiveness.

The economic questions raised by the SSRIs are certainly not more important than the clinical questions, but they are definitely pertinent. One reason is because depression is such a costly illness; for example, a few years ago, the direct and indirect costs were estimated at $44 billion annually in the United States (Rice et al. 1990). Another reason is that a high proportion of total expenditure on drugs in most countries is already accounted for by antidepressants (over 3% in England in 1991; National Health Service Executive 1996) even before the more widespread use of the higher-priced SSRIs. Although hospitalisation is costly in both the United Kingdom and the United States, these high "total burden" costs arise for a host of reasons, and similarly large figures would be found for other countries.

Four completed studies of treatment with fluoxetine illustrate a range of economic evaluative types and research designs (Table 2). Sclar et al. (1994, 1995) conducted two observational studies in an American health maintenance organisation (HMO), using multivariate statistical methods to interrogate a large retrospective data set. In the first study, they compared three TCAs (amitriptyline, nortriptyline and desipramine) with fluoxetine ($n = 555$ patients with depression); in the second, they compared three SSRIs (paroxetine, sertraline and fluoxetine; $n = 744$). They

Table 2. Economic evaluations of fluoxetine

Study	Research design	Evaluation mode	Treatments evaluated
Sclar et al. 1994, 1995	Retrospective, observational studies	Cost-offset analyses	Fluoxetine versus amitriptyline, nortriptyline and desipramine
Le Pen et al. 1994	Decision (tree) model	Cost-offset analysis	Fluoxetine versus variety of TCAs
Revicki et al. 1995	Decision (tree) model	Cost-utility analysis	Fluxetine versus nefazodone and imipramine
Simon et al. 1996	Prospective, randomised trial	Cost-effectiveness analysis	Fluoxetine versus desipramine and imipramine

TCA, tricyclic antidepressant.

were only able to compare costs, not outcomes (and the costs were not measured comprehensively), so that their evaluation fell into the category of a cost-offset analysis. There were other methodological weaknesses, but both studies at least endeavoured to avoid some of the biases which can sometimes arise with prospective trials. They found that the costs of all health care services used (including drug costs) in the year after initiating treatment were lower for fluoxetine than for the other drugs, partly because patients for whom fluoxetine was prescribed appeared to need dosage titration to a lesser extent.

Le Pen et al. (1994) and Revicki et al. (1995) both employed clinical decision models ("decision trees") built partly on trial data and partly on Delphi panel estimates of parameters for which no "real world" data could be obtained. Le Pen and colleagues pooled data from a number of short-term, randomised trials comparing fluoxetine with a variety of TCAs. Although the title of their paper suggests a cost-benefit study, in fact they merely compared costs incurred with costs saved, so that this is again a cost-offset analysis. They found that fluoxetine was potentially cost saving in France (through improved tolerance), so that higher-priced SSRIs might nevertheless bring about short-term financial savings. The authors are cautious about their methods and their findings – and clinical decision models are notoriously prone to error and bias – so that their deliberately conservative assumptions are sensible. Revicki et al. (1995) constructed their decision tree for Ontario, Canada, again using data pooled from completed randomised trials, estimates in the published literature and a Delphi panel. In this case, however, they sought to make cost-utility and not just cost comparisons (between fluoxetine, nefazodone and imipramine) over a 20-year period. They concluded that nefazodone is a cost-effective alternative to imipramine, but they found no difference between nefazodone and fluoxetine. Of course, decision trees of the kind reported by Le Pen and Revicki and their co-workers are not peculiar to economic evaluations – indeed many health economists are rather suspicious of them (Sheldon 1996) – but they often provide a starting point for discussion in the absence of better (prospective) data.

For fluoxetine, better data are now emerging from a large prospective, randomised trial underway in the United States. Simon et al. (1996) reported the results for the first 6 months of a 24-month trial to compare the costs and effects of desipramine, imipramine (both TCAs) and fluoxetine for a sample of 536 HMO patients. In common with the earlier studies, Simon and colleagues failed to measure costs comprehensively, but they employed a number of robust clinical and social outcome measures. They used these in a CEA. They found that fluoxetine patients had fewer medication changes and fewer side-effects, higher drug costs and lower in-patient hospitalisation costs. However, there were no differences between groups on the main clinical measures of depression, symptoms or quality of life, or on total costs. They therefore concluded that the higher drug costs associated with this particular SSRI did not lead to higher total costs in the short term, but equally it did not improve outcomes. However, patients suffered fewer side-effects, which probably explained the smaller number of medication changes.

Drug trials are well made for economic evaluations, and there are now many CEAs, CUAs and cost-offset analyses being conducted alongside prospective, randomised trials which should considerably help physicians and other decision-makers to make better use of the finite resources at their disposal. In other contexts – as we now illustrate in relation to hospital and community care – the design, implementation and interpretation of economic evaluations is not always so straightforward.

5.2 Hospital and Community Care

One of the major concerns expressed in the *Psychiatrie Enquête* was the heavy reliance on treatment in the

large, remote state mental hospitals (Deutscher Bundestag 1975). Among the report's recommendations was the development of community-based care tailored to individual needs. Between 1970 and 1988, the number of psychiatric beds in West Germany fell by 29%, with a more rapid decrease in the specialist mental hospitals and increases in the numbers of beds in psychiatric departments of general hospitals and in university hospitals (Rössler and Salize 1994). The decline and relocation of in-patient places is likely to continue, especially in the former GDR, where the system of treatment was dominated by this form of institutional care (Rössler et al. 1996). In fact, community-based provision is the preferred locus of care in most developed countries.

It has been difficult to gather evidence for Germany to shed light on the patient outcome and cost effects of shifting the locus of care from the hospital to the community, partly because of data protection issues (but see the ongoing study by Priebe et al. 1996). The study by Häfner and an der Heiden (1989) is one of the few to offer insights. (Sadly, data protection considerations forced the closure of the case register on which their study was based, and consequently the termination of this research study.) For 148 people with schizophrenia supported in community settings in Mannheim, they found that costs were generally considerably lower than continued hospital care. For only eight patients were hospital costs lower than community costs. Hess et al. (1989) had found similar cost differences in Bern. Salize and Rössler (1995) studied a smaller sample of Mannheim patients, each of whom had a diagnosis of schizophrenia and who had been discharged to the community from hospital, and reached the same conclusion: community care costs were markedly lower than hospital costs. Häfner and an der Heiden (1989) found that people living in sheltered accommodation derived more benefit from out-patient treatment than those living with their families or those living alone. Salize and Rössler took this question further, looking at cost predictors and cost-outcome linkages. Statistical interrogations of this kind can be very informative.

It has been easier to conduct economic research on the hospital/community balance in the United Kingdom and the United States. In the United Kingdom, for example, the number of people resident as in-patients under the psychiatric specialty today is less than one third of that 30 years ago, prompting many small and a few large studies (Fig. 3). Viewed historically, the hospital rundown policy in the United Kingdom has been part medical preference, part public opinion and part "hard political economy" (Korman and Glennerster 1990). Thus, although the rundown of the old psychiatric asylums was consistent with most psychiatrists' recognition that many people with long-term mental health problems could be successfully rehabilitated in community settings, economics also played its part in the reprovision or rehabilitation process. This alone justifies economic evaluation to check whether the *assumed* advantages of community care are in fact correct.

The most comprehensive U.K. study has been conducted by the Team for the Assessment of Psychiatric Services (TAPS) in North London, with hospital assessments, 1-year and 5-year outcomes after relocation to the community and a large economic element (Leff 1997). The clinical and social outcomes for former long-stay in-patients after 1 year in the community were at least as good as their "matched" counterparts who had remained in hospital. Moreover, their mental state and social disabilities were stable: the leavers had more diverse social networks (but fewer contacts with relatives), lived under less restrictive conditions and preferred life in the community (Leff et al. 1996). Of the 737 discharged long-stay patients (without dementia), 24 had died within the first year in the community, and virtually no one else was "lost" to services or to the research.

For most of these people leaving hospital for community residence, the costs of care were substantially lower (Beecham et al. 1997), although for the full

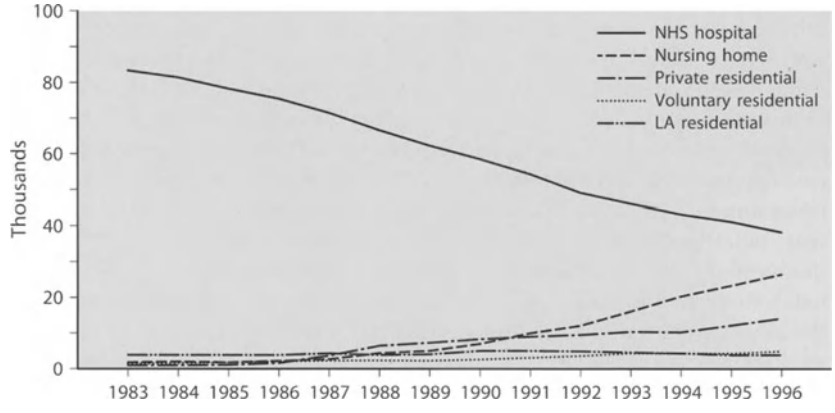

Fig. 3. Changing balance of mental health accommodation in England. *LA*, local authority

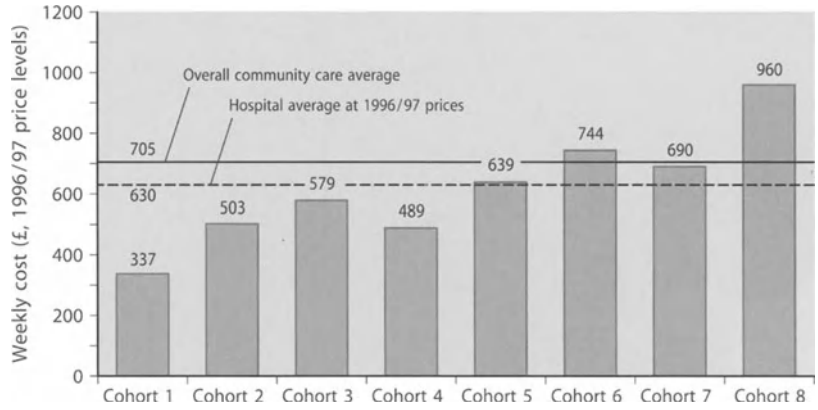

Fig. 4. Hospital and community care costs

hospital long-stay population there were no overall cost savings (Fig. 4). Five-year follow-up data suggest that costs increase slightly in the longer term. There was a clear link between costs and outcomes. For the early leavers, higher community care costs were associated with greater improvements in health and welfare (Beecham et al. 1991). In particular, improvements in negative symptoms, delusions and hallucinations, social networks (broadening) and the general need for care (from an index of physical health) were all associated with higher costs. Thus the hospital closure programme in Britain – which continues to gain momentum amid controversy about the effectiveness of treatment for the acutely ill – could offer both social and economic benefits for most people who would formerly have remained in hospital as long-stay in-patients.

Reproviding long-term care in the community for chronically ill people (many of whom no longer display active symptoms of mental illness) may not be straightforward, but it can be successful in terms of patient quality of life and it should be affordable from the savings from hospital rundown. However, successful and cost-effective community-based alternatives to hospitalisation for acutely ill patients have been more elusive. One model which has attracted a lot of attention is the assertive community treatment (ACT; sometimes called PACT) approach pioneered in Wisconsin by Stein and Test (1980) and recently reviewed by Scott and Dixon (1995). The economic evaluation of the original ACT model was a CBA conducted over a 12-month period (Weisbrod et al. 1980). Costs ranged beyond health care to include criminal justice, maintenance and family costs; benefits were measured (somewhat narrowly) as the monetary value of increased participation in the workforce. The study found a higher net benefit (i.e., benefit minus costs) for the community-based programme.

A replication of the ACT model in London (with some modifications) – the Maudsley Hospital's Daily Living Programme (DLP) – was the subject of a two-phase, 4-year evaluation. In the first phase (randomised allocation of 189 people with acute schizophrenia or severe affective disorder to either the DLP or standard in-patient care), the evaluation found better outcomes, higher patient and family satisfaction and lower costs over a 20-month period (Marks et al. 1994; Knapp et al. 1994). The second phase extended the research period to 4 years and included randomised withdrawal of DLP from 33 patients, continued DLP for another 33 and continued control care (in-patient/out-patient care) for 70 patients. At the end of this second phase, all of the earlier clinical gains had been lost, and there was no longer a cost advantage to the DLP (Audini et al. 1994; Knapp et al. 1998). The cost profile is illustrated in Fig. 5. The economic evaluation was a CEA: it included the fully comprehensive costing of all health, social care and other services; it examined the effects of DLP and standard care on patient employment and carer support; and it assessed outcomes in terms of symptoms, behaviour, social adjustment, personal functioning and patient and family satisfaction. No single outcome measure was assumed to dominate, and no attempts were made to obtain uni-dimensional "utility" measures or to express the outcomes in monetary terms.

6 Conclusions

There is a large unmet need for economic evaluation in the mental health field. Cost-effectiveness and similar insights are increasingly being recognised as relevant for drug licensing, budget-constrained case management, the increasing emphasis on evidence-based medicine and the more general and virtually perennial search for greater efficiency and equity in the delivery of treatment interventions and services. As discussed

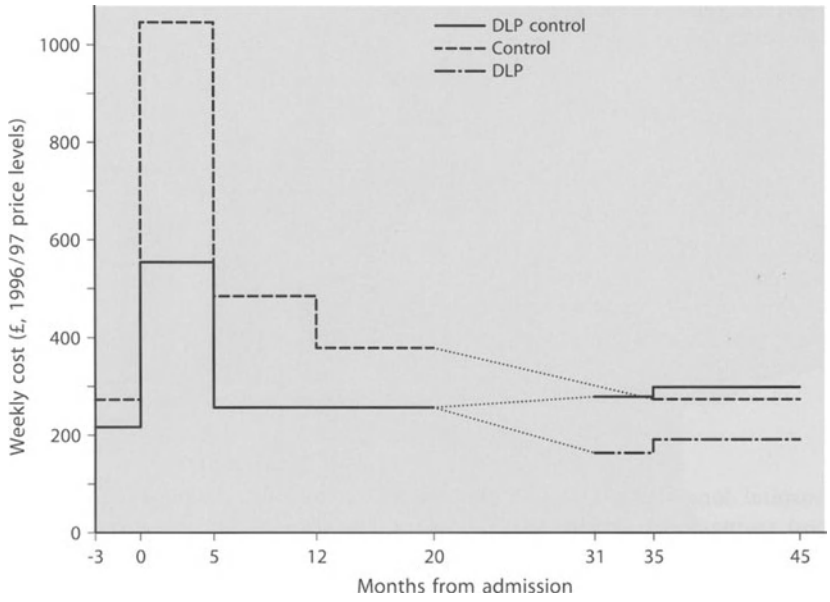

Fig. 5. Daily Living Programme (*DLP*): costs over 4 years

in this chapter, a number of factors are currently combining to raise the demands for health economics perspectives in psychiatry. These demands are likely to be greater when a country is in some economic difficulty, when government expenditure decisions produce a less generous settlement for a publicly funded health service, when employers, individuals or others are trying to negotiate lower health insurance premiums or when sickness funds are looking to cut providers' reimbursement rates. However, it must be emphasised that the relevance of economics does *not* stem solely from these fiscal difficulties and political pressures. Economics has relevance whenever there is scarcity of resources relative to needs.

Such scarcity characterises every country in the world, even if manifest demands for health economics are more commonly expressed in the developed world. In fact, there are clear signs of a recognition of the relevance of economic insights in the developing world.

Presently, probably the hardest task in conducting an economic evaluation of mental health care is finding a suitable economist. The demand for health economists worldwide – and particularly in Europe – outstrips the available supply. This might tempt clinical research teams to conduct their own economic evaluations, but they should take note of various potential complexities outlined here. Whoever seeks to undertake the evaluation should follow the well-rehearsed and widely accepted stages of a study of the kind set out in this chapter. They should also endeavour to learn from the mistakes and the successes of previous evaluations, as internationally there is now a gradual accumulation of experience upon which to draw. Many such experiences could be mentioned as relevant, but I will confine my closing remarks to just three.

Firstly, the best mental health economics research – and potentially the most influential – will be fully integrated into the work of clinical research teams. Although economic evaluations necessarily draw on a different disciplinary base from clinical research, there are many commonalities and complimentarities between the two which make it not merely sensible but almost imperative that integrated research is pursued.

Secondly, comprehensiveness of measurement is usually necessary. Clinical researchers would not willingly drop an outcome dimension from an evaluation without very good cause, and there should be an equivalent reluctance to omit any cost components from an economic study. Mental ill-health impacts on many aspects of an individual's and a family's lifestyle and functioning, and the treatment of mental ill-health often draws on the resources of many health care and non-health-care agencies and stakeholders. Evaluations should aim to assess all such impacts and resource consequences. Too many of the completed economic evaluations to be found in the literature today fail to measure costs comprehensively, which inevitably casts some doubt on their usefulness.

Thirdly, there are probably many causal and other links between the resource and outcome sides of mental health interventions – between costs and effectiveness. Some of these links will be direct and straightforward, others indirect and complex. Relatively few economic evaluations to date have explored those links, but those that have bear testimony to the insights that can be revealed and the benefits that may emerge for clinical practice and strategic policy.

7 Appendix

Average cost
: The cost of treatment per patient, equal to the total cost divided by the number of patients treated (e.g., average cost per in-patient day)

Cost-benefit analysis (CBA)
: Economic evaluation which compares the costs and the consequences of two or more treatment, placements or policies, where those consequences are measured in monetary units

Cost-effectiveness analysis (CEA)
: Economic evaluation which compares the costs and the level of effectiveness (see below) of two or more treatments, placements or policies

Cost-minimisation analysis
: Economic evaluation which takes as its criterion the minimisation of the cost of treating patients with particular clinical conditions

Cost-offset analysis
: Economic evaluation which compares costs incurred with costs saved, usually across two or more treatments, placements or policies

Cost-utility analysis (CUA)
: Economic evaluation which compares the costs and the level of utility (health-related quality of life) of two or more treatments, placements or policies

Economy
: Saving of resources; the pursuit of lower costs

Effectiveness
: Improvement in the health or quality of life of people with mental health problems or their caregivers

Efficiency
: Improvement in the level of effectiveness (see above) achieved from given expenditure or resources, or reduction in the cost of achieving a given level of effectiveness

Equity
: Justice of fairness in the distribution of resources, access to treatment, or achievement of levels of health or quality of life

Marginal cost
: The incremental cost of treating one more patient or the decremental cost of treating one less patient

Opportunity cost
: The cost of a service or resource expressed in terms of the value of the benefits forgone by not employing it in its best alternative use

Outcomes
: Changes in the health or quality of life of patients or caregivers (see "Effectiveness")

Quality-adjusted life-year (QALY)
: A measure of extended life expectancy adjusted for the patient's quality of life; used in cost-utility analyses (see above)

Value for money
: Another term for efficiency (see above)

Brown, Prof. P. Graham and Dr. J. Thompson (London, UK), Prof. Y. Nakane (Nagasaki, Japan), Dr. J. Novikov (Hamburg, Germany) and Dr. Dirk K. Wolter-Henseler (Münster, Germany).

1 Introduction

In 1866, Ernst Haeckel coined the concept of "ecology" (Greek: *oikos* = house, household, and *logos* = study; i.e. study of household [of nature]): the study of "all relationships of the organism with all other organisms with which it is in contact". As a scientific concept in biology, ecology had been clearly defined by 1870 as a branch of the biological sciences focusing on the relationships between animals and plants on the one hand and their animate and inanimate environment on the other hand. Human ecology is a discipline of environmental sciences that deals with the interaction of humans and their environment.

One hundred years after being coined by Haeckel, the concept of "ecology", along with that of "environment", has experienced widespread popularity and a change in meaning. Over the past two decades, the adjective and prefix (ecological, eco-) have come to mean "in line with environmental requirements/precautions" (Streit 1994) and often have political overtones.

The ecological approach, in sociology, has developed into a field of work in its own right. Urban sociology, on the basis of the work of the Chicago School, has evolved into a multi-faceted area of research (Burgess and Park 1925; Burgess and Brogue 1967). It first focused on the question whether urban surroundings can be divided into zones or natural areas in a valid way. These areas were supposed to be a result of the "natural" growth of cities, which was believed to be the reflection of interactions of unplanned forces. Studies of this line of thought have looked into issues relating to ethnic and religious groups, neighbourhoods and rules governing communal life within them, social/cultural prejudices, delinquency, the role of police forces and family life. Links with psychiatry result from the assumption that psychiatric morbidity and suicide rates are influenced by local living conditions in urban surroundings; there is much less emphasis on the study of the influences that mental illness or abnormality may have on urban life.

Faris and Dunham (1930) studied the distribution of psychiatric disorders in Chicago. They distinguished five urban zones: a central "business district" virtually without stable resident population, but with a high proportion of hotel/hostel lodging residents and homeless people; in a neighbouring, more peripheral zone, there were immigrants and unskilled workers' families; a third zone was characterised by a more stable resident population with a transitional zone leading on to areas of better housing conditions; the fourth and fifth zones contained residential areas of the upper middle class. The dependent variable, in the study of these authors, was the annual number of psychiatric admissions to Elgin State Hospital, the mental hospital admitting all mentally ill from the catchment area in the decade 1922–1931. Risk of admission for schizophrenia, alcohol-related psychoses and neurosyphilis was higher in the "downtown" central urban zones, whereas those admitted due to manic-depressive illness were more evenly distributed in the five zones of residence. Similar studies in other large cities subsequently confirmed the skewed distribution of mental health service utilisation by patients with schizophrenia; there have, however, also been a few negative studies (Schwab and Schwab 1978).

Methodological problems implicit in studies such as those by Faris and Dunham (1939) are discussed by Riley (1963). The approach chosen by the Chicago School aims at identifying the impact of "certain undetermined types of social processes" on urban psychiatric morbidity. The underlying assumption is that urban zones or geographically defined populations (aggregates) are characterised by homogeneous qualities which can be distinguished from qualities of the components (individuals, families) that make up their constituent parts. The zones are characterised by qualities such as mobility of the resident population or cost of housing/level of rents. The independent variable in the model (the impact of the urban zone) cannot be measured easily as it is itself the result of socio-demographic analysis and boundary definition.

One of the key elements of the ecological approach is that environment and health (or disease) are viewed as having a reciprocal relationship. Modern urban development can be associated with an increase in the number of homeless people, e.g. because of an increase in the cost of care. The presence of homeless people in the urban ecosystem can contribute to changes in urban living conditions which may be associated with population instability, changes in social relationships and delinquency, for example. These in turn may affect the state of health of all segments of the population, including the group of homeless people. The ecological approach suggests that we should look at individual and group characteristics simultaneously in clarifying such interactions.

2 Ecology and Epidemiology

Ecology and epidemiology are neighbouring disciplines which complement each other. Both epidemiological and ecological studies often have their starting point in aetiopathogenetic or prognostic hypotheses. "Epidemiology is concerned with the distribution of

diseases in a population and the factors that influence that distribution" (Mann 1993). The ecological approach concentrates on the analysis of reciprocal relationships between physical, biological and social factors on the one hand and mental health or ill health on the other hand.

The concept of the community based on "locality and community sentiment" (Frankenberg 1966) is a core component of the field of ecology. The traditional themes of ecological research include differences in social roles and role relationships in urban versus rural communities (Frankenberg 1966). Festinger et al. (1959), in a sociometric study, found an influence of the spatial distribution of student flats/apartments on their social contacts. Similar types of study have been performed in psychiatric research. Population density and residential unit density, residential living conditions, urban–rural differences, population mobility and noise were investigated with respect to their relationship with psychiatric morbidity and service utilisation. An ecological long-term study in Mannheim analysed the urban distribution of treated mental disorders in 20 urban zones in the years 1965 and 1974–1980. In spite of substantial social changes (increase in proportion of ethnic minorities, conspicuous urban structural change, setting up of community mental health services), the study reported a high degree of stability in the geographical distribution of treated mental disorders both in the long term (1974–1980 vs. 1965) and in individual comparisons of the years 1974–1980 (Weyerer and Häfner 1989).

The examination of mental disorders in urban areas illustrates the complementarity of epidemiological and ecological approaches to a problem. Epidemiological studies find differences in the prevalence of mental disorders among urban regions, and epidemiologists then explore whether these differences are the result of migration which may have occurred before illness onset or in prodromal or early disease states, which in turn may reflect pre-morbid deficits or early signs of the disease process (Schwab and Schwab 1978). People in the prodromal or early phases of a psychotic illness, from this perspective, would change their residence and choose inner city areas with cheap housing, space for social withdrawal and an unstable resident population. Ecologists use these results to explore further whether the increase in numbers of people with mental illness in a particular part of the town could result in more tolerance and/or indifference towards unusual or bizarre behaviour in inner city areas. Goldberg and Morrison (1963) studied 509 male patients admitted to English mental hospitals with respect to social class. The proportion of lower social class membership was higher than in the general population. When the comparison was based on the social class of patients' fathers (at the time of birth of the index patients), there was no significant difference. Detailed analysis of 94 patients with schizophrenia revealed a downward social trend in education/training and job careers, and both findings tended to strengthen the social drift hypothesis. This does not, however, diminish the importance of the ecological approach, because context variables are important in the manifestation, course and prognosis of mental disorders. Causal effects and modulation of outcome are in no way mutually exclusive (Schwab and Schwab 1978).

In examining the relationships between the context and individuals, state of health is important in order to study the rate of change, the duration of change and its impact (Fig. 1). The effects of environmental agents on the mental health of populations or population groups differ in accordance with the time course, degree and length of impact. A comparison of natural disasters and chronic low-dose lead exposure highlights the wide range of possibilities.

In the following, the relationships between mental health and various environmental situations and influences will be presented. For reasons of clarity, the interaction between mental health and environmental factors will be described separately, although the latter

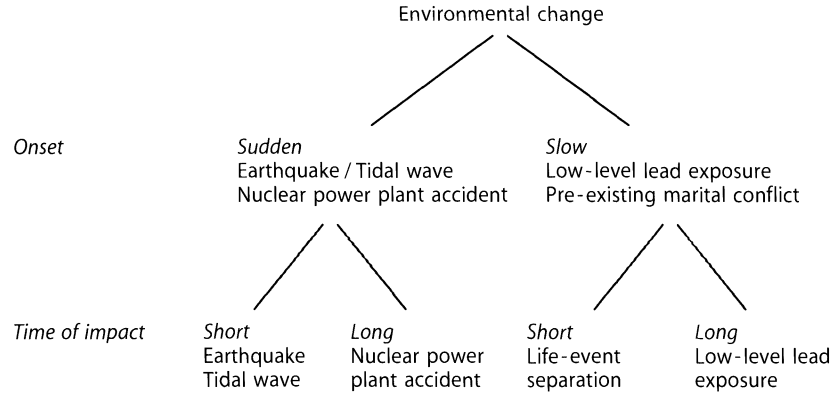

Fig. 1. Time course of environmental changes and their impact

often exert their effects on an individual or group simultaneously. An example may serve to illustrate this point: A life event may come up for a particular patient while he or she is in hospital; both the life event and hospital stay have an impact on the patient's mental state and social situation; this may occur in an overcrowded ward environment with significant noise problems; and simultaneously environmental hazards and socio-cultural stressors may be at work in the wider environment (e.g. because of environmental hazards in the immediate surroundings of the hospital). Environmental exposure and socio-cultural environment have simultaneous effects on the patient and interact with each other and with the above-mentioned factors.

3 Ecological Developmental Psychology

The study of human development in childhood and adolescence highlights a range of questions concerning context (family, school, neighbourhood). The importance of context results from the continuous interaction of the individual and the environment. Ecological developmental psychology or socialisation research (Bronfenbrenner 1979) pursued this approach to human development. The concept addresses interactions between individual and social context variables (person–context–time model; Moen 1995). Rutter et al. (1995), in line with this concept, describe a programme geared at minimising developmental risk in children. The elements of this programme comprise the following:

1. Identification of protective psychosocial factors (e.g. social support, confidants)
2. Reduction in psychosocial risk factors
3. Avoiding cumulation of risk factors
4. Improved problem-solving strategies

Prospective long-term studies by Rutter and his group revealed that emotional and behavioural abnormalities documented at the age of 10 years were related to life events which occurred in adulthood and to enduring psychosocial problems in the third decade of probands' lives. Behavioural abnormalities had a stronger predictive effect than emotional disorders. The likelihood of choosing a partner with antisocial behaviour or alcohol/drug abuse was higher in disturbed 10-year-olds. There were also relationships between adolescent peer group characteristics on the one hand and later practical life skills and choice of partner. Behavioural disturbances during adolescence were associated with later familial tension; school achievement was related with success in finding a job (Rutter et al. 1995). Wilson (1995) studied everyday adolescent life in North American ghettos and underlined how much deviant behaviour was embedded in the ecological context.

Rutter and Smith (1995) surveyed the literature on the prevalence of psychosocial disorders of adolescence in an attempt to elucidate secular trends. They found evidence for an increase in delinquency, substance misuse, depression and suicide among adolescents in the second half of the twentieth century. The evidence regarding eating disorders was not consistent. In summarising the factors which may have contributed to this secular trend, the authors emphasise the following points:

- It is unlikely that factors such as low social status, unemployment or health problems are responsible for the above-mentioned increases, as social parameters have on the whole improved during the time span considered.
- It appears plausible that problems in families, and parental conflicts in particular, have contributed to the increase in morbidity.
- The authors found factors whose importance was not quite clear. This applies to increased expectations in the young and the prolongation of adolescence (earlier onset of puberty, later end of school).
- The authors felt that media impact on the frequency of psychosocial disturbances in adolescence could not be ruled out, although it was likely that their contribution to increased prevalence was of minor importance.
- A number of mental disorders show secular increases in prevalence, and factors that could be responsible for these changes seem to differ from disorder to disorder.

One of the secular changes in our century is an increase in the variability of all social, economic, educational and family structures. Fergusson (1996) suggested that it is possible that an increase in variability of adolescent behaviour is an expression of both increased deviance and of the increase in successful forms of adaptation. This illustrates how a shift in focus from psychosocial disturbances to the broad spectrum of dysfunctional and functional juvenile behaviour might facilitate understanding of the data presented by Rutter and Smith (1995).

4 Mental Hospital and Illness Outcome

A series of reports from the 1950s and 1960s criticised living conditions and institutional standards in mental hospitals (Goffman 1961). Although it was not possible to find direct causal links between institutional

conditions and clinical state or symptom level (Wing and Brown 1970), negative effects of institutional care were plausible. An early study by Ullman (1967) found associations between hospital size and number of mental hospital staff on the one hand and mean length of stay on the other. Barton (1959) formulated the hypothesis that some aspects of institutional care, such as isolation from the wider environment, loss of social contacts and personal belongings, lack of stimuli in ward routine and loss of perspective, might lead to a syndrome he termed "institutional neurosis."

Wing and Brown (1970) examined therapeutic conditions in a longitudinal study of three English mental hospitals (Mapperley, Severalls, Netherne). They collected data on four occasions (1960, 1962, 1964 and 1968), which enabled them to analyse relationships between social impoverishment and a "clinical poverty syndrome" as well as poverty of milieu and patients' attitudes towards hospital discharge. They found: (a) differences between hospitals over time, (b) clinical improvement between 1960 and 1962, (c) patients receiving more social stimulation in 1962 experienced clinical improvement, (d) clinical improvement from 1960 to 1962 was a good predictor of hospital discharge between 1962 and 1968 and (e) most clinical and social improvement was observed between 1960 and 1962. Conditions in hospitals after this period stagnated or deteriorated. The authors concluded

> that a substantial proportion, though by no means all, of the morbidity shown by long-stay schizophrenic patients in mental hospitals is a product of their environment. The social pressures which act to produce this extra morbidity can to some extent be counteracted, but the process of reform may itself have a natural history and an end (Wing and Brown 1970, p. 177)

The findings of the study provide substantial evidence of a social hypothesis of so-called negative symptoms, i.e. of loss of drive, loss of interest, affective flattening and poverty of speech. They suggest caution where progress achieved in the recent past is extrapolated into the future; the maintenance of improved therapeutic conditions and clinical state requires continued and deliberate clinical effort.

5 Long-Term Studies of Psychiatric Morbidity

Longitudinal studies offer the opportunity to assess the effects of complex long-term environmental change on psychiatric morbidity and thereby enable the investigators to study interactions between environmental change and manifestation of illness. Sartorius et al. (1989) assessed the question of associations of economic and social/cultural change on the one hand and the incidence and prevalence of psychiatric disorders on the other by summarising longitudinal studies of mental disorders. Table 1 summarises the methodology and key findings, and Table 2 summarises environmental change on the one hand and changes in morbidity on the other hand. "Common" change indicates developments which are in keeping with broader social change in the same culture, while "significant" changes went beyond the average measure of change over periods of one to three decades (Strömgren et al. 1989). The tables show that associations between changes in the environment and changes in morbidity were rather weak. Taiwan, Berlevåg and Shetland experienced major environmental change. In the period between the studies, there had been immigration, social change, rapid economic development and foreign policy tension in Taiwan; in Berlevåg, the stresses of the Second World War had been felt drastically; and in Shetland, the off-shore oil industry had changed social conditions. However, changes in morbidity were observed only in the numbers of neurotic disorders (in older women in Shetland); however, they were not seen in endogenous psychoses. Environmental change in New York, Bavaria, Lundby and Stirling County was less dramatic. Neurotic disorders in New York decreased in women, and depressive disorders increased in Lundby; substance misuse and personality disorders increased in Bavaria. Regions with stable environmental conditions nevertheless experienced changes in morbidity of mental disorders.

Strömgren et al. (1989) conclude that, on the basis of the long-term studies reported, there is little evidence for the assumption that social changes such as industrialisation or disintegration of family structures lead to an increase in mental disorders. However, they arrive at the following conclusions:

- There is some data indicating a decrease in the prevalence of schizophrenia (Taiwan, Bornholm [for women]).
- Depressive disorders are increasing in prevalence; this is likely to apply to the group of so-called neurotic depressions rather than to severe depression with melancholic features (e.g. Lundby).
- An increase in neurotic disorders in response to socio-economic change appears possible. The authors mention the hypothesis of a U-shaped curve with a low incidence of neurotic disorders in instances of low environmental pressure and during particularly pressing external pressures (e.g. wartime).

Table 1. Long-term studies of psychiatric morbidity (Baxter 1990; Feldman 1991; Langolf et al. 1978)

Place	Target criterion	Sample	Years of sampling	Population	Main results
Taiwan	Prevalence	Census studies	1946/1948	19,931	No difference in psychosis prevalence rates except for schizophrenia (decrease), increase of non-psychotic disorders
			1961/1963	39,024	
New York (Midtown Manhattan)	Prevalence	Cohort study (probability sample)	1954	1,660	No difference in prevalence rates from 1954 to 1974, decrease in overall morbidity in women
			1974	Smaller sample at follow-up	
Stirling County	Prevalence	Census study (household sampling)	1952	1,003	Prevalence of depression and anxiety: no difference over time
			1970	1,094	
Lundby	Prevalence, incidence, morbid risk	Cohort study (cross-section of population)	1947	1: 2,550	Increase in morbid risk for depression 1947–1957 to 1957–1972, decrease in dementias
			1957	Cohort of 1947 plus 1,013 additional proband	
			1972		
Berlevåg	Prevalence	Census studies (all local residents)	1944	1,325	No difference in psychosis prevalence, 50% increase neurotic disorders
			1974	1,647	
Iceland	Morbid risk	Birth cohort	1957	5,395	Overall stability
			1971		
			1977		
Samsø	Prevalence	Census studies (island population)	1961	6,823	Reduction in frequency of organic disorders (most likely decreased incidence)
			1972	5,008	
			1977	4,907	
Denmark (learning disability)	Prevalence	Census studies (total population Denmark)	1888	2,172,380	Total prevalence 1965 and 1979 higher than in 1888
			1965	4,767,597	
			1979	5,111,534	
Upper Bavaria	Prevalence, incidence	Cohort study (cross-section population)	1975	1,668	No prevalence difference overall, increase in personality disorders and alcohol abuse
			1980		
Shetland	Prevalence	Cohort study	1975	Target population, 376; control group, 413	Increase in psychiatric symptoms in older women, otherwise no differences
			1978		
Bornholm	Prevalence	Census studies	1935	45,684	Decrease in prevalence of schizophrenia in 15- to 34-year-olds
			1983	47,313	

Table 2. Environmental change and changes in morbidity in long-term studies on the frequency of psychiatric disorder

Place	Environmental change	Morbidity				
		Marked decrease	Marked increase	Slight decrease	Slight increase	No change
Substantial change						
Taiwan	Political change, migration (from mainland), industrialisation, urbanisation, change in life-style and values		All psychiatric disorders neuroses	Schizophrenia		All psychoses
Berlevåg (Norway)	1944: poor fishing village 1974: More jobs in industry, increased housing		Neuroses			All psychoses
Shetland (Scotland)	–				Substance misuse, (neuroses)	All psychiatric disorders
"Usual" change						
New York (USA)	Significant changes in gender roles during first half of century			All psychiatric disorders (women)		No significant change in total sample
Upper Bavaria	–				Personality disorders, substance misuse	All psychiatric disorders
Lundby (Sweden)	Changes as in country as a whole, T2 vs. T1: more service jobs, more unemployment	Organic disorders (elderly population)	Depression, Substance misuse			
Stirling County (Canada)	T2 vs. T1: small-scale urbanisation, increased tertiary sector and living standard, families smaller					Depression, neuroses
Relative stability						
Bornholm (Denmark)	–	Schizophrenia				
Samsø (Denmark)	–	Organic disorders				
Iceland	–					All psychiatric disorders
Denmark	–				Learning disability	

- The Danish national census of learning disability (mental impairment) shows an increase in the overall rate from 1888 to 1966 which then levels off. The authors consider that this increase is not surprising, since (a) there has been a reduction in excess mortality and (b) diagnosis has been improved (i.e. the disorder is more readily recognised).
- There is some data suggesting a decrease in organic psychiatric disorders in the elderly, which is most likely the result of increased life expectancy due to improved health and social care. This trend is probably balanced, however, by a concomitant increase in functional psychoses of old age.

6 Life Events

The impact of life events on the manifestation of mental disorders has been studied by many authors. In schizophrenia, for example, several studies which followed the pioneer study by Brown and Birley (1968) confirmed that there was an excess of life events during the interval of 3 weeks to 6 months before manifestation of symptoms (Bebbington and Kuipers 1993). Despite methodological problems (e.g. those linked to the retrospective assessment of life events and precise definition of onset of an illness episode), the evidence obtained so far suggests a triggering effect of life events for the manifestation of episodes of psychotic disorders rather than a simple causal relationship between life events and psychotic illness.

Associations between stressful life events and depressive disorders were reported in different countries in several continents (Brown 1996; Creed 1993). Life events that are of particular importance include those life events which touch upon areas of life of particular subjective importance, life events associated with role conflicts, life events associated with pre-existing stresses such as sudden deterioration in the state of health of a relative (e.g. diagnosis of malignancy in a spouse) against the background of pre-existing long-term illness, separation following long-term marital problems and life-threatening experience (e.g. car accidents). Vulnerability factors have been described. Brown and Harris (1978) reported that only 10% of women with a severe life event and an intact confiding relationship developed depression, whereas depression occurred in 41% of women who experienced such a life event without a confiding relationship. Further vulnerability factors include loss of mother, unemployment, domestic care for three or more children and negative self-concept. Life events can also be relevant for the remission of depressive symptoms. Thus finding a solution for long-term difficulties or experiencing a "fresh start" (e.g. new confiding relationship) might facilitate remission. Moreover, having a positive self-concept can help.

Life events are probably not distributed randomly. Their incidence is influenced by individual and environmental factors. Such factors include social class and neuroticism scores, and personality variables may be of importance (Fergusson and Horwood 1987). There are data suggesting that different regions differ with respect to the type and frequency of life events and vulnerability factors. On a remote Scottish island, integration in the local community (church attendance, "crofting" as the particular type of organisation of rural economy) was important, but it was not important in London; in contrast, both in London and in the island community, lack of a confiding relationship and bringing up three or more children contributed to overall vulnerability. Some studies found that differences in prevalence of depression in different countries (South London, Outer Hebrides, Basque country, Zimbabwe) tallied with corresponding differences in frequency of life events (Brown 1996). On the other hand, an international study of life events before schizophrenic relapse found no significant differences in the frequency of life events between the countries concerned (Day et al. 1987).

7 Social Class

The incidence and prevalence of schizophrenia seems to be higher in the members of lower social classes. Hypotheses of social causation and social selection or drift have been formulated. The social causation hypothesis underscores a higher number of life event stressors, increased exposure with environmental, job and infectious stressors, disadvantages in prenatal care and lower social support under conditions of stress. The social selection or drift hypothesis rests upon data suggesting disadvantages in upward social mobility from one generation to the next and a downward social trend following onset of symptoms in people with schizophrenia. Since the publication of pivotal studies by Faris and Dunham (1939) and Hollingshead and Redlich (1958), causal inferences have become more cautious, and recent work has tended to strengthen the social drift hypothesis (Karno and Norquist 1995; Goldberg and Morrison 1963). Ample evidence suggests the association of socio-demographic factors with psychiatric service utilisation, and psychiatric hospital admissions in particular (Thornicroft 1991). Cox (1993) points out that the manifestation of traumatic life events in children is associated with lower social status.

The prevalence of child psychiatric disorders is higher in families with low socio-economic status than in upper-class families. However, the association is less marked than in adults, and the above-mentioned relationship is also weaker than the association between mental disorder and familial conflicts (Cox 1993). On the other hand, high socio-economic status may have a protective effect with regard to intellectual development (e.g. regarding the effects of perinatal stress on intelligence; Werner 1985).

8 Urban–Rural Differences

Affective and neurotic symptoms can become manifest following change of residence or under the impact of stressors in the immediate living environment (Freeman 1994). A large number of studies in the 1960s and 1970s assessed the mental health effects of living in England's "new towns" (conurbations with rapidly constructed, low-grade high-rise buildings, lack of social infrastructure and sense of community). Non-specific negative psychosocial effects of living in high-rise buildings have been documented. These effects, however, are not independent of other factors, in particular the specific social context. Simple causal relationships have not been established (Freeman 1994).

The rates of child psychiatric disorders are higher in urban areas, particularly in inner city areas, than in rural environments (Cox 1993). Differences are probably related to differences in mental health of parents, parent relationships, the living situation and schools. Pathogenetic links with child psychiatric disorders are not easily understood. The incidence of maternal depression is a possible moderating variable. Covariation of antisocial behaviour of male partners with living environment has been described, which suggests that simple causal models should be avoided (Coleman 1985, Wolkind and Rutter 1985).

Some earlier studies found psychiatric morbidity higher in urban regions. On the other hand, morbidity rates were higher in rural, isolated settlements or so-called "small boom towns" than in more diversified and stable communities (Webb 1984). In the 1950s, a review paper concluded that urban living by itself was not associated with mental ill health more frequently than a rural environment (Leacock 1957). Dohrenwend and Dohrenwend (1974) later came to the conclusion that mental disorders were more prevalent in urban areas. The Epidemiologic Catchment Area Program study of the NIMH (ECA study) did not show a difference in the prevalence of schizophrenia between urban and rural regions once factors such as ethnic group, gender and age had been controlled for (Shapiro et al. 1984). Recent studies have reported associations of urban place of birth and upbringing with a higher risk of developing schizophrenia later in life (Lewis et al. 1992). McCreadie et al. (1997) reported urban–rural differences between South London and a rural area in Scotland, which was however restricted to non-white ethnic groups.

Differences in the prevalence of non-psychotic disorders between urban and rural areas (in Taiwan) suggest interactions of residence with other psychosocial stressors (Cheng 1989). A study in Chicago assessed relationships between residential density (persons per dwelling unit), population density (persons per square mile) and psychiatric admission rates. The association of low residential density with high rates of hospital admission only applied to areas with low population density; in the elderly, there were interaction effects between population density and residential density (Magaziner 1988). Migration from rural into urban areas could result in a relative increase of mental retardation in rural areas and of schizophrenic disorders in urban areas; similar results were reported from China (Cooper and Sartorius 1996). In summary, a multitude of findings argue against simple causal relationships between living environment and mental disorder, but suggest some association between urban residence and morbid risk.

9 Industrial and Developing Countries

Prior to the NIMH ECA study, a total of about 50 studies covering the period 1931–1983 suggested the point prevalence of schizophrenia world-wide to be between 0.6 and 7.1 per 1000 population. The ECA study collected interview data from almost 18,000 individuals in five regions of the USA, and the study resulted in 1-year and life-time prevalence rates of 1.0 and 1.4%, respectively (Karno and Norquist 1995, Shapiro et al. 1984). In the 1960s, the World Health Organization (WHO) initiated and implemented the International Pilot Study of Schizophrenia (IPSS). In this study, more than 1200 patients were interviewed in nine countries (China, Colombia, CSSR, Denmark, India, Nigeria, USSR, UK and USA). It showed that schizophrenia can be found in similar frequency in different countries and that, in terms of symptomatology, similarities outweigh differences across countries. A follow-up study assessing outcome showed a large proportion of patients with good remission in all countries and some cross-national differences, with better clinical course in developing than in developed countries (Sartorius et al. 1987).

The follow-up study (Determinants of Outcome of Severe Mental Disorders, DOS) looked at estimates of incidence of schizophrenia in different parts of the world; 12 centres in ten countries participated (Denmark, India, Colombia, Ireland, USA, Nigeria, USSR, Japan, UK, CSSR; Jablensky et al. 1992). Incidence rates could be calculated in seven centres, and clinical data on treated patients with schizophrenia were reported from all 12 centres. A total of 1379 patients were included, and there was a follow-up study of patients over 5 years. In almost 80% of all patients, follow-up interviews were obtained at the end of 2 years. Broad diagnostic criteria of schizophrenic disorders were fulfilled in 80%, and more than half the patients had a syndrome which fulfilled the criteria for strictly defined "core" schizophrenia. Annual incidence rates for the broader diagnostic concept ranged from 1.5 to 4.2 per 10,000 inhabitants. In the broad diagnostic group, the highest incidence rate was found in India. There were significant differences in incidence across countries, but the rates for the more strictly defined core group varied comparatively little and were all between 0.7 and 1.4 per 10,000. There were no statistically significant differences in incidence rates of schizophrenia. The age of onset was higher in women than in men in both developing and developed countries. A total of 50% of patients had a single episode during the 2-year follow-up period, and 31% had two or more episodes followed by remission; 16% of patients had a chronic course without remission. The type of illness onset ("acute" better than "subacute" or "insidious") and country of origin were found to be the most important predictors of 2-year outcome; favourable outcome was significantly more frequent in developing countries (48%–57%) than in developed countries (6%–26%). Several studies have been undertaken to explain these differences. A study analysing expressed emotion (EE) data from Chandigarh, Aarhus and London found EE in India markedly less conspicuous than in either of the European centres (Wig et al. 1987). Other possible reasons for the differences in outcome were also studied (e.g. the frequency of life events, the perception of patients by relatives), but no definitive explanation of the differences was found. In addition to the type of onset and centre membership, outcome also depended on primary clinical diagnosis, marital state, gender, adolescent adaptation, social network (friends) and misuse of illegal drugs. In the final discussion of their data, the authors emphasise the cross-national and cross-continental similarities of incidence of schizophrenia and the importance of the cultural context for the course and outcome in schizophrenia.

There is no doubt that aspects of culture in general, and the perception of mental health and ill health in particular, are important for outcome in schizophrenia (Leff 1988; Pfeiffer 1994). There are culture-bound differences in psychiatric syndromes, some culture-specific differences in the symptomatology of endogenous psychoses and differences in treatment and outcome. This theme is among the ecological aspects in psychiatry and is addressed in other chapters of this book.

10 Unemployment

A number of papers address psychological and psychiatric sequelae of unemployment. Where mental health service utilisation is concerned, Brenner (1973) reported a much discussed study (Bhugra 1993). He found that unemployment was the most important single factor to explain variations in psychiatric hospital admission in New York over a period of 127 years. Hildebrandt (1994), on the basis of what was formerly Prussia, confirmed this relationship for the period 1876–1906 for alcohol-related psychoses but not for endogenous psychoses. Further authors reported associations between total psychiatric service utilisation and unemployment (Italian case register data; Thornicroft et al. 1993). Kammerling and O'Connor (1993) identified unemployment as a strong predictor of psychiatric admission rates in the UK.

Those who are currently unemployed report more physical and psychological complaints than those previously unemployed who have found a job (Studnicka et al. 1991). In Danish, Spanish and Finnish population samples, associations were found between unemployment and prevalence of total mental disorders (Fink et al. 1995; Vázquez-Barquero et al. 1992 [men only]; Viinamäki et al. 1995a). A Finnish study reported that re-employment and improvement of mental health were associated with each other (Lahelma 1992). There are data on increased prevalence of substance misuse and depressive disorders in the unemployed (Dooley et al. 1996). In schizophrenia, unemployment was a predictor of point prevalence, this relationship being more marked for wide diagnostic criteria than for the group of more narrowly defined schizophrenic disorders (Harvey et al. 1996). A significant association with non-affective endogenous psychoses was found for unemployment in the National Comorbidity Survey in the USA (Kendler et al. 1996). Causal relationships, despite the wealth of evidence available, cannot be inferred, and selection effects need to be considered (Goldney 1996). Viinamäki et al. (1994) attempted to distinguish those people unemployed and mentally ill from those unemployed but not mentally ill. They identified self-respect, social support and the degree of general

somatic complaints as discriminators. Personality was important in coping with unemployment (Viinamäki et al. 1995b).

At the aggregate level, positive associations were found between unemployment and suicide rates in the UK (Appleby 1992; Dooley et al. 1996). Increase in male suicide rates during the 1980s was associated with an increase in unemployment (Pritchard 1995); however, this relationship did not apply when 1970s data for men and women were analysed (Schmidtke 1997). Unemployment is a risk factor for suicide in younger people (Graham and Burvill 1992), and the same applies to the repetition of parasuicidal acts (Morton 1993) and to completed suicide following a prior suicide attempt (Hawton et al. 1993). Schmidtke (1997) reviewed European studies of suicide and parasuicide and concluded that simple causal models cannot deal with the complex findings.

Unemployment was also examined with respect to outcome. There were associations with psychotic relapse (e.g. Scottish Schizophrenia Research Group 1992). In a study by Rabinowitz et al. (1995), unemployment was a predictor of "revolving door" patterns of clinical contact. Tehrani et al. (1996) found loss of contact with psychiatric services associated with unemployment, and Os et al. (1995) reported on associations between unemployment and chronicity. Thornicroft et al. (1992) found the accumulation of so-called new long-stay patients related to unemployment rates. In a study by Wessely et al. (1994), unemployment and the diagnosis of schizophrenia were risk factors for delinquency of the mentally ill.

11 Migration

Mental disorders in migrants and refugees are discussed in other chapters of this book (e.g. Vol. 2, Part 1, Chap. 18). Migrations often involve large segments of a population crossing national boundaries. They imply drastic environmental change for all those involved. Looking at the level of social group alone is not sufficient; it is necessary to understand the interaction of individual- and group-level effects. Some studies reported a higher incidence of schizophrenia among migrant populations. On the other hand, findings in Australia suggest complex interactions between the situation in the country of origin, the level of life stress prior to emigration, stress associated with migration, the age distribution of migrants, growth of the migrant community and integration in the new social environment (Krupinski 1984). Methodological problems include the instability of family ties, the impact of additional factors such as social class, age or gender and the lack of a reference population in the country of origin. In addition, individual circumstances of the migration process are of great importance as they affect subjective appraisal (degree to which migration was voluntary, degree of preparation, time course). Some countries require evidence that applicants for an immigration visa do not suffer from a mental disorder, which clearly biases samples of those who arrive in the recipient country.

In London, the ethnic minority group of black Caribbean origin has a higher risk of developing non-affective functional psychoses (see Davies et al. 1995). However, methodological problems suggest that simple causal links between migration process and prevalence rates are unlikely (Harrison et al. 1988). In addition, the NIMH ECA study reported lower prevalence rates for schizophrenia among Mexican immigrants in Los Angeles. Selection effects need to be taken into consideration either way (i.e. in the case of reduced or increased prevalence rates). In a classic study (in Norwegian immigrants in Minnesota), Ödegaard (1932) differentiated between the effects of immigration stress on the one hand and selective migration on the other and weighed their impact in different disorders. Re-emigration to Norway was also associated with increased psychiatric morbidity. A review of a wide range of studies by Schwab and Schwab (1978) resulted in no clear picture, and this field of research is highly complex, as it requires the simultaneous examination of individual- and group-level phenomena. A critical methodological review by Leff (1988) highlights the range of methodological problems. The situation concerning migrants is clearly different from that concerning refugees and displaced persons (individuals forcibly relocated in the same country). These groups are at higher risk for mental disorders than migrants.

12 Disasters and Mental Health

The issues raised by psychiatric sequelae of disasters are covered by Bromet (Vol. 2, Part 1, Chap. 17). Environmental stressors cover a wide range: war and persecution, severe industrial accidents, natural disasters (e.g. volcanic eruption), other disasters (bursting of dam, see Buffalo Creek disaster) and possibly terrorist attacks. According to Thompson (1990), the sequels of the Three Mile Island accident in Harrisburg underscore the psychological dimension of the effects of such accidents. The prevailing feeling in the population concerned was described as a sense of insecurity about which information regarding the events at the nuclear power plant could be relied

upon. Eighteen months after the accident, there was a clear, albeit not dramatic increase in psychological complaints. There was an increase in the number of medical consultations and an increase in frequency of anxiety disorders. Goldhaber et al. (1983) describe the Three Mile Island accident as primarily exerting psychological stress.

In the case of the nuclear accident in Chernobyl in 1986, there were severe immediate, medium- and long-term health hazards. Severe health risks applied to a population of 600,000 people (Pivak 1992); there was acute radiation sickness in more than 200 individuals, and there were 28 deaths in the acute phase. Pivak (1992) reports on a study of 1572 patients who were surveyed during the acute phase, in the course of the first 6 months and in further follow-up examinations. Acute stress reactions (post-traumatic stress disorder, PTSD; anxiety; retardation/agitation) were found in about 75% of patients both in the acute phase and after 6 months, and this proportion decreased to 29% in the course of follow-up. While stress reactions decreased, neurotic disorders (asthenia, hypochondriasis, apathy and histrionic syndromes) increased from 13% to 29%. Psychoses were relatively rare (3.8% during the acute phase, 0.7% at 6 months: described as "reactive" and "hysterical" psychoses). In a study organised by the International Atomic Energy Agency (IAEA) which examined a large sample of about 1300 inhabitants in 13 villages, no immediate clinical radiation effects were found. However, the general level of anxiety and stress appeared high. The importance of detailed information for the population on exposure and consecutive risks was emphasised (Ginzburg 1993). Ginzburg and Reis (1991), in a large population sample of people exposed to the accident, reported reactive depression, PTSD and familial disorganisation as the most prevalent mental health consequences. Alexandrowski et al. (1992) reported on a study of 300 people exposed to the accident. They describe an increase in chronic medical disorders (e.g. hypertension), the phenomenon of "worrying tension" in many probands and five groups of maladaptation states: one group had neurasthenia (67 probands), and a second group psychosomatic disorders (77 probands); a third group was found to have irritability and histrionic features. There was a fourth group without clinical symptoms (the authors referred to this group as presenting with "preclinical" forms of disadaptation). Mistrust of official policy and guidelines were frequently reported. A total of 15 probands were considered to be in good mental health. Alexandrowski et al. (1992) conclude that their observations most likely reflect abnormal personality development under chronic stress exposure. Viinamäki et al. (1995c) reported on a study which included a control group without exposure to radiation. Seven years after the Chernobyl accident, they used the General Health Questionnaire (GHQ) in the highly contaminated region of Bryansk in a group of 325 individuals who had been resident in the area throughout, and they reported long-term impairment in mental well-being, this difference being significant in women compared with the control group without history of radiation exposure.

Ecological aspects are conspicuous, e.g. in studies of the Buffalo Creek mud slide disaster which killed 125 people in 1972 and made 4000 of the local residents homeless in a very brief time period (Titchener and Kapp 1976). Traumatic neurotic reactions (PTSD: grief, guilt, shame, rage or hopelessness) were found in 80% of those surviving and persisted over a 2-year period ("Buffalo Creek syndrome"). There are descriptions of how the disaster disrupted the close network of social support in the mining village, i.e. the local community which had been sustained by and had sustained the local residents. Six hundred and twenty-five of the Buffalo Creek survivors sued the mining company and claimed compensation due to the psychological impairment experienced. In an out-of-court settlement, they were awarded $13.5 million, of which $6 million was assigned on the basis of a scoring system based on proximity to the disaster (Stern 1976).

The nosological justification for the concept of PTSD has been confirmed by a variety of reports and studies from the USA and the UK referring to studies on individuals involved in the Vietnam war, natural disasters and ship and aircraft disasters. Psychiatric consequences of particularly stressful individual experience (e.g. torture and rape) can also be included in this category (Thompson 1990; Titchener and Kapp 1976; Williams et al. 1993). PTSD was incorporated in DSM-III, DSM-III-R, DSM-IV and ICD-10 (Williams et al. 1993). The syndrome comprises recurrent inner "re-enactment", dreams and behaviour related to the event (re-playing the experience in children). Those experiencing such syndromes tend to report avoiding associated stimuli, loss of interest, experiences of alienation and "numbness", irritability, insomnia and over-alertness. There are risk and vulnerability factors – not all those exposed develop PTSD. Some factors are related to the traumatic event itself (type of stimulus, closeness to victims, type and intensity of threat), while other vulnerability markers can be found in those exposed to trauma (interpretations, attributional style, additional life events, coping strategy and psychiatric history). There is some evidence that social support can reduce the likelihood of PTSD (Viinamäki et al. 1995c). The literature on PTSD covers a range of ecological mechanisms in looking at the effects of a serious stressor on social communities at a defined point in time under similar conditions.

The mental health consequences of the holocaust cannot be described in detail here. This is the focus of

another chapter in this handbook (Vol. 2, Part 1, Chap. 19). A comprehensive review on this topic is given by Peters (1989). In their book entitled *Psychiatrie der Verfolgten* ("Psychiatry of the Persecuted"), von Baeyer et al. (1964) presented their findings from a large series of medico-legal reports on psychiatric sequelae following Nazi persecution and concentration camp stays in particular. There are also a variety of chapters and monographs on the topic (Eitinger 1980; Niederland 1977; Stoffels 1991). von Baeyer et al. (1964) found a

Relatively homogeneous core syndrome with chronic anxiety, depressive mood and asthenia which after a latent period with symptoms of fatigue and exhaustion becomes manifest and is explained by the various authors according to their orientation in terms of neuropathology, psychosomatics or psychodynamic theory.

Peters (1989) used the concept of the survivors' syndrome coined by Niederland (1977) and summarised the literature on the multiple mental health consequences of the survivor syndrome. Symptoms comprise anxiety, fighting memory, tension, ruminations, a feeling of survival guilt, irritability and instability of mood, affective numbness, lack of initiative, apathy, restlessness, concentration and other cognitive deficits, non-responsiveness of mood, quest for meaning, lack of self-value and self-assertiveness, social insecurity and psychosomatic disorders. In addition, Peters (1989) described the peculiarities of Nazi persecution with respect to their role in the survivors' syndrome, mentioning the following: loss of home and culture of origin, non-respect, discrimination, social isolation, uprooting, mistreatment, lack of food, cold and other extreme physical conditions. Additional factors were the lack of judicial security, loss of individuality, permanent and recurrent acute fear of imminent death, the small number of survivors and a situation of individual, family and collective lack of identifiable burial sites.

13 Intoxication, Neurotoxins and Exogenous Psychoses

Huber (1988) wrote a comprehensive handbook chapter on the organic psychiatric disorders. He reported on psychiatric syndromes following intoxication and the effects of neurotoxins and of nutritional and vitamin deficiency states. Environmental medicine deals with acute and chronic intoxications of the nervous system through environmental agents. Acute intoxications as a rule entail central nervous system symptoms. The non-specific character of organic psychiatric syndromes in acute intoxication (disorientation, confusion, delirium, somnolence, stupor, coma) and the multitude of toxic substances make it difficult to establish firm causal connections between symptoms and toxins. In the case of some substance groups, the transition from medically tolerable exposure to chronic intoxication is not clearly defined, and multiple intoxications present particular problems. The clinical syndromes in acute and chronic intoxication are varied, and all organ systems can be affected (acute hepatic or renal failure, lung oedema, arrhythmia, cardiovascular shock, bone marrow depression, skin alterations). Delirium and impaired consciousness which may deteriorate to coma are the most important acute neuropsychiatric syndromes, while neurological findings include seizures, extrapyramidal features, ataxia, cerebellar symptoms or neuropathies. Chronic psychiatric consequences of intoxication include so-called pseudo-neurasthenic syndromes, organic personality change, organic affective disorders and dementias.

Neurotoxins lead to functional and/or structural impairment of the central nervous system. The range of noxious agents includes metals, organic solvents and pesticides. Table 3 summarises the neuropsychiatric sequelae of exposure to heavy metals, organic solvents and pesticides. The neurotoxic effects of solvents provide an example of the psychiatric effects of neurotoxins, and there has been considerable public and media coverage of what has been referred to as Danish painters' disease (Mikkelsen 1980; Triebig 1990). Long-term exposure to organic solvents (e.g. paint, varnish, glue) can induce organic brain syndromes which range from fatigue, irritability, subtle cognitive impairment and headache to marked dementia syndromes with neurological impairment, sulcal atrophy and ventricular enlargement on computed tomography (CT) (Triebig 1990). The pathogenesis of these states is still unclear because there are no clear correlations between dose and duration of solvent exposure and the severity of encephalopathy.

In the 1950s, significant lead exposure from fish led to severe neuropsychiatric syndromes in Minamata Bay, Japan (see Table 3). There was marked organic psychopathological impairment in some patients, and the degree of psychiatric impairment varied with the degree of exposure, but also with the compensation status of patients, i.e. it varied according to whether patients had claimed compensation and whether their claim had been successful (Sugisawa 1994).

Low-level exposure is another topic relevant in this context, and a series of studies have examined the issue of low-level lead exposure in children. Needleman et al. (1979) reported an inverse relationship between intelligence (as assessed by IQ) and the degree

Table 3. Selection of characteristic neurotoxins and psychiatric effects

Noxious agent	Industrial/commercial use	Psychiatric symptoms/syndromes	Neurological and other medical sequelae
Heavy metals			
Arsenic	Production of glass, semi-conductors, melting of copper, lead; insecticides, herbicides	Anxiety, amnestic deficits	Headache, peripheral neuropathy
Lead	Foodstuffs, water, air, dust, soil; metal industry, paint, petrol, pigments	Affective instability, irritability, hallucinations, lethargy, mnestic and concentration deficits, disorientation, word-finding and visual–spatial impairment	Polyneuropathy, myoclonus, intelligence deficit (early childhood exposure); brain oedema (acute/severe exposure)
Manganese	Manganese ore processing, production of paint, varnish, disinfectants	Irritability, obsessive–compulsive symptoms	Parkinsonian features, hyperreflexia
Mercury	Scientific instruments, alloys, paint, contaminated fish, pesticides	Depression, insomnia, fatigue, irritability, mnestic and concentration deficits, impairment in logical discourse	Peripheral neuropathy, ataxia, dysarthria, hearing loss, loss of vision, spasticity, extrapyramidal syndromes, coma, brain oedema, cerebellar and cortical atrophy, lethal complications
Tin	Widespread use	Affective instability, depression, loss of libido, insomnia, loss of orientation and mnestic functions, impairment of verbal memory and visual–motor coordination	
Organic solvents			
Carbon disulphide	Insecticides, plastic industry	Behavioural abnormalities, insomnia, irritability, affective instability, mnestic and attentional deficits	Peripheral neuropathies (acute intoxication), extrapyramidal syndromes, cerebral ischaemia
n-Hexanes, methyl-butyl-ketones	Shoe production, clothing industry, plastic, cosmetics		Peripheral neuropathies
Perchlorethylene (PCE)	Launderette, clothing industry	Irritability, sleepiness, confusion, impaired mnestic function and concentration	Dizziness, dysarthria, impairment of coordination
Trichlorethylene (TCE)	Industrial solvents	Fatigue, confusion, mental slowing, attentional impairment	Cranial nerve symptoms (trigeminal nerve)
Toluene	Printing, leather goods production, exhaust fumes	Irritability, fatigue, inadequate affect, affective instability, suicidal ideation, euphoria, cognitive impairment, confusion	Skin abnormalities
Pesticides			
Organophosphates	Insecticides (cholinesterase inhibitor)	Fatigue, restlessness, agitation, anxiety, emotional instability, irritability, impaired mnestic function and concentration	Cholinergic syndrome, coma
Carbaryl	Insecticides (reversible cholinesterase inhibitor)	Emotional instability, irritability, loss of drive, impaired mnestic function	Cholinergic syndrome, coma

of low-level lead exposure. Since that early study, there has been a range of studies on the topic, and Pocock et al. (1994) published a meta-analysis of the data from five prospective studies, including a total sample of more than 1100 children. Plasma lead levels in maternal or umbilical cord blood showed a lack of association with IQ in children over 5 years of age, while blood lead levels at the age of 2 resulted in a weak but significant inverse relationship. Cross-sectional analyses (14 studies comprising 3499 children) showed a significant negative relationship with considerable variation in findings. The seven cross-sectional studies based on lead content in teeth were more consistent in terms of findings and showed smaller effect size. The authors concluded that doubling blood lead levels (from 0.48 to 0.97 μmol/l) was associated with an average reduction in total IQ of 1–2 points. The methodological problems of these studies include representativeness of samples, comprehensive correction for confounding variables, selection bias and reverse causality. Pocock et al. (1994) are cautious regarding the priority which should be given to the recognition and reduction of slight increases in blood lead levels. An Australian study published since found a conspicuous association between environmental lead exposure and the IQ of 11- to 13-year-olds (Tong et al. 1996).

14
Noise and Mental Health Sequels

Exposure to noise is possibly the one environmental stressor which an urban population cannot escape. Among the consequences of long-term exposure to noise, deterioration of hearing and deafness need to be considered. Hearing impairment and deafness are associated with psychiatric morbidity in general and with manifestation of delusions in particular (Tarnopolsky and Clark 1984). Urban noise is associated with subjective reactions, most frequently the subjective impression of intrusion and anger. Irritability, insomnia, headache and tension can be observed following intensive noise exposure, and those who are exposed to noise at the workplace report similar complaints. Research findings suggest that anger is an important mediator between noise as a stressor and symptoms. Subjective appraisal can affect the intensity of stress reactions which are non-specific at a symptom level. Noise exposure, anger and socio-demographic variables interact with each other; there are, however, no simple causal relationships between noise and mental illness. In women with the maximum level of sensitivity to noise, Stansfeld et al. (1985) found significantly more psychiatric symptoms, higher neuroticism scores and a more marked reactivity to other (non-noise) stressors when they were compared with the least noise-sensitive women. In summary, subjective sensitivity to noise is associated both with sensitivity to stress and with neurotic depression, but not with other psychiatric disorders (Stansfeld 1992).

15
Protective Factors

Social networks and social support are of particular importance in protecting against the impact of psychosocial and other stressors. Brugha (1995) distinguishes instrumental, mostly material support and emotional aspects of social support. Regular positive feedback as one component of social support can exert direct, positive effects on mental well-being, it can improve coping resources and thereby act as a stress buffer and eventually improve self-appraisal (Brugha 1995; Lloyd 1995). Social support is important not only in the mentally ill; there are clear associations of a network of supportive social relationships and general mental well-being (Coyne and Delongis 1986). Life event research points to the lack of an intimate, confiding partner as an important vulnerability factor for manifestation of depressive disorders, which in turn underlines the protective function of social support (Brown 1996). An up-to-date review of relationships between social networks and social support on the one hand and a range of health indicators on the other suggests that social integration contributes to a reduction in general mortality rate and to improved mental well-being (Seeman 1996). Social support has also been shown to have a protective effect in alleviating the mental health effects of unemployment (Viinamäki et al. 1993).

16
Conclusion

Environmental aspects are undoubtedly relevant to mental health and psychiatric disease. Many of the findings reported, however, reflect correlations in groups of patients; in other words, causal links cannot easily be established. Correlations may be misleading where they are aggregates of different mechanisms which account for different types of relationship. Such complex associations may not be unravelled by an analysis restricted to the aggregate level (Riley 1963).

Group effects (increased morbid risk in a population) need to be distinguished from associations at the individual level (illness- or relapse-associated factors).

An ecological fallacy is possible where effects at one of these levels of analysis are taken to support conclusions at the other level (Selvin 1958). In the past, group effects at the ecological level have been considered less binding in a hierarchical model than findings of biomedical research at the individual level, and it has been assumed traditionally that such group-level data can only be used to generate hypotheses. However, a variety of findings suggest that the group (or "ecosystem") level permits the establishment of associations which are relevant to the understanding of mental disorders (Schwartz 1994). In the context of suicidal behaviour, this implies that a high-risk region (with high suicide rates) is not merely a place where individuals with a combination of individual risk factors are found, but that such an ecosystem has some characteristics which are specific to the place and social system rather than to each individual residing within it. Schmidtke (1997), in a review paper, discusses variation in suicide rates in Europe, which is by a factor of 22 and 20 for men and women, respectively. A simple biological or socio-demographic approach does not account for these differences; complex socio-cultual variables such as attitudes towards suicidal behaviour, type of media coverage ("labelling"), the attitudes towards the elderly and cultural variation in individual coping strategies are clearly at play. Schmidtke (1997) considers cross-cultural differences in the attitudes towards suicidal behaviour a particularly important factor accounting for variation in suicide rates. Neeleman et al. (1997) also report on associations between suicide tolerance and suicide rates. In male patients in 19 Western countries, they found a modulating (ecological) effect of the strength of religious beliefs (at national level) on the strength of (negative) associations between individual suicide tolerance and religious belief. Not everyone in a high-risk environment develops a particular psychiatric disorder. There are some people in a community who are at higher individual risk of developing symptoms, and it is likely that there is an ecological contribution to the distribution of these individual risk factors too.

Ecological research, within psychiatry, provides important clues to the generation and examination of hypotheses. It complements work done in the field of cross-cultural psychiatry (Leff 1988; Pfeiffer 1994) and epidemiology. Methodological problems of selection and reverse causality need to be taken into consideration (e.g. urban–rural differences, importance of social class and migration). Life event research has made substantial contributions to research into the pathogenesis of depression. This field of work has permitted researchers to look into pathogenetic mechanisms in some detail, and the interaction of life events with individual vulnerability factors and ongoing difficulties is important. Comparative research in different socio-economic and cultural settings offers scope for further development (Brown 1996). The pathogenetic life event mechanisms established so far do not apply to delusional depression and depression with melancholic features (Brown et al. 1994). This does not mean that social and environmental factors are irrelevant, but it suggests that the approach is strongest at the less severe end of the spectrum of depressive disorders.

Ecological work has also come to fruition in the field of developmental research in children and adolescents. This type of research has looked at depression, substance misuse, delinquency and successful adaptation to environmental stressors. Ecological research, however, should not be restricted to mental disorders in the young; it should include the whole range of successful and failed adaptation to environmental challenges (Fergusson 1996). In schizophrenia, the importance of environmental variables (such as social deprivation, housing, population structure or unemployment) has been established. Utilisation of psychiatric services and outcome of schizophrenic disorders are modulated by social factors, and the clarification of outcome-moderating variables is one important aspect of psychiatric research.

Ecological studies of service use can be used in service planning. However, research into differences in incidence across communities does not clarify illness onset in any individual patient. The latter requires the analysis of aetiological factors, pathogenetic mechanisms and susceptibility factors. Interactions between the two levels are best considered in a vulnerability–stress model.

Susser and Susser (1996), in a comprehensive conceptual paper, describe a new paradigm for epidemiological research which they describe using the image of successively smaller Chinese boxes put into each other – from the broader ecosystem to the individual level. For instance, in considering mental health consequences of unemployment, different levels of analysis need to be taken into consideration. At the most aggregate social level, the macro-economic environment is important. Mental health consequences of unemployment are obviously more likely to be relevant in a period of mass unemployment than they are while full employment prevails. At the next level down, regional or local community characteristics are likely to affect both the extent of the problem and the availability of social support as a resource in coping with the stressor. Further down, coping in families or smaller social networks are relevant as protective factors. Furthest down in this hierarchy, the degree of vulnerability (self-appraisal, personality), at the individual level, is relevant to the manifestation of a mental disorder.

The complexity of such multi-level analyses is underlined by the fact that coping resources, relative risk and vulnerability at the various levels are not distributed at random, but related to the specific location of a person in his or her respective ecosystem (and also to the position of the local community in the wider ecosystem). The strength of the ecological perspective lies in the simultaneous examination of multiple influencing factors (patient – social group – environment) and their interactions. This degree of complexity both reflects the strength of the ecological approach and the methodological pitfalls. Susser and Susser (1996) coined the concept of "eco-epidemiology" and consider multi-level analyses particularly helpful. The ecological analysis of environmental aspects of mental health and psychiatric disorders presents a promising challenge to the field of psychiatry.

Ethology and the Use of Animal Models

1 Introduction

1.1 Definitions

Ethology describes animal behavior in the natural habitat and assumes operation of evolutionarily conserved basic plans encoded in the genome. Such basic plans determine behavioral patterns, including flexible variants involving learning. Human ethology has emerged as a subdiscipline, including observations of psychiatric patients. Animal models are experimental preparations developed in one species to study phenomena of another. For psychiatry, this refers to states in animals that resemble human mental disorders to foster laboratory studies of mechanism and treatment. These scientific areas supplement each other as part of psychiatry's basic science. The research involved has produced an enormous and varied literature. This chapter touches on principles and a few exemplary lines of research.

1.2 History

Present principles of psychopathology and pathophysiology stemmed in part from ethological approaches to animal behavior (McKinney et al. 1994). Early debates queried whether sets of animal behaviors represented specific human clinical syndromes (McKinney and William 1988). Field narratives used clinical terms when describing animal behavior. For instance, the concept of "experimental neurosis" in animals deployed terminology familiar to clinicians, yet the behaviors were foreign and the action patterns described likely stemmed from different experiential and brain mechanisms than did those operating in distressed people. On the positive side, early describers began to rate behavior quantitatively, now a central research practice. Presently investigators seek reaction patterns and their mechanisms without requiring that they be specific counterparts to particular psychiatric conditions.

1.3 Animal Models

No comprehensive animal model exists in that no nonhuman animal condition mirrors exactly etiology, symptoms, mechanisms, and treatment responsivity of any psychiatric syndrome. However, animal model research has instructed investigators and clinicians about across-species behavioral similarities, provided tests for etiological and pathogenetic theories, and pointed to new effective drugs (Cooper and Hendrie 1994).

Behavioral models in psychopharmacology are of three kinds:

- Screening tests
- Behavioral assays
- Simulations of clinical phenomena

For screening effective drugs, false-positive and false-negative results indicate lack of perfect modeling, but animals used in this way have produced the clinical relevance of developing a broader range of effective safer medications.

Pharmaceutical companies often focus on practical utility. Thus, if an animal demonstrates a possible counterpart to the human syndrome in question regardless of known mechanism, their experiments will typically study whether the medication response resembles that of humans. If it does, the method is considered to have empiric validity.

Empiric validity can be limiting, however. For instance, candidate antipsychotic drugs for many years had to have neuroleptic or motor properties as a shortcut indicator of efficacy. With more research on mechanism, however, dopamine receptor-blocking drugs clearly affected a variety of dopamine receptors. Drug action on some of these cell constituents affected behavior but caused no or fewer neuroleptic problems. This finding newly permitted development of a generation of antipsychotic drugs without motor effects, which were in fact deleterious. Indeed, at times, new drugs such as clozapine in fact reversed seemingly permanent conditions such as tardive dyskinesia.

2 General Principles

2.1 Central Concepts

Animal action and reaction patterns stem via darwinian natural selection from the survival tasks of food, defense, reproduction, and adaptation to habitat. This includes the social environment of other animals of the same species (conspecifics). Modeling depends upon brain–body factors that the animal and humans possess in common. Ethologically studied behavior patterns may be species specific, but core components shared by related animals are typically embroidered through natural selection to produce modified methods of survival and reproduction.

For example, human brains contrast in size to those of other animals, weighing three times more than

brains of surviving large primates or those of human ancestors 3 million years ago. Cerebral cortical area is four times greater, so the contrast with other primates especially stems from a massively enlarged neocortex, especially the frontal lobes. The increases likely stemmed from advantages of social functions. Mammalian cortex and overall brain size correlate with species-typical group size. Such cortical attributes as language obviously serve social functions.

Yet the human brain and behavior also show comparability to other species through widely shared, conserved features. This comparability makes continued use of animals important for the study of the pathogenesis, mechanisms, and treatment of mental disease. Conserved body features contributing to such illness are in the early stages of detection and exploration. Lack of a sufficient database as yet limits other modeling efforts such as computer simulations, mathematical models, and experimentally induced states in humans, and research on animal models remains indispensable.

The concepts of homology and convergence apply to across-species study. Homology means that a common ancestor once possessed a trait now shared by two species. At points in the past, humans shared common ancestors with monkeys, mice, chickens, fish, insects, and single-celled organisms, each such forebear more remote in biological history. In contrast, convergent traits are similar features that stem from environmental shaping through natural selection, although basic plan starting points vary. Wings of insects, bats, and birds illustrate this. Ancestors of each animal group had not flown, so airborne ability evolved separately and the three kinds of wings illustrate convergent evolution on the level of aerial locomotion. As vertebrate upper extremities, however, wings of bats and birds are homologous to each other, but not to the wings of insects. If the starting point of the basic plan generalizes to contractile tissue, however, locomotor body extensions of all three achieve homology.

In the nineteenth century, Darwin examined processes influencing variation in species traits conceptualizing what he called "descent with modification." He outlined natural selection to replace divine intervention, helping the then half-century old discipline of biology enter the scientific realm. The "Darwin machine" is now considered a general process operating not only for evolution of species, but also for processes as varied as neuron migration during development to the mental generation of particular thoughts. Its six components are as follows: (1) An entity or pattern must exist (2) for which there is a mechanism for copying; (3) variations on the pattern co-occur, (4) competition for a work space exists, (5) a multifaceted environment biases the competition for which pattern version will win (selection), and (6) the process reiterates: there are closed, repeating loops for the variation-and-selection steps.

2.2 Basic Plans

With molecular biology's explosive development, including genome projects of species at different phylogenetic levels, layered basic plans on molecular levels have taken on new meaning and importance. Much deciphering is necessary, but the genome seems to contain at least a partial record of the organism's ancestry. Decoding this will help determine evolutionary history (homology), which in turn fosters knowledge of proximal neuronal determinants of behavior. However, detection and description may be difficult. At the behavioral level, redundant, multiply determined brain–behavior adaptations complicate inference, and at the DNA level, genetic transformations such as chromosomal crossovers reduce certainty about genomic hypotheses.

Basic plans obviously operate in varied species, e.g., the body plan of anatomic structures such as anterior–posterior axis and limb number. Behaviorally, mammals show high investment in offspring. Body constituents may operate complexly at the molecular level, however. Serotonin, norepinephrine, and dopamine exemplify this. These monoamines are important for humans and are implicated in schizophrenia, affective disorders, and parkinsonism and involved in eating, sleep, and aggression. However, their body usefulness stemmed from the early evolution of metazoans, and they possess many functions in the diverse organisms in which they are found, acting, for example, as neurotransmitters, neuromodulators, neurohormones, and true hormones. They also operate in many ways within the mammalian body, sequestered in various body compartments and systems for extraordinary complexity and flexibility. Each impacts many receptors with differing downstream functions.

At a still more basic level, receptors are members of conserved superfamilies. For instance, some cell membrane receptors for serotonin, γ-aminobutyric acid (GABA), and glycine share common protein elements, although glycine and GABA, at least, have the opposite functions of stimulation and inhibition. Although likely derived from the same ancestral molecule with components in common, they mediate varied cellular communications.

Moving to higher organizational levels and behaviors familiar from anxiety disorders, flight–fight mechanisms involve the vertebrate locus coeruleus of the brain stem. This structure evolved early and has not disappeared for lack of usefulness, although its presumed activation in schizophrenia and paranoid

states in addition to panic and anxiety disorders may reflect maladaptation. This pontine structure supplies the brain with most of its norepinephrine and includes the subcortical temporal lobe nucleus, the amygdala, which is also activated during fearful states. This more recently evolved structure with increasing prominence in mammalian species overlays and modifies the functions of the locus coeruleus to which it directly and indirectly connects. From animal studies, we know the amygdala in association with the orbital frontal cortex to be also involved in maternal and familial bonding, so that disruptions of such states naturally affect the activities of this neuronal structure. Loss of social affiliation after lesions of this system caused speculation about their importance for the deficit syndrome of schizophrenia.

Jackson in the nineteenth century first highlighted such layered brain features, followed by MacLean in the twentieth century (MacLean 1990). MacLean resurrected Broca's term, "limbic system," for his triune brain formulation, correlating these brain components, including the amygdala, with paleomammalian evolution. These structures had little importance in reptiles. However, in the mammalian brain stem, he noted counterparts of a reptilian evolutionary stage including the locus coeruleus (actually such neuroanatomic features exist still more primitively in prereptilian fish). In the other direction, after limbic system expansion, neocortex development correlated with neomammalian evolution, including the orbital frontal cortex. Critics of the triune brain have noted that not only neocortex but also the brain stem and limbic structures changed with later developments, apparently modifying their functions in concert with the cerebrum's expanding capacities.

3
Animal–Human Continuity and Psychiatry

3.1
History and Pioneers

Thorndike and Pavlov, early twentieth-century research pioneers on animal modeling of human psychopathology, tested hypotheses about internal states with behavioral observations. Pavlov's experimental study of psychopathology included an interactive model with genetic and developmental factors interacting with current stressors and neurobiology, in fact initiating the modern biopsychosocial paradigm. He based his model on data from animals in the laboratory as did Cannon, whose research focused on principles of learning and autonomic responsivity generalizable to humans. Selye discovered a general stress response to noxious stimuli and founded the study of stress psychophysiology as a general adaptation of many systems in many species. This concept has been fundamental for psychosomatic medicine in its search for emotional factors in medical illness.

Darwin's *Expression of the Emotions in Animals and Man* (1873) had focused on continuities in animal behavior rather than the discontinuities among species emphasized in his earlier *Origins of the Species* (1859). A century after this pioneering work, still quoted in comparative behavior analysis, European ethologists extending his work won the Nobel Prize for Medicine and Physiology. Two winners, Lorenz (1965) and Tinbergen (1972), along with their peers of the time, paid special attention to stereotypical behavior patterns in natural settings, made across-species contrast comparisons, and described developmental sequences. Scott (1989) studied genetic influences on behavior by observing varied dog breeds. Harlow, Spitz, and Bowlby focused on attachment behaviors and found that primate and human infants react powerfully to loss of the mother (Bowlby 1969). This has had heuristic importance for clinicians and has fostered much animal model research in a separation paradigm. Hofer and coworkers extended this work to rats, discovering the importance of the mother in regulating infant autonomic processes such as heart rate and gastric secretion (Hofer and Myers 1996; this paper is an introduction to an entire journal number on the topic of research in psychosomatic medicine).

After World War II, Chance used animals to examine behavior patterns stimulated by wartime concerns: English aviators had used amphetamines without prior study of their effects. Chance found that mortality in mice given the drug varied greatly depending on housing. Joint housing caused more deaths. He concluded that an animal's social circumstances must be considered when investigating drug effects (Chance 1988).

3.2
Social Rank Hierarchy

Stimulated by Chance, Price's theoretical statement (Price 1967) related depressive behaviors to low social rank in nonhuman animals, such as that observed in low-ranking chickens observed by the definer of "peck order," Schjelderup-Ebbe (Price et al. 1994). Price noted that yielding behaviors that resemble defeat behaviors might blunt conspecific aggression. Fruitful work on depression and stress effects stemmed from the now extensively investigated resident–intruder paradigm. Tubular cage arrangements of multiple mice housed together produced fatal hypertensive heart disease in subordinates who could not escape

the punishment of the dominant (Henry and Stephens 1977). This was the first convincing animal model for "psychosomatic medicine." In a gentler version, a new male rat will alert to the olfactory presence of the potential territory holder when newly put into a cage previously used by a stranger male rat. This represents a model stressor for some studies, such as those on sleep stages and mechanisms. Sapolsky (1994) studied stress effects in primates in the wild and showed subordinates to be more affected than dominants, as measured by adrenocortical hormone levels. In nonprimate species also studied in the wild, however, dominants also exhibited elevations of stress hormones.

Returning to the physiology of social rank hierarchy, Raleigh et al. (1991) showed that vervet monkey groups in captivity exhibit marked variations in blood serotonin levels. Males with alpha status in mixed sex troops produced levels twice as high as other monkeys in the cage. This effect required the presence of both other males and females in the cage. Removed from the cage and isolated, the alpha male's increased level faded over time, but increased again if reinstated (if in time so that another would-be alpha male with increasing serotonin had not gained ascendancy). Humans with energetic type A behavior and fraternity leaders also have elevated blood serotonin. When subordinate vervet males were administered a selective serotonin reuptake inhibitor (SSRI), an antidepressant drug that increases synaptic serotonin, they increased their rank to that of alpha status. In addition to treating human depression and anxiety, SSRI medications increase ratings of self-directedness. Social rank effects were detected at the single-neuron level in invertebrates. Thus Yeh et al. (1996) found that "serotonin reversibly enhanced the response to sensory stimuli of the lateral giant tailflip command neuron in socially dominant crayfish, reversibly suppressed it in subordinate animals and persistently enhanced it in socially isolated crayfish."

Research on social rank hierarchy represents an integrative top-down, bottom-up approach that relates top/up behavioral and social dimensions of experience to bottom/down cellular and molecular levels of body mechanisms.

4
Behavioral Observations of Humans

4.1
Human Ethology

Human ethology uses direct observations of people. In *Human Ethology* (1989), Eibl-Eibesfeldt aimed at human universals presumably transmitted via genome inheritance, basing his inferences on cross-cultural observations. Other work showed that direct observations of sleep behaviors in conjunction with instrumented recordings characterize two distinctive forms of sleep, rapid eye movement (REM) sleep and non-REM forms (Gardner and Grossman 1975). Salter (1995) reviewed studies on the ethology of command and found it markedly affected by institutional context.

Time-sampled direct observations of behavior in depressed inpatients showed differentiated stages of recovery from major depression: motoric features recovered first and cognitive features later (Schelde 1998). These findings correlated with the paradoxical clinical finding that depressed patients die from suicide disproportionately frequently during the early stages of recovery.

Troisi (1994) pointed out that behavioral analysis of human conditions would enhance the field. For instance, he found that response to an antidepressant drug negatively correlated with observed coded nonverbal behaviors. Responders and nonresponders did not differ in sex, age, education, clinical diagnosis, or severity of disorder, but did differ in their coded behaviors: nonresponders were more assertive and affiliative. Moreover, his observations cast doubt upon depressive subtypes defined by the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM). He discussed the third edition of this manual (American Psychiatric Association 1980), but subsequent editions have not significantly augmented behavioral observations; rather, self-report and subjective histories–though gathered in a systematic manner with formalized interview schedules – have had greater sway with researchers.

Despite this contemporary and valid criticism of the recent DSM-IIIR (American Psychiatric Association 1987) and DSM-IV (American Psychiatric Association 1994), major developments in modern psychiatry have stemmed from the importance of systematically assessing behavior. Robins and colleagues strongly fostered operational criteria for diagnosis in the mid-twentieth century when psychiatry in the United States was dominated by theory free of verifiable observation. Behavior, thought, and feeling patterns assessed from systematic criteria in the DSM echo an observational approach to human behavior. That stereotypical patterns can be detected in the specialty helps dissect core behavior patterns and provide hypotheses about their origins and most appropriate treatment. Thus panic resembles a motivational state to escape fear-producing stimuli, mania behaviorally resembles dysfunctional leadership behavior, depression may reflect defeated or yielding animal behaviors, and persecutory delusions are fixed self-definitions of outgroup status (Gardner 1997).

4.2
Genome-Neural-Behavioral Analysis

Such behavioral descriptions represent hypothetical formulations to be tested further with cellular/molecular correlates examined as well. Advances in modern psychiatry in the form of highly effective drugs with known, or researched, brain actions provide avenues to explore these research domains. That animals of various sorts are comparable to humans has allowed considerable impetus to both drug development and increased knowledge of mechanism. Use of animal models moved clinical psychiatry from simple-minded deterministic views of psychopathology towards integrative ones. Moreover, the work fostered hypothesis testing with prospective studies.

4.3
Genome Deletion Syndromes

Eventual genome-neural-behavioral analysis may be assisted by the systematic observation of the behavior patterns of individuals with known genomic deletions or aberrations on the one hand and characteristic behaviors on the other. For example, Prader-Willi syndrome patients do not have paternal genes at chromosome 15q11-12; in addition, they overeat in a fashion typical of animals and people with hypothalamic lesions and demonstrate obsessive–compulsive symptoms, temper, and stubbornness. Among other genes, they are missing one that translates to a intracellular protein usually located primarily in the hypothalamus. Hyperactive Angelman syndrome patients missing maternal genes in 15q11-12 exhibit profound retardation with frequent laughter but absent language. Their missing genes include one that codes a $GABA_A$ receptor protein. Carrier fragile X syndrome patients with varying production of diminished fragile X mental retardation protein show social avoidance and depression as the first evidences of diminished protein. Missing genes on chromosome 7 result in verbal fluency, social skills, and creativity with mild mental retardation (Williams syndrome). Frontal structures apparently form adequately, but posterior cerebral cortical structures do not.

5
Illustrative Animal Models in Psychiatry

5.1
Bond Disruption Model

Disruption of important bonds such as mother and infant often cause states that appear to be similar to depression. Of course, clinical depression may follow the loss of a loved one in humans. In animals, these are considered experimental systems in which a clear social inducer results in a reliably seen response with species-dependent variation. Clearly, separation and loss do result in protest and despair phases in infant primates, including humans, though with considerable individual variability. Much work in primates and other mammals has characterized the response, which typically includes increased adrenocortical responses, increased arrhythmias, and decreased body temperature and immune system function. Antidepressant medication produces reversal of the pattern. At low doses, alcohol alleviates peer separation response but at high doses exacerbates it.

Formerly, an idea guiding clinical action held that depressive syndromes could be distinguished based on loss factors (reactive versus endogenous). Evidence for this distinction does not exist, however, so the nosology no longer persists. Animal models at times present confusing data. Closely related species may nevertheless demonstrate marked differences in social organization that may in turn differentially affect the reaction of animals to the same stimulus. Thus pigtail and bonnet macaque infants differed when separated from their mothers; the pigtails showed signs of despair and depression, but the bonnets did not. Bonnets ordinarily intermingle with their conspecifics, but by contrast the pigtail mothers typically focus only on their own offspring.

The characteristic behavior pattern that emerges when a monkey mother is lost can be "treated" by putting the infant with a peer, but later deprivations show the animal to have heightened vulnerability. Separation studies in animals have documented systematically the powerful effects of disrupting attachment systems and have fostered theories of attachment now part of the conceptual backdrop for general and child psychiatry. Specifically, this category of study has provided empirical support for long-term effects of early losses and the neurobiological impact of such experiences.

A rat version of the maternal deprivation model entails rat pups being removed from their mothers for 3 h per day during days 2–14 of the young rats' lives (Nemeroff 1998). At day 21, they are taken from the mother to live in groups. When exposed to an airpuff startle, the deprived animals have an increased hypothalamic–pituitary–adrenal response that persists for life. This is mediated in the animal model by corticotropin-releasing factor (CRF). Messenger RNA for this gene is increased, meaning that the gene has been turned on. Catheters in their epidural space show that CRH increases are parallel to those in depressed humans. Antidepressant medications reverse the condition, although if then removed, the rats become

hyperreactive again. With antidepressants, the increased gene response normalizes. This is one of the few animal models of depression in which the animal drinks additional alcohol and cocaine. The effect surely does not involve maternal deprivation only, however, because the mother rejects the pup upon its return to the litter, thus implicating agonistic features in the pathogenesis.

5.2 Uncontrollability Model

In the uncontrollability model, the experimenter first shocks the animal in a manner that allows predictability and control (e.g., the animal is forewarned of a shock and an escape route provided). The rules then change so that the shock recurs but with no control options. The animal then assumes a position of stolid, unmoving defeat and does not participate further in learning tasks. Norepinephrine lowers in the locus coeruleus, GABA lowers in the hippocampus, and the endogenous opiate system changes. Recovery from the state takes considerable time, but hastens if the animal is treated with antidepressants. Injection of imipramine into the rodent forebrain also normalizes the animal.

Often called learned helplessness (LH), this phenomenon was interpreted as "learning" because learning theorists discovered and publicized it. Development of an inbred rat strain with a low threshold for LH allowed other analysis of the mechanism. Findings implicated the hypothalamus–pituitary–adrenal axis. Study of a rat's social rank prior to imposition of the LH stressor showed that subordinates responded less than dominants did. This is congruent with a social rank interpretation of LH in that dominants would exhibit more change in status after experimenter-imposed defeats.

The clinical implications of animal studies of uncontrollability (learned helplessness models) include documentation of significant effects when an individual is unable to control what happens. This line of research has linked neurobiological substrates of uncontrollability with cognitive theories of depression and might provide information on how such factors operate in this treatment.

Depression may represent a psychobiological final common pathway, but numerous variables influence its stimulation as well as the specific form it takes. Influencing variables include genetic, developmental, interpersonal, personality, social, and physiological factors. Given this complexity, animal models are needed as experimental systems for controlled, prospective studies and provide approaches with clinical implications.

5.3 Olfactory Bulbectomy Model of Depression

The olfactory bulbectomy model of depression in rodents exemplifies empiric validity. The rat olfactory bulbs are a complex structure making up 4% of the total brain weight that directly connects to limbic system structures. After removal, the animal typically demonstrates many behavioral abnormalities. Delay in learning a stepdown passive avoidance task measures impairment quantitatively. This model does not possess face validity as the condition is not one that mimics the human condition. However, it exemplifies the opportunity to screen therapeutic agents for efficacy. For example, given chronically, 18 known antidepressant drugs improved the state, and nine non-antidepressants did not. One non-antidepressant gave a false-positive and a known antidepressant a false-negative result.

5.4 Approach-Avoidance Ratios and Threat Model Anxiety

Rodents confronted with the possibility of exploring open versus closed arms of a maze with two pairs of closed and open arms will theoretically experience approach-avoidance conflict. When more fearful, they will preferably explore the closed arms. Measures of drug effect include the ratio of open to closed arm explorations. Classical anxiolytics such as benzodiazepines increase this, whereas anxiogenic drugs decrease it. Considerable research experience has shown this to be pharmacologically valid with a range of drugs enhancing or diminishing the activities of the GABA receptor/chloride channel ionophore. Rodgers and Cole (1994) argue that an ethological approach to the data collection was important. Did the animal demonstrate typical antipredator defensive maneuvers? Thus, in addition to typical postures, fearing animals show diminished activity generally, not just avoidance of open arms.

Other animal modeling work aiming at anxiety-involved study of animals reacting to external threats, conflicts, trauma, etc. Operant techniques elicit a behavior. In a well-established response, the behavior was then punished, which suppressed it. Potential antianxiety drugs can be screened for response restoration to presuppression levels. This approach has empirical validity in terms of predicting clinical drug responsiveness and has more recently been used to begin investigations on the neurobiology of anxiety. No longer responding in punishment paradigms has been considered a passive avoidance response; in view of the findings, perhaps some human anxiety arises from passive avoidance of social situations.

Finally, work on the more fundamental neurobiology of the flight-flight response has used animals infected with a double-virus transneuronal labeling technique. Jansen et al. (1995) demonstrated that the hypothalamus and brain stem contain a set of central autonomic command neurons that dually innervate both the sympathetic neurons regulating cardiovascular function and adrenomedullary function, both of which are quickly needed in emergencies.

6 Genetic Alterations in Animal Models

Bottom-up research involves alterations of cells and molecules with behavioral measurements as the dependent variable, e.g., using mutants with missing genes. Thus environmental events trigger immediate-early genes that induce quickly. For instance, the *fos* family of genes are expressed in the brain in regions that produce nurturing behavior. Mutants without the *Fos*B variant fail to show usual nurturing behavior, although the reproductive tract, hormonal status, and brain show no obvious differences. However, staining for *Fos*B in the brains of normal animals shows that the key regions are the olfactory bulb and pyriform cortex, but not the cortex or, more generally, the amygdala or hippocampus (Brown et al. 1996).

New technology involves splicing into the genes of animals, usually mice, a DNA sequence without the gene under investigation. At the same time, an attached constituent renders it immune to an injected agent so that all other versions of the gene are eliminated ("knocked out") from the animal. What the gene product usually accomplishes in the resulting experimental animal can then be assessed using a kind of ablation procedure. Male mice lacking neuronal nitric oxide synthase, for instance, exhibit major increases in aggressive and inappropriate sexual behavior (Nelson et al. 1996). Moreover, indifference to cocaine and amphetamine in knockout mice lacking the dopamine transporter protein show that this molecule is usually the target of these drugs of abuse. In addition, replication of human gene defects in mice provides direct models of human disease, although when this does not happen, new information about the basic biology is revealed by the differences in the two species.

7 Conclusion

Psychiatry's basic science should have parallels with the basic sciences of other medical specialties that conceptualize their illnesses as deviations from normal biochemical and physiological processes. Emerging databases make this possible for psychiatry as well. We predict that the material reviewed in this chapter will make important contributions to that effort.

Evolutionary Biology of Emotion

Men ought to know that from the brain and from the brain only arise our pleasures, joys, laughter, and jests as well as our sorrows, pains, griefs and tears. . . . It is the same thing which makes us mad or delirious, inspires us with dread and fear, whether by night or by day, brings sleeplessness, inopportune mistakes, aimless anxieties, absent mindedness and acts that are contrary to habit . . .

HIPPOCRATES (c. 460–375 B.C.), *The Sacred Disease*

Translator: E. Taub

1 Introduction

The idea that evolutionary considerations may aid in the understanding of mental processes in both healthy and diseased states has a long history, but has now receded into the background because of recent major advances in molecular and cellular neuro- and psychopharmacology. Kraepelin (1920) was thinking along these lines when he wrote that one could form, at that time, no more than an "exceedingly crude and incomplete" picture of the origins of mental illness. He reflected on the phylogenetic origins of personality and suggested an investigation of "the extent to which certain impulses, dormant since the prehistory of personal and phylogenetic development, may come back to life in diseased states" (Krapelin 1920, p. 29).

Kraepelin also referred directly to Darwin in his 19th lecture on hysterical mental disorders (Kraepelin 1916), in which he interpreted the forms of expression of the emotions as "remnants of ancient defense mechanisms." Ernst Kretschmer (1953) likewise made use of evolutionary theory when he spoke of "psychomotor templates," by which he meant standardized motor sequences constituting phylogenetically prefigured "reflexive and instinctive patterns." We refer to these as preprogrammed motor sequences (Ploog 1957, 1958), which correspond to the "fixed action patterns" discussed by Konrad Lorenz (1937, 1953, 1992), insofar as they are neither learned nor automatized.

2 Function of Emotion

The concept of emotion includes that of affect, i.e. the motor component of emotion, which typically consists of brief movements. A single cerebral system underlies both emotion and affect. These two concepts are not systematically distinguished in the literature. In what follows, we shall take an evolutionary approach alongside the conventional medical one, and we shall largely limit the discussion to emotion, although the evolutionary approach to psychopathology may also be applied to cognition. As is well known, Darwin himself laid the foundations for all future work on the evolutionary biology of human emotion in his book *The Expression of the Emotions in Man and Animals* (1872). He considered the emotions to be important biological adaptive responses in many species.

Until recently, the field of psychopathology has largely ignored or underestimated the importance of evolutionary processes for the biological foundations of human emotion in the context of our social behavior; the studies carried out by Bowlby (1969) and Trivers (1985) were exceptions. Even today, this subject is far from exhausted. It is discussed, sometimes controversially, by psychologists, anthropologists, human ethologists, and sociobiologists (Frijda 1986; Reeve 1992; Oatley and Jenkins 1996). The ethological and evolutionary approach to psychiatry was formulated as early as the 1960s (Ploog 1964; Plutchik 1962, 1994) and was recently revived by McGuire and Troisi (1998).

Issues remaining to be clarified include the functional relation between emotion and motivation, and that between emotion and cognition, as well as the correspondence between subjectively experienced emotion and its expression. It also needs to be clarified which emotions are primary and which secondary, i.e. derived from the primary emotions (Schneider and Scherer 1988).

Since the time of William James (1890–1950), all of these issues have been bound up with the argument over the causation of the emotions. The James–Lange theory holds that a suitable stimulus can release a physiological reaction, which is then internally perceived as emotion; the emotional experience follows the physical change. The physiologist Walter B. Cannon (1927) was the first of a long series of investigators to contradict this notion. He demonstrated, among other things, that an emotion is experienced *before* the corresponding physiological reaction is produced through the action of the autonomic nervous system. A further complication in the argument came from the hypothesis presented by Schachter and Singer (1962), according to which an emotion arises from the interaction of a stimulus-dependent arousal reaction and the recognition of the releasing stimulus. The subject's evaluation of the stimulus (e.g. as dangerous) determines the type of emotion experienced (such as fear), while the degree of arousal determines its intensity. Cognitive concepts of the causation of emotion remain in opposition to biological concepts even today (e.g. Buck 1988; Reeve 1992).

While the "nativists," invoking Darwin, assume a genetically programmed link between the basal emotions and their expression (Izard 1977; Tomkins 1962; Zivin 1989), the "cognitivists" maintain that emotional expression arises from emotional inner states only after passage through an amorphous matrix that can be influenced by the individual's cognitive development and social learning (Emde et al. 1976; Sroufe 1979). Although the nativist and cognitivist theories stand in opposition to one another even today, they nonetheless agree in considering the emotions (as inner states) to be psychophysiological entities within the organism, and the basal emotional expressions to

be their species-specific outward manifestations. Plutchik (1985) considers this theoretical debate to be pointless. He maintains that emotions result from a dynamic interaction of biological and cognitive factors, quite aside from the fact that cognitive processes, too, are biologically based and have their own evolutionary history.

Wolff (1987, 1993) is critical of both of the approaches outlined above and, proceeding from his own experiments with infants, arrives at a different conclusion. He found that a given experience of the environment may evoke any one of a number of qualitatively distinct motor responses, just as a single motor expression may be produced by qualitatively distinct environmental experiences. The internal state of the child at the moment of the stimulus determines which coordinated motor response is realized (Prechtl 1974). The relationship between a socially relevant event and its emotional expression is thus better and more specifically described by a nonlinear relation between a releasing stimulus pattern and several possible motor expressions, or between a single motor expression and several possible releasing stimulus patterns, than by any preprogrammed isomorphic correspondence between releasing stimulus pattern and motor expression. Wolff concludes that it is impossible to draw a clear boundary between emotions, i.e. "internal states," on the one hand and "outwardly-directed" motor expressions on the other – an important conclusion indeed for an understanding of the entire complex system.

The so-called facial feedback hypothesis, which describes the functional connection between subjectively experienced emotions and the corresponding facial expressions, is particularly relevant to psychopathology in this context (Steiner 1974). According to Tomkins (1963), certain emotions are experienced when certain facial expressions are fed back into consciousness. More precisely, feelings can be induced by mimetic movements and by the changes in facial musculature that compose them. Facial expressions are activated by subcortical centers in which emotion-specific "programs" are localized, a different one for each emotion. These programs are genetically fixed and phylogenetically old. The emotion-specific programs can activate specific expressive movements and vice versa.

Much experimental energy has been consumed in attempts to confirm the facial feedback hypothesis. The first demonstration of functional relationships of the type posited by Tomkins was provided by Ekman et al. (1983), who correlated certain autonomic response patterns with certain facial expressions as well as with certain experienced emotions. Reeve (1992) drafted a circuit diagram representing the neural basis of this feedback process (Fig. 1). The actual neural circuit is, of course, much more complex, and one may doubt whether the cortex plays the primary role in the

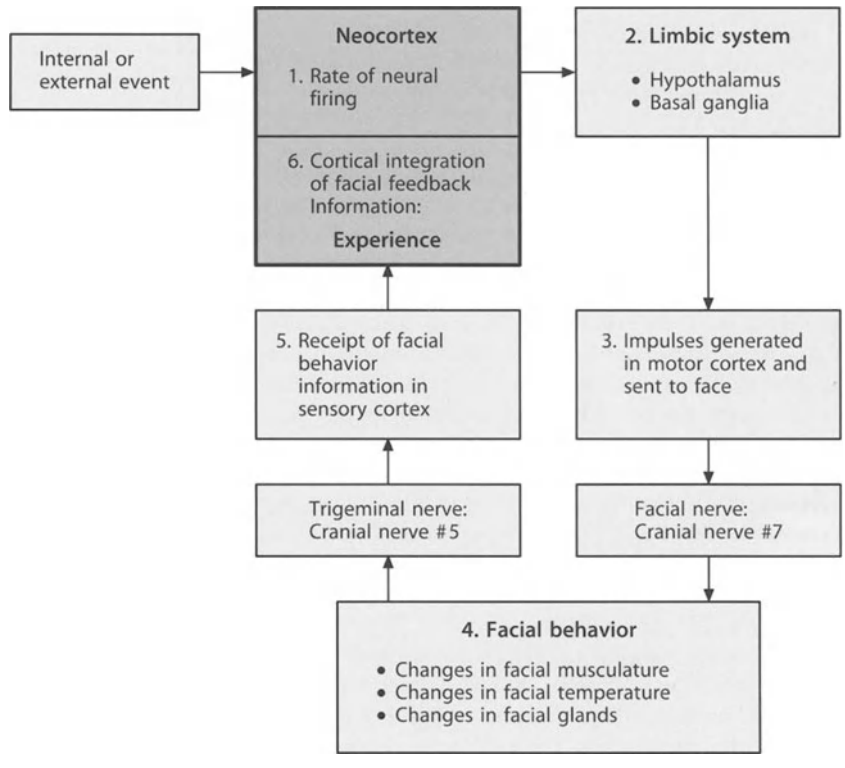

Fig. 1. Sequence of neural events in the facial feedback hypothesis. (From Reeve 1992)

internal processing of the facial feedback expressions (box at upper left). Recent experiments involving functional magnetic resonance imaging (MRI) have clearly demonstrated that empathic observation of pictures of sad or happy facial expressions can induce the corresponding emotions and that this occurrence correlates with neural activation in the amygdala, among other structures (Morris et al. 1996; F. Schneider et al. 1998a,b). These and similar studies provide verification of the facial feedback hypothesis.

In the field of motivational theory, it was again Tomkins (1970) and also Frijda (1986) who identified not physiologic drives, such as hunger and thirst, but rather the emotions as driving forces of motivated behavior. Not drives, but emotions are the determining factors of the primary system of motivation (see below). This conclusion is supported mainly by three arguments.

1. Emotions influence drives: hunger fades in the presence of fear or disappointment; thirst is driven away by disgust when the water is foul; excitement and joy promote sexual behavior, while fear and anger inhibit it.
2. Drives are periodic and temporally restricted, while emotions (in the sense we are now using) have no time limit: one can be afraid momentarily or for a long time. The function of drives is limited to homeostasis and the regulation of sexual behavior, while the motivational function of the emotions pervades all areas of life.
3. Unlike drives, emotions can always be consciously experienced, whatever their quality or intensity, while drives signify homeostatic imbalance (e.g. hunger, thirst, fatigue, sexual disposition).

The emotions constituting the primary system of motivation are also called fundamental or basal, because it is generally assumed – even by cognitive psychologists – that they have an inborn basis, are common to all human beings, and are of phylogenetic origin (Eibl-Eibesfeldt 1984). The recognition that emotions have an evolutionary history leads directly to the question of their function and thus also to that of their adaptive value. How does an emotion contribute to the adaptation of a living creature to its physical and social environment? An evolutionary theory of emotion should apply not only to humans, but to all vertebrates. Darwin's assumption that emotion increases the likelihood of an individual's survival, while simultaneously, in its expression, signifying behavioral intent remains the point of departure for all evolutionary considerations of emotion today.

The names we give to the (subjective) emotions on the basis of common human experience, the behavior corresponding to each of these emotions, and the functions they perform for the organism

Table 1. Three languages that may be used to describe emotional states. (From Plutchik 1984)

Subjective language	Behavioral language	Functional language
Fear, terror	Withdrawing, escaping	Protection
Anger, rage	Attacking, biting	Destruction
Joy, ecstasy	Mating, possessing	Reproduction
Sadness, grief	Crying for help	Reintegration
Acceptance, trust	Pair bonding, grooming	Incorporation or affiliation
Disgust, loathing	Vomiting, defecating	Rejection
Expectancy, anticipation	Examining, mapping	Exploration
Surprise, astonishment	Stopping, freezing	Orientation

are listed in corresponding columns in Table 1 (Plutchik 1984). Double naming in the first column indicates that emotions vary in their intensity. Fear and terror, in subjective language, correspond to withdrawing and escaping as the indicated behaviors, and both serve to protect the individual (functional description). Sadness and crying evoke offers of help, and so on.

When an ethologist speaks of the "cause" of a particular phylogenetic development, the word is being used in two senses. One concerns the molecular, cellular, and neural mechanisms underlying the behavior (or behavioral disturbance) in question; another concerns its purpose. The former are the so-called proximate, the latter the so-called ultimate causes. Both are required for the explanation of an evolutionary process; the questions "How?" and "Why?" necessarily go together. Both questions have been discussed repeatedly in earlier articles (e.g. Ploog 1964, 1980a, 1988); the second is of primary concern to us here. The answers offered will never be more than merely plausible, because teleological questions cannot be answered empirically.

A word on the concept of adaptation is in order before we embark on a discussion of the function of the emotional system. Both Darwin's expression "the survival of the fittest" and his term "adaptation," as well as their German translations, have been liable to misunderstanding for a long time and remain so today. It is not the strongest organism that preferentially survives, but rather the one best adapted to the prevailing social and environmental conditions, i.e. the one whose particular abilities and strengths give it the greatest chance of surviving and reproducing. The individual achieves these goals by deriving the maximum possible gain from its physical and social

environment. This also implies optimization of reproductive potential or, in other words, the greatest possible propagation of the individual's own genes. The business of reproduction thus not only serves to maintain the species in general, as classical Darwinism holds, but also gives each individual the means to propagate its own genes as effectively as possible (Dawkins 1976, 1988).

The ability of the organism to propagate its genes to the largest possible number of descendants is known as its "inclusive fitness." Since the late 1960s, sociobiologists have studied the behavioral strategies used to achieve this goal (Hamilton 1964, 1975; Wilson 1975). The methods of sociobiology allow the collection of empirical data about the ultimate causes of behavior. Discoveries have been made in this way about the behavior of social animals of several different phyla. This fact alone implies that the adaptive behavioral strategies observed (which correspond to the ultimate causes of behavior) cannot be considered conscious processes. Even in humans, adaptive behavior is a conscious process only in very small part. It is certain, however, that adaptive behavior is continually demanded of all participants in a hierarchical society – and this is, of course, the universal mode of human social organization. The behavioral analysis of a depressive female patient, shown in Fig. 2, concerns an extreme example of an adaptive process leading to illness.

Adaptive behavior is always based on emotion and is not only found among primates; it has, of course, a long evolutionary history. Prototypical behavioral sequences in which primary emotions manifest themselves are listed in Table 2 (Plutchik 1984). The first column lists typical releasing stimuli that activate behavioral sequences, and the second column lists the inferred cognition of these stimuli. The releasing stimulus either is recognized by an innate mechanism or else operates as a conditioned stimulus. The third column lists the primary emotions corresponding to the adaptive behaviors (fourth column), which have an innate basis and serve a particular purpose (last column).

3 Canon of Emotions

Which emotions underlie the primary or fundamental system of motivation? Carroll Izard (1977), in a further development of Tomkins' ideas, proposed a

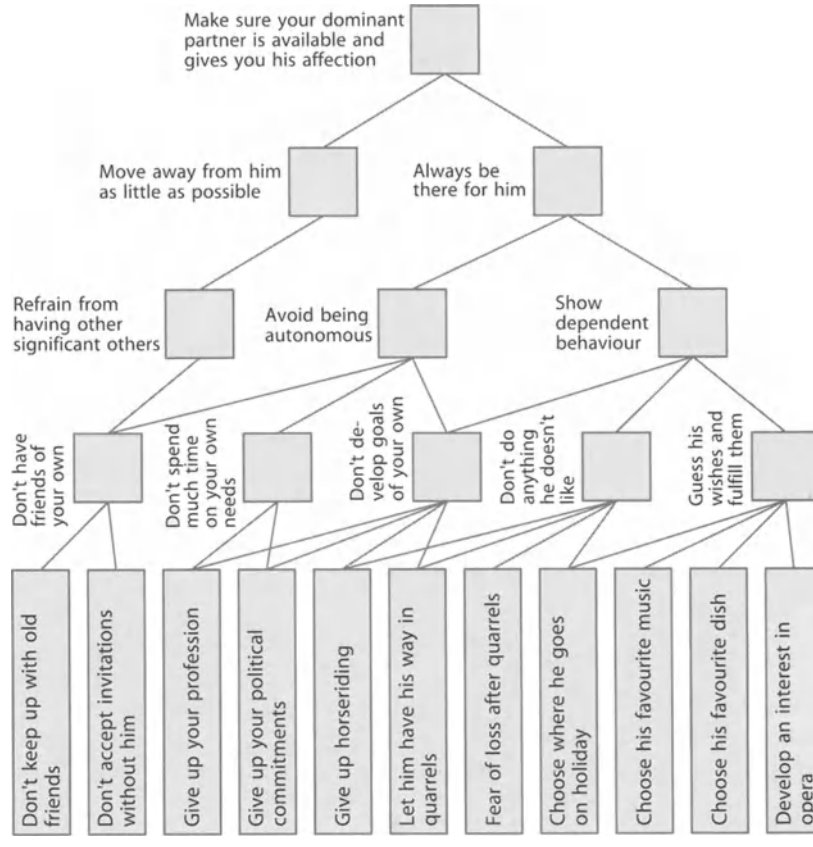

Fig. 2. Behavioral analysis of a depressive female patient. (From Sulz 1993)

Table 2. The complex, probabilistic sequence of events involved in the development of an emotion

Stimulus event	Inferred cognition	Feeling	Behavior	Effect
Threat	"Danger"	Fear, terror	Running, or flying, away	Protection
Obstacle	"Enemy"	Anger, rage	Biting, hitting	Destruction
Potential mate	"Possess"	Joy, ecstasy	Courting, mating	Reproduction
Loss of valued individual	"Abandonment"	Sadness, grief	Crying to be reunited	Reintegration
Group member	"Friend"	Acceptance, trust	Grooming, sharing	Affiliation
Gruesome object	"Poison"	Disgust, loathing	Vomiting, pushing away	Rejection
New territory	"What's out there?"	Anticipation	Examining, mapping, organizing	Exploration
Unexpected object	"What is it?"	Surprise	Stopping, alerting	Orientation

differential theory of emotion according to which the fundamental emotions are those that give rise to differential motivations. Each of these fundamental emotions has a specific subjective quality and a specific corresponding facial expression. Each emotion is assumed to be brought into consciousness through a specific pattern of neural discharges, and each one leads to specific behavioral dispositions. There is, however, no consensus on the number of basic emotions.

Panksepp's psychobiological theory (1982) limits the number of "primitive" emotions to four, which are assumed to arise during the development of the infant brain, arise in at least four visceral–limbic circuits, and activate corresponding modes of behavior. These are expectation (curiosity), anger, fear, and panic. Tomkins (1962, 1963) lists eight basal emotions, three of them positive – interest, surprise, and joy – and five of them negative – anger, fear, shame, disgust, and rage. Izard (1977) posits ten basal emotions.

Since the time of Spinoza and Descartes, there have been many lists and classifications of human emotions, most of them without justification. The earliest empirical studies of emotional expression, including some experimental studies, are those of Darwin (1872). Experimental studies of facial expression in psychiatry (e.g. those of Ellgring 1989; Ellgring and Smith 1998; Flack and Laird 1998) commonly make use of the list given by Ekman and Friesen (1978):

- Surprise
- Anger
- Fear
- Happiness (joy)
- Sadness (distress)
- Disgust
- Contempt (a later addition)

Plutchik (1980, 1994) adds two further emotions with an evolutionary and ethological basis, namely expectancy and acceptance. Expectant (i.e. curious) behavior is an important "drive" for juvenile animals and facilitates coping with the environment. Acceptance is striven for in all hierarchically oriented societies, especially among primates (including humans), and is one of the most important forms of reward. There is controversy over whether shame and guilt should be counted among the fundamental human emotions, mainly because cross-cultural study reveals no facial expressions that unambiguously express them in all cultures (Ekman et al. 1969).

The likely objection that the human emotions, at least, are not exhausted by a list of four, seven, eight, or ten primary ones can be answered by positing the existence of secondary emotions that are mixtures of the primary ones, in much the same way that the color spectrum is generated by mixing the primary colors (Plutchik 1980). Such mixtures or superpositions of emotions have been described by ethologists with regard to emotional expression, e.g. in wolves by Schenkel (1947), in dogs by Lorenz (1963), in cats by Leyhausen (1973), and in subhuman primates by Chevalier-Skolnikoff (1973). In these species, a spectrum of facial expression is generated by superposition of expressions signifying varying intensities of different emotions, e.g. readiness to attack or to flee. Similar mixtures have been found in humans; the best-known example is the mimetic superposition of surprise and fear (Ekman 1973; Fig. 3).

From an ethological and evolutionary viewpoint, the existence of such phenomena leads to certain conclusions concerning the cerebral organization of emotion (MacLean 1949, 1990; Ploog 1989). It is a basic principle that every peripheral structure of the body has its representation in the central nervous system. Thus, if a peripheral structure (such as the facial musculature) develops into a progressively more complex apparatus, then a corresponding organization of the central nervous system must take place to subserve the function of this apparatus. This principle is no longer open to doubt (Ciompi 1991).

Over the course of mammalian evolution, the facial apparatus has undergone a remarkable differentiation, as may be observed by comparing the variety of

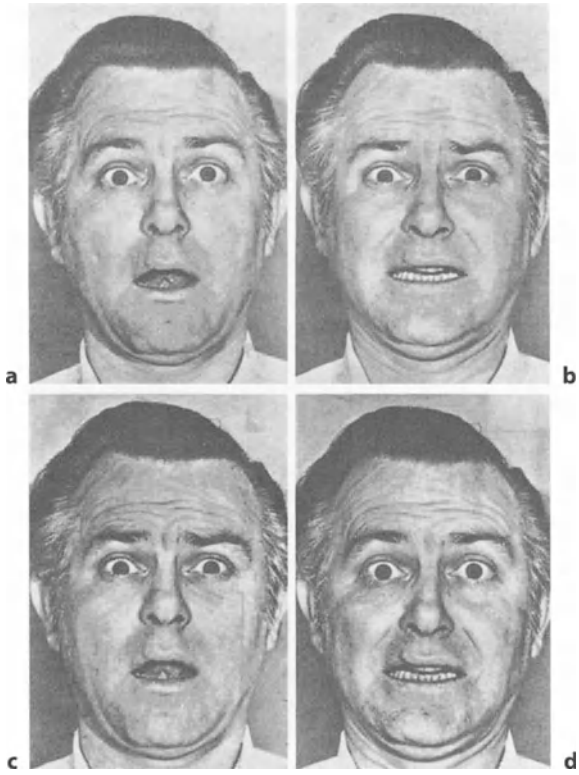

Fig. 3. Superposition of emotions in facial expression. *Upper left*, pure expression of surprise; *upper right*, pure expression of fear; *lower left*, this expression represents a superposition of surprise (mouth) and fear (eyes, eyebrows, forehead); *lower right*, superposition of surprise (eyebrows, forehead) and fear (mouth). (From Ekman 1973)

facial expressions of a rat to that of a dog or chimpanzee. Emotional expression in primates is almost exclusively concentrated in the face and the voice (Ploog 1986a). The facial musculature and the larynx have correspondingly undergone considerable structural and functional change over the course of human evolution, which has its reflection in the central nervous system. A good illustration of this is provided by the progressive increase in central representation of the facial and glossal musculature as one considers first the cat, then the monkey, and finally humans. If the premise is correct that a distinct emotion corresponds to each facial expression – even though higher primates may voluntarily suppress the expression itself – then there can be no doubt that the canon of emotions has evolved to its greatest extent, and greatest degree of differentiation, in humans. This is not to say that the total number of emotions that can be experienced cannot exceed the number of possible facial expressions (Leonhard 1997).

In view of the increasing complexity of emotion and the increasing complexity of the morphology and physiology of facial expressions over the course of evolution, it is questionable whether the notion of primary and secondary emotions accords well with the current understanding of nervous system function. A branching model, such as is found in many different biological systems, seems a likelier candidate to explain the processes underlying emotion. In such a branching system, the idea of a specific, and specifically localized, cerebral representation for each emotion would be better supported than that of primary and secondary systems of emotion. This idea was merely theoretical until recently, but has now gained experimental support with the aid of functional imaging techniques (e.g. Morris et al. 1996).

4
Emotion and Communication

The remarkable development of the facial and vocal apparatus for the expression of emotion serves an obvious purpose: each evolutionary step forward improves the ability of members of the species to communicate with each other (Jürgens and Ploog 1976). Especially in social mammals, including the subhuman primates, the extraordinary differentiation of communicative processes facilitates communal living and thereby promotes the survival of the species. It cannot be determined whether this differentiation of communication was a cause or an effect of the increasing complexity of social systems; the two developments probably went hand in hand, in small increments. It may be concluded, in any case, that there must have been constant selection pressure promoting the development of modes of communication (Ploog 1997).

Modes of communication among primates overwhelmingly serve social functions, while those devoted to the outside world are relatively few. The latter are mainly limited to warning and alarm cries and perhaps a few indicative sounds as well (Ploog 1972; Winter et al. 1973; Hopf et al. 1985). Facial and vocal expression, and also to a lesser extent bodily posture and some autonomically driven functions (hair position, glandular secretions, urine odor), are not only expressions of emotion, but also messages to other members of the species. Each expression is a signal which may occur at varying levels of intensity, ranging from a brief and (to humans) barely perceptible intentional movement to a long, repeatedly displayed complete movement. The best-known illustration is the intensity scale of threatening movements, ranging from a slight raising of the head, to facial and vocal expressions of varying intensities, to an imminent attack.

Even if the nonverbal aspects of human communication seem relatively insignificant in comparison to speech and may sometimes be manufactured or suppressed at will (particularly facial expressions), these phylogenetically old modes of communication are still very much in action. They unconsciously guide dialogue between individuals (as already in subhuman primates) (Ploog 1995) and are important indicators of defensiveness, approach, and other behavioral tendencies. As psychiatrists, we make diagnostic use of these nonverbal modes of expression. It may be questioned how well we succeed in decoding all of the messages they contain (Ploog 1992, 1993). Perhaps the greater or lesser ability to recognize such messages underlies the once decried and now rather derided "clinical intuition."

5 Hierarchy and Adaptation

As we remarked above, an evolved, differentiated system of communication is advantageous for communal life. A closer look at this communal life, with a sidelong glance at the human situation, will yield evidence for this assertion. Van Hooff (1973) used factor analysis to identify five categories, or systems, of social behavior in chimpanzees (our closest relatives): play, aggression, submission, bonding, and excitement. Only the last system mentioned partly concerns nonsocial, environmentally oriented behavior, while all of the other systems are partner or group oriented. No one observing chimpanzees, even superficially, could deny that these animals manifest emotions of each of these types that influence the behavior of their partners or of the group. The repertoire of communicative signals is selectively distributed and differentially applied within the different systems.

It is true of all primates, though to a variable extent depending on the species, that the use of social signals creates a hierarchical social organization, and a large amount of social activity is used to determine which animal takes which position in the rank ordering, and who plays what role. The maintenance of hierarchy is a dynamic process over the entire life cycle and is continually in flux because of aging, changes in group composition, and numerous environmental factors.

We described this process in squirrel monkeys in the early 1960s using sociometric methods (Ploog et al. 1963; Hopf 1967; Castell and Ploog 1967); it applies equally well to all old and new world monkeys studied thereafter. We shall see below that our primate inheritance plays a major role in human emotion. In any case, hierarchical organization seems to confer a reproductive advantage despite the large investment made by each member of the group. The sociobiologist's cost-benefit calculation comes out positive as long as the physical environment is favorable.

Human emotion is expressed mainly through facial expression and the voice. Animals, particularly subhuman primates, have innate expressive movements, homologous to human ones, which are generated by "preprogrammed" cerebral structures. The functional relationship between subjective (experienced) emotions and their expression is bidirectional: the neural programs generate expressive movements, and these movements activate patterns of central nervous activity (Ploog 1989). Expressive movements have a function. They occur mainly, but not exclusively, in the social context and act as communicative signals, which inform other members of the species of the individual's emotional state, thereby influencing their behavior. Social signals thus have an adaptive function with manifold effects in a hierarchically organized society.

Expressive movements highlight the adaptive function of the emotions. Emotions are at the root of every adaptive behavior. The ultimate causes of the emotions lie in the effects of adaptive behavior, e.g. self-protection, the appeasement or defeat of an opponent, reproduction (see Table 2). Just as appetite motivates the search for food, emotions motivate adaptive behavior in general. The emotions act as springs of activity.

6 Ethology of Affect

Up to this point, we have been discussing emotion as a general concept and have largely avoided more highly differentiated terms, such as mood, emotional state, feelings, and affect, that may involve the temporal dimension and imply a shorter or longer duration of the inner experience. We shall now discuss the origin and adaptive function of affect, by which is meant an acute, temporally limited, intense emotional occurrence.

According to Salzen's theory (1991), negative affect results from the prevention or frustration, by whatever means (often by a social partner), of an initiated or intended instinctive behavior (e.g. capture of prey). Positive affect, in contrast, is evoked when the removal of an obstacle enables the performance of instinctive behavior. The motor and autonomic phenomena appearing during this process serve as signals for the social partner and may evolve into ritualized movements (see examples below). The individual's own perception of the preprogrammed movement as it is performed, and of the accompanying autonomic changes, form a part of the experience (perception)

of the emotion, which in turn motivates further behavior and learning. Lorenz (1937) described this process, which he named "Instinkt-Dressur-Verschränkung" ("instinct-training interlock"), and thereby provided an ethological explanation for conditioned and learned behavior. This process may also be exploited in behavioral therapy (Ploog 1969).

Breland and Breland (1966) have shown experimentally that the execution of species-specific preformed movements ("fixed action patterns") is a necessary reinforcement in the learning process. The reward, or reinforcement, at the end of a behavioral chain with a desired objective need not always be food; it might be the sight of a long-absent member of the species, for example (Hupfer and Maurus 1975). Many mammals have developed species-specific sounds that signal separation from the group and, in turn, are answered by the group and bring about reintegration into it. We exploited this separation effect in learning experiments with juvenile squirrel monkeys. The isolated animal expresses its "separation distress" through an innate sound that we named the "isolation peep" (Winter et al. 1966). Production of this cry stops immediately upon the animal's rejoining the group.

Experimental attempts to get the animals to discriminate species-specific from synthetic sounds uniformly failed when food or water was used as the reward; the animals appeared to learn nothing. However, when another animal of the same species was shown to the isolated animal through a window, even for as little as 10 s, the learning curve climbed rapidly to a highly significant level. The sight of another species member is thus the reinforcement (reward) that guides this learning process (Hupfer et al. 1977). The innate behavior (isolation peep) is both an expression of emotion and a signal to the group, with the adaptive function of causing the reintegration of the isolated animal. Reintegration then leads to further emotional behavior in the form of a greeting ritual, consisting of mutual stereotypic movements and "positive" vocalizations.

The separation-and-reintegration model (Bowlby 1969, 1973) describes two situations that evoke affect: separation prevents fulfillment of the innate desire for affiliation (bonding), while reintegration satisfies this desire. The isolation peep is a rare instance of a behavior whose function (ultimate cause) and neural mechanism (proximal cause) can both be empirically demonstrated (Ploog 1979).

7 Bonding and Separation

Deprivation and separation experiments in monkeys, especially macaques, provide a well-known model for the human depressive syndrome (Harlow and Harlow 1962; Harlow and Suomi 1974). When juvenile monkeys aged 4–7 months are separated from their mothers, they let out loud cries, look for their mothers, and run around restlessly (phase of protest and despair). After 1–2 days, a state described as depression sets in. The animals cower, take no notice of their surroundings, and are apathetic. A similar picture results if one separates 3-month-old monkeys raised together, even after multiply repeated separations. The "friends" pass through the phase of protest and despair after each separation, and each reunification leads to new bonding. Ultimately, behavioral development is arrested. The animals cling to each other, lack curiosity, do not play, and show no interest in their surroundings (Suomi et al. 1970). Even 3-year-old adolescent monkeys develop a depressive behavioral syndrome after separation.

Considering the accumulated results of experiments on primates of various ages, with varying lengths of separation and varying lengths of prior social experience, it can no longer be doubted that the separation of tightly bonded animals leads to severe disturbances of affect and social behavior (Kaufman and Rosenblum 1969). It is, however, usually not mentioned that there are large individual differences in the severity and duration of the apathetic behavioral disturbance (Ploog 1980b).

Genetic differences play a role as well. It has been shown in two closely related macaque species that small interspecies differences in social structure and mother–child behavior produce different results in separation experiments. Bonnet macaques cling closely to one another, while pigtailed macaques maintain a greater distance. The bonnet macaques and their newborn infants remain in close contact with the group, while pigtailed macaque mothers and their infants keep away from the group. When juvenile bonnet macaques are separated from their mothers, they are "mothered" by the group as a whole and "adopted" by an "aunt," while the juvenile pigtailed macaques are left to themselves and are not uncommonly chased away by other group members. They develop a severe depressive syndrome, while the juvenile bonnet macaques, though they are upset and whimper for a time, nevertheless continue to show interest in their inanimate and social environment (Kaufman 1973). In humans, too, there are undoubtedly major individual differences in the realm of bonding, separation, and grief behavior. Twin studies reveal that such differences are, to a significant extent, genetically determined (Schepank 1982; Plomin et al. 1997; Segal and Bouchard 1993).

Rather than attempting to analyze the causes of depressive syndromes, we are discussing here the changes in emotionality resulting from interference

with the adaptive function of an emotion – in this case, the prevention or reinstatement of bonding (Ploog 1986b; see Table 2). The protest-and-despair reaction and the subsequent emotional disturbances are affected by multiple factors:

- The change of social environment after the loss of a tightly bonded member of the species
- The time of life at which the loss occurs
- The individual's own predisposition to the reaction
- Genetic determinants of social behavior

Attempts to explain human depressive disorders, invoking each of these factors in turn, have included the life-event, ontogenetic, vulnerability, personality, and genetic hypotheses. All of these are probably valid, depending on the circumstances. Only a few investigators have favored an evolutionary hypothesis (e.g. Price 1969; Sloman 1976; Gardner 1982; Price and Sloman 1987; McGuire and Essock-Vitale 1982; Pedersen et al. 1988; McGuire et al. 1992; Gilbert 1992); this will be discussed below.

We shall maintain that emotions, from the evolutionary point of view, represent basic phylogenetic adaptive processes that promote individual fitness and, thereby, the maintenance of the species. They not only inform the organism about internal bodily processes and external events, but also provide feedback regarding the effectiveness of its own behavior. Unpleasant emotions cause a change of goal-directed behavior, while pleasant emotions reinforce the organism's goal-directed behavior and thus enhance its fitness. Emotions of the former type include feelings of disappointment, of sadness, of fear, of powerlessness, of anger, of disgust; emotions of the latter type include feelings of being recognized, of being loved, of love, of happiness, of power, of triumph. These and all other emotions determine our behavior to a much greater extent than reason. In regard to human depressive disorders, we must ask what adaptive value is associated with depressive affect (Nesse 1998).

8 Grief and Empathy

In our search for the adaptive value of depressive affect in a sense relevant to psychopathology, we shall direct our attention to grief and its associated affect. These are evoked by the loss of a loved person and are certainly closely related to pathological depressive affect, though not identical with it.

A component of the Minnesota Twin Study (Segal et al. 1993) was devoted to the intensity of grief after the loss of a monozygotic twin or other near relative. Grief affect was expected to be stronger the more closely related the person who had died. A total of 49 mono- and 19 dizygotic surviving twins, as well as mothers, fathers, grandparents, and other relatives, were questioned about their grief and its (quantified) intensity in a standardized interview. The results were statistically significant and confirmed the hypothesis: the surviving monozygotic twins grieved more intensely than the dizygotic ones, and all twins grieved more intensely than mothers, fathers, and grandparents. Although the authors were cautious in their multidimensional evaluation of these results, it seems definitively demonstrated that there are genetically determined individual differences in the grief reaction, which, according to this study, are highly correlated with the closeness of the genetic relationship.

Empathy affect is closely related to grief affect (Brothers 1989). Darwin (1872) wrote: "When we witness any deep emotion, our sympathy is so strongly excited that close observation is forgotten or rendered almost impossible." It might seem that Darwin was concerned here merely with the "contagiousness," or transferal, of emotion from one individual to another. Other passages reveal, however, that he meant to describe the communication of an emotional state. Many developmental and experimental findings from human ontogeny show that the capacity for empathy matures in a number of developmental stages (Grossmann 1989; Grossmann and Grossmann 1991; Papoušek and Papoušek 1974).

The studies carried out by Bischof-Köhler (1989) conclusively reveal that receptive empathic understanding arises in the 20th to 24th month of life, in close association with the new ability to recognize oneself in a mirror. Empathic understanding contrasts sharply with the empathy defect of autistic children, who perceive social signals wrongly or not all, and with the alexithymia of adult patients (Krystal 1979; von Rad 1983), which presumably reflects a primary inability to perceive their own emotions.

9 Neuroethology of the Recognition of Social (Emotional) Signals

Up to this point, we have not explicitly distinguished the transmission of social signals from their reception. The fascinating and still unsolved problem of biological communication resides precisely in the coevolution of the transmitting and receiving apparatus for social signals. How can a human infant distinguish certain universal phonemes of speech as early as the first week of life and react to them with autonomically mediated responses (sucking frequency, heart rate) (Eimas et al. 1971)? How can it perceive and imitate

certain facial movements (sticking the tongue out; Meltzoff and Moone 1983) or modulations of the voice (Papoušek and Papoušek 1986)? Certain groups of neurons in the simian forebrain fire not only when the animal intends to move a limb (e.g. hand), but also when it sees the experimenter making such a movement (Rizzolatti et al. 1996).

The neural basis of the recognition of facial expression is particularly important to research on emotion. In the mid-1980s, workers in several laboratories independently discovered neurons in the midportion of the superior temporal sulcus and the amygdala of monkeys that displayed various responses only upon the presentation of pictures of monkey faces, with a preference for identical faces. Certain cortical cells in the superior temporal sulcus also responded to isolated portions of faces, such as the eyes or hairline, but fired more strongly when the entire face was displayed. Selectivity for facial features was found: some cells responded more strongly to the eyes, others to the mouth or the hairline. Finally, and most importantly for our purposes, there were significant differences in neuronal response depending on different facial expressions, directions of gaze, and facial orientations. There is no longer any doubt that the neuron populations studied are components of a module for the analysis of facial expression (Baylis et al. 1985; Leonard et al. 1985; Rolls and Baylis 1986; Perrett et al. 1982, 1984, 1985; Hasselmo et al. 1989).

More recently, it has also been demonstrated that injury to the amygdala leads to selective deficits in the perception of facial expression. A remarkable patient was studied by Adolphs and colleagues (1994). The total destruction of this phylogenetically ancient structure by calcium deposition (Urbach-Wiethe disease) made the patient unable to perceive facial expressions of fear and other emotions that normal individuals can distinguish effortlessly. A female patient with bilateral partial amygdalar injury, similarly impaired in the recognition of facial expressions, had great difficulty determining whether someone was looking at her or not (Young et al. 1995).

Experiments on the question of "being looked at," carried out on paranoid schizophrenics and controls, have revealed that normal individuals can reliably tell whether someone is looking them in the eye up to a distance of 80 cm, while paranoid patients imagined they were being looked at considerably larger distances (Ploog 1970). In social communication, whether among human beings or among subhuman primates, the direction of gaze signifies the individual concerned, while the facial expression signifies the intention, or readiness to act, of the "sender." Eye contact creates a reciprocal loop between the sender and the receiver. The amygdala has multisensory cortical inputs as well as outputs to the hypothalamus and brain stem (Aggleton and Mishkin 1986; LeDoux 1998) and is doubtless an important nodal point in the complex anatomy of emotion and social communication.

An indication that the perception of social signals (facial expressions) can be differentially impaired comes from the studies carried out by Berndl et al. (1986), Harrington et al. (1989), and Grüsser et al. (1990) in schizophrenics and by Sprengelmeyer et al. (1996) in patients with Huntington's disease. These patients had a mild impairment of the perception of direction of gaze, could not differentiate the expression of anger from that of fear, and were totally unable to recognize the expression of disgust. The authors rightly propose that certain primary emotions are subserved by specific neural substrates. Our own studies of simian vocal communication have demonstrated such functional relationships with certainty (Jürgens 1979; Ploog 1981).

10 Depressive Syndromes

After these preliminaries, we can now return to the question of the adaptive value of depressive affect (Price 1991). The likelihood that a depressive syndrome will develop is greater in the presence of excessive life stress, major material losses, loss of a loved one, divorce or loss of a partner, loss in conflict situations (e.g. sports), or loss of social position and power (i.e. loss of control over other persons and property). The common features of all of these life circumstances are that they dissolve bonds, make the achievement of expected goals questionable, and threaten the individual's position in the social rank ordering. Loss of fitness results. Depressive emotion might thus be seen as a suboptimal adaptation to negative life circumstances, an adaptation that no longer serves the purpose of optimal fitness.

In fact, however, depressive affect and its symptoms – be they exogenous, endogenous, or neurotic – evoke an empathic reaction in other individuals. They act as signals for help, lead to a temporary deferment of the material and social demands placed on the involved person, keep him or her in the family group, and preserve his or her social position. Depressive affect thus provides a grace period in which deficits can be made good and temporarily shifts the balance of material, personal, and social give-and-take toward the side of taking, i.e. toward a reduction of demands on the involved person.

It might be objected that any form of suffering or illness similarly evokes compassion and help from others, and that depressive affect therefore has no *specific* adaptive effect. This objection can be answered

as follows: The tremendous, organized effort against illness that modern culture has developed has biological roots and is likely a product of the coevolution of expressions of suffering and innate empathic reactions to them.

Further hypotheses are needed, however, to account for depression of moderate or prolonged duration, and for bipolar disorders, on an evolutionary basis. It remains to be explained how the primal fears that originated over the course of evolution – the fears of failing to meet excessively high demands, losing one's property, becoming powerless, feeling guilty and worthless, losing persons close to oneself, losing the respect of society – may arise and grow spontaneously, entirely without apparent cause. Biochemical hypotheses of proximate causation will have to be introduced (Nemeroff 1998).

If proximate causes are assumed to operate in the framework of ultimate (evolutionary) causes, then experimental findings relating to proximate causes must be reinterpreted as revealing not deficient neural or biochemical functioning, but rather attempts at compensation by the central nervous system, leading to suboptimal adaptation.

The temporal dimension of the depressive condition also requires explanation. Emotions have a limited temporal course. They usually arise suddenly and then subside. The depressive affect occurring during a depressive illness, however, may be moderately or extremely prolonged; abnormal duration is, indeed, the sign that this is a pathologic rather than a normal process. When depression becomes subacute or chronic, the benevolent attention of others may, not infrequently, give way to abandonment. The depressive signals that at first evoked empathy later habituate.

Price et al. (1994) developed an evolutionary hypothesis to explain human depression, while taking account of its temporal course. This hypothesis, too, rests on the fact that humans – like most terrestrial vertebrates – are born into a hierarchically organized society and have to compete for their place in it over the entire course of their life. Adaptive behavior is continually demanded. We have already shown (see Fig. 2) an extreme example of this. It is described how a wife's subordination, on the basis of a strong emotional bond, progressed ultimately to self-sacrifice (Grossmann 1993).

This case reveals the nature of the "social contest hypothesis." The contest consists not only of the attempt to be "better" or more successful than the next higher individual in the rank ordering, but also the attempt to gain confederates for mutual support in the upward struggle, as well as the attempt to obtain recognition and confirmation. Simultaneously, and (as we are about to discuss) paradoxically, close bonds may be formed at any time of life, primarily within the family group (to parents, children, siblings and their children, and so forth), but also outside it. The paradoxical aspect of this social network is that bonding behavior can either promote or impede the process of social adaptation.

The description provided here of the individual's immediate social environment applies not only to human society, but also to that of our nearest primate relatives (de Waal 1989). Only in the human case, however, can we appreciate the importance of recognition, and the intensity of the associated emotions. The recognition or admiration of those of equal or higher social rank or prestige raises an individual's mood and self-esteem more than the recognition or admiration of those considered of lower status (Gilbert 1992). Nonetheless, the admiration of many (or even of "the masses," as one might say) adds strongly, sometimes even excessively, to the individual's self-esteem.

The unfortunate wife we have mentioned gradually maneuvered herself into the position of a hopeless loser who can no longer offer any resistance. Her submissive posture manifested itself in chronic depressive symptoms. Alongside this model of depression is the analogous one of a persistently "agonistic" position. Such patients, despite generally being the loser in conflict situations, can never free themselves from the interpersonal power struggle with those close to them and therefore remain permanently at odds with their spouses, families, or other persons, are routinely "defeated," and therefore develop feelings of worthlessness, failure, incompetence, and helplessness.

In the normal course of development, a child acquires a realistic understanding of its own place in the family hierarchy, in kindergarten, and in school and learns to accept occasional defeats. In adulthood, too, there are good and poor losers. The latter are repeatedly beset by internal conflict over whether to keep fighting or give up. When this conflict becomes protracted and intense, the individual becomes depressed and is thereby relieved of the need to resolve the conflict. In a smoothly functioning hierarchical system, the winners cease their aggression and the losers their submissive behavior once the conflict is over. Individuals prone to depressive behavior, however, fail to recognize the signals that indicate the end of the conflict. They continue to behave as if they could be attacked again at any moment, and they thus fall, more readily than others, into a vicious circle in which attack and appeasement maneuvers follow close upon one another.

This model of depression also includes the idea of evolutionary selection mechanisms resulting in a hereditary predisposition to depression (Halliday 1983). Such arguments date back to Darwin's principles of sexual selection (1871) and have to do with the

attractiveness of the individual as a potential partner (Sloman 1977). Repeated success in social competition leads to increased self-confidence and improves the chances of future success, while repeated failure diminishes these same chances.

The effect is felt in partner selection as elsewhere: winners radiate a more powerful attractiveness than losers. A differential amplification of traits and status behavior results, so that winners are more likely to pair with winners, and losers with losers. The predisposition to depressive behavior patterns could thus be explained on a familial or population-genetic basis, considering that human history has now been in progress for hundreds of thousands of years. Indeed, recent studies have shown that attractiveness and social success are important parameters for partner selection even in our modern society (Grammer 1995; Grammer and Thornhill 1994).

Years ago, in ethological studies of the green iguana, we were literally eyewitnesses to the fact that the individual's position in the hierarchy affects the function of its autonomic nervous and endocrine systems. These animals live according to a linear pecking order. The alpha animal's head is bright white, an emblem of its rank, as it were. One such "boss," splendidly green with a white head, had increasingly to defend himself against a challenger one level down in the hierarchy. One day, it lost a major duel and immediately thereafter became grayish brown, and its head lost its white color. It crept away into a corner and remained submissive for the remaining months of the period of observation (Ploog 1970).

Sapolsky (1990) described hypercortisolism in subordinate free-ranging baboons, and many other investigators have described similar associations of rank ordering and central nervous function in mammals. Ethological and neuroethological studies thus provide a significant contribution to both the "state concept" and the "trait concept" of depression.

11 Anxiety

In this concluding section, we shall consider anxiety, the most common accompaniment of depressive affect, in its evolutionary aspect. The neuroanatomical, neurophysiological, and neurochemical bases of anxiety have come under particularly intense study in the past decade (Charney et al. 1998; LeDoux 1998). Anxious feelings are among the most common psychopathologic symptoms and undoubtedly arise from many different causes (Strian 1983, 1996). Nevertheless, it is easy to see that anxiety is an affect of enormous importance to the survival of the individual.

The development of a warning system that signals danger to the organism, and consequently induces fight-or-flight behavior, is an early evolutionary achievement of high adaptive value. In the ongoing concert of emotions, anxious affect drowns out all others and thus ensures the fastest possible reaction to danger. The releasers of anxious affect and its behavioral consequences – avoidance or flight – in lower vertebrates are exclusively innate; thus the behavioral reaction to the releasing stimulus does not have to be learned (Liebsch et al. 1998). Even among subhuman primates, species-specific warning sounds release innate behavioral patterns of searching for cover (Winter et al. 1966; Hopf et al. 1985). Countless experiments in rats and many other species have shown, however, that anxiety reactions can be conditioned, and then released, by practically any arbitrary stimulus. The original, innate releasers of anxiety may be replaced by others through experience and learning, but the anxious affect itself, and its behavioral consequences, remain the same.

In the case of pathological human anxiety released by a known stimulus – such as phobia of various types, or social anxiety – the methods of behavioral therapy may be effectively applied, as is well known, but the treatment of indefinable anxious states is more difficult. Post-traumatic stress syndrome, however, is an exception to this rule (Strian and Ploog 1992; Bronisch 1997). The cause of this disorder – the traumatic event or series of traumatic events – is known, retains its intensity and vividness over a long period, and evokes the same mental and autonomic symptoms of anxiety each time it is recollected. Nonetheless, attempts to neutralize the anxiety-producing event or events by behavior therapy appear to be ineffective.

Among patients with anxiety of one or more types, those with social anxieties are most common. From the evolutionary viewpoint, even these anxieties, which often seem easily explicable in terms of the sufferer's life history, have a phylogenetic origin. It lies in the establishment of a hierarchical rank order, a form of organization common to most social vertebrates, including all diurnal primates. Clearly, this social structure results in optimization of the probability of survival of the individual and of the species.

From childhood onward, human beings learn to fit into the hierarchical order through dominant and submissive modes of behavior, through coalitions and behavioral strategies, and thus to achieve the highest possible rank. Every day so lived is a new source of anxiety. In any case, the forms of expression of anxious affect through vocal and facial expression and autonomically regulated functions may be observed as early as the first days of life, and there is scarcely any

doubt that these are an important part of a primary, innate system of affect that directs our social behavior (Ploog 1997). All human beings have social anxieties, but only some experience a major limitation of their freedom to act because of them and thus become socially dysfunctional.

12 Conclusions

The emotions acquired over the course of evolution – pleasure, displeasure, surprise, anger, rage, anxiety, fear, disappointment, worry, and grief; feelings of love, of belonging, of hatred, of disgust; and all other emotions – are the common possession of mankind. They are the aspect of phylogenetically based, species-specific adaptive behavior that is open to subjective experience, and they serve the purpose of sustaining the life of the individual and of his or her progeny. The means by which they are expressed by various bodily organs, mainly through facial expressions and the voice, have evolved over millions of years and are subserved by the central and autonomic nervous systems. Facial expressions are primarily innate and are among the instinctive movements of the species ("fixed action patterns"). Each emotional expression creates an impression in other people ("receivers"), acts as a signal to them, and affects their behavior in turn; this process gives expressive behavior its adaptive function. The reciprocal exchange of signals constitutes a process of communication that guides and regulates the behavior of all individuals concerned. Humans have brought their expressive behavior under voluntary control and can apply it manipulatively in both verbal and nonverbal communication.

The function of emotion is not limited to expressive behavior and communication; indeed, emotion is the spring of all adaptive behavior in general. Human beings live in a social system and are equipped with species-specific behavior, which enables them to pursue biologically relevant objectives. Any behavior that brings them closer to these goals is adaptive. Despite the extraordinary variety of goal-directed human behavior, most of which is learned, the emotions that drive it and those that accompany its failure or successful accomplishment have remained remarkably universal over the entire documented course of human history. These emotions are undoubtedly anchored in the human genome; the canon of emotions capable of being experienced by humans is innate. Emotions cannot be learned, whether by imitation or by any other means. What can be learned, i.e. stored in memory, are those objects, events, persons, and social constellations that have evoked certain emotions and remain associated with them. The experience of emotion can be conveyed to others only by human speech, although, as with the recounting of dreams, what is conveyed is probably no more than a pale shadow of the experiential reality. I understand the feelings of others only because I have had similar feelings myself; I understand primarily by empathy, not by experience. I shall never know whether the anxiety, sadness, or joy of another person is exactly the same as mine.

In a hierarchically organized society, like those of subhuman primates and of humans, a large part of social activity is devoted to attaining the highest possible rank and to defending one's rank and role as long as possible. The goal of all adaptive behavior is the securing of the greatest possible gain from the physical and social environment with which the individual is confronted. This fact of life also lies at the root of human psychopathology. Emotions underlie all motivated activity and are the motor of all adaptive behavior. As the human population grows, the universal human objective of maximizing personal gain, which is anchored in the human genome, is gradually becoming the greatest threat to the survival of our species. The current appeals for the limitation of population growth are thus justly founded in human biological nature.

Philosophical Anthropology: Basic Science of Psychiatry

Translator: S. Henn

1 Introduction: Significance of Philosophical Anthropology for Psychiatry

The basic question in philosophical anthropology concerning the nature, the characteristic features, of human beings is, in a sense, the starting-point of all science, because the acquisition of knowledge, the understanding of "what in actual fact is" (Hegel 1807; see Spaemann and Löw 1981), cannot completely disregard the essence that acquires this knowledge. In this respect at least, all scientifically sound and lasting cultural epochs of humanity were epochs with questions of philosophical anthropology. However, anthropology has an additional, an even more specific significance for psychiatry, because anthropology is irrefutably a fundamental science for psychiatry inasmuch as psychiatric illnesses, viewed as departures from healthy psychological life, always both refer to and are counterpoint to what it means to be human. At the same time, the fundamental problem of all psychiatric anthropology arises, namely that, whether we like it or not, it is always concerned with ideal typology, with establishing criteria for normality, even though this might be problematic and might open up the way to both misunderstandings and abuse (see Weber 1993; Mitscherlich and Mitscherlich 1987; Lifton 1988).

On the other hand, psychiatric anthropology can, if it has learned to handle the problems of understanding normality appropriately, enrich general anthropology and many specialized branches of it (e.g. philosophical, phenomenological, and cognitive anthropology). The problematic situations particular to psychiatric illnesses can be understood as "nuanced phenomena" to a certain extent. Many different ways of explaining and many different explanatory contexts that have already been formulated in general anthropology can be clarified here, e.g. in the anthropology of perception by Sartre (1943) and Merleau-Ponty (1966) or in the anthropology of time by Theunissen (1992).

Viewed in this way, psychiatric illnesses are not "defects," "injuries" to the state of health, or – as Binding and Hoche (1920) irresponsibly argue according to social Darwinism, an argument fraught with consequences (see Lifton 1988) – in the extreme case "naked existences"; with the exception of profound mental disorders, psychiatric illnesses are often simply normal psychological variations, out of which an extremely rich mental life can arise. Especially in the connection between creativity and psychosis, there are indications that distinctive psychiatric features can represent an integral part of a person's creative mental essence (see Jaspers 1922).

Blankenburg (1971) has presented a survey of the question of "normality" in psychology, according to which Kurt Schneider (1923) asserted that the "average norm" for psychopathology as the "statistic norm of being" is inadequate. The same has been said by Spaemann and Löw (1981, p. 284): "Health is itself a normative, teleological notion." It cannot mean the suitability of an organism for anything specific, rather "suitability in and of itself," judged by a standard of normality which is neither a statistical nor a utilitarian measure. If 99% of all people had headaches, headaches would still not be "normal." Accordingly, Blankenburg refers to the idea developed by Müller-Suur of the "actual individual norm" as the "individual norm of becoming which is restricted by the collective norm of becoming," an individual norm at which therapy is aimed (cited in Blankenburg 1971).

Philosophical anthropology in psychiatry – and psychiatry in general – cannot, therefore, exclude the problem of "normality" and its criteria, but rather must face the difficult challenge of noting a deviant cognitive and mental event in a manner which acknowledges and does not condemn, includes it in a scientific context, and takes this as a basis to suggest and develop further therapeutic treatment methods in collaboration with the patient.

In this respect, psychiatric anthropology is both a danger zone and an ethical challenge for the development of a nonjudgmental systematization and classification of fundamental anthropological conditions of cognitive psychology.

Thus the essential and very difficult task of providing a meta-theoretical background for the theory and practice of psychiatry falls to philosophical anthropology. Consequently, Sullivan states (1953) that there are only a few psychiatrists with a solid theoretical frame of reference within which to think about life problems, their origins, their reliable manifestations or relatively reliable improvements. What matters to him is the level of all common human existence, which is necessary for an explanation of mental disorders. The difficulty of such a concept, as Sullivan says, has its origin in the fact that psychiatry deals with life (Sullivan 1953), and the fact that this is not purely an academic matter is expressed by Karl Jaspers in the following way: "We must free ourselves from the idea that to philosophize is in itself essentially a matter for professors. It is a concern for humankind, clearly, under all conditions and circumstances" (Jaspers 1978, p. 112).

However, psychiatry as "a concern for humankind," in comparison to other medical disciplines, is more indebted to a philosophy such as this, because philosophical reflection frequently shows a close relationship with psychologically exceptional circumstances.

Philosophizing appears naturally among children and among the mentally ill. It is at times (seldom) as if the ties of universal disguises come off and a touching truth is spoken. Deeply distressing metaphysical revelations occur at the beginning of many mental illnesses. In their form and language, their quality is admittedly not without exception such that their expression gains objective significance, outside of cases such as the poet Hölderlin or the painter van Gogh. But anyone present cannot deny the impression that a covering is tearing open here, under which we usually lead our life. Many healthy people also experience uncannily deep meanings upon awakening from sleep, which are then lost again when fully awake (Jaspers 1978, p. 35f).

An understanding of the naturalness of human philosophical reflection, the breaking through of fundamental questions of human self-interpretation in psychiatry, is only possible in the context of our knowledge concerning the exceptional features of human selfhood, as developed by philosophical anthropology (von Weizsäcker 1982; Russell 1959).

2 History of Philosophical Anthropology

The whole 2500-year history of philosophy is like a single, large moment of growing human self-awareness.
JASPERS (1978, p. 112)

The account of the "moment" of self-discovery of the human mind characterized by Jaspers (see Snell 1986) would require an entire reference book of the history of philosophy (see, e.g. Windelband 1976; Krings 1973). Only a few key ideas can be set forth here to serve as guides.

Jaspers refers to philosophy as that "which concentrates, through which the person becomes himself, and in which he partakes of reality" (1978, p. 37). Spaemann and Löw (1981, p. 23) describe philosophy as "human self-understanding within the totality of reality." The history of philosophy – and with it the development of philosophical anthropology – describes the considerable transformations that human self-understanding has undergone in the past approximately 2500 years. Aristoteles' work *De anima* (384–322 B.C.; Aristoteles 1995) presents an important starting-point in this respect in thinking about the human psyche, as mental life is seen here as so lively that it is an irreducible phenomena which cannot be reduced to yet another basic category of knowledge.

Modern human self-interpretation, oriented to the development of consciousness, is related mainly to the *Meditations* of Descartes (1596–1650). Here Descartes (1641), in the pressing question of the certainty of reality, arrived at the irreducibility of the *cogito*, which was able to put an end to the infinite regress of doubt about possible fictional realities in that moment of coming to the inability to question doubt itself. Thus *cogito*, self-consciousness, is at the crux of knowledge in modern "subjectivistic" philosophical reflection and is certainly associated with the constitutive difficulty, reaching into the present, of the split between *cogitatio* and *extensio*, between consciousness and complex, organic unity, between soul and body, between mental and physical. For psychiatry, in particular, this dualism, which has governed thinking since Descartes in the form of the mind-body problem, represents a central challenge which is difficult to overcome (see Metzinger 1995).

Thereafter, a new philosophical foundation emerged with the method of "transcendental apperception" developed by Kant (1724–1804) in his *Critique of Pure Reason.* Here, the a priori conditions of the possibility of experience are questioned and a formal categorical analysis of the mental sphere is carried out, a structure that is decisive for the entire subsequent formation of theory about subjectivity and consciousness. Hersch (1989, p. 190) writes as follows: "Through Kant, the philosophical climate has decisively changed, not only in Germany, but quite generally. One can no longer reflect philosophically after Kant as one did before him." German idealism thus represents one of the possible reactions to Kantian philosophy.

With his *Phenomenology of Mind* in 1807 and his *Science of Logic* in 1912 (Hegel 1986), Hegel attempted in a highly structured way to reconcile intellectually all elements of existence with one another, namely, in the sense of a systematic structure in which all contradictory moments of reality appear as dialectical mediations of the universal mind; in contrast, the philosophical psychologist Franz Brentano proposed a rather modestly argued conception of the difference between mental and physical, albeit one which was fundamental for the further development of philosophical anthropology, namely the idea of "intentionality." In his work *Psychology from the Empirical Point of View,* published in 1874, he stated:

Each mental phenomena is characterized by what the scholars of the Middle Ages called the intentional (also probably mental) inner existence of an object, and which we, although without completely unambiguous

Authors' note: the original German word *Inexistenz* means *innere Existenz,* Engl.: "inner existence."

expressions, would call reference to content, direction toward an object (where no reality is to be understood) or immanent objectivity. Each (mental phenomenon) includes an object intentionally within itself, although not everything in a similar manner (Brentano 1874, p. 124f.).

Jaspers describes intentionality in the following way: "We are conscious of objects, intending them, directed toward them. It is a unique opposition, not comparable to any relationship between objects" (Jaspers 1978).

The Danish scholar, theologian, and philosopher Søren Kierkegaard (1813–1855), both referring to Hegel's systems construction of the absolute and very strongly rejecting it, developed a concept of the subject, decisive for the later philosophical development of existentialism, as a "synthesis of soul and body, carried by spirit" (Kierkegaard 1843). As Rohde (1992) emphasizes in his biography of the philosopher, Kierkegaard actively tried to oppose the disappearance of subjectivity in the perspectives of world history in the dominant Hegelian philosophy. His pioneering conception of subjective freedom is described in 1844 in his work *The Concept of Dread*. The fundamental ideas to understand here are "existence" and "moment" (see Hersch 1989), whereby the subject works his or her way through to the moment of the "reality of freedom," namely to the condition of "dread." Dread is not really to be understood as an emotional state, but rather as an existential condition, a form of existence, as an increased form of existence of the subject who is autonomous ("choosing the self"), in the paradoxical situation of the "leap" (see Sect. 3.3).

In addition to Franz Brentano, Kierkegaard can also be described as one of the founders of modern (existential) philosophical psychology. Whereas Kierkegaard mainly influenced the French school (Sartre, Merleau-Ponty, Camus), Bretano had an enormous effect on his student Husserl (1859–1938), who founded the school of "phenomenology," which is essential to the history of psychiatry (Husserl 1950).

"Phenomenological reduction" can be understood as attention to the "nature of the condition of things" and thus "things as phenomena": "the world is excluded by the method of reduction. The eye of the philosopher is directed back to consciousness, in which every sense develops (Hersch 1989, p. 190). The consequence of this, which the phenomenological analysis of the act of consciousness tried to describe, is how the "corresponding intentional object (that is, the consciousness correlate) is found" (Hersch 1989, p. 298).

An additional concept that is essential in philosophical psychology comes from the philosophy of language of Ludwig Wittgenstein (1889–1951), at the center of which is the philosophy of the "language game" (Wittgenstein 1984). The psychological and depth psychology aspects of the late philosophy of Wittgenstein were developed by Fischer (1991).

The significance of the philosophy of language for philosophical anthropology becomes clear if we acknowledge, as Jaspers did, the "universal character of speech," although speech appears as the "work of individuals": "Speech is one work among other human works, but of a unique character, because it is universal" (Jaspers 1978, p. 299). This means that the coming-to-one's-self of the person, described above as "philosophy," is only possible on the basis of this self-creating work of speech:

> It is the expression, the tool, the foundation of community, an independent work (even if only incidentally pursued in language art). These can all be called a language, but language itself is none of them in particular. In its essence it is not a peculiarity. Language is rather a work of the whole person. But if it is omnipresent as this work, where the person is effective and conscious of him- or herself, it is at the same time still vanishing, because it cannot itself be an appropriate object of attention. In its universality, it has not taken on a determined content as language, but everywhere the person is directed in and through language to the other. Where language itself becomes an object, it may be used superstitiously for supposedly magical effect, or used aesthetically as specific art material, or positivistically to be analyzed as one human product among others in words and grammar, in the study of motor and sensory functions of speech (Jaspers 1978, p. 300).

Very important contributions to philosophical anthropology were made by Arnold Gehlen (1904–1976), taking particular account of the components of action. For Gehlen (1966), a person – following the formulation of Friedrich Nietzsche – is a "non-determined animal," whereby Gehlen interprets human nature as "acting" insofar as it creates its world, precisely by means of the characteristic of openness to the world. This is possible for Gehlen on the basis of the problematic assumption for evolutionary biology of human beings as "defective" creatures (see Wetz 1994).

A fundamental concept of human self-interpretation for philosophical anthropology is also the work of Helmuth Plessner (1892–1985), who developed a graduated order of living things in his central concept of "positionality." In contrast to animals, which show a "centered positionality," humans live "positionally eccentrically" (Plessner 1970). As Wetz (1994, p. 249) emphasizes, "the individual lives as the center, insofar as he knows himself as the center. The animal rests in

itself, without knowing about itself. It lives and experiences, but it is not aware of its experiencing." The subjective competence of the individual for self-relating, accompanied by human beings' eccentric positionality, plays such a decisive role in psychiatry because disorders of this competence can lead to many and diverse psychiatric illnesses, such as persecution mania, sensitive psychiatric delusion of reference, and affective disorders (see Emrich 1992).

Gadamer (1972, p. 25) emphasizes the cultural openness in Plessner's conception:

From the eccentric conception of human liveliness then arises the differentiated ways in which he works out his eccentricity and which we call culture. ... Plessner summarizes all this in the expression that the person 'is embodied.' Here that other spring of human knowledge has its source and pours itself out in advance of natural science, and it has given and shaped for the naturalist the manifold contributions to knowledge about the person as a topic. For, thanks to this knowledge of the person by himself, 'science,' which seeks to understand everything accessible to it by methodological means, is confronted in a particular way with the topic, the human person. Its task of discovery is constantly brought home as one which is open into infinity.

For present-day conceptions of philosophical anthropology, French existentialism, as reflected in the work of Jean-Paul Sartre (1905–1980) and particularly in his major philosophical work *Being and Nothingness*, is especially meaningful. An immediate connection to Kierkegaard is unmistakable, especially with regard to the concept of freedom, as developed by Kierkegaard in *The Concept of Dread*, as well as the idea of "choosing the self," which is taken as the general theme by Kierkegaard in the work *Either – Or*. As Bertrand Russell (1959) emphasizes, in Sartre the existentialist view of human freedom is driven to the extreme; we are constantly choosing our own fate, and every new decision brings with it total obligation.

An additional aspect in Sartre's *Being and Nothingness*, important for psychiatric anthropology, is the phenomenological analysis of the "glance." As Sartre shows, the process of "looking at," which belongs to "my distances," means first objectifying the other. However, it is then shown in phenomenological analysis that indications of effectiveness arise with regard to Plessner's concept of eccentric positionality, insofar as the world view of the observer is "decentered" by the observed person being a subject: "The appearance of the other in the world thus corresponds to a motionless slipping of the entire microcosmos, a decentering of the world" (Sartre 1943). What is more, the observed person can, by the spontaneity of looking back, move the observer into being "shamed": "But shame is ... shame about oneself; it is the recognition of the fact that I am really this object which the other sees and judges. I can only be ashamed of my freedom, insofar as it escapes me and becomes a given object" (Sartre 1943).

A strengthening and radicalization of this analysis by Sartre of the interpersonal relationship of the mutual exchange of glances ensues in the philosophy of Emmanuel Lévinas (1905–1995), in which interpersonal relationships are represented as the philosophy of capturing the face. According to Lévinas' analysis in his major work *Totality and Infinity*, "looking at" means an act of "totalizing" in the sense of an "ontology of war." It is – in contrast to Sartre's position – only able to be transcended by a radical ontological change in the view of reality, namely by the appearance of the conception of "infinity." The dimension deduced with "face," with "the otherness of the other," is ultimately "language" for Lévinas, connected to truthfulness: "The epiphany of the face is itself a word of honor in a certain way. All language as exchange of verbal signs already relates to this original word of honor" (Lévinas 1987, p. 291). This view of responsibility in the interpersonal encounter plays a decisive role in psychiatry in for understanding the empathic aspect of the doctor–patient relationship (see Theunissen 1965, 1992, 1993).

3 General Cognitive Anthropology

3.1 Intentionality, Understanding, and Explanation

A basic problem in philosophy is the question of the difference between two possible questions: first, that of "why?," of the principle of causality, i.e. the question of the relationship between cause and effect; and second, the question "for what?," directed at the principle of purposefulness, of orientation toward purpose, of teleology. Natural science research has restricted itself most generally to developing causal mechanistic principles to explain natural processes, and this has resulted in decisive progress. According to Spaemann and Löw (1981, p. 284):

Thus medicine, for example, owes its enormous progress in modern times above all to the mechanistic examination of nature, to the discovery of causal connections. The question remains, however, whether the radical implementation of the reification of the human body does not in the end cause health once again to suffer.

Precisely in those scientific areas which have humanistic and therapeutic implications, teleological methods of explanation cannot be excluded.

Two explanatory models are given for the basic goal of asking the "why" question, as Spaemann and Löw (1981) emphasize. Both are ultimately aimed at increasing the degree of familiarity with outer reality which has been reduced by unexpected events (misunderstandings). One type of explanation is the mode of "understanding," and the other, the mode of "explanation." Karl Jaspers, in his *General Psychopathology* (Jaspers 1913), described understanding and explanation as the two fundamental ways of accessing the psychological course of events, standing opposite one another, one being the hermeneutic, empathic way and the other the scientific, causal-mechanistic process of explanation. It is then emphasized that both these methods have to be used in psychiatry to achieve a balanced relationship. According to Spaemann and Löw (1981), the "process of understanding" describes the "reestablishment of intimacy through the reconstruction of an intentional structure," i.e. the "intentionality structure" of the other, the acting person, is comprehended psychologically. The "process of explanation" on the other hand is interpreted as the "reestablishment of intimacy by specification of a conformity to natural law" (Spaemann and Löw, pp. 17, 19).

Thus the idea of intentionality has played a decisive role in the development of philosophical psychology since the end of the nineteenth century up to the present. Mimetic processes of psychological interaction, as they will be described in detail below, are based on the reconstruction of the psychological intentionality of the other and are connected with it through the mode of "empathic understanding."

One of the main difficulties for present-day cognitive anthropology is the question of the connection between understanding and explanation. The psychoanalytic project of Sigmund Freud aimed to reduce psychological understanding and causal explanation to a common denominator, i.e. psychoanalysis should simultaneously understand and explain. It should be both hermeneutics and neurophysiology. However, Wittgenstein had already objected that Freud confuses cause and motive. His reasoning goes along the same line as the strict separation between understanding and explanation made by Jaspers, which can be formulated in line with Fischer (1991, p. 114) in Wittgenstein's sense as follows: "Physiological or neurological causes are completely irrelevant to the question of the meaning of an action." In agreement with this, we can see that current basic research in neuroscience has still not been able to develop a convincing neurophysiological model for the origin of semantics. Only the elucidation of a "meaning generating code" (see Emrich 1990) would also be able to lead to the standardization of understanding and explanation in the realm of the psychological, because the theory of psychosis (see below) means that, at present, a dual way of consideration is still necessary, in which understanding and explanation are used in parallel. From the concept of intentionality, it can be said, as Wulff (1993) has done, that a psychotic event represents a "form of intentionality frustrating itself." This means that the establishment of meaningful performance is disturbed in psychosis, a fact which, according to Fischer (1991), can be represented in a psychotic event as "altered grammar."

3.2 Constructivity and Consciousness

As the twentieth century draws to an end, the question of human existence has become essentially that of human *consciousness*. Thus, as explained in the introduction to the anthology *Theory of Subjectivity* by Horstmann et al. (1987, p. 9):

> The theme of subjectivity in the philosophy of this century is one of the areas of greatest differences of opinion and most severe conflict. While individual thinkers in the course of modern tradition still tried to defend subjectivity as the guarantor of absolute transparency, freedom, and foundation of all possible discovery, other philosophers proposed the complete renunciation of the acceptance of any entity with this name. The simplified label 'philosophy of consciousness' represents what remains of the history of this dispute.

Cognitive anthropology is at the center of the question about the individual, and the contributions it makes to our understanding of psychiatric illness can be verified. The characteristic of "constructivity" is generally attributed to consciousness-generating systems (see Roth 1992). According to Roth, the internal reality generated through the constructivity of the central nervous system (CNS) is judged by processes of assessment and, of course, on the basis of previous experiences. This internal process of assessment seems to be the source of consciousness: "Sensory perceptions only become conscious if they have been assessed in the light of earlier experiences" (Roth 1994, p. 310).

The conception giving rise to neurobiological constructivism here is part of that realm of a collective notion now common which is specially designed to emphasize a perspective connected with two alternative models. Either the human subject is seen as more of a basin, i.e. as a receptive system for processing information contained in signals entering from out-

side, or the subject is interpreted more strongly in the "constructivist" sense as a source, precisely in the way that a "world design" is generated, which can be corrected or modified in accordance with all the incoming data. Thus we can differentiate between a more psychological, a physiological, and a philosophical form of constructivism.

Psychological constructivism, e.g. that of Watzlawick, turns out to be particularly the projective character of subjective reality. For Watzlawick (1985), the decisive point is the "reality-creating fiction," also called "as-if fiction" following the *Philosophy of the As-If* by Hans Vaihinger (1927). Philosophical constructivism is traced back by von Glasersfeld (1985) to the Italian Renaissance philosopher Giambattista Vico, who writes in his work *De antiquissima Italorum sapientia* (1710) as follows: "If the senses are 'active' abilities, then it follows that we make colors by seeing, tastes by tasting, sounds by hearing, cold and hot by touching" (Vico 1710; see also von Glasersfeld 1985).

For physiological constructivism, perception is a "confirmation of previously dreamed reality," whereby this hypothesis of prestructured reality is once again based each time on previous experimental materials (Singer 1994; Roth 1992).

As Kurthen (1990, p. 23) emphasizes, what is called 'consciousness' is "nothing uniform, but rather a complex of heterogeneous phenomena such as awareness, carefulness, self-reflection, cognitive capability, and other things." From the point of view of evolutionary biology, the question of the origin of this complex event "consciousness" is interpreted as a reconstructible process of development, explainable by paleoanthropological and cultural-anthropological studies.

According to Donald (1991), the basis of the development, as Wolfgang Köhler's chimpanzee experiments show, is episodic memory, with the help of which these animals also show problem-solving behavior, e.g. using boxes to reach bananas. The next evolutionary step assumed by Donald is the transition from "episodic to mimetic culture." By this he understands an archaic, but already human culture in real ways in the sense of the transition from apes to humans. Donald applies this to *Homo erectus*, a species that appeared about 1.5 million years ago and that was already able to make a wide variety of complicated tools and to move far away from Africa, its place of origin. *Homo erectus* was able to use fire, cook food, and maintain complex, stable societies, within which cooperation was highly significant, especially in communal hunting, teaching the use of tools, etc. It is accepted that a cognitive ability had developed in *Homo erectus* that could not yet really be described as "language." It is hypothesized that "mimesis" represents a cognitive ability which has led from episodic memory to higher forms of communication and representation of cognitive meanings.

Mimesis makes it possible to use symbolic gestures in social communication or artistic expression. Mimesis is still used today, especially to transmit social and practical abilities (see Webb 1995).

The third stage, which first appeared in *Homo sapiens*, is the mythical stage, and the fourth, the theoretical stage. In the mythical stage, language is developed and used to build up narrative structures (with the goal of emphasizing topics taken from individual episodes and conveying their historical connections, topics which are good for interpreting human life). Donald assumes by this that these myths play an important role in the formation and stabilization of group identity (see Webb 1995).

In contrast to this, the modern, "theoretical" structure of consciousness is bound up with external symbolic representation. Writing, painting, the use of graphics, etc. are part of this. Voegelin (1988) speaks in this sense of a noetic differentiation of consciousness.

3.3 Anthropology of Cognition–Emotion Coupling

A basic experience of human life consists in the fact that humans not only have perceptions and thoughts, but that they also have feelings that are reducible neither to thoughts nor to perceptions. What is noteworthy in the world of emotions is that it is beyond the conceptual, i.e. it can only be described incompletely by thinking. Insofar as quite important emotional states are conceptually transcendent phenomena for psychiatry, Wittgenstein (1984, p. 107) analyzed pain and regarded it not as an "incident in the world," but described it as a subjective quantity in the sense of "there are toothaches if one has them" ("the question 'Are you sure that *you* are the one who has pain?' would be nonsense"). Thus emotional states belong to the subjective universal realm.

With computer simulations of cognitive processes and perceptive capabilities, much has been learned in recent years about the way in which information processing functions in the brain. In particular, it has been shown that information is not really generated and processed in the brain, but rather significance is, i.e. biological information is highly dependent on context and, finally, it is a matter of internal assessments. However, these assessments are significantly released in the form of emotions. Thus, for example, the cognition researcher and neurobiologist Edelman (1987) showed in robotics experiments that a connectionistically built sensorimotor robot, which he named "Darwin II," was only functional if an "internal value-world" was incorporated into it, i.e. internal context-related

assessment quantities that had a quasi emotional, simulating character. The problem of perception–emotion coupling is thus a central question of cognitive anthropology.

To explain transmissions between perception and emotion, McLean's model of the "triune brain," the three-part brain, is generally referred to; this model assumes that, as a consequence of the mammalian revolution, three structures in the CNS have settled down more or less on top of each another: the first, the "reptilian brain," is sited in the brain stem and is responsible for vegetative functions; the second, the limbic system, is situated above the reptilian brain and is related to the primeval mammalian brain; and the third are the neocortical structures (McLean 1982). The connections between the cortical association structures and the limbic system are thus fundamental to the question of the nature of perception–emotion coupling. While McLean still emphasized the hermetic character of the boundaries between the systems, greater value is certainly now placed on research into the transmissions between the cortical and limbic structures (see, e.g. Roth 1992, 1994).

The discovery that the olfactory brain, the rhinencephalon, probably played a role in leading the way in cortical evolution in higher mammals is especially meaningful from the biological evolutionary perspective. Here, there seems to be a direct relationship between olfactory brain functions and the "reward system" in the basal forebrain, which is decisively significant in addictive behavior, for instance, as experiments with microinjections and electrode self-stimulation have shown. In addition, it performs important functions in the regulation of food supply.

There are two other connections between cortical structures and the limbic system that neurophysiology has been able to characterize well in recent years. The first, the so-called hippocampal comparator structures, facilitate important context-dependent internal assessments. The second, which is connected to these structures, is the nucleus amygdala, which is sited in the temporal lobe and whose significance in the regulation of affect has only become clear in the last few years.

According to neuropsychological investigations, which have been pushed ahead by the English psychologists Gray and Rawlins (1986), in particular, an important function of hippocampal structures is generated with the particular situation of a compatible internal "model which runs along with the world" and particular comparator functions carried out between "expected reality" and the incoming sensory data. This comparator function leads to the generation of an internal "alarm signal" when a critical threshold is exceeded, which is transmitted to the limbic system as an anxiety-triggering signal. On the basis of this idea, which is well supported by animal experiments and neuropsychology, it is assumed that anxiety-relieving medications raise the threshold at which the internal alarm signal appears or reduce the alarm signal amplitude, so that context-dependent anxiety stimuli are less likely to appear.

From this concept, a self-consistent neuropsychological and biochemical theory of anxiety not only can be developed, but the high number of γ-aminobutyric acid (GABA)-benzodiazepine receptor complexes in the hippocampus is plausible. In agreement with this theory, it can be shown that patients with benzodiazepine dependency show high anxiety and emotion scores in assessment scales by self and others after withdrawal and an overintensity of perceptions, e.g. oversensitivity to light and noise and hyperarousal (see Apelt and Emrich 1990).

These hippocampal comparator functions are closely related to the function of the nucleus amygdala lying in the temporal cortex. In particular, the American author Aggleton (1992) was able to show that an important function of the nucleus amygdala is that it exercises a "gate function" between the cortical association structures and the various perception systems. Disorders of this function can bring about abrupt emotional changes and even a crazed rampage, etc.

The neuropsychological idea of cognition–emotion coupling, represented in this way, can also be compared to a similar concept based on the anthropology of language. Language, understood in a universal sense not as something lexical and grammatical, but as a general expressive ability, is the area in which cognition–emotion coupling takes place mentally. A possible interpretation of this arises on the basis of the "mimetic" coupling of emotion developed by Girard (1992), within which the "language" of the mimetic processes of interaction within socioculturally conditioned hierarchies of values brings out the internal fine-tuning assignment of emotions to cognitive achievements. Since this fine-tuning process is of considerable importance for the appearance or non-appearance of psychiatric illnesses, these events play a central role in psychiatric anthropology.

4 Evolutionary Anthropology

The way in which human beings are seen in German intellectual history is greatly influenced by the concept of the defective human being. Plessner (1970), following Herder (1772), Gehlen (1966), and other authors, bases his view of *Homo sapiens* on old models as a being who is deficient not only morally, but also

biologically. Bischof (1985, p. 513) suspects that philosophy and the social sciences are trying, by means of the myth of the defective being, "to escape the biologically inherited burden, in which one mourns its alleged loss." The Persian physician Avicenna, originally Ibn Sina, one of the great Arabic-speaking interpreters of classical Greek medicine, characterizes human beings as biologically deficient beings; hence physicians constantly have to take countermeasures (Schipperges 1990). In those cultures influenced by Christianity, the concept of "original sin," the fundamental moral inferiority of Adam, Eve, and their descendants, corresponds to that of physical inferiority. Similar themes are found in the traditions of other religions.

Especially in modern medicine, the concept of the deficient being continues to have an effect. Clinical textbooks are necessarily concerned with disorders of the human organism, which is obviously inclined to malfunction. It is also beginning to become increasingly clear which individual gene defects have which pathological consequences, and where precisely described disorders have somatic or psychological effects. Indeed, the wonder of organic life, developed by evolution and maintained in a fine balance of functioning by an incredible diversity of extremely complex biocybernetic control processes, is not usually part of medicine's field of vision.

Further development, above all based on the evolutionary biology of Darwin (1859, 1872, 1871), has yielded advances in recent decades, especially in the precise formulation of theoretical positions and development of hypotheses and models. Their inherent predictive power makes predictions about even human behavior possible or at least can make other good suggestions for empirical investigations.

Alexander (1974) and some other authors (see vol. 8, special edition of *Ethology and Sociobiology*, 1987; also Ploog 1993; Voland and Voland 1989; Nesse 1994; Schelde 1994; Schelde and Hertz 1994; Marks and Nesse 1994) have drawn attention to a common point of intersection between psychology, psychiatry, and evolution, i.e. there are biologically related perspectives where the observation and evaluation of basic conflicts and disorders in the phylogenetic or ontogenetic dimensions of relational development are concerned. The current debate about the observable and real basis of adaptation is also significant for psychiatry.

A mark of the evolutionary and biological interpretation of the phenomenon of life is the search for functionality, for adaptive ability brought about (in the classical manner) through mutation and selection. That the past explains the present is a central statement of evolutionary biology, which, interestingly enough, like history or archeology, is a discipline in which events that occurred in the distant past have explanatory power.

In recent years, the term "environment of evolutionary adaptedness" (EEA) has gained acceptance for this way of observing. This refers to a scenario established in the Pleistocene age, during which, 1.5 million years ago, the first representative of the genus *Homo* arose, whose descendants were our Stone-Age ancestors. The fact that we exist proves that they not only survived the climatic, ecological, social, psychological, and cognitive kinds of challenges of the time, but also had sufficient descendants. It is also quite likely that this "evolutionary adaptation to the environment" in the form of abilities to adapt, which are typical for our species, continues in us. This is something that is generally accepted for the morphological, anatomical features of our phenotype, even by critics of human evolutionary biology. These widely uncontentious areas include the biped with its hand permanently freed (measured by subhuman primates) from the requirements of locomotion, the (possibly associated) further development of the neocortex, and the complete picture of *Homo sapiens* and the externally rather similar characteristics of human beings.

The argument reaching far back into Western history about "nature versus nurture," about genetically conditioned structure versus adaptation to the environment achieved by learning, is explosive where psychosocial and/or cognitive domains are concerned, i.e. the area which was traditionally investigated and interpreted in the humanistic approach. Following advances in knowledge in general evolutionary biology and in human ethology (Eibl-Eibesfeldt 1984), human behavioral biology (Hassenstein 1973), and evolutionary anthropology (Durham 1992) and psychology (Tooby and Cosmides 1989, 1990), in particular, it can be assumed that this kind of research will lead to future discoveries of additional ways of perceiving, thinking, and behaving based on primarily biological mechanisms. This in no diminishes the humanistic approach to understanding the expression of human life. On the contrary, the more knowledge we obtain based on biology and evolutionary biology, the clearer the puzzles of our existence will become, puzzles that are unsolvable or not yet solvable (Chalmers 1996; on the synthesis of evolutionary biology and the social and cultural sciences, see Schiefenhövel et al. 1994).

In addition to wide agreement in the fundamental accuracy of the Darwinian hypothesis, contradictory positions are also taken up. For example, at present the real basis of adaptive ways of human perception and behavior is being discussed. Tooby and Cosmides (1989, 1990) and other authors assume that a very large number of specific, genetically mediated programs are effective, which can be described using a Darwinian type of psychology and must have been found as

universal characteristics in all (or at least most) members of our species, independent of geography and culture.

Other evolutionary biologists (see MacDonald 1991) assume that a considerably limited set of genetically mediated perceptual and behavioral tendencies suffice in order for humans to behave "adaptively" in particular situations. MacDonald postulates that, instead of delicate domain-specific psychological mechanisms for coping with the many and diverse daily problems, "evolved motive dispositions," which emerge evolutionarily as motivational dispositions, guide our perception and behavior in more general ways. He and other authors also point out that the evolution of *Homo sapiens* is not over and that, because of the separate development of various populations on earth – which according to Erikson (1966) takes place as a kind of co-evolution between biology and culture, as "cultural pseudospeciation" – genetically explainable differences in behavioral repertory can also occur between populations.

The search for particular adaptations and basic underlying mechanisms inspired by evolutionary biology has also led psychiatry to interesting new perspectives, including the idea that psychiatric illnesses can be interpreted as excessive forms of evolutionarily adaptive biological achievements. Thus philosophical anthropology also gains in significance precisely from the evolutionary biological point of view as a culturally related and intercultural science.

Phenomenological–Anthropological Psychiatry

Translator: O.P. Wiggins, Jr.

1 Introduction

A number of overviews have been published in periodicals and as book chapters on phenomenological-anthropological psychiatry (Boss 1951; Kuhn 1963; Lanteri-Laura 1963; Natanson 1963; Straus 1963; Zutt 1963a,b; Edie 1966; Wyss 1976; Blankenburg 1977, 1980a,b, 1991b; Rovaletti 1994; Mooij 1995; Figueroa-Cave 1996a,b, 1997a,b; Kimura 1996; Naudin et al. 1997; Schmidt-Degenhard 1997). Presentations of the field can also be found in several monographs (Spiegelberg 1972; Tatossian 1979; Kruger 1981; De Koning and Jenner 1982; Tellenbach 1987; Herzog and Graumann 1991; Kimura 1997; Dörr-Zegers 1995; Lopes 1996; Fédida and Schotte 1991; Braun 1992-1994; Holzhey-Kunz 1994a; Passie 1995). The sources of these selected overviews confirm the impression that, although the approaches subsumed under the title "phenomenological-anthropological psychiatry" had their origins largely in German-speaking areas, they have now gained a foothold in France and Italy, in Spanish-speaking countries, in Japan, and most recently in the United States. Moreover, the number of works in this field has grown steadily during the course of the century.

In this chapter, various approaches will be considered, ranging from the purely phenomenological, through the phenomenological-anthropological, to the purely anthropological. Daseinsanalytic and existential approaches can be understood as phenomenological, but not always anthropological, in their methods.

2 Anthropological Approaches

Like the concept of "phenomenology," the concept of "anthropology" can have very different meanings. The concept of anthropology, in particular, is extremely broad, and in English it is only seldom used in the sense in which it is used here. In the natural sciences, anthropology is concerned with the natural history of human beings as a species, while in the field of ethnology and cultural anthropology, it relies mainly on sociological and socio-psychological methods.

For anthropological medicine and above all for phenomenological anthropological psychiatry, the philosophical anthropology of M. Scheler (1976), H. Plessner (1928), A. Gehlen (1966), F.J.J. Buytendijk (1967), the life-philosophy of H. Bergson, W. Dilthey, L. Klages, and O.F. Bollnow, and the phenomenology of E. Husserl (1950), the fundamental ontology of M. Heidegger (1963), and the existential philosophies of J.-P. Sartre (1943), M. Merleau-Ponty (1966), E. Levinas, and P. Ricoeur were of primary significance. Until quite recently, the phenomenological-anthropological orientation in psychiatry was most strongly inspired by M. Heidegger (1963) and E. Husserl (1950) and by the French phenomenologists J.-P. Sartre (1943) and M. Merleau-Ponty (1966). It was established primarily by L. Binswanger (1955a,b, 1958, 1960, 1965, 1992, 1994), E. Straus (1963, 1978a,b), and V. von Gebsattel (1954). Other chief representatives of the older generation include J. Zutt (1963a,b, 1958), R. Kuhn (1963), von Baeyer (1978), W. Blankenburg (1969, 1970, 1971, 1972, 1977, 1979a,b, 1980a,b, 1981, 1982, 1983, 1987, 1989, 1980, 1991a,b, 1995, 1997), H. Tellenbach (1968, 1983), Bräutigam (1961), M. Boss (1951), G. Condrau (1963, 1990, 1992), D. Wyss (1973, 1976, 1990), Callieri and Castellani (1981), B. Kimura (1975, 1980, 1982, 1995, 1996, 1997), L. Lanteri-Laura (1963, 1982), H. Kunz (1962), von Uslar (1989a,b, 1991), and Tatossian (1979, 1996).

Anthropological approaches were introduced in internal medicine by V. von Weizsäcker (1986) and others and are to be found in the existential analysis of V.E. Frankl (1959, 1984), in the psychoanalysis of P. Schilder (1968) and J. Lacan, and in the humanistic psychology and therapeutic methods of Rogers (1973). Influences of phenomenological-anthropological psychiatry are also recognizable in the structural-dynamic approach of Janzarik (1959, 1988) and in the interactionist psychopathology of J. Glatzel (1981a,b, 1998). Heimann (1994) pleads for a neurobiological anthropology.

Binswanger called his (at that time) new methodological approach "phenomenological anthropology." However, he also understood his later "daseinsanalysis" as anthropological and thus sought to distinguish it as a form of existential anthropology from Heidegger's daseinsanalytic approach with its philosophical intention as a fundamental ontology.

In attempting to point out the most important goals of an anthropological approach in psychiatry, it must be emphasized that, with regard to method, this should be understood as almost exclusively phenomenological. The great interest in present ethical problems not only in psychiatry but also in medicine in general entails the danger that the anthropological approach will be understood primarily as simply an ethical entreaty or appeal to deal with patients in a humane way, sympathizing with their affliction. That, however, would not require us to move along a new path of psychopathological knowledge. The humanization of psychiatry is certainly the ultimate goal of all anthropological endeavors in psychiatry, but this ought to occur by way of a methodology that is appropriate for the essence of human beings and a corresponding

understanding of psychiatric disorders. Because psychiatry cannot disregard the human being as a whole, i.e., in his or her individuality, subjectivity, freedom, and historicalness, it poses the question of how psychiatry as a science of mentally ill human beings is possible. In this way, the anthropological approach is connected with the general problem of securing a high-quality scientific method that is adequate to deal with its subject matter.

Phenomenological–anthropological psychiatry makes the essence of human existence the locus of interpretation and that which is human in us the organon of experience (Blankenburg 1979b). However, even then, we are not concerned with human existence in its entirety in the sense of defining all meaningful content. According to Jaspers (1965), such an exhaustive definition cannot be achieved, nor can it be an object of scientific psychopathology. Instead, we are concerned with the significance of formal determinations of human existence for an understanding of the essence of psychiatric disorders. Only in this way can we prevent an anthropological approach from deteriorating into a *Weltanschauung*.

The issue of an appropriate methodology for psychiatric patients and their disorders continually creates a methodological openness that allows us to achieve two goals: it allows us to steer clear of a one-sided anthropological or ontological reductionism, and it makes it possible for us to recontextualize the objects of the individual objectivating sciences, which out of methodological necessity have to reduce their objects. It is also possible in this way to provide new impetus for research in the field of phenomenological–anthropological psychiatry and to initiate new therapeutic approaches.

Since this approach can allocate the objectivating sciences their epistemic places in psychiatry and can thus correlate them with one another, it is the indispensable field of basic principles in psychiatry, as Kisker (1964), Blankenburg (1991b), and Tatossian (1996) have pointed out. Moreover, outside the realm of psychiatric illnesses, it is hardly possible to introduce existential border experiences into our understanding of the essence of human beings. By doing this, the approach also has important repercussions on philosophical anthropology, a field from which it also draws inspiration.

At the center of all anthropological approaches in medicine stands the concept of person and hence of his or her world. The person is understood as the subject in the relation of the human being to the world and as the irreducible center of intentional acts. Hegel's statement that "individuality is that which is its world as its own" (Hegel 1952) thus serves as a leitmotiv in the research by Binswanger and in other phenomenological–anthropological approaches. If we wished to specify the central themes of more recent phenomenological–anthropological approaches, we would have to mention above all that of the self or identity, role (Blankenburg and Haltenhoff 1994; Kraus 1977, 1980a, 1982a,b, 1996c,d, 1997b), and the body (Blankenburg and Haltenhoff 1994; Blankenburg 1983, 1995; Fuchs 1998; Northoff et al. 1992; Schmoll and Koch 1989; Schmitz 1987; Schmoll 1992) ("embodiment") as well as time and space (see below) in their significance for various psychiatric illnesses and for various therapeutic approaches.

Phenomenological–anthropological approaches, in particular, including that of an existential–anthropological orientation, focus on the attempt to understand and describe schizophrenic, melancholic, phobic, anankastic, manic, and other patients on the basis of a priori structures of human existence. Here, two distinct directions can be seen. The first attempts to understand psychopathological phenomena by comparing them with normal psychological phenomena, e.g., by comparing delusion with the imagination of dreams and oneiric phenomena with creative imagination (Schmidt-Degenhard 1986, 1991, 1994, 1995) or with archaic or paleological encounters with reality. Both neurotic and psychotic signs are thus usually conceived merely as intensifications of normal forms of experience.

The second direction taken by phenomenological–anthropological research was developed by Binswanger, in particular. He conceived forms of delusion, schizophrenia, mania, depression, neurosis, psychopathy, etc., as possible modifications (grounded in the essence of human world- and self-relationships) or as "factual" (qualitative) modifications of the "a priori uncovered" structure of being-in-the-world or of *Dasein*. This procedure disregards for the time being the fact that what is at issue here are forms of mental or psychic illness.

Although here the distinction between health and illness is undercut, these analyses, as I will try to point out later, are not without significance for psychiatric classification, because this second direction shows how patients with various disorders differ from healthy individuals and from one another. In other words, on the basis of an understanding of the essence of "psychiatric disorders" such as this, the issue of psychopathological entities can be addressed anew (see below).

Binswanger's approach (1955b) has proved to be especially fruitful by delineating the anthropological proportions of a height and breadth dimension in human existence. Other authors (e.g., Blankenburg 1972, 1980a,b; Kraus 1977), following his example, have expanded this to include additional proportions such as self-realization and world-realization, individuation and community-relationship, tolerance of

ambiguity and intolerance of ambiguity, over-identification and under-identification, etc. The particular advantage of this way of looking at things is, as Blankenburg (1980a,b) has shown, that what is psychopathologically abnormal is not measured only by one norm, be it a real, ideal, or mean norm, by which the abnormal manifests itself as such. Instead, both the "abnormal" and the "normal" are located in a polar field based on ideal norms that oppose one another, a field in which "deviations" can always occur from at least two sides. Thus no absolute essential norm is posited, but rather different proportions are possible, even in the domain of the nonpathological. A possible variability in the measure therefore exists which is significant for transcultural investigations with regard to the culture-specific relativity of psychiatric abnormality, among other things.

However, as Blankenburg has shown (1981, 1987), a really new way of viewing psychopathological phenomena results not from merely seeing these phenomena under the aspect of a deficiency of particular structures and functions characteristic of human existence, but rather from a dialectical perspective. From a dialectical point of view, delusion, for example, is conceived positively as what happens when one of the integrating roots of human reality becomes independent, while in healthy individuals these roots are integrated. Thus, according to Blankenburg (1987), a theory of delusion can be referred to as "anthropological" only if it lies in the essence of reality-founding intentional acts to be able to go off the rails into delusion. In other words, the normal formation of representations and judgments must be able to be portrayed as a continually negated *in status nascendi* formation of delusion.

Compared with this, it is evident that a completely different understanding of anthropological aspects in psychiatry is envisioned when the view is advocated that structures that are in themselves alien to meaning are filled with anthropological content in psychosis simply because of the "anthropological matrix" (Weitbrecht 1971). The problem of all anthropological approaches is whether, with regard to anthropological bases (*Radikale*), only a quantitative abnormality or also (and particularly) a qualitative abnormality can be conceived and described.

3 Phenomenological Methods

Anthropologically oriented psychiatry employs chiefly phenomenological methods (Strasser 1964; Spiegelberg 1972; Herzog and Graumann 1991; Waldenfels 1992; Azorin 1996; Embree et al. 1997; Gros-Azorin 1997). "Phenomenological" and "phenomenology" are concepts which are often used in psychiatry in different ways. In phenomenological-anthropological psychiatry, the emphasis is on the methodological aspects of these concepts in the sense of a label for a definite theory of methods in psychiatry. The ambiguity of the concept of phenomenon goes back to Greek antiquity, where a phenomenon is, on the one hand, that which is open to view and, on the other hand, that which appears to be something which it is not. A different understanding of phenomenon is found when, as in medicine, people talk about phenomena of illnesses or symptoms of illnesses. Here the phenomena, which are called symptoms, indicate something, namely, an illness, which does not manifest itself as such. In contrast, phenomena in phenomenological-anthropological and daseinsanalytic-existenzanalytic psychiatry always means that which shows itself in itself. The usually very broad, promiscuous use of the terms phenomena and symptoms is therefore not permissible in this form of psychiatry.

For Heidegger (1963, p. 34), phenomenology means "to let that which shows itself as it shows itself from itself be seen from itself." That "which shows itself in itself" can be understood in a twofold sense - on the one hand as the manifest, the indubitably observed, and on the other hand as that which has yet to appear and therefore must still be elicited.

Blankenburg (1991b) pointed out this double meaning of the concept of phenomenon, which has evidently led to different phenomenological approaches but also to many misunderstandings. Phenomenology in the first sense is usually understood as descriptive phenomenology, e.g., that of Jaspers. In this sense, "phenomenological" is equated with "descriptive." On the other hand, phenomenology as the science that aims to make the logos of phenomena visible and to demonstrate the essence of experiencing and structures of experience has primarily become significant in the various approaches of hermeneutic psychiatry.

In the following, in carefully considering the details of different phenomenological approaches - which can be classified as descriptive, eidetic-essentially scientific, constitutive-phenomenological, daseins- and existenzanalytic - further distinctions in the meaning of the concept of phenomena are indicated. The important discovery of the meaning-establishing significance of the subject in phenomenology has led to a polarization of the concept of phenomena such that the focus is sometimes on the subjective meaning of phenomena, i.e., reception by the subject (e.g., Husserl 1950; Sartre 1943), and at other times on the objective meaning of phenomena, as the "self-showing" of the object (e.g., Heidegger).

4 Phenomenological Approaches

4.1 Descriptive Phenomenology

In common with all the other approaches that have been mentioned, Jaspers' descriptive phenomenology (1965) refrains from all theoretical presuppositions. Jaspers' phenomenological approach became significant for psychiatry because in it "the subjective appearances of the sick mental life" (p. 47), i.e., the subjective symptoms as opposed to the objective ones, achieved due importance in psychiatry. Compared with the currently prevailing "externalized approach," i.e., a line of research oriented chiefly to external observations of data as these are deposited in diagnostic glossaries and classifications of psychiatric pictures of disorders, Jaspers' phenomenology seems to present a challenge even now and increasingly so (Schwartz and Wiggins 1987; Wiggins et al. 1992).

Descriptive phenomenology in Jaspers' sense is based methodologically on the intuitive presentation (*Vergegenwärtigung*) of the other person's mental life through a self-transposal into the patient in the sense of an empathic understanding. In this manner, Jaspers arrives at the forms in which that which the patient experiences is given.

Since, unlike my originary experience of my own mental life, patients' mental lives are always mediated through their interpretations, a problem arises which Jaspers overlooks or does not recognize: namely, how the other person's mind can be made accessible to the investigator (Schäfer 1996). For this reason, he is unable to recognize the importance of the processes of mutual understanding for diagnostic inquiry as this has been worked out in the constitution-phenomenological approaches and also in Glatzels' interactional psychopathology (1978, 1981a).

The influence of Husserl's phenomenology on that of Jaspers has been surveyed by Wiggins et al. (1992) and Wiggins and Schwartz (1997). While Jaspers wanted to contrast his phenomenology with eidetic and constitution-phenomenological approaches in Husserl's sense, his writings also contain essence-phenomenological insights and a methodological procedure which follows Husserl by varying individual psychopathological phenomena in order to work out what is identical in the pattern of the eidetic (Schäfer 1996). This is shown clearly in his analysis of the essence of the hysterical, for example. The emphasis on the form as opposed to the content, i.e., a formal taxonomy of modalities of the experienced independent of any nosology, which Jaspers inaugurated and which is so important for psychiatry is a further agreement with Husserl's phenomenology. Differences between the two phenomenologies have been set out by Blankenburg (1980b, 1991b), among others.

4.2 Eidetic-Essence-Phenomenological and Constitution-Phenomenological Approaches

The significance of Husserl's phenomenology for psychiatry lies in its particular empirical access to the experiences of the world-situated subject. According to Husserl, among the empirical "objective sciences there is also a science of subjectivity, but this is a science of the objective subjectivity which belongs to the world" (1950, p. 68). In this statement it already becomes clear that, for Husserl, consciousness is not, as it is in the natural sciences understanding of it, a kind of container, but rather consciousness constantly goes beyond itself toward things or toward the world. Consciousness is characterized by a being outside of itself with things. When it goes beyond itself, consciousness also goes beyond things toward the unity of a meaning. This going beyond Husserl calls "transcendence" (1950). Consciousness is therefore transcendence. The going beyond occurs in intentional acts which are at the same time constitutive acts because, through them, objects are constituted.

Because consciousness is always directed, intentionality (which is not to be confused with purpose) is characterized as the mode of being of consciousness. Intentionality forms a unity with what is produced by it. Because "seeing" and "the seen" cannot be separated from one another, phenomena, for Husserl, are nothing other than "consciousness of," the appearance of the thing. Husserl's phenomenology draws its empirical claim from the evidence of what is immediately given in consciousness. Like the evidence of the *ego cogito* for Descartes, every originary perception, for Husserl, is evident, i.e., "unquestionable" ("*selbstverständlich*"). Evidence does not, according to Szilasi's interpretation of Husserl (1959), supervene on the content of experience. Rather to be "evident" and to be "experienced" (*erfahren*) are identical designations.

What in psychiatry and psychology are designated as eidetic- or essential-phenomenological and also qualitative methods are often only loosely connected to what Husserl understood by "eidetic" (1950). Husserl's methodological process of free imaginative variation allows us to get from a fact to the essence of a fact, from a sensuous to a categorial intuition. In playing through various conditions of experience and contexts of experience, we can advance to the essence of a thing, i.e., to what asserts itself as invariant (see Waldenfels 1992). The goal of eidetic variation is to arrive at the

unity which encompasses all possible factual divergences and all individual cases.

Thus a great number of hysterical phenomena can be thrown into relief in a unified essence as a "seeming instead of being" (to express it in a formula) (Jaspers 1965). Through the comparison of psychopathological phenomena with one another and with comparable normal phenomena, a differential phenomenology of the pathological arises. In this phenomenology, it is less a question of the "what" than of the "how" of an experience, i.e., of the modes of givenness of a hallucinatory experience, for example (Merleau-Ponty 1966; van den Berg 1982; Naudin 1997; Kraus 1994a; Silva and Silva 1975).

Constitutive phenomenology, when it applies the so-called transcendental or phenomenological epoché (bracketing), goes beyond the previously mentioned descriptive and essential-phenomenological approaches by not only thematizing the "what" of that which appears, but also analyzing the occurrence of the "something as something" (Waldenfels 1992, p. 31). The eidetic reduction to the essence of a thing (*Sache*) takes place in a believing in the being of the real existence of the world and things (*Dinge*) independently of an intending subject; in the transcendental reduction, however, one refrains from this belief in being. "Transcendental" means precisely this disregarding of the mundane contents of acts of consciousness. Through the bracketing (epoché) of the objectives intended in the intentional acts, the conscious acts as such, i.e., the synthetic accomplishments of constituting consciousness in its peculiarity, should be able to be investigated. The object of investigation here is not the factual experiencing but rather the transcendental conditions for the possibility of experiencing.

In this manner, it becomes clear that the phenomenological epoché, the analysis of the constitution of psychopathological phenomena, is of decisive importance as an organ for the understanding of the "ununderstandable" experiences of any psychotic person. This presupposes that we also to some extent bracket our own world-behavior and that we make it a theme of constitutional analysis in order to attain that free space that makes it possible for us to turn to and elucidate without prejudice a world-relationship judged to be pathological (Blankenburg 1979a).

If we speak of the constituting accomplishments of consciousness, it seems obvious to think only of an active constitution. However, Husserl - especially in his late work - thematized a passive constitution, i.e., passive syntheses, alongside active constitution. In this context, "constitution" signifies that for a specific person something appears or exists as something.

In the constitution-phenomenological approach, it is no longer a question, as it is in descriptive or eidetic approaches, of only describing the world of a manic or delusional person, for example, but rather a question of coming to know the elements of its construction. This results in a completely different way of viewing manic behavior, for example. Thus the objectively undistanced behavior in mania can prove to be "adequate" in relation to a changed intersubjectivity to which a different distance between fellow human beings corresponds (Kraus 1998a). Mania and depression then no longer appear as they usually do, as disturbances of mood, but rather as disorders of temporal constitution, for example (Binswanger 1960). Specific psychopathological phenomena, especially psychoses, point to a modification of "transcendental organization," as Blankenburg (1971) described this in schizophrenia with few symptoms. Binswanger (1960) saw the investigation of transcendental accomplishments as so important for psychiatry that he equated the importance of Husserl's phenomenology for psychiatry with the importance of biology for the medicine of the body. He sought to show the bearing of this not indisputable thesis not only for melancholia and mania (1960), but also for delusion (1965).

An especially difficult problem for phenomenology is the knowledge of other minds or the constitution of others. The contribution of phenomenology to the question of communication and interaction with patients and also to pathological modes of communication and interaction is crucial for psychiatry and consists in the following: each specific encounter with a patient already presupposes and is made possible by an intersubjective relatedness to others and to community with them. This set of problems is addressed by Husserl (1950, vols. XIII–XV, summary in vol. I) under the title of transcendental intersubjectivity. A similar set of problems is intended by Heidegger (1963) with the concept of "being-with" as an existential.

Such transcendental intersubjectivity is to be distinguished from a factual relatedness to personality. Pathological modes of communication and interaction of psychotic individuals are mostly related to a changed intersubjectivity. The importance of the problem of intersubjectivity becomes recognizable in the fact that not only the common lifeworld but also the self and the body are intersubjectively constituted. Transcendental intersubjectivity as the condition for the possibility of factual-concrete being related to others and of encounter with others are related to each other like intimacy and trusting (Blankenburg 1991a). This is a distinction that has become particularly important for Zutt (1963a,b), Zutt and Kulenkampf (1956), and others in understanding the paranoid syndrome.

Relatedness to intersubjectivity makes it possible not only to see ourselves and the world with the eyes of others and to widen our field of vision, but also to relativize our own ways of seeing. An impairment in

the relatedness to intersubjectivity can be supposed in connection with many delusional phenomena and in schizophrenic disorders in general (Kimura 1975, 1980, 1997). In relation to others and to society, I experience an alteration of myself. This happens because I become an object for others and of their normative (role) expectations. There accrues to me an identity (a role-identity) which is designated through others' decree, but which at the same time makes it possible for me to comport myself socially and in relation to others.

Here a connection ensues between phenomenology and socio-psychological role theory, which has also become important in the realm of phenomenological-anthropological psychiatry. Role theory aspects have been highlighted for manic-depressive illness (Kraus 1982a, 1996c,d, 1997b), schizophrenia, personality disorders, and alcoholism (for an overview, see Kraus 1980b, 1982b). Intentional (Mundt 1984, 1985, 1988) and preintentional disorders (Parnas and Bovet 1991) have been observed in schizophrenia and other disorders. Attempts have been made to render these accessible to empirical research (Mundt et al. 1985).

4.3 Lifeworld

The problem of intersubjectivity was widened in Husserl's later work to form that of the intersubjectively constituted lifeworld. This concept, which had already been taken up by Jaspers (1963), was developed further by Heidegger (1963) as "the world of everyday being" and in the work of Merleau-Ponty (1966) as "being-in-the-world" ("*être-au-monde*") and by Schütz (1962–1966) and by Schütz and Luckmann (1979) for the social sciences. The concept of lifeworld was introduced into psychiatry by Natanson (see Wiggins 1995), Callieri and Castellani (1981), and Blankenburg (1979a), among others. This results in the recognition that the "objects" of consciousness are constituted not as individual objects, but as objects of the world as the open total horizon.

The world in which we constantly live with a naive-natural attitude is referred to by Husserl (1950, 1954) as "lifeworld." This pre-given world is defined by cultural-historical concerns and by the practical occupation with everyday concerns. By way of our body, our consciousness is always already originally and inseparably bound to this world. Through the body, consciousness is always already united with its world, bound to its situation at the time and its horizon. Since we are always already passively-pathically related to it, there arises a tension to active-spontaneous intentional relating-oneself-to-something (Blankenburg 1987).

Schütz (1962–1966) has shown that this unreflective living in the everyday world can be characterized by an epoché II, which inverts the phenomenological epoché I (see above). While the epoché I deliberately puts out of action the naivety of our "belief in the world" (*doxa*) – all the way from our absorption in unexamined suppositions, prejudices, and self-evidences to believing in reality generally – in epoché II, which characterizes our carrying on of everyday life, we comport ourselves in precisely the opposite manner. Here, in contrast, not only reality, but also the meaning that we give the world is taken for granted just as it is. In epoché II, in contrast to epoché I, all doubt in the lifeworld in which we live at any given time, all doubt in the validity of its norms and consciousness of its intersubjectively constituted being, is bracketed. This bracketing characteristic of the "natural attitude" makes possible our everyday actions which inevitably presuppose self-evidences.

The self- and world-relationship of the schizophrenic individual, according to Blankenburg (1979a), resembles the phenomenological epoché I. This occurs through the loss of natural self-evidence in schizophrenic experience. While the schizophrenic individual undergoes or suffers this negation of self-evidence, the phenomenologist carries it out deliberately. Through a lack of rootedness in the lifeworld, the contexts and relevances become muddled up, which is manifest not only in delusion but also in the extravagance and oddity of schizophrenic patients (Binswanger 1992).

A special expression of rootedness in the lifeworld, indeed precisely the logic of this rootedness, is common sense (Blankenburg 1969). While individuals with schizophrenia, especially those with hebephrenia, frequently appear to lack an inner standard which makes it possible for them to behave in a way that fulfills social norms, people with melancholia and manic-depressive illness appear to be too strongly dominated by common sense (Blankenburg 1969; Stanghellini 1997). This is already shown premorbidly by their hypernomic behavior, which is characterized by a lack of distance in their relationship to normative expectations (Kraus 1977, 1980b, 1991b). This is found in the typus melancholicus (Tellenbach 1983) in patients' over-identification with their social roles at any given time, i.e., a predominance of role-identification over ego-identification (Kraus 1977, 1991c, 1996c,d).

From this perspective, role-identity and ego-identity are distinguished by the degree of absorption or nonabsorption in the lifeworld. In this regard, individuals with schizophrenia appear to have special difficulties in taking on social roles: in such roles they frequently experience themselves as alienated. This is

obviously connected with the fact that each role performance, on account of the reciprocity of each role with other roles, contains the capacity to imaginatively transpose the self into others, to assume their point of view (Kraus 1982b).

Through the epoché II of the lifeworld with its typifications and its predominant "oneself" ("*Man-Selbst*"), the existential situation of human beings, which is characterized by "being-toward-death" and therefore by threat, anxiety, unavoidable guilt, and loneliness, becomes concealed.

We can thus ask, as Wiggins (1995) does, closely following Natanson (1963), whether the anxiety syndrome, neuroses, and psychoses represent something new as against health or rather, like the primordial anxieties of Kurt Schneider (1950), they become revealed simply through a breakdown of epoché II. Analyses of the lifeworld are in principle possible with all mental disorders. Callieri and Castellani (1981), for example, have very vividly described the different lifeworld relationships of senile, phobic, depressive, phobic-compulsive, manic, and schizophrenic patients (on the latter, see Corin 1990).

4.4 Daseinsanalytic and Existenzanalytic Approaches

Kuhn (1963), Condrau (1992), Blankenburg (1977), and Holzhey-Kunz (1990, 1994a-c), among others, have provided introductory presentations on daseinsanalytic and existenzanalytic approaches.

Binswanger's psychiatric daseinsanalysis as an empirical phenomenological method differs from Heidegger's daseinsanalytics as a philosophical-phenomenological ontology, even though the former is grounded on the latter. Heidegger's point of departure is a fundamental distinction between beings which have the being of *Dasein* and beings which do not. The former are characterized by so-called existentials which strictly depend on one another, such as being-in-the-world, oneself (*Man*), historicity, attunement, etc., while determinations of the being of the latter are designated by categories. Being-in-the-world is the leading concept of Binswanger's daseinsanalysis (Holzhey-Kunz 1990). This concept rejects the being of human beings in the world as in a container. Being-in-the-world is rather the fundamental dimension of this being itself. The dichotomy of subject/object and of conscious/unconscious is thus circumvented.

Although in his later work Husserl (1954, 1986), with his notion of the lifeworld, his emphasis on the primordial, prereflective world of everyday experience, and his concept of passive syntheses, paved the way for Heidegger's fundamental ontology, the latter represents a certain reaction against Husserl's philosophy of consciousness. By turning the focus to the prepredicative or prepopositional determinations of *Dasein*, i.e., to its projecting-thrownness (which is not experienced but rather lived) or to its being-in, being-with, being-body, "being-to-the-world" (Merleau-Ponty 1966), "being-for-oneself" and "being-for-the-other" (Sartre 1943), more is kept of the whole human being, in his or her existence, situation, and freedom, in the bodily, interpersonal, social, and historical conditions of his or her existence. In this lies the advantage of psychiatric daseinsanalysis – as well as of existenzanalytic approaches – over constitution-phenomenological approaches.

For the most part, these approaches mark a greater closeness to individual patients and therefore also to therapy, while constitution-phenomenological approaches, as we shall see, become increasingly more closely connected with empirical-experimental and cognitive research approaches. Even if with the concept of *Dasein* a "transanthropological matrix" (Blankenburg 1967) is ontologically intended, Binswanger's earlier anthropological procedure, which is methodologically oriented in "natural-ontological experience" (Szilasi 1961), appears to entitle us to classify his daseinsanalysis as a phenomenological-anthropological approach. We cannot go into the set of problems involved in the difference between ontic and ontological here.

Daseinsanalysis seeks to use various psychiatric concepts of disorders to describe the modification of the fundamental condition of *Dasein*, i.e., being-in-the-world in the modification of the components of its structure. These components of its structure are, for example, its temporalization and spatialization showing event-character, its self-being, and being-with. Through "hermeneutic communication" with patients (Binswanger 1958), daseinsanalysis seeks to investigate the mode of being or condition of being of patients with specific clinical disorders, or it seeks to uncover which possibilities of *Dasein* are opened up at any given time; it does this against the background of the general, i.e., a priori, fundamental structure of human *Dasein*, which it uses as a guiding rule or norm. Daseinsanalysis is not satisfied with describing in a manic patient, e.g., his or her flight of ideas and the flow of mental processes connected with it; it rather seeks to define that form of being human which the flight of ideas, and also delusion, hallucination, etc., first makes possible.

With the description of different forms of being-in-the-world of a unified form of *Dasein*, something like the recognition of a principle of order occurs (Kuhn 1963). According to Binswanger (1958), this principle of order is not a logical principle, but rather an eidos or intuitable schema. Insofar as daseinsanalysis refers to the life-history of a patient, it is a matter of uncovering

the style of life of the patient; in others words, it is a matter of the connection of a whole conduct of life (Kuhn 1963) out of which the particular modes of experience and motive become intelligible.

With psychiatric daseinsanalysis, the horizon of understanding, according to Binswanger (1958), should be transcended to its a priori horizon of understanding, i.e., to the a priori framework structure and the a priori movement of *Dasein*. Daseinsanalysis should be understood, however, as being basically a science based on experience "with its own methods and its own ideal of exactitude" (Binswanger 1961, p. 191; Szilazi 1961). We cannot discuss daseinsanalysis in the sense of Boss (1951) here, for whom phenomenology is a "method-free intuition of the essence of things" (Holzhey-Kunz 1990, p. 94).

Among the manifold influences on psychiatry of French phenomenologists such as Merleau-Ponty, Sartre, Ricoeur, and Levinas, I can only refer to Sartre's "existential psychoanalysis" here (Sartre 1943). In addition to his problematization of the unconscious, shame, guilt, the emotions, and other important psychiatric themes, Sartre's existential psychoanalysis has become significant for phenomenological–anthropological psychiatry as an empirical method for the illumination of the psychic constitution of an individual *Dasein* or of a type of *Dasein*. For this reason, it can certainly be compared with daseinsanalysis, even if it is less well known. "Existential psychoanalysis" begins with the fact that the individual, despite all the heterogeneity of his or her inherited and acquired biological and psychic traits and dispositions, projects and comprehends him- or herself at any moment as a personal unity. There is correspondingly an original choice ("*choix originelle*") of the individual which, in all of his or her modes of behavior, inclination, and striving, comes to expression as a choice of a totality, i.e., in a definite kind of existing. According to Sartre (1943), this choice is not thetic but rather prereflective. And because it enters into the fundamental relation of being, this choice is, as choice of being, much more fundamental than, for example, sexuality or the will to power.

The significance of "existential psychoanalysis" for psychiatry lies, among other things, in discovering eidetic or essential entities in the sense of existential types in the traditional entities of classification and in going beyond these (Kraus 1977, 1996c). The multitude of factual findings, which can be reduced to a common denominator under the hypothesis of a determinate being-relation, serves as a criterion for such a type. The issue of the conditions or causes of such a type can be left aside. Like the forms of being-in-the-world of daseinsanalysis with regard to self-being (authenticity), being-with-others, body-being, temporality, etc., "existential types" can be read purely structurally as definite modes of being-in-the-world in the sense of an existential enacting of being. In the latter sense, they can provide immediate indications for rehabilitation and therapy.

Kraus (1996c) has portrayed people with melancholia and people with hysteria with regard to their relation to social roles, to their value stances, in relation to their bodies, to their emotions, etc. as contrary existential types of identity formation: a tendency to over-identification in the individual with melancholia contrasts with a tendency to non-identification in the individual with hysteria. In melancholia, increasing over-identification leads into depersonalization, which is conceived as the core of melancholic disorder (Kraus 1991a, 1992).

In connection with Bachelard's "*psychoanalyse des choses*" (1987) and the existential analysis of thing metaphors of dirt in dirt phobia (Kraus 1996a) and metaphors of specific qualities of space in agoraphobia and claustrophobia (Kraus 1997a) and also of the technical in technical delusion (Kraus 1994a), pictures of these disorders can likewise be characterized as existential types of specific self-world relations and relations of being-with-others.

5 Psychotherapy and Rehabilitation Therapy

From early on right up to today, phenomenological–anthropological psychiatry has intensively concerned itself with problems of psychotherapy and rehabilitation, or rehabilitation therapy (von Gebsattel 1954; Bräutigam 1961; Condrau 1963, 1990, 1992; Blankenburg 1982, 1987, 1990; Csef 1990; Wyss 1990; Lang 1990, 1997; Holzhey-Kunz 1994c; Holm-Hadulla 1997). The focus is generally on reflections on the doctor–patient relationship and therapeutic possibilities rather than the elaboration of therapeutic techniques. The therapist is a *Dasein* partner. Psychotherapy ought to work through establishing a "real" relationship, through empathy and experience of existential truth (Wyss 1990). This has created a special culture of intimacy with patients (Mundt 1989), which has also had an impact outside this psychiatric approach.

Beginning with the a priori fundamental structure of being human, Binswanger's anthropological proportions as polar structures in the development of *Dasein* make it possible for the therapist to partially identify him- or herself with patients (Blankenburg 1980a) and hence to enter into a special kind of "hermeneutic communication" with them (Binswanger 1958).

In phenomenological analyses of constitution, Blankenburg (1982) sees the possibility of a "constitutive psychotherapy." The former addresses the issue

of how something is constituted as something for someone and of how someone is constituted as someone for someone. It is a matter of performing an epoché (bracketing) of the self-relation and world-relation of patients in order to realize processes of the formation of reality for them and to work with them; it is also a matter of eventually achieving help with constitution. What is crucial, however, is that therapists should also be ready to bracket their own self- and world-relationships in order to produce that special space which makes it possible for them to "translate" themselves into a different form of being-in-the-world, e.g., the psychotic (Blankenburg 1979a, 1982). With the phenomenological approach, Blankenburg (1987, 1991a) also sees possibilities of developing procedures for training in intentionality and of provoking a flexibility of perspectives which can be started with hallucinatory and delusional patients with their fixation on a definite theme or with their "rigid perception" (Matussek, see Blankenburg 1987).

Phenomenologically-anthropologically oriented forms of psychotherapy are better aligned to helping patients exercise their own responsibility than are psychotherapies which analyze conditions. They assert what is at least a relative autonomy on the part of patients by requiring of them and offering them new possibilities of being (Blankenburg 1997b). Paradox intervention, which was introduced by Frankl (1959) and propagated in a modified form by Blankenburg (1990), therefore appeals to the autonomy of patients for a quasi-active bringing forth of symptoms which were previously only passively suffered. The therapist sees him- or herself as someone who makes it possible to point out the future. These therapeutic approaches are therefore less oriented to the past than to the future (Blankenburg 1989), corresponding to the great significance which is accorded by phenomenological-anthropological authors to the experiencing of time and temporalization (Alonso-Fernandez 1982; Bollnow 1963; Bühler 1986; Kobayashi 1989; Kraus 1985, 1998a; Minkowski 1971, 1972; Mooij 1995; Mundt et al. 1998; Kimura 1982; Pauleikhoff 1979; Csef 1985) and to the experiencing of space and spatialization (Tellenbach 1987; Fuchs 1994, 1998) in people with neuroses and psychoses.

Pretherapy was established by Prouty and further developed by Van Werde and Portner (Prouty et al. 1998). It can be regarded as standing entirely in the tradition of phenomenological psychology and psychiatry. The therapy is seen as indicated for patients with chronic schizophrenia who have been hospitalized for years. This form of therapy starts from Minkowski's thesis (1971, 1972) of the lack of vital contact between the person and reality as the chief characteristic of schizophrenia, and it seeks, through so-called "reflections of contact" (responding to the situation or facial expression, reproducing body posture, verbatim repetition of what the patient has said, etc.) to bring patients into contact with reality again, i.e., to bring them into contact with themselves or with others and then to strengthen these functions of contact.

Sartre's "existential psychoanalysis" (1943) provides possibilities previously little used before in order to illuminate the "original choice" (see above) of the grounding project of the individual or of people with specific neuroses (Kraus 1996c, 1997a, 1998b), personality disorders, and psychoses (Kraus 1996c, 1977, 1998a). On that basis, it seeks to understand specific, typical ways of behaving and experiencing and hence to find a therapeutic clue for a new possibility of being. On the basis of "existential psychoanalysis," Kraus (1997b) has developed an identity therapy for people with melancholia and manic-depressive illness which starts from the above-mentioned over-identification of these patients with their social roles, spatio-temporal givens (dwelling), etc. This also expresses itself in the social behavior of these patients, namely, in their hypernomic, i.e., overly precise, fulfillment of social norms or role expectations and in their emotional and cognitive intolerance of ambiguity (Kraus 1988). Their intolerance of ambiguity helps to maintain the identity they find in particular role relationships. On the basis of this concept, which was designed to be empirical, it is possible to undertake a psychotherapeutic management of these patients which is guided by theory and to conceive of definite measures for the prevention of phases and for rehabilitation.

There are analyses of transcendental-intersubjective constitution of the lifeworld or of identity formation in people with endogenous psychoses which have led to practical implications for their rehabilitation. The concept of "accomplishing life," whereby Husserl in his later work (1954, 1986) understood the entire stratified structure of meaning-bestowing acts which constitute a world or the "having of a world," and Heidegger's (1963) being-in-the-world as accomplishment caused Blankenburg (1970) to plead for a more comprehensive concept of accomplishment that includes categorial accomplishments. In this way, it is possible to characterize the loss of accomplishment and the condition of exhaustion of the schizophrenic deficit syndrome, e.g., the syndrome of apathy (Mundt 1985) under the aspect of a deficiency of categorial accomplishment. By characterizing them in this manner, they can be more precisely distinguished from an insufficiency of accomplishment that is purely bodily conditioned, as can occur, for example, under the aspect of a loss of energetic potential (Conrad 1958) or a dynamic insufficiency (Janzarik 1959).

For the healthy individual, the coherence of ego and world is given in a basic way, namely, through the natural self-evidence of the embeddedness of the

accomplishment in the common lifeworld. However, according to Blankenburg (1970), people with schizophrenia have to "co-accomplish" this coherence of ego and world, the access to reality and to everydayness, as their own specific categorial accomplishment, and doing this frequently demands too much of them. This leads to an interweaving of bodily and categorial exhaustion such that categorial failure is experienced as bodily frailty and bodily exertion as ego loss.

6 Phenomenological–Anthropological and Daseinsanalytic Approaches and the Empirical-Objectivating Sciences

In a certain sense, a one-sided relationship exists between sciences of essence and sciences of fact insofar as, according to Husserl (1954), any eidetic science can in principle be independent of factual sciences, while no empirical science can be completely free of eidetic knowledge. The empirical sciences cannot be completely free from the eidetic sciences because any factual science essentially has theoretical foundations in eidetic ontology (e.g., the natural sciences in the ontology of nature) (Husserl 1950, vol. I, p. 111). Not only do the empirical sciences draw their fundamental categories directly or indirectly from the lifeworld (Husserl 1954), but also the interpretation of empirical data often relies on a connection with the lifeworld.

Empirical–objectivating approaches are frequently characterized entirely as reductionistic, and phenomenological–anthropological ones as holistic. However, a distinction needs to be made between methodological and ontological reductionism. Methodologically, the empirical sciences deal with human beings as objects of investigation in an unavoidably reductive manner insofar as they abstract from the full essential reality of human beings, from their subjectivity and historicalness, for example. However, essential sciences no less than empirical sciences are exposed to the danger of an ontological reductionism.

Through their primarily heuristic alignment with the essence of human beings, the phenomenological–anthropological and daseinsanalytic forms of psychiatry attain a special place in the realm of scientific concerns in psychiatry. They attain this special place insofar as it is one of their tasks to display the reductionism of empirical–objectivating approaches in order to open up for those sciences, through referring to the more comprehensive "essence" of human reality, new questions and dimensions, but also to promote the adequacy of their methods for the object. As a circular relationship exists between problem-oriented (e.g., phenomenological–anthropological) and method-centered empirical investigations, Mundt (1989) speaks of a relationship of alternation between hermeneutic–holistic seeing and empirical–distancing objectivating. Qualitative investigation frequently precedes quantitative investigation, but qualitative research can also follow quantitative research in the interpretation of results.

The psychiatric subdisciplines have become increasingly more anthropological, i.e., more adequate for the essence of human beings. This is associated not only with the influence of phenomenological–anthropological or other "humanistic" approaches. It has also frequently developed out of the aporias of the findings in these subdisciplines. As an example, we can point to life-event research, which saw itself increasingly compelled to consider personality-specific sensitivity to traumatic events.

Human beings cannot be exclusively natural objects, and, on principle, not all of mental life can be objectivated (Herzog 1994) (although, insofar as the mental and the psychic can be distinguished, this is only valid for the psychic in the narrow sense of the term). Because of this and because of their orientation to subjectivity and human freedom, phenomenological–anthropological and daseinsanalytic psychiatry can claim not only a methodological, but also a systematic autonomy. And they can claim this autonomy in addition to their auxiliary function for the empirical sciences.

In contrast to the fixing of human beings in an objectivity which is definable in various ways in the empirical or, more adequately characterized, objectivating sciences, phenomenological–anthropological and daseinsanalytic psychiatry allow human beings to be what they are in all their transcending possibilities. These disciplines thus enter into an openness of questioning which is not only their strength but also their weakness, because of the greater difficulties involved in planning and designing, e.g., in the domain of research projects. Among the manifold fruitful relationships between phenomenological–anthropological and objectivating research approaches, I shall refer here only to the personality research concerning manic-depressive illness (see Mundt et al. 1996; Kraus 1991c, 1996d) and to empirical investigations of time experience and temporality in melancholia (Mundt et al. 1998) and mania.

7 Phenomenology, Cognitive Theory, and Cognitive Neuroscience

Between phenomenological orientations and cognitive approaches there exist manifold but as yet insufficiently

disclosed historical and systematic connections. Thus the relatively earlier emphasis on the subject's individual experiences and meaning-bestowing by Husserl (1950), Jaspers (1965), Binswanger (1955a, 1961), Minkowski (1971, 1972), Straus (1963, 1978a), and other representatives of phenomenological-anthropological orientations found a parallel later in Kelly's "personal construct theory" (1955) and the cognitive theory of Beck (1970), among others. As a representative example, I shall refer only to Straus. In his early monograph, *Event and Experience* (1978a, first edition 1930), and in his chief work, *On the Sense of the Senses* (1978b, first edition 1956), Straus conceived an individually and culturally constituted world of experience and developed the notion of a "representative meaning" of traumatic events. In this respect, he can be viewed as one of the predecessors of contemporary cognitive psychology.

Reciprocally fruitful relationships have been noted between phenomenology, in particular the phenomenology of constitution in Husserl's sense, in its original form plainly a science of cognition, and the cognitive neurosciences by Baumgartner (1996), Wiggins and Spitzer (1997), Gallagher (1997), Moss (1981), Naudin et al. (1997), and Schwartz et al. (1997).

Phenomenology, especially existential-anthropological approaches, continue to present a great challenge for the cognitive sciences. A chief difference exists in the dual status of the mental and the world. Phenomenology does not adopt this dualism because, in a certain sense, consciousness is always already embodied and socialized "in the world." In Gallagher's words (1997), the cognitive sciences tend, at least implicitly, toward an "internalism." Phenomenology, however, could be characterized rather as an "externalism," as Heidegger's concept of being-in-the-world (1963) and that of embodied existence (Merleau-Ponty 1966) make especially clear. Cognitive behavior is not primary, but rather secondary in relation to a primary involvement in an already precognitively meaningful world.

According to a number of phenomenological-anthropological authors, analyses of precognitive, prepredicative world-relatedness and social world-relatedness result in a critical revision of cognitive approaches to delusion (Sass 1992; Kraus 1991a, 1994a, 1996b; Lopez-Ibor 1982; Schwartz and Wiggins 1992), hallucinations (Blankenburg 1987; van den Berg 1982; Naudin 1997), and mania (Kraus 1998a), for example. If in the sciences of cognition there exists a tendency toward scientific explanation on the subpersonal level, then, according to Gallagher (1997), subpersonal and subintentional processes are frequently treated as isomorphic, i.e., as if they were directed intentionally, and this is littered with the danger of anthropomorphizing or intentionalizing them.

Varela (1996) proposes a neurophenomenology, and we can certainly agree with him if, as he says, it is a matter of showing not only correspondences and correlations, but also oppositions between phenomenological and cognitive approaches, including the cognitive neurosciences. In this manner, both research approaches can enrich and reciprocally illuminate one another, but also be distinguished from one another.

8 Diagnostics and Classification

The diagnostic glossary of DSM-IV (APA 1994) and analogously that of ICD-10 (Dilling et al. 1991) were drawn up on the basis of the logical empiricism of the philosopher Carl Hempel (1965). Through the application of the procedures of multivariate statistics, such as factor and cluster analysis, but also through consensus and compromise, these glossaries have led to entirely new diagnostic entities, which, in relation to the traditional entities, have led to a growing crisis in taxonomy.

The diagnostic glossary largely replaces intuitive-eidological acts with the generation of so-called diagnostic criteria and the introduction of algorithmic decision trees. However, this ignores the originally "hermeneutic nature of diagnostic processes" (Spitzer 1994), with their acts which are anticipatory-proleptic and retrospective with regard to part and whole (Kraus 1996b).

At the beginning of the diagnostic situation in psychiatry - if we view it phenomenologically - we are primarily given phenomena of a particular being-in-the-world and being-ill. With reference to medical models of illness, we reduce these phenomena to symptoms or criteria of an illness. This initial intuition of a totality of a particular being-in-the-world is more than merely a characteristic combination of symptoms, as Wyrsch (1946), Kraus (1996b), and others have shown. This totality expresses itself not only in so-called expressive symptoms, but also in a definite mode of *Dasein.* As the being-schizophrenic, being-manic, being-depressive of the person, it can be contrasted with schizophrenia, mania, and depression as illnesses.

There are therefore two forms of diagnosis, a phenomenological one and a symptomological-criteriological one (Kraus 1991b,d, 1994a,b; Ballerini 1997). Both forms of diagnostics supplement one another, but they also stand in a certain relation of tension with one another. What intuition as such apprehends only vaguely can be typologically differentiated with the aid of the phenomenologial categories of temporalization, spatialization, embodiment, relation to self and to others, etc. In this way, the oneness apprehended through intuition is definable, e.g., as an existential

type (Kraus 1991b; Mishara 1994). The significance of this phenomenological diagnostic method lies primarily in the fact that, through reference to the form of being-in-the-world, a higher degree of phenomenological specificity can be achieved, as Rümke (1958), Wyrsch (1946), Müller-Suur (1958), and Dörr-Zegers and Tellenbach (1980) have pointed out. This can be contrasted with a vast lack of specificity in symptomological diagnostics (Weitbrecht 1957). Such existential types and essential entities can, like the ideal types in Jaspers' sense (1965), contribute to the discovery of real, i.e., etiologically based illnesses (Wiggins and Schwartz 1994). On account of their reference to the lifeworld of the patient, they are especially important for rehabilitative and therapeutic measures.

In summary, phenomenological-anthropological approaches in psychiatry make the following contributions to diagnostics and classification:

1. They analyze more precisely the procedure of diagnosis itself, to which too little attention was previously paid.
2. They generate ideal-typical and essential-typological entities.
3. They carry out critical reflection on previous descriptive categories with regard to evaluative elements.
4. They advance a phenomenological form of diagnostics which takes account of prepredicative world-relationships and social world-relations.
5. They contribute to the development of psychiatry's own conception of illness.

The methods of psychiatry may change, but the issue of the conditions in the essence of human beings for the possibility of being mentally ill and of the methodology that is right for these conditions will always continue to exist.

Development, Attachment and Relationship: New Psychoanalytic Concepts

Translator: G. Schmücker

1 Introduction

In the last decade, the term "depth psychotherapy" has lost much of its fascination. This is reflected by its omission in the index of recent textbooks on psychoanalytic therapies (Thomä and Kächele 1987, 1991; Heigl-Evers et al. 1993). In therapeutic settings, the terms "psychodynamic" and "psychoanalytic psychotherapy" have won much ground, especially in the empirical world.

Three manuals published in 1984 (Luborsky 1984; Strupp and Binder 1984; Klerman et al. 1984) were all akin in different ways to the interpersonal and dynamic way of thinking. They demonstrated that it was obsolete to contrast psychodynamic procedures with procedures that were empirically supported.

The systematic pathology of conflict in Freud's paper (1917) characterised the scientific paradigm of psychoanalysis, which Freud summarised by stating: "We seek not merely to describe and to classify phenomena, but to understand them as signs of an interplay of forces in the mind" (Freud 1917, p. 67).

A significant assumption of psychoanalytic theory is the role which conflict plays during the lifespan of a person – starting from birth, manifest in interpersonal contact and personal well-being. If the role that conflict plays in the emergence of a psychic or psychosomatic illness is considered purely as intrapsychic and not also as interpersonal, the implications of the theory, as well as the technique, would be limited. Psychoanalysis and both the Jungian and Adlerian schools are based on the concept of development. Traditional psychoanalytic understanding of a symptom almost requires a search of its origin in the life-history of the person. This genetic point of view is not incompatible with Kurt Lewin's belief that only forces and conditions which are present in the here and now can induce an effect in the here and now. He would say that much of what is "presently seen" in the individual (in the here and now) can only be identified by the genetic discovery of what came before (Rapaport 1960).

The main tool with which the developmental dimension is captured is reconstruction. Freud based his psychoanalytic theory on the treatment and observation of adults. It was only incidental that he also observed young children. One of these observations is the well-known so-called reel of string game, which can be found in Freud's *Beyond the Pleasure Principle* (1920). Here, Freud recounts how his 1½-year-old nephew comes to terms with the absence of his mother by playing with a reel of string. Emde (1992) sees this contribution as being ahead of its time. Freud attributes the small child with the ability to actively reduce tension by repeating his experience of separation and reunion in the game. In contrast, in traditional psychoanalytically based developmental psychology, infants were seen as passive, undifferentiated beings who were governed by their instincts (Dornes 1993).

In the last 30 years, there has been a great change in the understanding of the various developmental processes that take place in early childhood. Empirically based research into the early mother–child relationship was initiated by Spitz. As early as 1935, he was able to observe hundreds of infants growing up in orphanages and described the "hospitalism" he saw, which he attributed to emotional deprivation. Research into the evolution of the mother–child relationship in the first year of life, as reported by Spitz (1965), provided the psychoanalytic world of the infant or child with new ideas, a world which until that point had largely been constructed or reconstructed. Mahler et al. (1975) followed the tradition of Spitz and developed his work further in her groundbreaking monograph entitled *The Psychological Birth of the Human Infant.*

In addition to observing psychotic children and working with them (Mahler 1958, 1969), she focused on the effect that being separated from the main caregiver had on children. Based on her work, Mahler conceptualised a developmental theory which was mainly pathomorphic. Bowlby (1969) was the first psychoanalyst of his generation to use ethological terms to describe the infant's biologically predisposed availability of attachment to a main caregiver. He saw relatedness in early childhood as a primary and independent developmental goal that is not subservient to a physiological need such as hunger (see also Künzler 1969). These theoretical developments perceive the infant more from an interactional point of view and also focus on relationship aspects. The concept of dyadic interplay replaces the drive-conflict model. A dynamic and conflict-oriented psychology which describes psychic processes has been extended by more current concepts of development, attachment and relationship. The new theories of child development have had two main effects. They have promoted an integration of ethology and of theories of communication and action and they have also had a marked impact on psychoanalysis and other psychodynamic schools (Stern 1995; Dornes 1997; Krause 1998). In the following chapter, these three concepts will be explored further in order to demonstrate the ways in which each has made a contribution to new psychoanalytic thought.

2 Development

The diversity of methods used to observe infants has contributed to a change in the perception of

children's development and hence led to an increased base of knowledge.

The function attributed by psychoanalysts to direct observation was initially to correct the retrospective information obtained in therapeutic analyses. Today, psychoanalysts are required to also use empirical and experimental information gained from direct observation and to reflect on the consequences for clinical and retrospectively obtained knowledge. Daniel Stern (1985) captured this element of tension by talking about the "observed infant" and the "clinically reconstructed infant". His work criticises traditional psychoanalytic concepts such as "normal autism" (Mahler 1958), the process of splitting into "good" and "bad" (Klein et al. 1952; Kernberg, 1968), orality, undifferentiatedness or "normal symbiosis" (Mahler 1969) and manages to demonstrate the absurdity of some of the clinical constructs. Lichtenberg (1983) sums up the infant's world in the first year of life: Firstly, infants are capable of much more than was previously thought possible and secondly, they are not as able in some matters as had previously been assumed. They can master complex developmental steps when their activities are guided and enhanced by affect. However, the infant does not have or even need the ability to imagine symbolically.

Clinical reconstruction primarily focused on the revelation of subjective experience, but the interest in direct observation focuses on identifying what really happens in childhood, in so far as it can be observed from the outside. However, therapists are always in danger of reifying experiences recounted by patients and of taking them as the real picture of the event. Freud took great pains with the retrospective attribution of meaning when it concerned the conception of psychological causality:

> I admit that this is the most delicate question in the whole domain of psycho-analysis. I did not require the contributions of Adler or Jung to induce me to consider the matter with a critical eye, and to bear in mind the possibility that what analysis puts forward as being forgotten experience of childhood (and of an improbably early childhood) may on the contrary be based upon fantasies created on occasions occurring late in life (Freud 1918, p. 137).

However, the path "inexorably led analysts to trace the etiological conditions of psychic and psychosomatic illnesses back to the first hour and even earlier" (Thomä and Kächele 1991, p. 100). The analysis of pathological development provided the basis for an uncritical view of normal psychological development (Peterfreund 1978). This peculiarity of psychoanalytic theory formation so far is reflected by the fact that infants' characteristics are described as deficient modi of the adult world. In addition to this so-called adultomorphism, pathomorphism can also be found and is equally abundant. Here, the infant is described using pathological categories. This is based on the assumption that formative processes that constitute development can be derived from the observation of pathological states. The key to discovering early phases of psychic life lies in the data concerned with fixation and regression (e.g. Tustin 1994).

In the following sections, some concepts which have modified the psychoanalytic view of development from infancy to childhood will be described further.

2.1 Complex Abilities of the Infant

Freud's assumption that the tension/relief principle representing the pleasure/unpleasure principle is the basis of developmental processes can no longer be maintained.

Since the 1980s, developmental psychologists have emphasised that a newborn infant is provided with basic activity which has a tendency to stimulate the organism to increase psychological complexity (Brazelton et al. 1974; Stern 1974; Emde 1992). Newborns have a substantial repertoire of possible behaviours that prepare them for interactive relations in a care-taking environment.

The drive/discharge model viewed development through the eyes of the entropy model. However, today's developmental psychobiologists take into account the fact that the neurobiologically determined complexity due to 10^{10} neurones with thousands of interconnections leads to uncertainty and a limited ability to predict behaviour (Spitzer 1997). This degree of complexity guarantees individuality and assures self-determination (Emde 1992). Complexity grows in the course of development. Humans are attributed with the ability to socialise themselves into the animate and inanimate world. Activity generated endogenously represents a fundamental principle and has taken the place of the drive/discharge hypothesis. Similarly, we should be critical of the perception that the infant is born as a psychological "blank slate" and is only formed by parental socialisation. Schaffer (1982) states that, from the beginning, a baby's behaviour shows organisation and order. It is only due to our inadequate recording methods that the small child seems as if it is in a state of bubbling confusion. The discovery of this complexity is attributable to the detailed work that has been done on different types of behaviours, each demonstrating its own intricacy.

Finally, the revolution seen in research into infancy was based on methodological innovations (Stern

1985). Today, we ask what reactions an infant shows that can be taken as an answer to the questions put by the researcher. It has been demonstrated that, from the beginning, infants are able to show a preference, habituate or let themselves be taken by surprise. These signs, which point to the complex abilities of infants, have led to the development of research paradigms.

Research has shown that infants have excellent olfactory abilities. They are able to distinguish their mother from others by their scent from the eighth day of life (Brazelton and Cramer 1991).

In addition, the visual abilities of infants have long been underestimated. Experiments with intrauterine ultrasound have shown that the fetus turns towards a moderate source of light, but turns away if this source is intense (Brazelton 1981).

The postnatal auditory abilities of infants are also remarkable. Even during the first hours after birth, newborns are more likely to turn their head and eyes towards a tone, noise or a voice than away from it.

Infants also have a capacity for intersensory co-ordination or cross-modal perception. Hence, an infant is able to co-ordinate sensory perceptions with different sensory canals (seeing, hearing and touching). This incredibly complex ability has been investigated repeatedly (e.g. Meltzoff and Borton 1979). It can be concluded that infants perceive objects as a gestalt and do not live in a world of separate sensations (Dornes 1993). Psychoanalytically based developmental psychology assumes that, at the beginning, self and object perception is fragmented. However, the findings concerning cross-modal competence seem to show that from early on the separate aspects of sensory information are put in relation to each other. It is not the case that separate part objects are perceived next to each other.

Newborns are organised in such a way that, after birth, they can start interacting in a complex way with the animate and inanimate world. The regulation inherent in these interactions imprints the patterns of sleeping and waking cycles, feeding and social exchange. This regulation is established in the first 2 months of life. It is manifest in various phases replacing one another, such as alert attention, calm wakefulness, arousal, crying, rapid eye movement (REM) sleep, non-REM sleep and the infant's search for different stimuli (Greenspan 1989). The concept of self-regulation acts as a basic motive of development and is related to the organism's ability to smooth out deficits which arise out of challenges or disturbances (Clarke and Clarke 1976). Another strong motive in the developmental plan of the small child is the innate willingness to adapt socially. Surprising to some, research in developmental psychology has shown the great degree to which taking part in social interactions is pre-programmed. Many of these abilities are already present at birth and include a preference for eye contact or a state-dependent susceptibility for the activating and pacifying effect induced by being held and touched by one's mother.

Social pre-adaptation is manifest in a multitude of communicative channels. According to Papoušek (1981), social pre-adaptation is based on an ability to discover and master contingencies in stimuli. This would imply a biological basis. In addition to children's behaviour as described above, parental response to children's communicative offers should also be mentioned, which Papoušek and Papoušek (1983) defined as "intuitive parenting." Such parental behaviour seems to be characteristic of the species, not conscious and not a product of individual experience. Many microscopic interactions between mother and child may be subsumed under the terms synchronicity and reciprocity (Jörg et al. 1994).

The psychoanalytic pleasure/unpleasure principle has lost its economic quality. Today, it is conceived of as affective monitoring. This is a basic motivational system that evaluates affective experiences according to the quality of "pleasurable" or "unpleasurable" (Emde 1981). Infants do not divide the world into two, but instead abstract daily experiences into different levels of pleasurable and unpleasurable experiences. This will eventually lead to the formation of schemata as conceived by Piaget, where cognitive elements play as important a role as emotional quality. This principle will govern both the mother's and the child's actions. At the age of 3 months, a stable emotional organisation can already be seen that includes three dimensions, namely, hedonic quality, activation and internal/external orientation. Early coherent emotional experience forms the affective core of self (Emde 1983). This emphasises the significance attributed to the emotional attention provided by the caretaker in early childhood.

In this process of emotional exchange, attunement is attributed with a special meaning (Stern 1985). A series of dialogic sequences in different communicative channels provide this exchange, which is seen in the ninth month. Stern assumes that around this time the subjective self is formed and joint affective experience becomes prominent.

A mother interacts with an infant who is motorically active (e.g. kicking the legs rhythmically) by responding in the verbal channel (e.g. with "lalala"), hence she does not change the rhythm but adds variation by verbalising.

Kohut's concept of mirroring (Kohut and Wolf 1978) comes closest to the process of attunement. In the clinical world the use of the term encompasses other different affective processes. Empathy is more closely linked to cognitive processes than the

unconscious process of attunement (Moser and von Zeppelin 1991; Basch 1983). In all research approaches addressing early mother–child interaction, the processes of reciprocity, intersubjectivity, intentionality and a willingness to relate are emphasised. These represent signs of the early processes of communication.

From the beginning, children are equipped for social interaction. They partake in reciprocal exchange with the caretaker. We cannot see our fellow man as static targets of drive. From this point of view, terms such as object relationship are not suitable due to their implications (Emde 1983).

2.2 Implications for the Psychoanalytic Understanding of Development

These developments caused the fundamental position of the drive theory in classical psychoanalysis to be given up. The psychoanalytic object psychology of Balint and Winnicott, for example, prepared the way for this critique. The libido theory did not account for the process of affective reciprocity. Freud regarded the libidinous object from the point of view of the child (and his or her unconscious wishes) and not from the view of the reciprocal relationship between mother and child. This tradition was so deeply embedded that Kohut (1971) derived his "self-objects" from the hypothetical view and experience of the infant. Self-psychologists assume a significant phase of undifferentiation between the self and others (Stern 1985).

From today's point of view, the inner object is not seen as an isolated object, but rather as a memory framed by a context of activity. From birth, the object representations take place in a multiple context of acts of varying quality. By repeated communicative, acts unconscious schemata are created and these can become very stable.

Stern (1985) refers to this active process as the representations of interactions that have been generalised (RIG). He assumes that the infant divides the flow of an interaction into episodes (e.g. feeding), and from repeated similarities (invariances) a prototype or schema is built and generalised. This schema guides expectations and behaviour in the interactional sequences. More recently, Stern has extended his theory of the representation of interaction by starting from the subjective perspective of the infant.

Stern (1996) conceived a model of infant representations not so much concerned with behaviours, but much more with feelings of the infants. He refers to the generalised representations of interactions as "schemas-of-being-with". However, in each interactive episode, different feelings are experienced (e.g. subjective feeling of hunger, negative affect, tactile contact with the mother, kicking). These feelings are stored in the form of protonarrative envelopes (series of events such as in a narrative). In summary, the infant experiences the world of interactive events as if they had the structure of a story.

The main difference between Stern's concepts and those of psychoanalysis are that, in traditional psychoanalysis, unconscious fantasies have been attributed to the infant which originate in his or her instincts. Stern, on the other hand, assumes that the infant develops his or her representations from real interactions. These are not motivated by tension or a lack of it, but are created and processed continually (Dornes 1997).

It may be asked to what extent psychoanalytic clinical thought has changed theoretically and practically due to the rich data set on early parent–child interaction. It is feasible to maintain that these early processes are interesting, but do not have any significant influence on the complex process of symptom formation observed in neuroses and other disorders, as the psychological organisation of adults is fundamentally different. With the development of language and accompanying symbolic processes, early experiences would be transformed in such a way that the familiar ground of the psychotherapist would not be disturbed. Parallels can be drawn here with a phenomenon which is also familiar from developmental psychobiology. The developmental context of a child permanently changes and transforms along a developmental pathway, and later behaviour cannot be predicted from earlier events that have taken place at a predetermined sensitive phase.

The consequence would be that infants should not be seen as "pseudo-adults" by ascribing to them the ability to symbolise in the first year of life (Lichtenberg 1983). However, the Kleinian notion of fantasy and/or the theory of splitting as an early form of defence would imply this.

These new insights make Kernberg's (1984) concept of splitting questionable as an explanatory concept of early ontogeny. If infants split good and bad, they would be forced into "double bookkeeping" (Stern 1985), but this does not correspond to the infant's abilities at this developmental stage. Clinical use of the concept of splitting as a description of pathological states has also been affected by these research developments (Reich 1995). These states require a certain degree of symbolisation, such as a labelling of memories and cognitive reorganisation. Hence the process of splitting is most probably found at a later developmental phase when symbolic transformation of experience is possible.

Similarly, it is difficult to justify the concept of an undifferentiated phase of the id and ego in which the inner world of the infant consists of separate elements. This would equally be the case for Mahler's concepts of "normal autism" and "symbiosis" (Stern 1985;

Lichtenberg 1983). Even though Mahler does not conceive of symbiosis as biological, research into the abilities of infants indicate that the term "symbiotic merging" as an appropriate category of early experience needs to be reviewed. Terms such as "primary narcissism" equally become set terms of what are most probably outdated theoretical positions (Eagle 1984).

Psychological research emphasises the characteristic of openness and also limited predictability from one developmental phase to the next as being important for healthy development. This is especially the case if we focus on individual behaviours. With the term "transference", Freud tried to capture pathological development which is formed in accordance with psychodynamic theory through established motivational and relationship-regulating structures (Thomä and Kächele 1987).

Instead of aetiological assumptions concerning which phase of development may be the origin of a specific disorder, it is possible to establish that the different developmental steps are linear, even though they continue to interact in parallel as functional contexts. Erikson's epigenetic model (1950) is relativised by Stern's concept of four senses of the self. Disorders may develop at any time of life in one of the four senses of self: the emergent self, the core self, the subjective self and the verbal self. The simplified link of severe disorders with early development is undone, something which has substantial therapeutic implications (Stern 1985). Instead of seeing the development of disorders fixed at critical phases, the whole chain of interacting influences should be taken into account. The focus should not only be on the first or the last link in the chain. The formation of psychopathology can thus only be understood as an accumulation of pathological patterns of interaction (Blatt 1990).

The value of this object psychology approach, which is also developmentally oriented, can be seen in the reanalysis of the Menniger and the National Institute of Mental Health (NIMH) depression project (Blatt 1992; Blatt et al. 1995). Here, a differential effect of therapies with regard to specific developmental and psychoanalytic configurations (anaclitic vs. introjective) could be demonstrated.

2.3 Mother–Child Psychotherapy: A New Development in the Therapeutic World

The developmental theory of Sander assumes that, in the first 3 years of life, the mother–child system represents an interconnection of mutual regulation and self-regulation (Sander 1985). The negotiation of self-perception, self-determination and initiative are the core problems which an infant has to tackle with his or her caretaker. These configurations become the enduring adaptive strategies of an individual (Quinton and Rutter 1988), the implications of which may be found in the transference patterns (Luborsky and Crits-Christoph 1990). This process of fitting and experience of what is possible in a relationship becomes clinically relevant when the caregiver introduces neurotic aspects into early interactions, leading to maladaptive interaction patterns.

Cramer (1991) describes the first attempts at mother–baby psychotherapy, where such disturbances may be therapeutically resolved. In his psychoanalytically oriented therapy, Cramer assumes that the mother has her own unresolved conflicts, which become reactivated through the birth and the child's behaviour. The unresolved conflicts are then projected onto the child and distort and burden the interaction.

In his latest book Stern (1995) compares the different psychotherapeutic approaches in mother–child psychotherapy and critically discusses their theoretical foundation. He develops his own theoretical model of a so-called motherhood constellation, which should be the starting point for an all-encompassing view of mother–child psychotherapy.

He defines this constellation as a mother's fundamental psychological organisation, which should be acknowledged in the therapeutic relationship. The central themes are as follows: Can this mother provide the nourishment and care this baby needs to survive? Can she have an emotional relationship, build up a system of support and help the baby find his or her own identity? A new trilogy develops: the mother's mother, the mother herself and the baby. This motherhood trilogy is central in every therapeutic intervention. Stern pleads for a positive and supportive transference in mother–child psychotherapies to counteract any additional hurt and insecurity.

An all-encompassing concept of preventive intervention was conceptualised by us for parents of extremely premature infants. This intervention programme consists of four components (Brisch et al. 1996), which were conceived to help parents cope better with the accompanying insecurity and anxiety brought about by this situation. In addition, the intervention programme was designed to help establish a positive parent–child relationship.

Immediately after the birth, parents were offered individual attachment-focused therapy to enable reflection of reactivated experiences of loss and separation, as these could interfere in the establishment of close contact with the premature baby. The focus of a continual parent group was to provide the possibility for emotional exchange and support with other parents. Once the child had been discharged from hospital, a home visit from a neonatal nurse was offered to provide information of a medical nature.

The final component of the intervention programme consists of a video training to improve a parent's sensitive handling of the child.

According to attachment theory, a sensitive parent–child interaction allows secure development on the part of the child. This significant direction of research will be explored in the following section.

3 Attachment

John Bowlby, a psychiatrist and psychoanalyst, formulated his attachment theory in the 1960s (Bowlby 1969, 1973). He turned away from the traditional psychoanalytic view of fantasy life during childhood and focused on the implication of actual real events such as separation and loss on the emotional development of a child. Hence Bowlby's theory has long been the topic of heated debate among psychoanalysts (Bretherton and Waters 1985; Bretherton 1995).

The independent motivational aspect of attachment has now been widely accepted as safeguarding the establishment of social relationships independent of hunger and sexuality. Freud's view that social relationships are primarily formed because of the need for nourishment would not find support by the researchers working in the field of attachment (Grossmann et al. 1989). The theory of attachment has taken up aspects of psychoanalytic theory and also developed some aspects further (Diamond and Blatt 1994). Contrary to the psychoanalytic theory of development, attachment theory has also managed to establish itself empirically. Observation of important aspects of dyadic interactions (also prospective) are possible and are systematically described and operationalised.

3.1 Basic Concepts and Methods of Attachment Theory

Attachment theory sees the desire for close emotional relationships as specifically human. This desire, which is already present in the newborn, remains present until old age and is a basic element with a function for survival. In infancy and childhood, attachment to one's parents ensures shelter and care. Analogously, the task of the parents is to provide sensitive care for their child. These two systems are in delicate balance and develop in a specific sequence.

In the middle of the first year of life, using his or her attachment behaviour and reactions of the attachment figures, the child develops an inner representation of attachment, a so-called inner working model (Bowlby 1969, 1973, 1979). The child's daily interactions with his or her attachment figures are the basis of the inner working models. The experiences gained from the interaction of the attachment figures are integrated into a whole. For the child, this model is a basic organisation of expectations and corresponding feelings which accompany him or her in different situations. This basic organisation remains the same even if the child changes his or her behaviour in different situations (Fremmer-Bombik 1995).

The inner working model is seen as a construction that becomes increasingly complex over a life time; however, the focus is exclusively on relationships to attachment figures. To assume an internalisation of relationship experiences shows a parallel to other psychoanalytic theories, especially the object-relations theory. The difference is one of specificity, as attachment theory only concerns itself with experiences of attachment to specific attachment figures and operationalises these.

The term "working model" corresponds to the "basic assumptions" of Beck et al. (1979) and to the "representations of interactions that have been generalised (RIGs)" of Stern (1985), which are now referred to as "schemas-of-being-with" (Stern 1995, 1996), in addition to the "role relationship models" and "self-other schemas" of Horowitz (1991).

Attachment quality between mother and child finds its expression in the second half of the first year of life. The child experiences whether the attachment figure responds sensitively to his or her signals and needs and whether availability is shown. A sensitive mother is alert and notices her child's signals; she interprets them correctly and reacts promptly and appropriately to the needs of her child (Ainsworth et al. 1974). This dialogue enables the child to have inner security, to show flexibility in situations of conflict and to have confidence in his or her continually expanding competence, emotional reactivity, sensitivity and assertiveness (e.g. Grossmann et al. 1988).

The relationship between parental sensitivity and a secure attachment classification is moderate ($r = 0.32$; van IJzendoorn 1995). However, the relationship between parents' ability to reflect (see below) upon their own childhood and the development of secure attachment by the child is much stronger ($r = 0.47$, $\kappa = 0.49$; Main et al. 1985; Grossmann et al. 1989; Fonagy et al. 1991a). A so-called transmission gap exists, which is the "gap" of knowledge concerning the interactive ways in which attachment experiences are passed on (van IJzendoorn 1995).

Ainsworth and Witting (1969) developed the so-called strange situation, where the attachment quality of the child to the mother was operationalised. This standardised laboratory situation is made up of eight episodes, each lasting 3 min. The behaviour of 12- to 18-month-old children is observed while in contact with a "stranger", after two short separations from

their attachment figure and reunions with this person. The episodes of separation were conceptualised to activate the attachment system and to trigger attachment behaviour (e.g. clinging, seeking proximity, crying). Behaviours of attachment and exploration are the central paradigms of attachment research, which ideally should be balanced. How children react in the reunion episodes enables a reliable assessment of the quality of their interactional life so far (for a review, see Buchheim et al. 1998).

Four patterns of attachment have been identified to date, and data from other cultures have confirmed these:

1. Securely attached (B pattern). These are children who have made reliable attachment experiences. In the separation episode, they can show their distress openly; the attachment figure is usually able to comfort them easily, and the children are able to return to play and exploration.
2. Insecure-avoidant (A pattern). These children have usually had predictable but rejecting experiences with their attachment figure, especially concerning the expression of negative feelings. They avoid this rejection by concentrating on play in a seemingly unaffected manner. When the attachment figure leaves or returns, they show no distress or need of proximity. Spangler and Schieche (1995) measured the children's cortisol level and found these children to be very stressed, thus indicating maladaptive avoidance strategies.
3. Insecure-ambivalent (C pattern). These children have had unpredictable experiences with their attachment figure, who is sometimes very sensitive in responding to their needs and sometimes not sensitive at all. Upon separation, insecure-ambivalent children cry a lot and are characteristically difficult to comfort. They show anger or passive despair as an expression of their ambivalence. Their attention is mostly focused on their attachment behaviour.
4. Disorganised/disoriented (D pattern). This group was described as such in the 1980s (Main and Solomon 1986) and is assessed separately from the other classifications. After separation, the children have not developed an organised coping strategy. They are neither able to approach the attachment figure (as B or C does), nor can they distract themselves (avoid as A does). Upon reunion, they show unintegrated behaviours, such as stereotypic movements after seeking proximity, phases of rigidity, so-called "freezing" and an expression of fear towards their parent. This disorganised behaviour is especially seen in abused children (Carlson et al 1989), neglected children (Lyons-Ruth et al. 1993) or children whose parents have not worked through their own process of grieving (Main and Hesse 1990). Internationally, the distribution of attachment patterns has been shown to be 66% for the B pattern (secure), 20% for the A pattern (avoidant) and 12% for the C pattern (ambivalent) (e.g. Baltimore study, Ainsworth et al. 1978). In non-clinical samples, the proportion of the D pattern can be assumed to range from 15% to 35% (Main 1995). In clinical populations of abused children, the frequency of the D pattern is 80% (Main 1995).

So far, the results confirm a stability of the attachment quality of children from 1–10 years of age (Grossmann and Grossmann 1991). The prognostic value of attachment experiences or attachment deficits is high for the later social development of the child, his or her self-image, self-esteem, social competence and cognitive ability (Grossmann and Grossmann 1991).

An early secure attachment relationship can be a protective factor in the development of psychological disorders (Bowlby 1988, 1995). However, early avoidant or ambivalent attachment relationships may start negative mechanisms, which can establish themselves in inappropriate psychic structures (Fonagy 1993). At the same time, early experiences may be changed by subsequent stress. A straightforward stability of attachment security cannot be assumed. Bowlby never took a deterministic view of early attachment experiences. He saw the developmental path of attachment organisation as flexible and would not subscribe to the view that once an attachment relationship was secure it would always be secure (Bowlby 1988, 1995). Extreme emotional experience due to separation or loss may change attachment quality and may lead to a change in self-esteem (Zimmermann et al. 1995). Similarly, it may be assumed that the inner working model of an early insecure attachment experience may be reorganised. This might be the case after a new positive experience with a partner or psychoanalytic therapy (Fonagy et al. 1995).

The systematic description of childhood relationship experiences enables an attachment theory with a life-cycle perspective to be constructed (e.g. Ainsworth and Bowlby 1991). Since early relationship experiences seem to influence adult relationships, there has been a growing interest in the attachment representations of adults.[1] An essential step in this development was the so-called "move to the level of representation", which was taken by Main et al. (1985). She assessed the attachment representations of 6-year-olds (Strage and

[1] A critical review of alternative methods to assess adults' attachment representations can be found in Crowell and Treboux (1995) and Buchheim et al. (1998).

Main 1985; Main and Cassidy 1988; Grossmann and Grossmann 1991) and of adults (Main et al. 1985) by using language. The Adult Attachment Interview (AAI) (George et al., unpublished) was developed to capture the attachment representations of adults. The themes touched upon in the interview correspond to Bowlby's trilogy of relationship, separation and loss.

The semi-structured AAI assesses current attachment experiences with respect to the past and the present using 18 questions. The scoring method focuses not so much on the content of the narrative, but on the ways and means of linguistic organisation. The coherence of the discourse in the linguistic sense is essential (see Grice 1975).

Parental attachment representations have also been classified into four groups (Main et al. 1985; Main 1991; Grossmann et al. 1988; Ainsworth and Eichberg 1991) and correspond conceptually and empirically to the attachment qualities of children:

1. Autonomous secure adults recount their childhood memories/experiences in an open and coherent fashion. They provide positive and negative examples, can reflect on them and are able to integrate them into an appreciating whole.
2. Dismissing adults provide incomplete, incoherent examples and often have blanks, especially when concrete examples are required. Attachment figures are either idealised or devalued in order to avoid painful memories.
3 Preoccuppied adults relate in an angry and never-ending way the conflicts they experienced with their caregiver. They are entangled and give the impression that their experiences were very recent. These adults characteristically oscillate between positive and negative value judgements without being aware of the contradiction.
4. Specific passages in the AAI may show unresolved grief. These passages are rated separately and relate to traumatic events (loss or abuse) which have not been resolved. The linguistic presentation seems disorganised (confusing senses of time and space, long silences, unusual details), incoherent and at times irrational.

Longitudinal results show the clear relationship between a mother's attachment representations and the observable attachment quality of her child (Main 1991; Fonagy et al. 1991a). Hence the transgenerational aspect of attachment is a confirmed result.

The statistical proof of the transmission of attachment experiences is satisfactory. Agreement between the category of attachment representation in adults and the quality of attachment of their children was examined in 18 studies (854 dyads) (van IJzendoorn 1995). The agreement (secure vs. insecure) is 75% ($\kappa = 0.49$) (Main 1995). In a study by Fonagy et al. (1991a), the predictive validity of the AAI is clearly shown. The attachment quality of the child could be predicted from the attachment representations obtained during an interview conducted while the mothers ($n = 100$) were pregnant ($\kappa = 0.44$; 69%). These results have been replicated in several studies (Benoit and Parker 1994; Ward and Carlson 1995).

3.2 Clinical Relevance of Adult Attachment Research

It has also proved useful to apply the AAI clinically. Van IJzendoorn and Bakermans-Kraneburg (1996) demonstrated a higher distribution of insecure representations of attachment in clinical than in non-clinical samples. Hence a distinction of clinical and non-clinical groups could be made using the AAI, even though a differentiated correlation between insecure attachment and psychopathology is not yet possible. The coding system of the AAI takes into account the extent to which attachment-relevant information has been processed. The way the information is presented, especially regarding linguistic aspects, is central to the AAI, and the coding system therefore also incorporates defensive processes. This semi-structured interview can "surprise" the unconscious, and there have been discussions on whether to include the systematic application of this instrument in clinical training.

Psychoanalytic research into borderline personality has already profited from the results of attachment research (Clarkin et al. 1992). A lack of sympathetic understanding, being untouched by the feelings of others and an inability to have relationships are all phenomenological characteristics of dissociated and narcissistic personality disorder and of a borderline personality type. Among other factors, a pathological component of this disorder is discussed, where from the perspective of object psychology disorders of "containments" (Bion 1962) are assumed.

People with borderline disorders have a greater preponderance to have had unresolved traumatic experiences and have an attachment classification of "entangled" when compared to a control group (Patrick et al. 1994). They also seem to have an inadequate meta-cognitive ability for self-reflection (self-reflective function; Fonagy et al 1991b, 1995). Successful psychoanalytic therapy is able to improve the ability to self-reflect, i.e. to be able to identify with another person's state of mind. Patients are able to obtain an adequate representation of themselves and others through the continual and repeated evaluation of the therapist's and patient's consciousness in transference (Fonagy et al. 1995). The following section will deal with the core concept of transference

from an interpersonal perspective, also presenting methods of operationalisation.

4 Interpersonal Relationship Pattern

From the beginning of the 1970s, the shibboleth of psychoanalysis, namely transference, has been investigated theoretically and empirically in a differentiated manner. A multitude of different methods have been developed to capture this interactive process of regulation.

The methodology of structural analysis of social behaviour (SASB; Benjamin 1993, Tress et al. 1990), in which each speech act of a therapeutic interaction becomes the object of analysis, is distinct from approaches that draw systematic information from verbal exchange about subjectively relevant structures. Examples of the latter approaches are the Central Conflict of Relationship Theme (CCRT; e.g. Luborsky and Crits-Christoph 1990), the methods of cyclic maladaptive pattern (Strupp and Binder 1984), plan diagnosis (Weiss and Sampson 1986), Dahl's FRAME method (Dahl 1988) and the role-relationship-conflict constellation (Horowitz 1991). The observation focuses on identifying functional and dysfunctional, observable or experienced interactions which may be influenced therapeutically. Microanalytic investigations of individual speech acts (SASB) are found at one end of the spectrum, and the global instruments which capture complex psychological processes of conflict (e.g., plan diagnosis, FRAME) at the other. The description of individual components of the interaction (CCRT) to different, partly parallel intrapsychic and interpersonal schemata may be seen as situated somewhere in between the two.

These procedures of interactional analyses with which interpersonal relationship patterns were established correspond to biographical methods which have experienced a revival over the last decade (Jüttemann and Thomae 1987). The SASB is based on the interpersonal circumplex model. This enables the analysis of connections between interpersonal and intrapsychic processes through the introduction of three levels of foci: the transitive (active: cause something to happen in others), intransitive (reactive: tell others about oneself) and introjective (focused on the self) (Benjamin 1974). The systematic application of the SASB model for psychiatric diagnosis and classification (Benjamin 1993) shows the influence of the approach. Other approaches use narrative material.

Luborsky developed the best-known approach for the systematic analysis of individual transference disposition, the CCRT (Luborsky and Kächele 1988). This procedure is based on the assumption that the narrative of the patient transports and condenses "clotted", subjectively meaningful interpersonal relationship experiences. Poignant subject-object behavioural relations such as burnt-in clichés are made visible by this method.

This instrument, which judges a relationship event that is experienced, prepares narrative material so that the imprinted internalised relationship structures that can be seen in individual behaviour become transparent. The relationship world of an individual is represented with a type of enduring life-history "motto", "chiffre" or "schema". Even more differentiated insights into the "macromolecular" relationship structures can be obtained from a further development of the Central Relationship Pattern (CRP) method (Dahlbender et al. 1998). This method demonstrates the variable organisation with different objects and contexts, shows a lifetime regulation and manages to demonstrate a change in therapy.

So-called relationship episodes are filtered from accounts of interactions from which three components are extracted. These are presented as sequential schemas.

The subject's wish for something from an object leads to a satisfactory or unsatisfactory reaction from the object, which is subsequently followed by a corresponding reaction from the subject. We can remain at the idiographic level, so that the patient's formulations are in speech form, or the statements can be transformed into an abstract categorical level.

One remarkable result obtained in this area of research is that the more relationship episodes with a variety of objects are recounted from the past and present, the clearer the differentiated patterns of clotted relationship experiences are (Luborsky and Crits-Christoph 1990). Research into convergent and discriminant validity of therapy transcripts confirms the value of analysing interpersonal relationship patterns and allows consideration of clinical progress and diagnosis (Luborsky and Barber 1995; Kächele and Dahlbender 1993).

In addition, self-rating methods were developed which assess interpersonal behaviour and experience, such as the Inventory of Interpersonal Problems (IIP) presented by Horowitz et al. (1988). This instrument is theoretically based on Sullivan's interpersonal theories (1953) from which the circumplex models of interpersonal behaviour were derived.

The circumplex model is based on the assumption that all interpersonal behaviours can be represented using two orthogonal and bipolar dimensions. The dimension of control ranges from dominant/controlling to submissive behaviour, and the dimension of affiliation ranges from affectionate/oriented towards to hostile/distanced behaviour. In Leary's model (1957),

16 interpersonal categories or segments were defined which are arranged around two orthogonal dimensions. Starting from this model, different groups of researchers have developed other models for the taxonomy of interpersonal behaviour that partly differ from one another in the number of segments they use (e.g. Wiggins 1982; Kiesler 1983).

Empirical relationships of the attachment style and people schemata underline the interconnection of constructs based on two different theoretical traditions (Horowitz 1994; Strauß and Schmidt 1997).

5 Implications

Psychoanalytic therapies have been influenced by the concepts of development, attachment and relationship. It has been shown that psychopathology can begin anywhere on the developmental path (Stern 1985). Modern psychoanalysis takes account of the environmental aspect. Instead of the pleasure/unpleasure principle, the principle of safety is a prime regulating mechanism using such concepts as mirroring, communication, affective exchange and bodily contact. Research into pathological development supports these new concepts with impressive evidence. The results of attachment research show the overriding significance of attachment needs for personality development.

Even though stringent empirical confirmation has yet to be delivered, knowledge of the patterns of attachment imply differentiated therapeutic strategies. It is reasonable to assume that the development of disorder-specific, axis II-oriented therapies would prove useful.

Knowing the implication of loss and the influence of death on the development of children is helpful for the therapeutic process (Köhler 1995). Diffuse associations made by the patient when touching upon such a topic should not be interpreted as a defence, but are developmentally based deficits of attention and concentration.

The therapist should not treat his or her patients as infants and should not mother them. However, it can be an advantage if the process of understanding the patient's childhood is enriched by images provided by new developmental psychology. The current interaction during therapy can be understood with as much differentiation as the mother-child relationship has illustrated. This leads to a multitude of communicative and interactive processes which enrich clinical conceptualisation (Emde 1991).

The process of empathic agreement takes shape through preverbal processes which are manifest in eye contact, position of the body and verbal adjustment. The saying that with our own unconscious we decode the unconscious of the patient would not be much more than an empty metaphor without these microstructural processes of exchange (Krause 1998). We may assume that the empathic understanding and intuitive grasp of the therapist are based on consciously or subconsciously perceived affective and motor patterns. These may be rooted in the early mother-child, father-child and sibling-child interactions (Lichtenberg et al. 1992).

The great progress made in infant research demonstrates the necessity to decode the grammar of non-verbal interactions (Krause 1990). The results focus on the importance of situational factors that play a part in both dyadic and group therapy situations.

In order to attain a helpful relationship, which is a prerequisite for good therapy, many different verbal and non-verbal communicative subprocesses may be seen as important. Their significance has already been demonstrated in the mother-child relationship, and parallels may be drawn with the therapeutic relationship. Therapy research has shown (Henry et al. 1994) that mutual esteem is an important ingredient in a helpful therapeutic relationship.

To summarise the significance of new insights in early development, attachment and relationship, the following may be said: They provide us with relevant facts and plausible models that allow us to create and enrich (Bornstein and Masling 1998) a current relationship, while having access to the so-called present unconscious and past unconscious (Sandler and Sandler 1984).

R. Michels

Psychoanalysis in Practice

Excerpts from Michels (1985, 1995, 1997) were used in this chapter and have been reprinted with the permission of the publishers.

1 Introduction

Psychoanalysis developed out of the clinical experience and theoretical speculations of Sigmund Freud, a Viennese physician born in 1856. In 1883, Freud's senior colleague, Joseph Breuer, told him of a fascinating patient, an intelligent young German woman, Bertha Pappenheim, who in later years was to become one of the founders of psychiatric social work. Breuer's clinical observations on this patient, who suffered from the symptoms of what was then called hysteria, led to a new theory about the nature of the disorder and some suggestions for a possible new treatment (Breuer and Freud 1895). Breuer himself stopped working in the area, perhaps in part because of his discomfort over the intense personal feelings stimulated by his relationship with his patient and his inability to understand those feelings. Freud explored Breuer's method further with other patients, continued to develop the theory, and in time even came to understand the meaning of Breuer's discomfort. The theory and the treatment based upon it were the beginning of psychoanalysis and psychoanalytic psychiatry (Freud 1925).

Bertha Pappenheim, like other patients diagnosed with hysteria, had multiple symptoms related to several organ systems, altered states of consciousness, and disturbances of thought, affect, and communication. Nineteenth-century psychiatry had understood these as reflecting abnormalities of the nervous system, i.e., as signs of an underlying neuropathology that had not yet been identified. First Breuer and then Freud began to employ a practice that grew out of the tradition of nineteenth-century medicine far more than that of nineteenth-century psychiatry: they spent many hours talking with their patients or, to be more precise, listening to them. As they did this, they noted a relationship between their patients' symptoms and what was on their patients' minds, and – particularly exciting – they discovered that talking about these issues actually influenced the symptoms. Freud and Breuer reconceptualized the symptoms as communications – symbolic expressions of thoughts and memories of which the patient might not be aware – rather than as signs of a disordered nervous system. In brief, the meaning of the symptoms and the cause and treatment of the disorder were to be discovered through a dialogue between the patient and the therapist rather than by a dissection of the brain and nervous system. Psychoanalytic psychiatry was to be a science of mental life. In Freud's famous formulation, his patients suffered not from brain disease, but from "reminiscences" (Breuer and Freud 1895).

Freud's background as a neurologist and neurobiologist shaped much of his early thinking; he initially attempted to formulate his theory as a neuropsychology, a project that quickly ran into difficulty because of the then primitive understanding of the nervous system (Freud 1895). Freud was also interested in evolutionary biology, cultural anthropology, and history, and one can trace each of these themes, as well as the ideas of late nineteenth-century positivist natural science, throughout his work. All of this is to say that psychoanalytic theory has been richly informed by the dominant ideas that influenced its creators and the intellectual climate in which it developed. In recent years, developmental psychology (Mahler et al. 1975; Stern 1985) has largely replaced neurobiology (Reiser 1984) and evolutionary biology as the source of its basic psychological concepts, and linguistics (Shapiro 1979), cognitive neuropsychology (Benjamin and Freidrich 1991; Stinson and Palmer 1991), group dynamics, and clinical psychopathology have contributed to its conceptual models as well.

According to Freud, psychoanalysis is three things: a psychology, a method of treatment, and a method of inquiry (Freud 1923). We will first discuss those principles of psychoanalytic psychology that are fundamental to the treatment (Michels 1995), then the clinical concepts that are central to contemporary psychoanalytic practice (Greenson 1967), and finally the scope of psychoanalytic psychotherapy and psychoanalysis today (Michels 1997).

2 Basic Principles

2.1 Mentalism

Psychoanalysis is about the psyche, i.e., the mind. It is about thoughts, feelings, experiences, wishes, fears, fantasies, and memories. It is not about the brain or the body, except insofar as these are seen as the substrate of mental activity having an impact on the mind or as being represented in mental imagery. It is also not about behavior viewed "objectively" from the outside, as by a behaviorist, seen as the activity of an organism without regard to the realm of subjective experience. Contemporary psychiatry often pushes neurobiological reductionism to the extreme, regarding mentalist concepts as referring to epiphenomena, with the "real" action occurring at the level of the nervous system (Kandel 1979). Psychoanalysis regards mental phenomena as its subject matter, and therefore it is of greatest value in understanding the world of inner experience. It is not an important tool in understanding brain dysfunction, seizure phenomena, or the psychological defects caused by the biologic

diatheses that underlie the major psychoses, but it is a major tool in understanding wishes, fears, and fantasies and the relationships among them – how these phenomena arise from earliest experiences, are transformed in the course of development, predispose to both adaptive and maladaptive behavior, and change in response to meaningful human relations. If we want to understand mental life and mental symptoms, we must employ mentalist models (Michels 1995).

2.2 Psychic Determinism

Common-sense psychology is, like psychoanalysis, mentalist; in other words, it explains people and their behavior in terms of thoughts, wishes, fears, and fantasies and the interplay among them. However, common-sense psychology, unlike scientific thinking, is not strictly determinist; although it explains many things, it accepts that other things might not be explainable – they just happen. For example, most people eat because they feel hungry and stop because they feel satisfied; their behavior reflects a mental experience. However, some people stop eating while still hungry, while others continue to eat although sated. These behaviors can be labeled as pathological – anorexic or bulimic – and attributed to neurobiological abnormality or unspecified "disease," but there is no common-sense psychological explanation for them. Even more familiar are so-called Freudian slips (psychoanalysts call them parapraxes). Most often we say what we are thinking, but sometimes we "just make a mistake." Other mental phenomena that seem to common-sense psychology to be unexplained by psychic determinism include dreams and most forms of neurotic symptomatology, such as obsessions or phobias.

Psychoanalytic theory is different from common-sense psychology in that it asserts a strict and all-embracing psychic determinism – all mental events can be understood as the result of antecedent mental events rather than as epiphenomena of brain events (except perhaps for the behavioral aspects of a seizure) and certainly never as random or without cause. An individual who does not eat may have the unconscious fantasy that food is poison, while one who overeats may – without being aware of it – see food as evidence of love. In short, dreams and symptoms are symbolic representations of disguised thoughts and fantasies. Psychoanalytic theory argues that mental determinism is pervasive and in doing so accepts that self-awareness or consciousness – a characteristic of mental life that common-sense psychology views as universal and constant – is in fact only partial and intermittent. The anorexic or bulimic individual, the dreamer, and the person with a neurosis all share a lack of awareness of the mental forces that govern their experience and, through it, their behavior. From a psychoanalytic perspective, these individuals' behavior is totally determined, although the determinants are unconscious. The psychoanalytic method allows us access to unconscious mental life and thereby permits us to fill in the gaps in the incomplete psychic determinism of common-sense psychology.

2.3 Mental Dynamics

The psychoanalytic approach is not only "psycho," i.e., mentalist, but also "dynamic," i.e., about forces, motives, and inevitably (because multiple forces have multiple and disparate goals) about conflict. Psychoanalytic thinking views mental life as the product of conflicting mental forces, wishes, fears, and emotions, each of which "presses" and all of which together direct thoughts and behavior. One of the ongoing theoretical dialogues in psychoanalysis relates to how such forces are best conceptualized. Freud thought of these mental dynamics as biologically rooted drives which unfold in a largely predetermined maturational sequence. Others have emphasized socially and culturally determined attitudes and desires (Kardiner 1945). The classification of mental forces, their origins in biology or social experience, their development over the life span, their plasticity, and their basic content – sexuality, aggression, mastery, curiosity, self-fulfillment, and others – have been ongoing themes of psychoanalytic discourse (Rapaport and Gill 1959). Much dispute in psychoanalytic theory relates to the basic nature of these forces. There is much more agreement as one moves from theoretical to clinical phenomena and observes the central role of the wishes and fears that stem from these forces in organizing patients' mental lives (Brenner 1982).

2.4 Unconscious Mental Life

Recognition of unconscious mental processes long antedates psychoanalysis. People frequently remember things they had previously forgotten and that must have been "stored" somewhere in the mind during the interval. Furthermore, they can be shown to know something they were not aware of knowing, by hypnosis or by less exotic means, such as behavioral responses to subliminal stimuli. However, unconscious mental processes assume a unique importance in psychoanalytic thinking because not only casual memories but also major dynamic forces – the wishes and fears that shape our lives and, particularly, our

neurotic symptoms and character traits – are believed to be unconscious (Arlow 1969). That mental processes could occur without our awareness was known to Aristotle; that many of the determinants of our major life choices are unknown to us, but nonetheless – and even because of this – exert powerful influence on us was one of Freud's great discoveries. Psychoanalysts further differentiate unconscious mental activity into "preconscious" (i.e., out of awareness, but easily accessible if attention is directed) and "unconscious" in the narrow sense, (i.e., inaccessible to the individual under normal circumstances). The clinical psychoanalytic method, with its free association (Kris 1982) and dream analysis (Altman 1978), is designed to facilitate the exploration of unconscious mental activity, making it preconscious and thus accessible to consciousness.

2.5 Repression and Defense

Why are mental themes unconscious? The most obvious answer – and the one largely accepted by common-sense psychology – is that they are likely to be forgotten if they are unimportant. However, this cannot explain why major dynamic forces that shape our lives are unconscious. Freud recognized that dynamic unconscious forces are unconscious for the very reason that they are important and would cause distress if they were to become conscious. The psychological force or mechanism that actively keeps powerful and potentially disturbing wishes or fears unconscious is called repression. First Freud himself, and then his daughter Anna and other psychoanalysts, came to recognize that repression was only one of the mental mechanisms available to avoid conscious distress engendered by the emergence of disturbing unconscious mental themes, and the term defense was introduced to encompass all such mechanisms, with repression as the prototype. In contemporary psychoanalytic thinking, defense is a function which may be served by almost any mental activity which is used to avoid conscious awareness of a disturbing unconscious theme. While early models of psychoanalytic therapy focused on helping people become more aware of forbidden unconscious wishes and fears, contemporary views emphasize helping people understand their defensive strategies and diminish the power that these exert in mental life.

2.6 The Present and the Past

Psychoanalysis is about the dynamic mental forces that shape behavior, forces that are very much alive in the present. It has no interest in the past except insofar as that past is preserved in those present dynamic forces. In their earliest inquiries into the unconscious forces that determined psychopathologic symptoms, Breuer and Freud had no special interest in childhood. However, within a few years, Freud discovered (and countless psychoanalysts since him have confirmed) that the persistent wishes and fears of childhood are the major themes of unconscious mental life. Thus the study of psychoanalysis, which is the study of unconscious mental forces, became of necessity the study of childhood psychology. The influence of unconscious forces on behavior is the influence of persisting themes of the mental life of the child on the adult. One of the important methodologic issues in contemporary psychoanalytic thinking is the relationship between the direct observation and scientific study of the psychology of children and the exploration of themes in adult mental life that can be traced back to childhood. The inner subjective record of the past is not the same as the past that would have been observed by a contemporary onlooker. The record is constructed, shaped, and reshaped during the course of development, and then is profoundly influenced by the circumstances in which it is eventually recounted. Thus, although the study of developmental psychology has relevance for psychoanalysis, it is only one source of data relevant to the clinical exploration of persisting infantile themes in unconscious mental life.

The concept of transference refers to a particularly important instance of the role of the past in shaping the present. Emotionally charged personal relationships, such as the relationship between a patient and doctor, are always shaped by the capacity for and the style of relatedness that the patient acquired in childhood. It is similar to the accent that is always present when speaking a language learned in adult life. The forms and characteristics of the first language shape the sounds of all later ones. All important relationships are to some extent repetitions of primary relationships, and a patient's relationship with his or her doctor reflects the patient's relationship with earlier caregivers, particularly parents. The appreciation of this process of transference is vital to our understanding of how therapy works, how it helps patients, and why they often struggle against it (Michels 1985).

2.7 Infantile Passions

Adults generally think of infants and small children as having bland and innocent thoughts, if indeed they think of them as having any thoughts at all. However, the truth appears to be quite otherwise, based on

observations made by experienced infant caregivers and developmental psychologists and, most importantly, on the persisting unconscious fantasies of adults. The child's mental life is driven by elemental passions and primitive terrors, unchecked by the understanding of reality available to the adult. The child's experience of the external world is organized in terms of the role it plays in the gratification and frustration of basic needs. Freud emphasized the sensual pleasures of bodily experience, which he labeled by the name of the bodily pleasure central to adult experience, sexuality. Other psychoanalysts have emphasized aggressive as well as sexual drives, and the psychological meaning of attachment to and separation from primary caregivers. These themes – sexual, aggressive, clinging, and autonomy-seeking wishes and fantasies persisting from the mental life of childhood as unconscious dynamic forces in adults – are the building blocks of psychoanalytic models of psychic conflict.

2.8
Mental Structures

Psychoanalytic models of mental life focus on dynamic forces. However, certain patterns of mental activity are stable over long periods of time, and the concept of structure has seemed more appropriate than that of force to describe such stable patterns. Motivational systems such as sexuality and aggression, believed by many to stem from the neurobiological organization of the nervous system, are structures. Patterns of defense resulting from innate styles and developmental experiences are also structures. Freud's so-called structural model organized mental activity into three overarching structures (Arlow and Brenner 1964). One was the id, which referred to the organismic and biologically rooted drives and their psychological representations. The second was the ego, which referred to the adaptive and external reality-oriented aspects of the mind, including perception, cognition, memory, motor control, and adaptive behavior as well as defensive processes. Finally, there was the superego, a specialized portion of the ego that tended to function as a coherent organized system and that was often in conflict with the rest of the ego as well as with the id. The superego encompasses values and standards, notions of good and bad, right and wrong, approval and disapproval, and the inner sources of guilt, shame, and pride. The common-sense psychology notion of "conscience" refers to that small aspect of superego functioning that is conscious. Psychoanalytic developmental theory views the primary origin of the superego as the child's internal psychological representation of the parent – approving and disapproving, loving and criticizing, rewarding and punishing. Some psychoanalytic writers separate the positive ideals from the critical injunctions of the superego and call the former the "ego-ideal."

2.9
Adaptive Function of Behavior

Common-sense psychology views most behavior as adaptive, but sees some behavior differently, as a mistake, wrong, stupid, or pathologic. In many ways, this view is a corollary of seeing some behavior as not fully determined. Psychopathology seen from a common-sense perspective is not adaptive; it is wrong, and the goal of treatment should be to expunge it and replace it with correct behavior.

Psychoanalytic psychology holds a different view. All behavior, including pathological behavior, is seen as adaptive. Instead of being a mistake, pathological behavior involves the effective pursuit of goals that may be concealed both from the patient and from the rest of the world. Such behavior constitutes an adaptive component of an unconscious strategy. The central goal of treatment is not to expunge the "wrong" behavior, but rather to identify its hidden goal and bring it into the open. When the goals of pathologic behavior become known to the patient, the patient is freer to integrate them with the rest of his or her life, either to purge them or to abandon them, but their maladaptive impact is diminished.

Modern clinical psychiatry classifies the phenomenology of psychopathology according to the familiar clinical diagnostic categories. Psychoanalytic psychiatry, by contrast, sees behavioral phenomenology as the product of underlying mental forces. Whereas a clinical psychiatric diagnosis is a summary description of pathological phenomena, a psychoanalytic formulation is a statement of the major mental themes, wishes, fears, conflicts, and compromises leading to that behavior and the history of their development (Perry et al. 1987). Diagnoses focus on the boundaries and discontinuities between health and pathology; in contrast, psychoanalytic formulations focus on the continuities and similarities that reveal the underlying integration of the patient's healthy and pathologic mental life.

2.10
Conflict and Compromise – Symptom and Character

Psychoanalytic psychology views behavior as the product of conflicting and often unconscious mental forces. Psychological conflicts lead to internal signals of potential dysphoria, anxiety, and depression, signals

that will lead to conscious distress and the disruption of functioning if other psychological strategies are not called into play. Most often, these signal affects elicit coping strategies, such as the so-called defense or mental mechanisms – strategies for constructing compromises among the conflicting dynamic themes, wishes, and fears. Typically, such compromises manage to keep the potentially most disturbing themes unconscious, while partially and symbolically gratifying the wishes and accommodating the fears. These compromise structures may diminish adaptation to reality in order to satisfy unconscious needs, in which case they can lead to pathology. If the compromise structures are integrated into the individual's experience of self, they are called character traits (Auchincloss and Michels 1983). If they remain psychologically sequestered and alien from the sense of self, they are called symptoms. Paradoxically, an early task in the psychoanalytic psychotherapy of symptoms is to demonstrate to the patient that his or her symptoms are meaningful products of inner psychological themes (i.e., they are linked to character), whereas an early task in the psychotherapy of pathological character traits is to establish some potential dystonicity from the patient's sense of self (i.e., to support the patient's image of a possible self without the undesirable pathology).

3 Clinical Principles

The initial focus of psychoanalytic study was on the exciting new discoveries in the psychology of the mind. Many of Freud's most famous early publications – on dreams, parapraxes, jokes, sexuality, art, culture, and even psychopathology – had little to do with psychoanalysis as a therapy. It was as though knowledge of the psychology would be sufficient to conduct the therapy, and no further concepts would be required. However, problems soon emerged, and the basic concepts of clinical psychoanalysis were formulated and developed in response to these. Today, psychoanalytic discourse and the psychoanalytic literature is more interested in issues of clinical therapy than in basic psychologic matters.

3.1 Relationship

The early clinical interest of psychoanalysts focused on the content of the therapeutic sessions – the dreams, fantasies, and memories of the patient – with the hope that their exploration would lead to the recovery of repressed childhood memories and the reconstruction of a coherent account of the forgotten past. However, it soon became apparent that the relationship between the patient and psychoanalyst within which this exploration occurred was important as well, perhaps even more important than the content of what was discussed. Today, it is widely recognized that the therapeutic effectiveness of psychoanalysis, as that of all other psychotherapies, is heavily dependent on the quality of the relationship between patient and therapist.

3.2 Alliance

Early formulations of the relationship emphasized two aspects: (1) the transferential relationship between the regressive infantile neurotic themes in the patient and the responsive aspects of the therapist's personality and (2) the relationship between the mature, rational adult, self-observing and help-seeking themes in the patient and the corresponding expert professional aspects of the therapist. This latter "mature" relationship was first differentiated from transference and referred to as the "therapeutic" or "working" alliance. It was seen as an essential frame for the psychoanalytic process to progress. Today, a broader notion of transference has become more prevalent, one that emphasizes the transferential origins of all relationships, both adaptive and maladaptive, and thus of the alliance as well.

3.3 Transference

Transference refers to the impact of unconscious mental themes that persist from childhood relationships on the experience and form of contemporary relationships.

While transference phenomena are important in understanding unconscious motivating factors in all human relationships, they are particularly prominent in those that are strongly charged emotionally and, like that between patient and analyst, recreate aspects of early parent–child relationships. In most situations in life, and in many therapeutic situations, we try to emphasize external reality and minimize or suppress the impact of transference. In psychoanalysis, we do the reverse – we try to control, limit, and minimize the determining effect of contemporary external reality so that the transferential determinants of behavior will be clear and vivid, both to the patient and the therapist.

Transference phenomena are essential in understanding both the motivating and resistive factors in

any type of treatment, biologic or psychologic, psychoanalytic or otherwise. However, in psychoanalytic treatments, they have additional significance. Because the treatment itself revolves around an exploration of the transference, an attempt is made to study and explore the persistent unconscious dynamic forces that shape the patient's relationship with the therapist rather than merely to exploit or control their impact, positive or negative, on the therapeutic process. The exploration of the expression of these themes in the transference relationship is the essence of psychoanalysis and psychoanalytic psychotherapy.

Transference responses are shaped by contemporary external reality as well as by persisting unconscious determinants from the past. Therefore, the transference in psychoanalysis evolves in part in response to the psychoanalytic process itself. It is the exploration of this aspect of the transference, the development and evolution of transference phenomena within the relationship between patient and therapist, rather than the exploration of the initial transferentially determined attitudes toward the therapist that is at the core of psychoanalytic treatment. The concept of "transference neurosis," considered essential by some and superfluous by others, refers to the integrated cohesive transference that develops in the course of psychoanalysis and that encompasses the core themes of the patient's psychopathology in the newly developed relationship between patient and analyst – a constellation that may in some cases provide a substitute for the patient's neurotic symptoms.

Any aspect of mental life may be involved in transference responses, e.g., wishes, fantasies, emotions, defenses, attitudes, patterns of relationship with others. Further, transferences may stem from any of the various developmental epochs. Transferences may be positively or negatively toned. They may motivate the patient or may stimulate resistance. They may be erotic or aggressive. At times, they may be traced back to specific early relationships; at other times, they may be seen as embodying mixtures of characteristics from several different relationships. Transferences have been classified according to each of these characteristics, and for specific purposes each type of classification may be useful.

Although it is common to think of psychotherapy as exploring the links between past and present, these links are already established in the transference, and it is the exploration of the transference that is central to psychoanalysis and much exploratory psychotherapy. A common misunderstanding of psychoanalysis would emphasize the discussion of the historic past and its relation to contemporary external reality as a core theme. However, if such discussion is conducted in arenas other than the transference, it rarely has the emotional power or conviction that accompanies the analysis of the transference. Some have argued that the only really effective interpretations are transference interpretations. The degree to which this is true, the extent to which transference interpretations are qualitatively exceptional, as opposed to merely frequently important, is a matter of contemporary controversy.

Exploration of the transference entails not only exploration of the patient's response, the unconscious themes that shape it, and their origins in the past, but also exploration of the current situation that has precipitated it. All transference responses are real responses to contemporary stimuli; they are all more or less appropriate. Some of the most important transference phenomena are thoroughly realistic and adaptive. That something is transferentially determined by unconscious mental factors does not mean that it is wrong, pathological, or maladaptive, and all human relationships are transferentially determined by unconscious factors (Michels 1985).

3.4 Countertransference

Just as the patient's response to the therapist reflects persisting unconscious themes, so does the therapist's response to the patient, or the countertransference. Indeed, our notion that transference is universal would require that this be so. Like transferences, countertransferences can be both motivating and resistive factors. Furthermore, like transferences, they are responses to contemporary determinants, i.e., to the patient. As a consequence, they may become valuable sources of information about the patient's mental life.

The first and most vivid indication of the patient's transference may be in the therapist rather than in the patient; hence the study of the therapist's countertransference is an important source of information about the patient's transference. The patient in effect expresses the transference by eliciting, provoking, or seducing responses in the therapist. The extent to which there are unique mental mechanisms involved in this type of phenomena, the extent to which they have central clinical significance, particularly in the treatment of more disturbed patients, and the close link of this idea and certain technical notions emanating from it to specific schools of psychoanalytic thought are areas currently being debated (Sandler et al. 1992).

3.5 Resistance

Resistance refers to the forces within the patient that oppose the treatment. It is a reflection of the patient's defenses and character structure in the treatment

situation and is manifested by a variety of behaviors, including not coming to treatment, coming late, being silent, avoiding emotions, ruminating about trivia, journalistic accounts of daily events, keeping secrets, forgetting, not paying, and focusing on obtaining transference gratifications from the analyst even at the risk of destroying the treatment.

Resistance appears early in every therapy and was recognized early in the history of psychoanalysis. The initial response to this recognition was the obvious one, the development of a variety of techniques for overcoming the resistance, e.g., rational persuasion, exploitation of the positive transference, hypnosis. With time, psychoanalysts came to realize that resistant behavior presented a therapeutic opportunity as well as an obstacle and that the dynamic structure of the patient's character could be explored as it emerged in the therapeutic setting. The focus shifted from what was being resisted, with the corollary of penetrating, dissolving, overcoming, undermining, or circumventing the resistance to the study of the resistance itself, with the goal of understanding its form and its history and exploiting its potential as a model of the patient's character structure in the therapeutic process.

3.6 Interpretation

Interpretation is the major specific activity of the psychoanalyst and is one of the essential ingredients of psychoanalytic psychotherapy. Interpretation has been defined in various ways. For some, any intervention that aims to increase the patient's insight and understanding or to expand his or her awareness is an interpretation. For others, interpretations must be differentiated from the preliminary steps of clarification and confrontation or from the more comprehensive process of construction and reconstruction. The term interpretation may refer to the process of discovery, decoding, and translation of latent or concealed meaning, or it may refer to communicating the results of that process to the patient.

Psychoanalysts discovered that the meanings that individuals create from events can be far more significant than the events that serve as stimuli for those meanings. This is as true of interpretations as other events. The analyst may believe that he or she is interpreting the here and now or the past, but the patient will hear the analyst's interpretations in terms of the psychological complexes that are active at that time in his or her own mental life and in terms of the phase of the treatment and the nature of the transference. As a result, if we wish to know what an interpretation is about, it may be more important to know what was going on in the analysis and in the patient's mind at the time that the interpretation was made than to know the words that the analyst said. Most of the time in a successful analytic process, the patient is involved in a complex mixture of concerns: concerns with his or her current relationship with the analyst, concerns with memories of earlier relationships reactivated by the current one, concerns with the impact of the current relationship on the memories, and so on in a never-ending process of reverberating resonance.

Individual interpretations may be aimed at one or another concern, at the past, at the here and now, or at the interaction between them. If they are successful, however, it is because they become part of the reverberating process and because they in turn influence it. An interpretation directed to the here and now must therefore be related to or at least open to the patient's memories and fantasies of the past if it is to have the possibility of enlarging the patient's experience of the here and now, of providing it with new meanings. Similarly, an interpretation directed to the past must be about the living past that is shaping and forming the patient's present if it is to have a therapeutic impact and alter the present. Some interpretations do both at once. Some poor interpretations may be "true," but they are truths which have no psychic relevance. Such statements about the patient's mental development or mental functioning may be of interest to a psychodynamicist or a psychogeneticist, but they will have no impact on the patient's inner world. The question is not whether a specific interpretation is directed at the present or at the past, but whether it is part of an interpretive net, a therapeutic process that involves both. It is the nature of this process, rather than the focus of a specific interpretation, that defines psychoanalysis (Michels 1983).

4 Psychoanalytic Psychotherapy

Many other treatments have been developed from various components of Freud's early experiments with the complex mixture of activities which occur when a patient and a therapist talk to each other. Some derivative treatments focus on the patient's symptoms; others on pathogenic cognitive strategies; still others on interpersonal relationships; some focus on the therapeutic relationship itself or on constructing a story about the past. Thus we have symptom-oriented treatments, cognitive therapies, interpersonal therapies, relationship and existential therapies, and reconstructive therapies that create stories about those early experiences which are thought to be of pathogenic significance.

All of these treatments have evolved in parallel with the continuing evolution of psychoanalytic psychotherapy and psychoanalysis (Michels 1997). Certain contemporary themes are of particular importance. A prominent one is the trend toward technical innovations that make the treatment more "user-friendly," with less emphasis on developing a painful awareness of disavowed aspects of oneself, and more on relieving the pain and suffering involved in coming to know oneself more deeply. Modern psychoanalytic psychotherapy is more concerned with making the process of therapy comfortable for patients.

A second trend is toward a sharper definition of goals. Today, few psychoanalytic psychotherapists or psychoanalysts believe that one should try to reconstruct a complete account of early life, resolve all psychological conflicts, or understand all dimensions of the transference. One of the goals of treatment – prominent early in the field's history, lost in the middle third of the century, and now recognized again – is to end the treatment.

A third trend is the widening of scope of the mental theories that constitute the content matter of psychoanalytic psychotherapy from their original focus on sexual motivations or wishes to a broader interest in other kinds of motives (e.g., aggression), in self and object representations, and in mental structures other than motives. The modern psychoanalytic therapist has a larger range of metaphors upon which to draw in making interpretive interventions.

The psychoanalytic psychotherapist listens with more directed or focused attention than does the psychoanalyst, with a goal in mind other than the analyst's goal of full comprehension and communication. Both therapist and analyst are guides on a journey, but the analyst is a guide in an uncharted territory, while the psychoanalytic psychotherapist is a guide with a map and a plan for the trip.

The goal of psychoanalysis is change, often understood as a continuation or resumption of an arrested course of development with overt behavioral change viewed as a product and sign of more fundamental, deeper change involving integration of previously unintegrated experiences. The goals of other psychotherapies may also include change, either intrapsychic or behavioral. They often emphasize relief or maintenance and support as well. When change is sought in other therapies, it may or may not be through insight (Wallerstein and Nemetz 1979).

In general, psychoanalytic psychotherapy tends to draw on the same array of techniques as psychoanalysis does. However, noninterpretive techniques are relatively more prominent in psychotherapy. Techniques are selected in regard to specific therapeutic goals. Insight is not the privileged route to change; what works best is preferred.

Psychoanalysis is more importantly differentiated from psychotherapy by the process than by the various techniques employed. The process of psychoanalysis involves the relatively spontaneous evolution of a regressive transference with the goal of its understanding and resolution. Most psychotherapies involve some activity designed to direct or influence the nature of the transference or to focus the therapeutic process on some other aspect of the patient's experience. This may be required by the patient's pathology, the therapist's capacity, or situational variables. The diagnostic assessment may lead the therapist to avoid analyzing certain infantile themes that contribute to a stable adult adjustment.

Psychoanalytic therapies have grown in significance so that they now constitute some of the major treatments of contemporary psychiatry. The range of disorders to which they have been applied has broadened, so that today a large number of individuals appear to be potential patients to some practitioner of psychoanalysis or psychoanalytic psychotherapy.

Much of the literature suggests that psychoanalysis is for healthier patients and psychoanalytic psychotherapy for sicker ones. This formulation is both misleading and impolitic. Not everyone who is analyzable is best analyzed. Positive indications for psychoanalytic psychotherapy would include the value of theories other than psychoanalytic theories in guiding the treatment, the value of noninterpretive and noninterpreted techniques, and goals not mediated by insight and integration.

Today, psychoanalytic psychotherapy is a valid treatment for a number of anxiety disorders, with the exception of obsessive–compulsive disorder. Psychoanalytic treatments are effective for nonpsychotic affective disorders and for mixed anxiety and depressive syndromes. They remain the dominant treatments for personality disorders, excluding antisocial personality.

Psychoanalytic psychotherapy is an important treatment for people who have problems in living, adjusting to stress, adapting to medical or psychiatric disabilities, complying with treatment regimens, rehabilitation, and other situations in which subthreshold personality characteristics limit happiness or successful adaptation. Psychoanalytic psychotherapy is probably at its best with patients who do not have disorganizing psychopathology but nonetheless have some psychological limitations, and therefore might be helped to function more effectively through treatment.

Finally, it is a powerful adjuvant combined with biological therapies for the chronic and persistently mentally ill, both by enhancing compliance with the other therapies and by alleviating secondary demoralization.

5 Psychoanalysis Today

Psychoanalysis proper, in the narrow sense, is only about 70 years old, emerging several decades into the "official" history of psychoanalysis. The treatment that was called psychoanalysis before that, from the late nineteenth century until the end of the second decade of the twentieth century, was more akin to contemporary short-term psychoanalytic psychotherapy than to contemporary psychoanalysis. It was not until 30 years into the history of the discipline, with the discovery of the central role of the analysis of transference and resistance rather than the reconstruction of childhood experiences, that patients routinely came back to a second year of treatment after their first summer vacation. Contemporary psychoanalysis is thus one of the offspring of the original treatment rather than the direct continuation of it (Michels 1994).

Psychoanalysis proper is far less prevalent than the various psychoanalytic and other psychotherapies that have been derived from it. It is more time consuming and more expensive, and therefore practical considerations often lead to the selection of a psychotherapy instead. However, the scope of psychoanalysis is broader, its potential greater, and, when the modification of pathologic character structure is the primary indication for treatment and the patient can tolerate the frustrations and deprivations of the process, it is often the treatment of choice. For some patients with serious character pathology, even though the prognosis is uncertain, it may be the only treatment that offers any real chance for change. Finally, it has remained the richest source of new concepts and ideas for the entire field of psychotherapy and for other areas of applied psychoanalysis as well (Cooper and Michels 1978; Michels 1988).

General Psychiatry

CHAPTER 1

G.E. Berrios

The History of Psychiatric Concepts

1 Introduction

Like any other intellectual and practical discipline (or, indeed, institution or culture), psychiatry needs a stable conceptual scaffolding. Such a structure can be found only after much effort, well hidden from the view of ordinary users. All the latter can see is putative "empirical facts" and (of late) what is grandly called "evidence-based" guidelines for their diagnostic and therapeutic interventions. What is more, since the nineteenth century, decisions as to which "scaffolding" to accept and what "facts" and "rules" to follow have been taken by small, changing cliques and are well beyond the control of ordinary users. This vaticanisation of psychiatry started in continental Europe and has since moved across the English Channel.

The history of psychiatry itself began in similar social circumstances. Thus, basking by the fires of a weekend tryst, the princes of psychiatry might on some occasion have felt that the past of their subject ought to be sung. Knowing what was good for him, some shivering minstrel would have then spun a glorious yarn leaving much unsaid, particularly concerning the rights of self-styled princes to decide what scaffolding to use (for examples of such accounts, see Berrios 1994a). Mercifully, things have changed since and the psychiatric historian of today waits upon no prince. He or she wants to know about the conceptual and moral warrants of princely powers, about the sources of their money and about the real motivation of the meek narratives that extol their virtues.

This started in the 1960s, when Foucault (1972a) and his epigoni first introduced the idea that the historian should be the scourge of psychiatry. Their exaggerations and pseudo-historical productions, however, alienated for a time the psychiatric brotherhood. Things have improved of late, and the clinical historian once again attends the high table of science and is allowed to tell his or her *roman d'épouvante*. Through this, the profession has learned that the conceptual scaffolding of psychiatry is on occasions tinkered with for purposes other than the good of patients. Although by no means perfect, this new historical approach is imbued with the idea that history *must* also contribute to the development of clinical psychiatry.

2 Conceptual History

Of all the historiographic approaches available, the one referred to as "conceptual history" is the most apposite to deal with scaffoldings and the other serious matter treated in this chapter. Such a method will need to focus on four interacting frames: descriptive psychopathology (DP), aetiological theory, pathogenesis and taxonomy. DP refers to the language of description; aetiology to the causes of disease (Berrios 1984a); pathogenesis to the manner in which disrupted brain mechanisms generate mental symptoms; and taxonomy to the rules governing the classification of disease. Ideological forces within and without psychiatry have contributed to the generation and maintenance of these frames. DP (i.e., "semiology"), for example, owes much to eighteenth-century linguistics and the theory of signs (Landre-Beauvais 1813; Lanteri Laura 1966; Juliard 1970; Barthes 1972), and aetiological theory and pathogenesis to developments in general medicine, microscopy and nineteenth-century psychological theory (Canguilhem 1966; Laín Entralgo 1978; Albarracín Teulón 1983; Berrios and Porter 1995), while taxonomy is partly based on seventeenth- and eighteenth-century metaphors of order (Whewell 1857; Boyer 1873; Delasiauve 1861; Larson 1971; Georgin 1980; Slaughter 1982). Little else will be said on the latter, as it is covered in Chap. 2 (this volume, Part 1).

It goes without saying that these interacting frames only gain full meaning when placed on the canvas of the nineteenth-century practice of alienism. The resulting fabric includes explanatory elements ranging from the evolutionary and biological to the sociopolitical – as rightly required by social historians (e.g., Foucault 1972a,b; Dörner 1969; Blasius 1980; Scull 1979; Donelly 1983). Conceptual historians start from the premise that the "meaning" of mental disorder is as dependent upon knowledge of its biological origins (i.e., the source of the distorted biological signal) as it is upon knowledge of the psychosocial envelopes. In other words, most "psychiatric" phenomena are the final expression of a biological signal modulated by personal and cultural grammars (Marx 1970; Berrios 1984a).

It follows that the stability of DP and of the disease categories that populate psychiatry is a function of the rate at which biology and language change (Daumezón 1957; Berrios 1994a); in other words, descriptions and diagnoses are kept stable as much by symbols, myths and other constructs (Devereux 1980) as they are by actual biological invariants (Berrios 1994a). Indeed, psychiatrists have not yet developed accurate ways of deciding on the relative contribution of each. For example, while "manipulative behaviour" (Mackenzie et al. 1978) may be fully the result of human interaction – and hence be "social" in origin – "grand mal seizures" (Berrios 1984b), "delirium" (Berrios, 1981a) and "hallucination" (Berrios, 1982b) can be considered as fundamentally "biological" phenomena.

Pre-nineteenth-century literature is rich in descriptions of insanity (Postel 1984; R. Porter 1987;

MacDonald 1981), but little is known about the conceptual frames that propped them up. More is known about the nineteenth century, but the three great changes that transformed the nature of psychiatry remain only partially understood (Berrios and Porter 1995). These changes are the following:

1. The transformation of "insanities" into "psychoses" (on this, see History of Psychiatry 1996)
2. The narrowing (and eventual disappearance) of the "neuroses" as a general category (López-Piñero 1983)
3. The fragmentation of the old monolithic descriptions of insanity into what are now called mental "symptoms" (Berrios 1996)

This chapter addresses some of these issues and chronicles the interaction between theory, observation and the biological phenomena of madness. To avoid confusion, it will keep separate the history of words, behaviours and concepts. It will also take as proven that the protagonists of the tale were men with families, political interests, fears and ambitions and that many of their choices were determined by "non-cognitive" factors. However, it will also assume that they were also ethical beings who, when faced with real patients, exercised (as current psychiatrists would like to be thought of as doing) objectivity and a modicum of descriptive freedom; hence their writings can be considered as scientific documents.

3
Development of Descriptive Psychopathology

3.1
Definitions

DP is defined here as a "language" comprising a syntax, lexicon and rules of application (Berrios 1996). Because DP imposes order on a universe of complex behavioural forms, it is also a "cognitive system". For each term (purportedly dealing with a self-contained piece of behaviour or "symptom"), DP is expected to contain "caseness" rules, i.e., ways of determining whether a given "symptom" is present or absent (Berrios and Chen 1993). Symptoms (conceived of as referents or signifiers) are defined by means of decision-making routines profitably analysed in terms of signal-detection theory (Macmillan and Creelman 1991). At a basic level, symptoms are assumed to result from a "fracturing" of insane behaviour, although things may be more complex than that (on symptom formation, see Berrios et al. 1995).

Consequently, observers may differ in the way in which this task is done; indeed, before estimations of inter-rater reliability (e.g., the kappa values; Shrout et al. 1987) were available, nineteenth-century alienists used consensual (qualitative) rules to determine *when* a symptom was present. For example, they might appeal to the higher tribunal of "common sense", to the "obvious" nature of some disordered behaviours and occasionally to intuition and the "clinical eye". When such aids failed, as not infrequently happened in court, particularly in relation to the predication of intentionality (Smith 1979), impasses might occur as to how symptom recognition could be achieved (Helmchen 1985).

3.2
Problems

Absence of a recognisable DP is a striking feature of psychiatric discourse *before* the nineteenth century. However rich in literary detail, earlier references to insanity (or germane terms such as dementia) were made in terms of "holistic" categories (Berrios 1987a,b). One explanation for this may be that detailed descriptions were unnecessary or inconvenient, because "insanity" in those days fulfilled a different social or legal function (Beaugrand 1865). For example, any assumption that there might be a continuity between mad and normal behaviour – often made by DP – would have threatened the "all-or-none" concept of "total insanity" which was so important before the nineteenth century. Furthermore, since Greek times, psychiatric categories were founded on descriptions of polar "overt" behaviours (Berrios 1987b) and of social competence (Platt and Diamond 1965) and left little room for nuances and transitions.

The creation of DP took about 100 years. It started during the second decade of the nineteenth century and was completed just before the Great War. It has changed little since. This means that the success of current clinical and research endeavours depend to no small extent on the quality of a conceptual machinery tooled during the nineteenth century (Berrios 1983, 1995; Berrios et al. 1995). The twentieth century has no doubt refined the psychiatric discourse by the introduction of techniques of statistical calibration and decision-making, but the historical question remains: how did nineteenth-century alienists manage to extract, based on longitudinal observation of what were often institutionalised patient cohorts, stable descriptions and classifications? Five factors will be explored in this regard:

1. The descriptive and medico-legal obligations of medical officers gradually introduced in nineteenth-century asylums
2. The availability of psychological theories

3. The changing importance of the notion of "sign" and "symptom" in medicine
4. The introduction of *subjective* symptomatology
5. The adoption of a *temporal* dimension in the description of abnormal behaviour

3.3 New Descriptive Needs

During the early years of the nineteenth century, a drive to build asylums for the insane simultaneously appeared in various European countries (Walk 1964). Once built, these institutions created social and scientific consequences of their own. First of all, they encouraged the accumulation of the mentally ill within confined physical spaces. Overcrowding and lack of medical care led to decimation through intermittent infections and highlighted the need for a regular medical presence. In Great Britain, this was made good by the 1828 Asylums Act (Jones 1972). The incorporation of medical practitioners into asylums generated, in turn, new changes. They brought with them the habit (and the medico-legal obligation) of monitoring and documenting clinical change. As long as this need related to the physical state of patients there was no problem, as, during the early nineteenth century, recognised methods of history-taking already existed (see Laín Entralgo 1961).

This was not so with regards to mental state. Perusal of pre-1840 clinical log-books shows a poverty of description consonant with the absence of "symptom lists". Early asylum doctors were thus forced to improvise and borrow, and their activity can be said to be an important factor in the creation of a "semiology" of mental illness. After 1850, however, a change is noticed in the quality of descriptions.

In this regard, it is important to point out that, although on occasions accounts of madness can be found *before the nineteenth century* that include elegant descriptions of mental states (e.g., Battie 1758; Burton 1883; Diethelm and Heffernan 1965; Hunter and Macalpine 1963; MacDonald 1981), they cannot be said to amount to a *common* language of description (i.e., shared by all physicians), nor were they intended to be. What emerged from the nineteenth-century descriptive enterprise is totally different, namely a common language based on an *analytical and pictorial epistemology* dealing with symptoms *independently* and assuming that the *same* symptom could be seen in *different* forms of madness. The creation of such language of description (DP) led to a shift in the *perception* of madness. (It could be claimed, of course, that it was the other way around – see Foucault 1972b – namely, that changes in the perception of madness, e.g., its medicalisation, led to treating these phenomena as if they were brain lesions expressed in signs and symptoms. This might have been so at a general level, but the point made here is that, once the old monolithic notion of insanity was broken up, semantic interpretation concentrated on individual symptoms and on the way they clustered together. Consequently, the general semantics of insanity became unimportant.) Changes in the "semiology" of medicine are no doubt important in this process. But the sine qua non for this change was the availability of psychological theories in terms of which behavioural profiles could be constructed.

3.4 Psychological Theories

DP started to emerge in France during the second decade of the nineteenth century. It did so in the way in which specialised books began to use illustrative case histories and to include sections on "elementary" symptoms. This is the main difference between the earlier books by Pargeter, Arnold, Crichton, Haslam, Rush, Heinroth or Pinel (predominantly holistic and taxonomic) and those published after the 1930s by Prichard (1835), von Feuchtersleben (1847), Bucknill and Tuke (1858), Falret (1864), Griesinger (1867), Krafft-Ebing (1893), Séglas (1895) or Chaslin (1912).

Melancholia, mania, phrenesis, delirium, paranoia, lethargy, carus and dementia were the main diagnostic categories inherited by the nineteenth century. By the 1850s, these clinical notions had undergone fractionation (Ey 1952; Berrios 1977), and recombinations of the fragments (i.e., of the new mental symptoms) gave rise to new clinical entities, many of which have survived to this day. Delirium was one of the few old categories to escape unscathed. Carus, phrenesis and catalepsy were not so lucky and disappeared altogether. Many old terms survived, but lost their old contents and were filled with new ones (e.g., melancholia and mania; Berrios 1988a,b). The fractionation of the old clinical categories of madness occurred along planes of cleavage contained in the templates of the mind that faculty psychology and (less obviously associationism) made available.

3.4.1 *Faculty Psychology*

Faculty psychology, an ancient (and recurrent) view of the structure of the mind (Blakey 1850) underwent a revival towards the end of the eighteenth century. In fact, the early development of DP in France can be partially explained by the fact that, in their reaction against associationism, alienists in this country opted for a form of faculty psychology (e.g., Damiron 1828;

Dwelshauvers 1920; Ravaisson 1885). Influenced by the Scottish philosophy of common sense (Boutroux 1908; Grave 1960) and under the leadership of Maine de Biran (Drevet 1968; Moore 1970), Royer-Collard (Swain 1978), Cousin, Jouffrey and Garnier, the French philosophical establishment accepted a "functionalist" view of the mind. This led to a shift from the reigning Condillacean sensationalism to a new essentialist view emphasising a form of Biranean "inner experience" (Royer-Collard 1843; Losserand 1967).

Phrenology was one of the nineteenth-century intellectual disciplines inspired by faculty psychology (Lanteri Laura 1970). Indeed, it has not been sufficiently emphasised that the conceptual basis of craneology (later called phrenology by Spurzheim) was but an "anatomised" form of faculty psychology. By suggesting "trait profiles", the phrenological approach allowed typological theories of character (later called "personality"; Spoerl 1936). These profiles were de facto conglomerates of faculties, and long after phrenology had been discarded, faculty psychology remained a conceptual matrix for nineteenth- and twentieth-century views on psychiatric taxonomy and localisation (Young 1970; Clarke and Jacyna 1987; Radden 1996).

3.4.2 Kant's Version of Faculty Psychology and the Nineteenth Century

Kant's tripartite concept of the mind was almost contemporary to that of the Scottish philosophers (Hilgard 1980; Radden 1996). Influenced by von Wolff via Knutzen, his teacher at Königsberg, and via Tetens, whose version of the "tripartite view" he was to follow (Windelband 1948), Kant rebelled against the "dogmatic rationalism" of his teachers (Brett 1953). Following the views of Baumgarten (Buchner 1897), Kant suggested that affect (and semantic appurtenances) constituted an independent faculty. In the *Critique of Judgement*, Kant (1914) put forward the view that the "three faculties are irreducible and cannot be derived from a common root" and believed that emotions had a causal role in mental disease (*Krankheiten des Gemüts*; Kant 1974). As Mora (1975) has remarked, "at the end of the 18th century, Kant came to think of mental illness as a form of weakness of the faculties, in line with his belief in Faculty Psychology. . ." (p. lix).

In addition to the *Anthropologie*, another early tract dating back to 1764 carried some of Kant's ideas on mental disorder (see Jalley et al. 1977). Influenced by Locke, Kant differentiated in this work between delusions originating from faulty perception and faulty thinking and suggested a separation between perceptual and thinking functions. The impairment of the former he called "hallucination" and of the later "delusion": "so far (in the hallucinations) the thinking faculty is not involved at least not necessarily, and the failure occurs in the empirical notions. . . as opposed to this, when thinking is impaired the conclusions from experience are wrong; the first degree of this disturbance is called delusion" (p. 225, Jalley et al. 1977). Sauri (1969) noted that the "ideal schema" of the faculties allowed Kant to classify delusional thinking no longer in terms of content, but as a manifestation of a disorder of intellectual function.

Little has been written on the influence of Kant on psychiatric thinking (Leary 1982). Leibbrand and Wettley (1961) remarked upon the fact that Kant's contribution was theoretical and was made in spite of the fact that he had no first-hand knowledge of clinical disorders. Evidence of the long-term influence of Kant's views in nineteenth-century psychiatry can be found, however, in an acknowledgement by Magnan and Serieux (1911), who referred to him as a "precursor" of the concept of *délire chronique à evolution systematique* (p. 607). Jaspers was also influenced by Kant (Kauffmann 1957; Stierlin 1974; C. Walker 1988; Berrios 1992a): "Kant became for me, and remained for me, the philosopher par excellence" (Kauffman 1957, p. 407). In his autobiography, on the other hand, Jaspers (1957) admitted that, in his university years, he found the German philosopher "hard to understand". Likewise, in *General Psychopathology*, Kant is only alluded to in relation to the role played by alienists in deciding on the legal responsibility of the criminal offender. The Kantian view has not been without critics; for example, from a Marxist perspective, Merani (1976) commented upon his over-descriptivism and anti-experimentalism.

3.5 Associationism

3.5.1 Before the Nineteenth Century

The atomistic model of associationism provided the epistemological basis for the development of seventeenth- and eighteenth-century science (Schofield 1970; Hoeldtke 1967). The notion of "simple idea" (the psychological counterpart of the Newtonian "atom") was used by Locke (1959) as a "unit of analysis" and is at the basis of the "laws of association", a combinatorial algebra in terms of which the mind reconstructed the world from simple experiences. This view found its ideal model in perception; in later years, this was to favour certain functions (e.g., the intellect) to the detriment of others, such as the emotions (Berrios 1985b; Gardiner et al. 1937). The intellectualistic definition was challenged during the

early nineteenth century. Thus, when describing cases with "lesions of the function of the will. . . whose symptoms appeared enigmatic upon the definitions of mania given by Locke and Condillac" (p. 102), Pinel (1809) was forced to write: "one can admire the writings of Locke, and agree nonetheless that his views on mania are incomplete in that he considers it to be always associated with a delusion. . . I thought likewise until resuming my research at Bicêtre; and I was not a little surprised to find many maniacs who at no period gave evidence of any lesion of the intellect, but who were under the control of a sort of instinctive fury, as if the affective faculties alone were impaired" (Pinel 1809, p. 156).

3.5.2 During the Nineteenth Century

For all its influence, pre-nineteenth-century associationism was more epistemolo ;ical than psychological. However, the books by Brown (1828) and Mill (1829) marked a change of emphasis: in spite of their heavy philosophising, these works also undertook to explain behaviour. John Stuart Mill (Warren 1921) and Alexander Bain (Bain 1859; Greenway 1973) developed this further.

A similar situation arose in France, where associationism was confronted, early in the nineteenth century, by faculty psychology and by the anti-analytic views imported from Scotland. The associationism of Condillac and Bonnet had been epistemological in intention, and development of its psychological aspects had to wait until Destutt de Tracy and the "ideologues" arrived (Destutt de Tracy 1818; Mora 1981). Upon becoming "psychological", associationism entered into conflict with faculty psychology, whose direct psychological usefulness (as in its application to phrenology and in the classification of mental disease; e.g., Esquirol 1838 inspired by his teacher Laromiguière 1820) had been obvious from the start.

The situation was also similar in Germany (Ribot 1885), a good illustration of which is found in the work of Herbart (1884), with his emphasis on education and psychology (Boring 1950; Watson 1963; Fritzsch 1932). These views influenced Griesinger (Ackerknecht 1957; Wahrig-Smith 1985; Verwey 1985), and through him the analytical tradition was passed on to Krafft-Ebing, Meynert and Wernicke. For example, it is reflected in the latter's "connectionist" view of aphasia. During the second half of the nineteenth century and influenced by Fechner's views on the correlations between stimuli and intensity of sensation (and the underlying metaphysics of the mind–body relationship) (Marshall 1982), German psychiatrists sought to establish objective experimental descriptions of some of the symptoms of insanity. Kraepelin (1896, 1983), a disciple of Wundt and follower of his particular brand of associationism, carried over this tradition into the twentieth century.

Most alienists accepted the analytical epistemology of associationism and adopted the important concept of "unit of analysis" as applied to behaviour and experience. Symptoms such as obsessions, delusions and hallucinations became the indivisible units of madness (Berrios 1996). This was consolidated in the work of Chaslin (1912, 1914) and Jaspers (1913). However, taxonomy remained based on faculty psychology, and this created a tension in the evolution of DP.

3.6 Surface Markers of Disease

As mentioned above, psychiatric "semiology" was born out of the observation of asylum patients, all of whom suffered from severe functional or organic psychoses. During the nineteenth century, the "neuroses" did not yet fall within the purview of alienists (López-Piñero 1983; Drinka 1984), so their "symptoms" and other clinical features contributed little to psychiatric semiology. There is also evidence that the symptomatology of the psychoses was modelled upon that of delirium (Calmette 1874; Roubinovitch 1896; Berrios 1981a).

The notion of "sign" is not free from ambiguity (Martinet 1973; Land 1974; Malberg 1977; Manetti 1993), particularly in the field of medicine (King 1968; Barthes 1972) and psychopathology. In some cases, it might relate to an underlying dysfunction rather directly in the same way in which smoke relates to fire (e.g., disorientation) (Berrios 1982a), i.e., analogous to Pierce's notion of (1931–1935) "index"; in others, it "signifies" a behavioural form (e.g., manipulative behaviour; what Pierce called "symbols"). It is plausible to believe that "indices" are more likely to reflect a specific neurobiological disorder than "symbols".

3.6.1 Assumptions and Concepts

Since descriptive psychopathology has changed little since the nineteenth century, a historical analysis of its conceptual bases should help to understand the enduring quality of some of the symptoms it generated (e.g., delusions, hallucinations). The following issues will be briefly touched upon in this section:

- "Form and content" of symptoms
- The role of numerical descriptions
- conographic representations
- The relationship between mental disease and "time"

- The incorporation of subjective information into the definition of mental illness

3.6.2 Form and Content

The distinction between "form" and "content" of a symptom is one of the enduring contributions of nineteenth-century DP. The Aristotelian *eidos* referred to the essence or common character of objects and is one of the origins of the current concept of "form" (Emerton 1984; Ferrater Mora 1958). With some modifications, the Aristotelian notion of form lasted well into the seventeenth century, when Bacon proposed that "form" might be simply considered as a synonym for "figure" (see Bacon 1858, Book II, Para 17, p. 474). Kant in turn suggested that the sense modality in which a perception took place, in conjunction with its cognitive network, should be called "form" (Abbagnano 1961).

Nineteenth-century DP, and indeed Jaspers (1963, pp. 58–59) at the beginning of the twentieth century, followed the Kantian definition: "form must be kept distinct from content which may change from time to time, e.g., the fact of a hallucination is to be distinguished from its content, whether this is a man or a tree . . . Perceptions, ideas, judgements, feelings, drives, self-awareness, are all *forms* of psychic phenomena; they denote the particular *mode of existence* in which content is presented to us. It is true, in describing concrete psychic events we take into account the particular content of the individual psyche, but from the phenomenological point of view it is only the form that interests us. . ." (for an excellent discussion of form and content in Jaspers' work, see C. Walker 1993).

To this day, "form" refers to structures that act as warrants of symptom stability, i.e., "constancy" elements which render mental symptoms recognisable in time and space. The notion of "form" is easier to understand in physical medicine. Colour, sound, surface, solidity, smell and temperature provide the natural media in which "form" achieves expression and stability (Laín Entralgo 1982). Inspired by medical semiology, alienists also expected to identify signs of insanity which were stable, public and observable. To do so, they committed themselves to the epistemology of "natural kinds" (Mill 1898; Markman 1994), i.e., to the view that the solutions of continuity between symptom and symptom (whether mental or not) existed in re. This led to a loss of interest in "contents": symptoms were just signposts to a brain lesion. This neglect of the semantic aspects of symptoms impeded the development of a comprehensive model; as a result, a theory that catered exclusively for "contents" was to develop with a vengeance at the end of the century (Ellenberger 1970).

However, in clinical *practice*, the "contents" of symptoms were never neglected altogether, and alienists made use of such information to establish aetiological connections between the subject's illness and his or her past. By the second half of the century, and before Janet or Freud had come on the scene, associations between content and past history had been already conceptualised as cause–effect chains. For example, it was felt that the content of a delusion or a hallucination, or the form of a hysterical conversion, might tell us something about the circumstances in which the symptom was first acquired (e.g., trauma, financial loss, infection; Bucknill and Tuke 1858). These putative cause–effect chains acted as veritable second-order "psychological" explanations (Billod 1861; Dagonet 1881a,b; Despine 1876), and their ubiquitous presence in nineteenth-century psychiatric practice calls into question the view that during this period alienists only entertained "somatic" aetiologies (e.g., Jacyna 1982). Not surprisingly, these psychological accounts matched beliefs in popular psychology. When the neuroses, particularly hysteria, came within the purview of alienists (something which only occurred towards the end of the century), they found that the content of a sign could reveal a great deal about the circumstances of its acquisition (e.g., Charcot's "idea" expressing itself in the symptom; Charcot 1971; Owen 1971; Bannour 1992).

The emphasis on "form" also led to changes in the type of explanation; for example, the "form" of a hallucination highlighted the informational value of the sense modality in which it occurred, and this in turn suggested a brain address (Tamburini 1881).

3.7 Numerical Representation and Measurement

The mathematisation of the natural world started in Europe during the seventeenth century (Dijksterhuis 1961). However, the Newtonian paradigm did not greatly affect psychological thinking during this period, as both Cartesian and Lockean psychology coincided on the view that numerical descriptions did not apply to behaviour (Moravia 1983).

The suggestion that "psychometry" (i.e., the measurement of psychological experience) was possible and desirable is attributed to Christian von Wolff. While describing ways of assessing the magnitude of pleasure and displeasure, he stated in a footnote: "these theorems belong to 'psychometry' which conveys a mathematical knowledge of the human mind and continues to remain a desideratum" (Ramul 1960). Ramsay, Baumgarten, Crusius, de Maupertuis, Buck, Mendelssohn and Ploucquet are mentioned among other eighteenth-century writers who prepared the

conceptual terrain for the advent of measurement in psychology; no one, however, seems to have carried out actual experimental work.

The path to numerical description, originally suggested by von Wolff (and opposed by Kant and Comte), was continued by Herbart, who suggested the development of a "statistics" of the soul (Ribot 1885). This conceptual change made the work of Müller and Du Bois Reymond easier (Rothschuh 1973), and the instruments (Sokal et al. 1976) they designed facilitated in turn the ideas of Weber and Fechner.

The introduction of quantification in medicine follows a different path (Underwood 1951; Shryock 1961; Murphy 1981; Matthews 1995). Numerical management of data was already familiar to pre-nineteenth-century epidemiologists and administrators (e.g., the bills of mortality), but inferential interpretations were scanty (Perrot and Woolf 1984). During the nineteenth century, statistical analysis of data, based on probability theory (Hilts 1981; T.M. Porter 1986; E.S. Pearson 1978) was started in earnest (Esquirol 1838). This is clear in the work of Gavaret (Wulff et al. 1986), Louis (Ackerknecht 1967), Radicke (1861), Renaudin (1856) (in this paper Renaudin reported on the positive view on the role of statistics taken during the 1856 Statistics Symposium in Paris) and Esquirol (1838), who also made use of inferential percentages.

Numerical descriptions extended only gradually to other areas of psychopathology, and this occurred around the middle of the century (Parchappe 1856). There is little historical evidence to suggest that any serious effort had been made before the 1850s to measure personality traits (Boring 1961; Zupan 1976; Bondy 1974; for a classical example of the use of mathematical and statistical reasoning in memory research, see Ebbinghaus 1964). This is surprising, as the ideas of Gall and Spurzheim had made available to psychology a conception of individual differences susceptible to quantification (Damiron 1828; Spoerl 1936; Lesky 1970), and phrenology had sought to establish correlations between anatomical and psychological magnitudes (Lanteri Laura 1970). After the 1830s, growing opposition to phrenology appeared in Europe (Cantor 1975; Cooter 1976). This might have discouraged alienists from espousing, at least publicly, Gall's interesting "modular" view of the mind (Fodor 1983; Shallice 1988).

3.8 Psychopathology of Non-verbal Behaviour

The great diagnostic categories of the past (mania, melancholia, phrensy, lethargy, catalepsy) relied on the observation of what the individual did, looked like and thought rather than on what he or she "felt". This is particularly so with regards to mania and melancholia (Berrios 1988a,b). The idea that these two notions are forerunners of the clinical categories currently bearing the same name is wrong. Before the nineteenth century, there was very limited historical evidence that "elation" or "sadness" (i.e., pathological mood) were the central "criteria" for the *medical* definition of mania and melancholia, respectively (Couchoud 1913; Heiberg 1927; Drabkin 1955; Flashar 1966; Siegel 1973; Simon 1978; for an illustration of the view that "melancholia" has more or less retained its meaning since ancient times, see Jackson 1986). The fact that literary uses of melancholia included a reference to "low spirits" (Babb 1951) is, of course, no argument in favour of a continuity in medical meaning.

The use of overt behaviour as the métier of psychopathological description seems to have been started by the Greeks (Simon 1978; Roccatagliata 1973). Symptom-mapping was influenced by their views on what constituted harmonious behaviour. The categories they created became the archetypal forms of insanity which, with little change, lasted well into the eighteenth century. Interest in the description of overt behaviour was renewed during this period (Bühler 1968), particularly in the study of facial expression in normal subjects, in what came to be known as the science of physiognomy (Lavater 1891; Mantegazza 1878; Caro Baroja 1988). During the late eighteenth century, Parsons (1747) attempted to establish correlations between emotions and gestures. The application of these techniques to pathological states gave rise in the fullness of time to an iconography of madness. This in turn influenced the way in which the mentally ill were perceived (Gilman 1982). For example, exaggerated or distorted facial expressions were thought to indicate the intensity of the underlying derangement. During the nineteenth century, a change occurred in the way in which the insane were depicted. The old stereotyped ways of Hogarth and Tardieu gave way to a more "realistic" approach; after 1839, this was made possible by the invention of the daguerreotype. This introduced another bias in the type of photographic records kept for posterity, as the long exposure times required by this technique encouraged its use in "static" conditions (e.g., stupor).

Likewise, the view that there was a one-to-one correlation between inner states and gestures became less acceptable; indeed, it was believed that the two factors could be dissociated. This in turn led to the idea that insanity could be either concealed or simulated. Morison, Laurent and the great Pierret, for example, developed a complex theory of "mimia" and "paramimia" during the second half of the century (Régis 1906). Charles Darwin's (1904) interest in this issue is also well known (Browne 1985).

3.9
Disease and the Time Dimension

Until the early nineteenth century, the descriptions of insanity had been, in a real sense, atemporal and identification of symptoms in cross-sectional analysis sufficed to make a diagnosis (Arnold 1806).

This resulted from the belief, based on the ontological view, that madness was an irreversible process. This view reflected similar notions in the field of physical disease. Referring to this period, Charcot (1881) wrote: "disease was formerly considered as being independent of the organism, a kind of parasite attached to the economy" (p. 4). Disease, therefore, was not considered as contained within the temporal and spatial constraints of the body (for a discussion of this problem, see King 1982, pp. 131–183; Haas 1864). The fact that subjects might occasionally show "normal behaviour" (which was then called the "lucid interval") was not considered as contradictory evidence, as patients could "stifle their disorder" (Haslam 1809).

Asylum psychiatry allowed for the first time the longitudinal observation of groups of patients. This forced a change in the observational framework, and as a result a *temporal dimension* was gradually introduced in the 1850s (Lanteri Laura 1972, 1986; Del Pistoia 1971). The longitudinal approach encouraged major changes in the concept of mental illness. Thus information obtained from longitudinal observation could be used to correct or modify earlier diagnosis. Kahlbaum (1863) used this to good advantage in his definition of mental disease, and for the first time a distinction between acute and chronic insanity was made (Berrios 1987b; Beer 1996a,b). By the end of the century, "duration" had become the central category in the analysis of disease. For example, in Kraepelin's work, the evolution and outcome of a condition were crucial to making a diagnosis (Hoff 1985; Berrios and Hauser 1988); indeed, it has been claimed that he purposely went to Dorpat to gain experience with chronic hospitalised patients (Marx 1980). It has also been suggested that the fact that the Dorpat patients spoke no German (Kraepelin did not speak Russian) forced him to choose "more objective" signs to define "dementia praecox" (Berrios and Hauser 1988).

3.10
Incorporation of Subjectivity

The incorporation of subjectivity is perhaps the single most important contribution of the nineteenth century to DP. As was mentioned above, pre-nineteenth-century descriptions of insanity relied heavily on the observation of overt behaviour, psychosocial competence and cognition. During the early nineteenth century, changes in psychological thinking, particularly in France, led to the acceptance of the "contents of consciousness" as a legitimate field of inquiry (Dwelshauvers 1920; Royer-Collard 1843). This opportunity was seized by alienists, who were at the time searching for additional sources of clinical information. Methods of eliciting and recording data were sought (Laín Entralgo 1961; Helmchen 1985), and the mental state assessment, in its dialogical form, appeared during this period.

Moreau de Tours can be considered as one of the protagonists in this development (Bollote 1973; Ey and Mignot 1947). In his *Psychologie Morbide*, Moreau (1859) attempted to legitimate the value of subjective information (Pigeaud 1986). At the same time as French psychiatry was paying great attention to mental contents, British psychiatrists were worrying about "morbid introspections" as a potential cause of mental disorder (Clark 1988). In addition to the analysis of hallucinatory images and delusional contents, this new source of symptoms also included a rich gamut of emotional, affective and volitional experiences (Lanteri Laura 1984).

During the early stages of this process, much emphasis was put on the "form" of the newly discovered symptoms. For example, efforts were made to decide whether hallucinatory voices were bilateral or unilateral, recognisable, single or multiple, etc. (Parish 1897; Gurney 1885). Towards the second half of the century, the influence of Brentano (Fancher 1977) redirected attention towards the "content" of the symptom. The psychodynamic doctrines can be said to be an extreme illustration of this trend (Bercherie 1983, 1988). This is not the place to discuss in any detail the changes in the history of psychology that legitimated the use of this new experiential source (Berrios 1987c). Suffice it to say that they pertain to the appearance of a *psychological* notion of consciousness (Burt 1962; Bastian 1870; Viziolo and Bietti 1966; Ey 1966) and to the acceptance of the epistemological value of introspection (Boring 1953; Danziger 1980).

The acceptance that purely subjective experiences could be mental symptoms encouraged the re-definition of some mental diseases. For example, the newer notions of melancholia and mania were made possible by the availability of direct experiential information with regards to mood states and emotions (Berrios 1988a,b). Likewise, the concept of paranoia was to reappear in the 1860s, this time based on the presence of delusional experiences (Lewis 1970a). The various types of stupor, until then lumped together, were

also classified according to whether or not there was amnesia for the episode (Berrios 1981b). Subjective data were also used to identify "subtypes" of insanity, and "symptomatic classifications" proliferated (e.g., religious, metaphysical and erotic mania; Berrios 1994b).

4 Development of the Concept of Mental Disease

Historians of psychiatry are struck by two major clinical changes that occurred during the nineteenth century: one concerns the metamorphosis of the insanities into psychoses, and the other the "cross-over" of meaning and aetiology that took place between the psychoses and neuroses (Beer 1996b). For reasons of space, only the first will be dealt with in this chapter. The change from insanity to psychosis was made possible by the development of a new concept of disease in general medicine (Ackerknecht 1967), by the availability of new ways of defining behaviour (Berrios 1987b) and by the appearance of new taxonomic principles for the classification of biological entities (Georgin 1980; Berrios 1987b).

4.1 Clinico-anatomical View

Already present in embryonic form in the work of Sydenham (Laín Entralgo 1978), the clinico-anatomical view reached full development during the early nineteenth century. By then, the view that symptoms were signs of an underlying anatomical lesion had been fully adopted (López-Piñero 1983; Ackerknecht 1967). As the century wore on, the concept of lesion was successively re-defined as inhabiting organs, tissues, and finally cells (Albarracín Teulón 1983; Canguilhem 1966; Foucault 1972b). The failure to identify *anatomical* lesions in many diseases led, during the second half of the nineteenth century, to envisaging "lesion" in *physiological* terms, and this led to concepts such as "irritation" and "inhibition" (López-Piñero 1983; Smith 1992). In this way, the concept of "functional" lesion was born. A logical continuation of this was the development of the notion of "psychological" lesion, which took place by the 1890s. Janet and Freud helped this view to be incorporated into psychiatry (López-Piñero and Morales Meseguer 1970).

4.2 Psychological Definitions of Behaviour

Associationism and faculty psychology helped alienists to map behaviour, to seek new sources of symptoms (e.g., subjectivity) and to develop new classifications. They also suggested ways of fragmenting behaviour. Consciousness was metaphorically described as a "theatre" with its "contents" captured by means of introspection. The acceptance of a view of the mind as a set of functionally autonomous modules provided a natural framework of classification. For example, and as mentioned above, Pinel (1809) and Prichard (1835) abandoned Locke's "intellectualistic view" of madness (still extant in Arnold's distinction between ideal and notional insanity; Arnold 1806) and turned to faculty psychology. By the end of the century, symptoms were considered as either exaggerations of normal behaviour (continuity view) or as new forms (discontinuity view) (Dumas 1908; Deshaies 1967; Griesinger 1865; Delasiauve 1861).

4.3 Taxonomic Changes

The philosophy of medical taxonomy also changed during the early nineteenth century. The botanical principles implemented by Linné, Sauvage, Cullen and others (Bowman 1975; Temkin 1965; Faber 1923) were replaced by an empirical approach based on the following:

1. Frequential analysis of symptoms (Griesinger 1865)
2. Aetiological speculation (Morel 1860)
3. Knowledge, later in the century, of the natural history of the disease (Remond and Lagriffe 1902; Baillarger 1853; Foville 1872; Vié 1940; Desruelles et al. 1934; Menninger 1964; de Boor 1954; Goldstein 1988)

The early nineteenth-century view that intellectual, emotional and volitional mental functions could be separately affected by disease offered a solid taxonomic principle. Thus the "intellectual insanities" became the nucleus around which the notions of schizophrenia and paranoia were to crystallise; the emotional insanities served the same function in relation to mania and depression (Berrios 1988a), and the volitional insanities with regards to the psychopathic disorders (Werlinder 1978; Ey 1978; Berrios 1993).

While the eighteenth-century view of the insanities was cross-sectional and related to specific life events (Postel 1984), the nineteenth-century view became longitudinal, particularly after Kahlbaum, Wernicke and Kraepelin. In the event, the latter two were to

developed rival systems of classification (Donalies 1971). Had Wernicke lived longer, the classification of the functional psychoses would be very different today, partly because his was a model based on a veritable physio- and psychopathology. However, Kraepelin was the victor, and in his scheme of things the number of insanities was drastically reduced to two psychoses characterised by stable and overlapping symptom clusters (Hoff 1994). Organic aetiology and recognisable natural history and prognosis became the final diagnostic criterion (Berrios and Hauser 1988). From the start, the finding of clinical anomalies ("intermediate" cases) challenged the Kraepelinian dichotomy, and Kraepelin was to abandon it in later years (Kraepelin 1920).

4.4
The "Combined Psychoses" Debate

Current preoccupations with the notion of co-morbidity (generated by the peculiar diagnostic structure of DSM IV; e.g., Wittchen 1996) are not new, and a similar debate took place during the early twentieth century, when the question was asked whether two independent psychoses could simultaneously affect the same individual. Jaspers (1963) clearly stated that "the idea of disease entity leads one to expect that no more than one illness can be diagnosed in any one person. Where a schizophrenic process is present we duly suppose that we should hold it responsible for all the symptoms, but that is a presupposition" (p. 612). However, if the two psychoses are truly independent, what prevents their simultaneous occurrence? It would be tempting (but historically inaccurate) to blame the "taboo of incompatibility" on the psychodynamic view in spite of the fact that, according to this doctrine, it is nonsensical for two such "diseases" to occupy the same "psychological space". This very issue was debated under the general heading of the "combined psychoses" (Meeus 1908), but no agreement was ever reached. Indeed, no answer to this question seems available yet in current psychiatry.

4.5
Heritability of Mental Illness

The view that mental illness was passed on from generation to generation was well accepted during the nineteenth century, but Morel, Magnan and others re-conceptualised this belief in terms of the so-called degeneration theory. However, the application of this doctrine led to a number of blind classificatory alleys and to the search for somatic stigmata and other genetic markers (Morel 1857; Saury 1886; Walter 1956; Friedlander 1973; Danion et al. 1985; Dowbiggin 1985; Pick 1989).

5
Transformation of Insanity into "Psychoses" During the Nineteenth Century

5.1
Adoption of the Word "Psychosis"

The word "psychosis" was used in the first half of the nineteenth century to refer to the subjective states accompanying insanity (Jastrow and Baldwin 1901). According to von Feuchtersleben (1847) (who, it must be remembered, used the terms "psychosis" and "neurosis" in their late eighteenth-century sense), the term "used with regard to normal processes is equivalent to the mental or psychical element in a psychophysical process, just as neurosis refers to that aspect of the process which belongs to the nervous system" (p. 392). In most cases, however, these experiences relate to "conditions which we usually call, in a more restricted sense, mental derangement" (p. 241). "Every psychoses (must be), at the same time, a neuroses; as without the intervention of nervous action, no change in the psychical realm can occur, (however) every neuroses is not a psychoses; of this convulsions afford a sufficient example. . ." (p. 246). A similar view was taken by another commentator, who chose to emphasise "the neural act corresponding to the mental phenomena" (Warner 1892, p. 1025).

These two usages ("normal" and "pathological") became official in German psychiatry by the device of using the singular form (*Psychose*) to name the former, and the plural (*Psychosen*) the latter (Tuke 1892a). Meyer (1901) attempted to clarify the issue: "used pathologically (and in this sense the usage is rapidly gaining ground both in foreign and in the English literature) the term designates an abnormal mental condition, specially inasmuch as it is correlated with a specific disease-process (a disease entity, if the term be allowed) with characteristic origin, course and symptoms. The typical forms of insanity which can be scientifically differentiated would rank as psychoses in this sense." Maudsley (1885) made use of the "pathological meaning": "no wonder that the criminal psychosis, which is the mental side of the neurosis, is for the most part an intractable malady. . ." (p. 33).

After the Great War, the term "psychosis" gained popularity and soon replaced "insanity"; indeed, Sir George Savage was one of the last to use it in the title of a textbook (Savage 1898). The fact that its original meaning referred to the *experiential* aspects of behaviour no doubt helped in that it dovetailed well with the

growing trend towards including subjective symptoms in the description of insanity. The word "insanity", on the other hand, was too laden with pre-nineteenth-century notions to be acceptable, and only survived in legal language. Another reason for the adoption of the term might have been that it lent itself to easy adjectival derivations (e.g., psychotic) (Sauri 1972).

5.2 The Defining Dichotomies

During the late nineteenth century, the "psychoses" became defined in relation to five dichotomies: psychoses versus neuroses, functional versus organic, exogenous versus endogenous, total versus partial and unitary versus multiple.

5.2.1 Psychoses Versus Neuroses

As has been mentioned above, during the first half of the nineteenth century, "psychoses" referred to subjective states and "neuroses" to the underlying neurological processes. By 1900, meanings had been exchanged: psychoses were the official name for all the "organic states" (whether exogenous or endogenous), and the neuroses had become psychologised (López-Piñero and Morales Meseguer 1970).

As mentioned earlier, the practice of alienism was very different before the incorporation of the neuroses into psychiatry. Asylum alienists only dealt with severe functional or organic psychoses and were (mercifully) free from worrying about the forms of deviancy and psychological incompetence that have since been thrown their way. Insanity therefore provided the descriptive, taxonomic and aetiological templates on which all future conceptions of mental illness were to be based.

This view demanded that a "lesion" be sought in all cases. Failure to identify such changes in the case of the neuroses led to a gradual watering down of the concept of lesion. The basis of the neurotic symptoms was successively thought of as anatomical (disorder of sense and motion), physiological (irritability and inhibition) and psychological (compromise between instinct and reality demands). This transformation was helped by the gradual expurgation from the class of the neuroses of real "organic" states. (The last conditions to be excluded were the vasomotor disorders, i.e., Raynaud's syndrome. A similar mechanism attended the development of neurology, which after the 1860s only encompassed motor and sensory deficits resulting from *localised* brain and spinal lesions.)

However, the mechanism did not work well, and a number of clinical states such as catatonia, motor stereotypes, sleep disorders, hallucinations and deficits of higher cortical functions remained in the borderland between neurology and psychiatry. During the late nineteenth century, the transient popularity of hypnosis and putative "functional mechanisms" (Barrucand 1967; Bercherie 1980), together with psychoanalysis, led to considering many of these states as "psychological". Soon enough, however, the epidemics of encephalitis lethargica pushed views in the opposite direction (for a discussion, see Rogers 1988; Berrios and Dening 1990).

5.2.2 Functional Versus Organic

At the dawn of the twentieth century, the distinction between functional and organic psychoses became a fundamental aspect of their classification.

The functional group included dementia praecox, manic depressive insanity, paraphrenia, the paranoid states and paranoia; the organic psychoses comprised delirium, dementia and a panoply of "symptomatic" psychoses. Since all "psychoses" were supposed to have, at some level, an "organic" basis, it is at first sight unclear why the dichotomy was necessary at all.

Mendel's work (1907) contains one of the earliest references to "functional" psychoses. He offered a negative definition: "on the other hand, there is a great difference of opinion amongst authors as to how to divide those mental diseases in which no anatomical findings have hitherto been met and which do not belong under any of the forms named. They are designated as *functional psychoses*, by which it is not said that anatomical changes do not exist, but only that we have so far been unable to verify them . . . in this respect (absence of a recognizable lesion) they resemble the *functional* peripheral neuroses" (p. 160).

Mendel considered the following as functional psychoses: delirium hallucinatorium, mania, melancholia, circular psychosis and paranoia and acute dementia (pp. 175–213). The first and last categories included conditions which would currently be diagnosed as schizophrenia. Mendel also recognised a separate group of "organic psychoses" which included progressive paralysis of the insane, senile dementia and atherosclerotic and syphilitic psychoses. He also distinguished between "psychoses which are called forth by focal diseases of the brain" (e.g., apoplectic attacks, brain tumours, traumata) and "psychoses arising from central neuroses" (e.g., epileptic, hysteric and choreic psychoses).

By the end of the Great War, the dichotomy between functional and organic had become sharper. For example, Jaspers (1963) listed three functional psychoses, genuine epilepsy, schizophrenia and manic depressive illness: "these three . . . have four points in common. In the *first* place their study gave rise to the concept of disease entity. . . in the *second* place the

cases which belong to this group cannot be subsumed under the disorders of group I and III (i.e., organic). One must however assume that many of these psychoses have a somatic base ... in the *third* place (they) are not exogenous but endogenous psychoses. Heredity is an important cause ... in the *fourth* place they all lack anatomical cerebral pathology..." (pp. 607–608; see also Beer 1996a).

5.2.3 Exogenous Versus Endogenous

Nineteenth-century neurobiological beliefs on the aetiology of mental illness are enshrined in the exogenous/endogenous distinction. Already controversial and unclear in meaning at the time of its inception, it is now but a noble archaism that has, nonetheless, survived its obituarists (Lewis 1971; Heron 1965; Gaston and Tatarelli 1984).

First of all, it must be stated that the term "endogenous", coined by Candolle in 1813 (Berrios 1987b), was never meant to signify "genetic" in the modern sense, nor "exogenous" to signify "environmental". As Kraepelin (1924) pointed out, it was the German neurologist Möbius who first introduced these terms into medicine in 1893. In his short neurology textbook, Möbius described endogenous disorders as those in which "the principal condition must lie in the individual, in a congenital disposition (*Anlage*), other factors being merely contingent and quantitative". Examples were neurasthenia, hysteria, epilepsy, migraine, Huntington's chorea and Friedreich's disease. On the other hand, "exogenous" diseases were toxic and infectious conditions, thought to be "engendered from without" such as trigeminal neuralgia, thyroid disease, multiple sclerosis and Parkinson's disease (Schiller 1982).

The value and meaning of the dichotomy hinged on the feasibility of drawing an operational boundary between "without" and "within". Möbius did not make his criteria explicit, but it would seem that he did not consider the skin as the natural boundary (hence for him exogenous is not necessarily environmental), nor did he mean the neck (hence for him exogenous is not necessarily non-cerebral). "Endogenous" in Möbius' work relates to the *Anlage*, to the intrinsic form or essence, and it is therefore not a spatial but a metaphysical concept.

The origin of this metaphysical view is to be found in nineteenth-century degeneration theory, a doctrine that, as has been hinted at before, dominated European psychiatric and social thinking during the second half of the nineteenth century (Mechler 1963). Phenomena as wide apart as Lamarck's inheritance of acquired features, somatic stigmata and the fact that disease could suddenly disappear after one generation were all explained by degeneration theory (Huertas 1987; Ribot 1871; Talbot 1898; Mairet and Ardin-Delteil 1907; Genil-Perrin 1913; Apert 1919; Salas 1920; Wettley 1959; Peset 1983; Hermle 1986). During the 1890s, the over-religious and fatalistic Morelian model of degeneration (Morel 1857) was made flexible by Magnan (Genil-Perrin 1913), and after the 1910s, it gradual merged with the new genetic views on mental disease (Saury 1886; Huertas 1985).

However, during the 1890s, the concept of "endogenous" was still a shorthand for degeneration theory and postulated that the cause of mental illness lay deep in the metaphysical being (Mechler 1963). Hence "endogenicity" was not just about genetic control or personality or constitution. Kraepelin liked the concept precisely because of these features. The terms "endogenous" and "exogenous", no longer current in neurology (where they started their career), might have also sunk into oblivion in psychiatry had it not been for Kraepelin, who had adopted them by the time the 1896 edition of his textbook appeared.

The dichotomies functional/organic and endogenous/exogenous therefore have a different historical provenance and overlap only partially. To a late nineteenth-century alienist, exogenous did not necessarily mean organic, and functional did not necessarily mean endogenous. Further obscurities have accrued during the twentieth century due to their well-nigh untranslatability into modern biological terminology.

5.2.4 Total Versus Partial Insanity

Before the nineteenth century, the clinical concept of insanity was thought of as representing an involvement of *all* mental faculties, most particularly the intellectual functions (i.e., presence of delusions) (Postel 1984). Furthermore, insanity was thought to be irreversible (Foucault 1972a; Quetel and Morel 1979); mania, for example, signified a behavioural, physical and metaphysical state (Middleton et al. 1780; Calmeil 1839). Insanity, in general, was defined as a genus whose species were each defined in terms of a salient behaviour (Arnold 1806). The categorical nature of "total insanity" is even clearer in legal usage. Bracton, for example, defined mania as "totally lacking in discern", and 400 years later, Coke and Hale were still defining it as "absolute madness" (N. Walker 1968).

The concept of "partial insanity", i.e., the view that insanity may be less than total, originated to some extent in the interaction between medicine and the law in relation to cases where the "all-or-none" concept seem to break down (Eigen 1995). For example, in 1736, Hale defined it thus: "there is partial insanity of mind...; some persons that have a competent use of reason in respect of some subjects, are yet under a

particular dementia in respect of some particular...; or else it is partial in respect of degrees..." (N. Walker 1968). During the early nineteenth century, however, partial insanity had more than one clinical meaning (Berrios 1991b):

1. Involvement of one faculty (from the view point of faculty psychology)
2. Intermittent insanity, i.e., presence of "lucid intervals" (from the longitudinal viewpoint) (Haslam 1809)
3. Mild or moderate (from the point of view of intensity)
4. Presence of a "partial" delusional system (from the point of view of the extension of the delusions) (Berrios 1994c)

The concept of "monomania" (fallen into desuetude after 1850; Reports of the Sessions of the Société Médico-Psychologique 1854) was formed in the 1820s around the first and last definitions given above (Kageyama 1984). In his translator's introduction to Hoffbauer's treatise, Chamberyon (1827) presented the simplest classification: "insanity is divided into mania and dementia, according to whether the mental faculties are overactive or weakened; mania is subdivided in turn into polymania (or total insanity) and monomania (partial insanity)" (pp. 10–11). The final acceptance of the tripartite classification (intellectual, emotional and volitional), in addition to the gradual ascent of the natural sciences view of disease, led after the 1850s to the quiet disappearance (in medicine) of the concept of total insanity. In the legal field, it never disappeared altogether and enjoyed a period of revival after the McNaughton rules were passed in Great Britain in 1843 (West and Walk 1977), because the narrowness of the criteria made it difficult to find a case of "partial insanity".

5.2.5 Unitary Versus Multiple Psychoses

One of the interesting offshoots of the nineteenth-century taxonomic controversy was the development of the unitary and multiple views of insanity. Reacting against the proliferation of classifications and inspired by the principle of the indivisibility of the mind, some alienists put forward the view that there was only one insanity which could take many forms and that its multiple clinical presentations were epiphenomenic, i.e., the result of pathoplastic factors (Llópis 1954; Menninger et al. 1958; Rennert 1968; Vliegen 1980; Janzarik 1969; Berrios and Beer 1994). These included factors such as idiosyncratic responses (i.e., individual styles of coping with the ravages of insanity), proximate and remote aetiologies (e.g., emotional precipitants), intensity (over- or under-activity of the mental faculties) and duration of the condition. It was suggested, for example, that mania, melancholia, delusional insanity and vesanic dementia might just be successive stages of the same disease.

This is an important point to remember when, for example, the history of circular insanity (bipolar disorder) is studied (Sedler and Dessain 1983; Pichot 1995). Thus the suggestion made by Baillarger and Falret (Pichot 1995) that mania and melancholia were related should not be considered as solely based on clinical evidence (as the observation that some patients might intermittently suffer from both had previously often been made); indeed, these two great alienists were also influenced by the "unitary psychosis" concept (Berrios and Beer 1994). A new factor was added to the factors mentioned above after 1857, namely degeneration theory (Morel 1857). According to this view, the degeneration taint was transmitted from parents to offspring and on each occasion gave rise to ever worse forms of insanity until dementia appeared.

5.3 Three Modules of the Mind and Their Insanities

Up to the beginning of the nineteenth century, the intellectualistic view of insanity reigned supreme (Berrios 1985b). The growth of faculty psychology led to the division of the mind into functional modules (Fodor 1983) and provided a new model both to phrenology and to later studies on brain localisation (Bentley 1916). As suggested by Kant (Hilgard 1980) and the Scottish philosophers (Seth 1890; Albrecht 1970; Brooks 1976), three modules were distinguishable: intellectual, emotional and volitional. The old forms of madness were re-defined as "intellectual insanities" (including both total and partial). This change in the original meaning of insanity (until then only considered as intellectual) opened a clinical space for purely "emotional" and "volitional" insanities. It also freed mania and melancholia from their secular duty as forms of delusional insanity (Linas 1871). The emotional insanities were to evolve into the modern concept of melancholia, mania and circular insanity (Berrios 1988a; Pichot 1995), and the volitional disorders played a role in the explanation of psychopathy (Werlinder 1978) and aboulia (Ribot 1904; Lapie 1902; Berrios and Gili 1995).

The decline in popularity by the turn of the century of "will" and "volition" undercut this neat arrangement (Herzen 1880; Paulhan 1903; Daston 1982; Keller 1954; O'Shaughnessy 1980). If "will" had no explanatory power, then it made little sense to ponder over its disorders; the question of what psychological functions (if any) are dysfunctional in psychopathy and aboulia was, however, left unanswered. Likewise, the shift in

the meaning of "emotional insanity" occurred during the 1850s. No clearer statement can be found than Bucknill and Tuke's remark: mania, "perhaps the most interesting and best recognized form of mental disease, has been usually treated of by writers, as essentially a disorder of the reasoning faculties. Dr. Prichard classed it under intellectual insanity. We are disposed however to regard it as belonging primarily to the affective group" (Bucknill and Tuke 1858, p. 221).

5.4 Separation of the Organic States

Ever since the times of ancient Greece, the symptomatology of delirium (phrensy) had included fever, fleeting hallucinations, delusions and behavioural disorder (Berrios and Freeman 1991a). Other "organic" psychiatric disorders, however, such as dementia, were not distinguished during this period from the rest of the insanities. Analysis of pre-nineteenth-century case reports confirms the view that, during this long period, mania and melancholia included "organic" states such as encephalitis, neuro-intoxications, brain tumours and certainly schizophrenia.

The modern concept of "organic disorder" only appeared after 1822, when Bayle described chronic arachnoiditis in patients with psychiatric manifestations of the type that were to be later called "general paralysis of the insane" (Bulbena and Berrios 1986). Battie (1758) had already differentiated between "original" and "consequential" madness, but the latter category cannot be said to refer to "organic states" in the modern sense. It was in fact Willis, in his description of dementia, who came closer than any other before the nineteenth century to separating dementia from insanity (Berrios 1987a).

The interesting aspect of Bayle's work (1826) was not so much that he identified anatomical lesions in relation to a given neurobehavioural syndrome, but that he made possible the view that kaleidoscopic psychopathology (ranging from typical mania to melancholia, hallucinatory states and dementia) could be associated with the same brain lesion (Bercherie 1980) and vice versa, i.e., that the same syndrome could be caused by many types of lesions. Griesinger (1865), in his perceptive lecture on the occasion of the opening of the Zürich Psychiatric Clinic, stated: "One can suffer of melancholia on account of eight or ten different brain diseases; and of dementia on account of twenty. . ." (p. 11).

It took the rest of the century for the "organic disorders" to be aggregated into a self-contained group. As expected, some of these clinical states had been included for centuries under the old "mania" concept, and hence their gradual separation contributed to the narrowing down of the latter (Couchoud 1913).

5.5 Narrowing Down of the Concept of Mania

The concept of mania underwent radical transformation between 1800 and 1900 (Berrios 1981c). At the end of the eighteenth century, it was tantamount to insanity (Linas 1871) or madness (Middleton et al. 1780; Chiarugi 1793), but by the end of the nineteenth century it was used exclusively to refer to "elated hyperactivity" with or without psychotic symptoms (e.g., Mendel 1907).

Gauchet and Swain (1980) have stated that the reconstruction of the concept of "mental alienation" during the early nineteenth century revolved around a repeated analysis of the concept of mania and point out that Esquirol himself used it as a synonym of "mental alienation" (p. viii). Likewise, Erasmus Darwin (1796), Charles Darwin's grandfather, described in *Zoonomia* three forms of mania, one of which included ecstatic states, despair and melancholia. Arnold (1806) put it thus: "maniacal insanity, properly so called, as a species, is of all others, perhaps, the most *comprehensive*; since it extends its dominion over the whole internal world of ideas, and comprehends every possible combination of sensible images which can enter into, and delude, a distempered brain. To enumerate all its varieties would not only be difficult, but impossible. . .".

The concept began to change in the work of Pinel (1809), who tellingly deleted the term "mania" (used in this general sense) from the subtitle of the second edition of his *Traité*. He classified "manie" in the *Nosographie* as a genre of the "vesanies" (insanities) characterised by "disorder of one or more faculties with sad, gay, extravagant or raging affect, occasionally free from disordered thought but always blind aggression". He also recognised delusional and non-delusional forms of mania (Pinel 1818, p. 592). Couchoud (1913) rightly stated that it was from the large group of the manias that melancholia, dementia and idiocy were eventually separated off.

In German psychiatry, situation is similar. In the historical introduction to his book, Heinroth (1818) wrote that "mania was a *general* insanity, accompanied by rages and by a bold execution of the demands of the will" (p. 65). He described four types of "rage" (mania): simplex (pure rage), ecstatica (insane), ecnoa (rage accompanied by folly) and catholica (common rage) and differentiated mania from the following: daemonomania, erotomania, raging melancholia, lycanthropia, mania cum tristitia (with sadness), continua acuta, chronica, periodica, nynphomania, satyriasis and melancholia saltans (savage impulse to jump).

At the other end of the century, Mendel (1907), perhaps the greatest specialist on mania in the late

nineteenth century (his work on mania appeared in 1881), defined it as: "a functional psychosis which is characterized by a) pathological acceleration of the efflux of ideas, b) motor unrest, and c) absence of symptoms which confirm an organic disease of the brain". In its symptomatology, Mendel included hallucinations, anomaly of thought, delusions, confusion, hypermnesia, heightening of motility and loss of weight. He also recognised four stages of mania, "initial, exaltation, frenzy and decline", and four subtypes, "hypomania, recurrent, gravis and periodic". Kraepelin's (1921) own definition was influenced by Mendel's.

Between Pinel and Mendel, "mania" had not only become narrower, but also more syndromatic (and defined in terms of exclusively affective symptomatology). How was this change possible? It is unlikely that it resulted simply from the gradual erosion of the old concept of mania. Historical analysis shows that the word "mania" almost dropped out of circulation around the 1830s, when some of its clinical functions were taken over by the concept of monomania (Kageyama 1984; Calmeil 1839; Goldstein 1988). "Monomania" itself lost popularity (Falret 1864), and its decline brought back the word "mania". On its return, however, it was furnished with a new meaning.

I should like to suggest that six factors (inter alia) contributed to the metamorphosis of the old into the new notion. First of all, "mania" was too general a category to be acceptable to the analytical view of mental disease popular during the nineteenth century (Lanteri Laura 1982, 1983). Secondly, the concept of "total insanity" (on which it was based) had been replaced by one of partial insanity (Kageyama 1984). Thirdly, faculty psychology led to the acceptance of emotional insanities as a separate group of disorders (Berrios 1987c). Fourthly, organic disorders such as "general paralysis of the insane", in the past a regular source of "manic states", were now well recognised and excluded (Berrios 1985a). Fifthly, the language of description became more rigorous, as alienists created stable definitions of the "elementary symptoms" (Griesinger 1867). Lastly, subjective symptomatology became incorporated into the definition of insanity, thus making it possible to include "elation" as a central symptom.

6 The Twentieth Century

Official time divisions have little meaning in history. For example, nothing special suddenly happened in the year 1900 (as nothing will in 2000) to alter the meaning of psychiatric concepts or the seamless way in which they had been flowing since their creation during the nineteenth century. Mental symptoms and diseases are born out of a historical mechanism or process which can be called a convergence, and it goes something like this: a particular observer reports a particular clinical phenomenon as discrete and stable enough to represent a mental symptom, syndrome or disease; the behaviour in question is described and examples (a casuistry) are usually reported. The observer may often give it a name (a neologism or a refurbished old term) and, if possible, an explanation (a concept) in terms of current medical doctrine. What converges in the work of an author are therefore a form of behaviour, a word and a concept. When enduring, convergences can be called successful or felicitous. The reasons for this are unclear. To say that success depends on the fact that the convergence has captured a true biological fact is not sufficient, as many convergences have been kept alive for social and political reasons.

Lasting convergences tend to produce collective mirages which contribute to their perpetuation. Psychiatrists cannot help but see things in that particular way (or dare not see them in any other way). Social and financial investment are also strong factors in the survival of a convergence. Once pharmaceutical companies and the reputation of pundits are committed to the truth of a particular convergence, it becomes very difficult for common mortals to call it into question. The success and stability of ICD-10 and DSM IV are, in a way, based on this social apparatus.

This can be said to constitute a triumph for psychiatry, but also its tragedy. It is a triumph because it is possible for researchers to claim that there is scientific continuity in what they are doing, that they are not standing on the shoulders of giants as it were. However, it can also be the tragedy of psychiatry if the convergence so sedulously defended turns out to be totally wrong. What, for example, if the current cognitive model of dementia were to prove infelicitous (what would happen to the enormous financial investment in a miracle drug) or if the view that delusions and hallucinations are crucial "positive" symptoms of schizophrenia were to turn out to be misconceived (as it is likely to)? What will happen to those whose reputation has been built on selling the idea of "positive symptoms", scales, neuro-images and specific neuroleptics?

This is why psychiatry must remain a conceptual broad church and why current pundits (particularly those locked within the Anglo-Saxon tradition) must look beyond the narrow confines of their language to listen to what is being said in French, Polish, Russian, German or Chinese psychiatry. For the same reason, marginalising psychopathologists and phenomenologists as fuddy-duddies who have not yet heard about neuro-imaging would seriously harm the future of

psychiatry. The main lesson of history, as iterated in this chapter, is that psychopathology and its attending concepts remain the very foundations of psychiatry. Without their help, it would not be possible to recalibrate the descriptions in response to secular genetic changes in the expression of disease, to social warrants and to the development of new investigative techniques. It is of the essence to understand that there will never be a stable set of psychopathological descriptions and concepts. Re-adjustments will have to be made every so often in order to do justice to our patients.

It is beyond the scope of this chapter to map out the twentieth-century fate of the ideas and concepts discussed in previous sections. However, something must be said to give younger colleagues a sense of continuity, emphasising French and British psychiatry.[1]

6.1 France

Writing on the history of French psychiatry during the twentieth century is a complex task, not so much because it is conceptually difficult (although on occasions it can be), but because there is too much to say. This embarrassment of riches forces selectivity, and the latter risks distortion.

Since the nineteenth century, French psychiatry has been characterised by (a) a fruitful interaction between concepts and clinical practice, (b) an interest in the creation of a second-order language and (c) the strong presence, after the 1850s, of a historicist, longitudinal (diachronic) perspective. Psychoanalysis (Mordier 1981) and the First World War had a negative influence on this epistemological stance in spite of the efforts of writers such as Semelaigne (1932), who tried in his work to reconcile the inter-bellum generation with their great psychiatric past. The 1930s also saw the development of a society of scholars which came to be known as *L'Evolution Psychiatrique* and which started publishing a quarterly under the same name. One of its members was Henri Ey, then in his early 30s and already intellectually productive. This group was characterised by a keen historical sense and what could be described as an ambiguous attitude towards their own psychiatry which included both pride and rejection. Thus, on the one hand, they referred to the great nineteenth-century debates at the *Société Médico-Psychologique* as the great source of concepts; on the other, influenced by psychoanalysis and a version of the Jacksonian model, they criticised French psychiatry as being excessively descriptivist. Their publications include classical articles on hallucinations, obsessions, etc.

Once again, the Second World War affected intellectual life in France, including academic psychiatry. Great men such as Dide (Mangin-Lazarus 1994) and Halbwachs (Coser 1992) were killed, and specialised publications slowed down or disappeared. This sombre mood can be noticed, for example, in the centenary issue of *Annales Médico-Psychologiques* (1943), in which all review articles were clearly written in a hurry and without the back-up of libraries, which were shut or hidden. Notable among these is the paper on the history of dementia written by Guiraud (1943), then one of the great figures of French psychiatry. Things started improving by 1950, when the First World Congress of Psychiatry was held in Paris, with Henri Ey as its president and with the supporting presence of world figures who gave a fillip to French psychiatry. Ey's explanatory views, whether of the origin of mental disorder or of the evolution of psychiatric thought, were based on a longitudinal, diachronic view. On account of the influence of Hughlings Jackson on his work, Ey saw disease and the historical process in the same way, namely, as resulting from dissolution and circular motions (Berrios 1977).

Another good example of a psychiatrist transversing three generations is Henri Baruk, who started in 1926 with a magnificent book on the psychiatry of brain tumours (Baruk 1926). In 1965, Coury, then the head of the Department of the History of Medicine at the University of Paris, organised a seminar in which Baruk gave five lectures on the history of psychiatry in the nineteenth and twentieth centuries. Published under the title "French Psychiatry, from Pinel to the present day" (Baruk 1967), it provides a useful division into what Baruk called the philanthropic, clinical, anatomo-clinical, psychopathological and medico-legal periods of French psychiatry.

From this historical sketch, it can be surmised that, during the twentieth century, French psychiatry tried to continue along furrows traced by earlier psychiatrists. Thus, on occasions, it resisted new concepts, and a good example is the debate at the beginning of the century on whether Kraepelin's concept of dementia praecox had clinical validity. On other occasions, this defensiveness became xenophobic, as it is the case with Chaslin's (1914) anti-German paper. More permeability was shown to other ideas, for example psychoanalysis, which since the time of the early writings of Hesnard (1971) found a special place in many a French hospital.

[1]Editor's note: On the development of psychiatry in the German-speaking countries in the twentieth century, see also Ackerknecht (1985), Finzen (1996), Hoff (1994), Kolle (1956, 1959, 1963), Kreuter (1996), Schliack and Hippius (1998).

On the other hand, some of the great nineteenth-century ideas were developed further. De Clérambault modified the old notion of *automatisme psychologique* and made it central to his rich, but idiosyncratic psychopathology (Marchais 1995). Inspired by Bergson and Durkheim, Charles Blondel produced one of the more original books on mental symptoms and pathological changes in consciousness ever written (Fuentenebro and Berrios 1997), and Henry Ey tried to reconcile psychoanalysis, Jacksonian ideas and the old French descriptive tradition (Berrios 1977). During the 1930s, Guiraud developed a subtle neurobiological model of mental disease, Mourgue helped to develop a fascinating diachronic model of mental illness (Monakow and Mourgue 1928), Lacan (1977) gave a hint of things to come with his powerful thesis on paranoia and Ajuriaguerra, after training in Paris, took up a chair in Geneva to undertake his legendary neuropsychiatric research (Berrios 1992b).

All these very French approaches had two things in common: one was the view that mental symptoms are not just units of analysis clustering together and occurring in clear consciousness, and the other that they are manifestations of deep structural changes in the psyche, of dissolutions and regressions, which also cause major changes in the frame of consciousness and which make mental illness a complex and dynamic phenomenon (similar in a way to the suggestive ideas developed by Janzarik 1959).

The historian can still sense the major effort made by French psychiatry after the Second World War to remain true to its nosology and philosophy of care. During the 1950s and 1960s, the impact of left-wing ideas and the intellectual and practical work of talented immigrants such as Fanon and Tosquelles led to the development of a new social psychiatry and the growth of the concept of sector and continuity of psychiatric care (Raynier and Beaudouin 1961; Fourquet and Murard 1980). Psychoanalysis, neurobiologism, descriptivism and phenomenology are allowed to run parallel, and little effort is made to find common ground. The great French journals continued to be published in French, and with few exceptions (e.g., Pierre Pichot) little effort is made inform the outside world of French ideas.

This landscape has began to change. Descriptive psychopathology and the clinical tradition – à la Séglas, Chaslin, De Clérambault, Guiraud or Ey – is in danger of being eclipsed by the growing acceptance of DSM IV. Important journals (e.g., *L'Encéphale*) have switched to English, and the results of French research projects are increasingly appearing in Anglo-Saxon publications. Let us hope for the benefit of mankind that the care for and interest in ideas which has characterised French psychiatry since the nineteenth century is preserved in the midst of these changes.

6.2 Great Britain

Twentieth-century British psychiatry has retained its earlier interest in the management of the insane (for a full history, see Berrios and Freeman 1991b; Freeman and Berrios 1996). Of course, there is also a conceptual story to tell which invariable reflects changes in German and French frameworks. For example, since the 1850s, the English term "psychopathology" is known to have changed its meaning at least three times. It started life in 1847 as a transliteration of the German *Psychopathologie*, as used by von Feuchtersleben (1845). At this stage, German usage was explicative rather than descriptive: According to von Feuchtersleben (1847, p. 70), "psychopathology has not yet acquired sufficient light respecting these critical processes", but this perspective was not influential in England; Winslow (1848), for example, disregarded it altogether. The term re-emerged at the end of the nineteenth century with a forensic meaning: "the science which treats of the legal aspects of insanity; i.e., of the rights and responsibilities of lunatics" (Tuke 1892b, p. 1014).

An additional explanation for the lack of success of "psychopathology" in Great Britain is likely to be that there were established competitors such as "psychological medicine", "mental science", "mental pathology" and "mental physiology". At the beginning of the twentieth century, the forensic meaning petered out, and the term started to gain the meanings debated in continental Europe. In 1903, Pierre Janet and Georges Dumas founded the *Journal de Psychologie Normale et Pathologique*, and 5 years later Dumas published his "Qu'est-ce que la psychologie pathologique" (1908), in which he made a case for psychological pathology becoming a branch of normal psychology. In 1889, Binet described the situation accurately: "with few exceptions, the psychologists of my country have left psychophysical research to the Germans and comparative psychology to the English, to dedicate themselves completely to pathological psychology" (Beauchesne 1986, p. 67).

At the beginning of the twentieth century, the French debate on whether there was continuity or discontinuity between normal and abnormal behaviour was rehearsed in Great Britain. Likewise, the need for a term was felt to refer to that branch of psychology dedicated to the psychological (rather than somatic) explanations of mental dysfunction. By then, "mental science", "psychiatry" and "psychological medicine" were all tainted by their use by psychiatrists and were not acceptable to psychologists (or psychiatrists of a psychodynamic persuasion). Thus, with Jastrow (1902), psychopathology acquired its widest definition:

"the general study of diseased mental conditions; a synonym of psychiatry and abnormal psychology but rather more comprehensive that either, because it emphasizes the general scientific study of all forms of mental aberration" (p. 391). This definition was to remain popular, particularly in the United States, where the term psychopathology was for a time used as a synonym of psychiatry (Berrios 1991). Soon enough, however, British psychiatry was affected by the arrival of psychoanalysis.

6.2.1 The Psychodynamic Period

The early impact of the psychodynamic ideas (those of Janet and Freud) on psychiatric matters in Great Britain has not yet been fully studied (Hinshelwood 1991). It is assumed that, in general, this impact was not marked, as British psychiatry remained protected by its "empirical" mentality and by the fact that it main clinical concern was the management of the insane. This was to change during and after the Great War, when the understanding of "shell-shock" (Merskey 1991) led to a gradual acceptance of psychodynamic views. Analysis of works published around that period suggests that these views may have been more influential than it has been hitherto considered (e.g., Hart 1927).

By the onset of the First World War, the term "psychopathology" had also reached its widest meaning in Great Britain. In the 1926 Goulstonian Lectures, Bernard Hart, an important psychiatrist of the period stated: "Psychopathology connotes not a mere description of mental symptoms, but an endeavour to explain disorder or certain disorders in terms of psychological processes" (Hart 1927, p. 2). He also differentiated this type of explanation from "somatic ones" used in "psychiatry". Hart's work illustrates well the manner in which psychoanalysis became assimilated into the epistemology of British psychiatry (Pines 1991). While using a number of classical Freudian categories, Hart constantly felt the need to appear to be practising a "scientific" and "empiricist" approach (in the British sense of these terms). This need is almost painfully expressed in the way in which he clung on to the definition of science developed by K. Pearson (1892), which was incompatible with Freud's.

Hart was not alone in this endeavour. Myers and Rivers, two Cambridge academics, were also influenced by psychoanalytic concepts and planned to develop a "science of psychopathology" (Crampton 1978). To this end, they were successful in the creation of a lectureship in psychopathology at the University of Cambridge. The first incumbent, McCurdy, a psychiatrist and psychologist from Canada, was at one with Rivers and Myers in regarding psychopathology as both the description and psychological (not somatic) explanation of mental symptoms (Banister and Zangwill 1949). This academic view reflected the zeitgeist. It was under McCurdy's tutelage that Gillespie (1929) developed the concept of "reactive" and "neurotic" depression.

Another interesting figure in this context is McDougall, who also carried out psychopathological research in Cambridge. His early conception of "clinical psychology" included the study of mental disorders, and he spoke persuasively on this subject in his presidential address before the Medico-Psychological Association of Great Britain and Ireland (McDougall 1919). In his *Outline of Abnormal Psychology*, McDougall (1926) used "abnormal psychology" for psychopathology, approvingly quoting Eugen Bleuler's statement that "one of the most important, if not the most important, of all paths to a knowledge of the human soul is by way of psychopathology" (p. vii). Later on, McDougall proposed an idiosyncratic model where the central role was played by an energising principle or "horme", which owed much to Freud's *libido*, Bergson's *élan vital* and Oskar Vogt's *neurokyme*. In his autobiography, McDougall wrote: "I built up my abnormal psychology incorporating what seemed most sound in the teachings of Freud, and Jung and Morton Prince, especially the principles of conflict, repression and dissociation, and the subconsciously working complex" (McDougall 1930, pp. 215–216). The influence of McDougall on British psychiatry has not yet been fully evaluated.

6.2.2 The Descriptive and "Phenomenological" Period

In the 1930s, Great Britain had the great fortune of becoming the country of exile for a group of major continental figures, including Willy Mayer-Gross, Eric Guttmann, Alfred Meyer, Stephen Krauss and the Austrian Erwin Stengel (for a history, see Peters 1996). Mayer-Gross arrived in Britain in 1933, and on his death he left a great intellectual heritage. As Slater and Roth (1969) were to write years later: "Mayer-Gross was educated in the German school of psychiatry, and was a pioneer contributor, with such other great men as Beringer, Gruhle and Jaspers, to the remarkable flowering of clinical psychiatry in the development of 'phenomenology', i.e., the exact study and precise description of psychic events, which are a primary requisite for their understanding". The same authors also suggested that Mayer-Gross helped to rejuvenate British psychiatry which was "until then bogged down in the unproductive generalities of Meyerian psychobiology". This statement is historically correct. Up to the 1930s, British psychiatry was drifting into a Meyerian and psychodynamic limbo and was closed to everything else.

For example, the four lectures on the "Phenomenological Method" delivered by Husserl at the University of London in 1922 had no impact whatsoever (Spiegelberg 1982). At an early stage of his career, Ryle is said to have been asked by his professor to learn German in order to read Husserl's *Logische Untersuchungen.* Thus armed, he went on to write a review of Heidegger's *Sein und Zeit* (Ryle 1929). In his autobiography, Ryle (1970) recalled the lack of interest for phenomenology in the Oxford of the 1920s and stated: "it is sometimes suggested that in my well or ill spent youth I had been for a while a disciple of Husserl's phenomenology. There is no much truth in this" (p. 9).

Mayer-Gross encouraged a precise description of psychic events and took pains to construct structured instruments to organise clinical information (Mayer-Gross and Guttmann 1937; Lewis 1970b). He also inculcated in his disciples a sensible combination of descriptivism and neurobiology. Moreover, he is said to have introduced many to the work of Jaspers. In spite of this teaching, however, it is of some historical interest that the historian cannot find any tangible proof of Jaspersian influence until the 1950s, when a group of psychiatrists in Manchester, under the leadership of Anderson, began to translate some German classics, including the 1947 edition of Jaspers' *Allgemeine Psychopathologie*, which rather surprisingly appeared for the first time in English in 1963.

Evidence for this lack of influence can be found in Ernest Nicole's book. The honorary secretary of the Psychopathology Subcommittee of the Royal Medico-Psychological Association, Nicole wrote in 1930 the first edition of what was to become a very popular book (it went through six editions). In its fourth edition, published in 1946, this work included about 1400 references, by far the longest list ever included in a book on psychopathology. Surprisingly, therefore, no reference can be found to either Jaspers or Mayer-Gross, and this because as late as 1946, Nicole's more or less official conception of psychopathology (Nicole 1946) remained pre-1930 in spirit and amounts to no more than a list of explanations for all mental disorders, including some somatic theories.

Yet another piece of evidence that Jaspers' influence on British psychiatry was much more tardy than is retrospectively allowed is the perceptive comment by Anderson (1963) "that this school [phenomenology] should have been insufficiently recognized in England is perhaps hardly surprising. Many reasons can be adduced for this, first and foremost of which is the linguistic barrier. Secondly, even for those familiar with the German language, Jaspers' thought and style are difficult, due no doubt to his training as a philosopher, and his consequent use at times of terms specially devised to express some nuance of meaning not easily, if at all, to be translated intelligibly. To the English with their ingrained empiricism such an approach might well repel . . . yet this is a superficial evaluation". And referring to the type of psychopathology which was popular in the United Kingdom, Anderson added: "By a remarkable paradox, however, our supposedly empirical countrymen have accepted readily enough, and on the whole with an astonishing lack of criticism, the unproven and unprovable assertions of the so-called psychodynamic schools" (Anderson 1963).

Other important accounts of psychopathology published during that period also remain unenthusiastic about Jaspers. For example, in the first edition of his *Psychopathology*, Taylor (1966) stated that "psychopathology is a word of many meanings. It has a chequered career in the history of modern psychiatric thought, acquiring new meanings and connotations with the advent of every new theory of mental illness", and in spite of his overt support for phenomenology, Taylor still conceived of psychopathology as a form of "physiology of the mind" (p. 10). The same year, Frank Fish, a psychiatrist of German descent, was invited to give a seminar on symptoms at the University of Manitoba, which he duly published as *Clinical Psychopathology* (Fish 1967). Although his emphasis was then descriptive, Fish (1967) felt forced to state that "this book has been written from the descriptive stand-point and hence over-emphasizes certain aspects of psychiatry. This does not imply that the author believes that interpretative psychology, such as Freudian psychopathology, and experimental psychology have nothing to contribute to our understanding of psychiatric signs and symptoms". After Fish's untimely death, the book was updated by Hamilton (1974) (also German born), who wrote that "anyone who is acquainted with Anglo-American psychiatric literature will know that the careful description of psychiatric symptoms in English is conspicuous for its absence" (p. 1) and, referring to Jaspers' *General Psychopathology*; "it is unfortunate that this should be the only account of German views on symptomatology in English, because the book is overloaded with philosophy, is somewhat out of date, and does not do justice to the views which Jaspers does not accept" (p. 1). A fairer and more succinct judgement would be difficult to make.

In 1960, another German writer, Hans Eysenck, edited his epoch-making *Abnormal Psychology*, which he dedicated to Kraepelin. This book was to be influential among psychologists and in fact included chapters by the best research psychologists of the late 1950s. Eysenck (1960) attempted an "integration through theory, an attempt to see abnormal psychology as a part of general, experimental psychology". His view was that symptoms were dimensional and

continuous with normal function and hence that psychopathology had as its task the working out of "the details of abnormal behaviour from general laws".

To summarise, the first psychopathological tradition to become established in Great Britain was a watered down variant of the Freudian approach. Its exponents strove for the development of a science of the abnormal mind that contained a set of descriptions and psychological explanations of mental symptoms. This tradition was predominant up to the 1930s, when the German-speaking psychiatrists brought with them views that combined Jaspersian descriptive psychopathology and a welcome search for organic causation.

6.2.3 The Present

How does the average British psychiatrist understand "psychiatry" and "psychopathology" and practice them in everyday clinical work? It is still customary to teach that "descriptive" psychopathology (divided itself into "phenomenological" or verbal or descriptive and experimental) studies the "form", whereas "psychodynamic" psychopathology studies the "content" of the symptoms. No set of rules exists, however, to cross-refer from one to the other; hence this classification is little more than a compromise between parallel psychopathological approaches.

The historian of the present can identify in current British psychiatry a combined or eclectic approach that has become its hallmark. However, while paying lip service to the objectivity of "atheoretical" descriptions, researchers in Britain make assumptions as to the nature of the mind and the brain causation of mental disease. They have also succumbed to an absolute need for "reliability" and increasingly rely on closed psychopathological glossaries (e.g., DSM IV). Most feel that a science of psychopathology is no longer needed, as the description of symptoms is now complete. In this regard, it is revealing that the Psychopathology Subcommittee of the old Royal Medico-Psychological Association has no counterpart in the present Royal College of Psychiatrists.

7 Conclusions

This chapter has given just few examples of how some of the concepts reigning in modern psychiatry (and constituting its hidden scaffolding) came into being. It has suggested that psychiatry is a complex medico-social activity whose historical success depends upon the progressive goodness of fit between man-made descriptions and mental symptoms, i.e., behaviours (mostly) resulting from neurobiological lesions. In all cases, however, social factors are crucial to their modulation. In practice, this means that more or less featureless experiences are always formatted by personal, social and cultural codes.

Behavioural signals and their biological mechanisms are in general opaque to understanding, for they are proto-behaviours that, in order to be intelligible at all, require severe cultural formatting. This means that the description and mapping of mental disorders are language dependent. This has led some to conclude (wrongly) that mental disorders can therefore be reduced (without residuum) to linguistic events. Although it cannot be denied that mental disorders are semantic and social artefacts, it is also undeniable that they are a manifestation of disordered neurobiology. From the point of view of explaining and understanding mental illness, both components are essential.

It also follows that the language of descriptive psychopathology is an intellectual, technical and social event. Like any other descriptive system, it includes terms, assumptions and application rules and can be studied by means of a cross-sectional (synchronic) or a longitudinal (diachronic or historical) methodology. While the former pertains to the philosophy of psychiatry, the latter gives rise to psychiatric history proper. If it is to be of any use, psychiatric history must do more than chronicle surface events. It must also unveil the particular structures of successive psychiatric discourses (i.e., the hidden scaffoldings often manipulated by the psychiatric elite). Current descriptive psychopathology, for example, emerged from a compromise between the need to capture the invariant features of mental disorder (i.e., the biological signal) and the need to achieve public order and contribute to the good functioning of society; the former was the expression of nineteenth-century science, the latter of socio-political demands. This encouraged psychiatrists to create a descriptive system that was both based on reality and socially committed.

However, the descriptive system also needed to be stable enough to withstand signal variation and redundant enough to cope with unskilful usage and perfunctory teaching. The conceptual stabilisers built into the language of description by the great alienists of the nineteenth century proved adequate for these tasks.

Unfortunately, the ensuing stability has been interpreted by some incautious twentieth-century psychiatrists as meaning that DP is correct in every detail and exhaustive and hence can be considered as transparent. This has encouraged a premature closure of the psychopathological glossaries. Closure has contributed to reliability, stability and communication, but might have curtailed clinical validity and the rights of psychiatrists to describe new mental symptoms.

Analysis of this historical process is only possible because records exist that document the language of

description and show that it has changed throughout time. Since the clinical historian cannot study first-hand the behavioural signals emitted by the countless patients that once came within the observational purview of his or her predecessors (and on which the language of description was calibrated in the first place), he or she must rely on documents enshrining partial accounts of what those signals were like. Confronted with a multiplicity of descriptions, the historian must map and "triangulate" these systems of words and assess the relative contribution of biological signal and social noise.

This sort of analysis shows that, from time to time, changes take place in the way in which mental illness is described. In principle, these might have resulted from either shifts in the language of description itself or mutations in the gene system that controls the biological signal. In this respect, clinical historians have the advantage of being able to resort to an internal catalogue of bedside experiences, i.e., to "knowledge by acquaintance".

When explaining the development of the language of psychiatry during the nineteenth century, the following factors have been considered:

1. The availability of new semiological and psychological theories that allowed for a fractionation and (eventually) a quantification of behaviour
2. Changes in the conception of physical illness itself, which demanded correspondences between lesion and signal and placed the disease firmly in the internal space of the body
3. The availability of patient cohorts (as a result of the creation of asylums), which allowed for longitudinal observation, thereby introducing a time dimension in the interpretation of symptoms
4. The acceptance of subjective experiences as legitimate sources of mental symptoms

Other factors will no doubt be uncovered by further research.

Once descriptive languages have reached a steady state, they show surprising stability and become almost transparent to their users. Mentally ill patients are perceived in a similar manner by most psychiatrists the world over. Stability and uniformity, however, should not be considered as features intrinsic to the descriptive system (or as necessarily advantageous). Part of the task of evaluating their usefulness is to explain their origin. In spite of the fact that an adequate theory of language stability (and change) would be of great use to current clinical practice, clinical historians have not yet started delving into these processes. Explanations for language stability can be based on assumptions of neurobiological invariance or on the effective and calming operation of social macro-concepts.

The historical and conceptual hypotheses outlined in this chapter have already opened a major research space for younger colleagues. There is urgent need to see whether the models in question apply to the history of each individual symptom and disease. The history of DP will achieve full usefulness only after such a painstaking analysis has been completed. Furthermore, the detailed historical study of concepts, documents, biographies, socio-political contexts and patient cohorts will in due course throw light on the mechanisms and rules whereby small cliques take upon themselves the honourable and awesome task of periodically reconstructing psychiatric nosology for all patients in the world and for the ordinary psychiatrists who look after them.

Psychiatric Classification

Nomina si nescis, pereat et cognitio rerum.
CARL VON LINNÉ

Translator: E. Taub

1 Diagnosis and Classification

Medical diagnosis is the differential recognition, assessment, and naming of disease patterns. The term "diagnosis" may refer either to the description of the disease pattern itself or to the process of formulating this description, i.e., the diagnostic process. "Classification" refers to the organization of a large number of different cases, all of which differ from each other in certain defined ways, into a system of classes or to the process of assigning individual cases or diagnoses to the classes within a system (Mombour 1975). Diagnosis and classification are closely related to each other: diagnoses require organization, just as classification requires content.

Diagnosis serves multiple purposes: differential description, the identification of cases, the identification of indications for therapy, the determination of a prognosis, scientific classification, and, finally, documentation in the health sector for administrative, accounting, and planning purposes (Dilling and Dittmann 1990). The multiplicity of demands placed upon diagnostic classification systems can perhaps be satisfied only by the use of several systems or system versions. In light of the remarkable progress made recently by scientific medicine, including in biological psychiatry, the field of clinical diagnosis and classification has considerable catching up to do (Jablensky 1988).

2 History of Psychiatric Classification

The systematic classification of medical diagnoses has its antecedents in the development of descriptive natural science in the eighteenth century. Carl von Linné (Linnaeus), after publishing his landmark work on the classification of plants, went on to produce the *Genera morborum*, a systematic classification of diseases, the fifth chapter of which deals with mental disorders (Linné 1742). William Cullen's *Synopsis nosologiae methodicae*, which also contained a classification of mental illnesses, appeared shortly thereafter (1772). These two broad surveys marked the beginning of the steady development of psychiatric diagnosis and diagnostic classification continuing over 200 years until the present.

In Germany, in 1768, Immanuel Kant published his *Kleine Onomastik der Gebrechen des Kopfes* ("Brief Nomenclature of Afflictions of the Head"), ranging from "Dummköpfigkeit" ("stupidity") to "Narrheit" ("folly") and from "Blödsinnigkeit" ("feeble-mindedness") to "Tollheit" ("madness") and including a classical description of delusional thinking (Kant 1983). In 1818, Heinroth, then serving as the first professor of psychiatry in Germany, published a quite extensive classification of mental illnesses, subdivided like Linnaeus' system into classes, orders, genera, species, and varieties (Heinroth 1818). Heinroth failed to base his system on unambiguous characteristics of illnesses, as Linnaeus had classified plants, for example, on the basis of distinct features such as anthers and calyces. What resulted was a set of disease designations rather than adequate descriptions that could be used to identify diseases reproducibly.

Pinel (1809) made a more practical, and thus superior, contribution by limiting the number of diagnoses to a few major ones such as mania, melancholy, dementia, and idiocy. He and his pupil Esquirol (1838) had wide-reaching influence in the mid-nineteenth century; psychiatric diagnosis in many countries, including Germany (Eschenburg 1855), followed the lines they laid down. In 1845, Griesinger published the first edition of his textbook, in which he propounded a unified concept of psychosis, like his teacher Zeller before him. He considered the various different phenomena such as depression, "exaltation" (i.e., mania), and dementia to be different symptomatic manifestations of a single underlying process. Griesinger seems to have switched to a nosological approach in his later years by adopting Snell's concept (1865) of separate disease entities.

2.1 Development of a Nosological Approach

The descriptions of "démence précoce" by Morel (1853), of "dementia praecox" by Kahlbaum (1863), and of "hebephrenia" by Kahlbaum's pupil Hecker (1871) may be considered as descriptions of groups of symptoms rather than diseases; Emil Kraepelin's approach, on the other hand, was clearly nosological. He created two inclusive disease entities, dementia praecox and manic-depressive insanity (Kraepelin 1896), and stated the characteristic symptoms and course of each, thereby becoming the major figure in psychiatry around the turn of the century. Kraepelin's theory found acceptance around the world, although not without opposition. Hoche (1912), for example, who propounded his own system of syndromes, compared the nosological classification of mental disorders to an attempt to cleanse muddy waters by "pouring them assiduously from one vessel into another." Kraepelin also created the triadic classification of mental disorders that is still used today, dividing them into mental disorders with physical causes, endogenous psychoses, and psychogenic disorders.

Eugen Bleuler took a position between those of Kraepelin and Hoche. He made use of Kraepelin's description of dementia praecox, while rejecting his pessimistic view of its prognosis, and instead used the new category of "schizophrenia," whose course he considered variable. The title of his most famous work (Bleuler 1911), which speaks of the "group of schizophrenias," indicates that he did not consider schizophrenia to be a single disease entity.

The scientific contributions of the nosologically inclined authors were incorporated into the Würzburg Diagnostic Scheme (*Würzburger Diagnosenschema*; Wilmanns 1930), which remained in general use in German-speaking countries until the 1960s. This classification scheme for both neurological and psychiatric disorders, however, failed to make adequate diagnostic distinctions in several areas, particularly among the psychogenic disorders.

2.2 National Diagnostic Classification Systems

While the classification systems of the nineteenth century generally arose in individual schools of psychiatry, many national classification systems were developed in the twentieth century. These largely made use of the diagnoses that had been propounded earlier in Central Europe. Numerous diagnostic classifications current in the early 1960s were described in 1961 by J.E. Meyer in an earlier edition of this textbook (Meyer 1961). By the mid-twentieth century, approximately 100 systems of classification of mental disorders were in use around the world (Wittchen 1994). Repeated suggestions were made for the improvement of these classifications, which were still considered unsatisfactory (Helmchen et al. 1966).

As it is impossible to give a full account of all of the historically developed and currently used classification systems, this discussion will be limited to a few examples illustrating their wide variety.

In French psychiatry, Magnan and Serieux (1893) developed a classification parallel to that of Kraepelin, which, unlike the latter, failed to achieve general acceptance (Pull et al. 1988) and was used only in French-speaking countries. This classification introduced a number of new categories of mental disorder, such as the various subforms of acute delusion ("bouffées délirantes") and of chronic delusional disorder ("délires chroniques"). The meaning of these terms, however, was only understood in France. The concept of schizophrenia was acknowledged despite some resistance, but was assigned a relatively limited scope. The concept of manic-depressive psychosis, however, found acceptance in France more easily, probably because of similar earlier descriptions by Falret (1854) and Baillarger (1854).

While no special diagnostic system was developed in England (Kendell 1990), it was Scandinavian psychiatry in particular that contributed not only the concept of psychogenic psychoses (Wimmer 1916), but also a number of early attempts toward multidimensional diagnostic assessment (Sjöbring 1919). Strömgren's repeated efforts (1988, 1989) led to international use of the concept of psychogenic psychoses.

Kleist and his pupil Leonhard (1986) proposed a classification of psychoses that provided definite prognoses on the basis of clinical phenomenology. This special, separate system was used in several places in Germany.

The Chinese Classification of Mental Disorders (CCMD) (Yu-cun and Changhui 1988) is an example of a system adapted to national needs. It is the product of an attempt to introduce modern diagnostic concepts while retaining certain traditional entities. The system is nosologically oriented and lists etiologic factors where possible. Neurasthenia is one of the subclassifications used in furtherance of tradition; this category is not present in DSM-IV, but appears again in ICD-10, certainly at least in part because of its use in China.

In the Meiji period, beginning in 1868, Japanese psychiatry turned away from traditional diagnostic procedures and took note of the latest developments in Europe. Kraepelin's system was adopted by the nation's leading university (Tokyo) and was largely adhered to until after the Second World War. In the postwar years, ICD-8 and ICD-9 were influential, followed by operationalized diagnosis, exemplified by the DSM-III. At present, the translated version of ICD-10 is in widespread use. Japanese centers participated in the international studies carried out by the World Health Organization (WHO) (Fujinawa 1994).

In 1989, in connection with the Japanese adoption of ICD-10, a special Japanese clinical modification was suggested (ICD-10 JCM) (Hanada 1994), which was based on the findings of a large national study.

In consultations on the construction of international classification systems, representatives of the so-called Third World have pointed out that many common disorders in Europe and North America, such as anorexia, anxiety disorders, sexual deviation, and borderline personality disorders, are rarely seen in their countries. The more common disorders there generally include acute psychotic episodes, hysterical manifestations, obsessions, and various somatization disorders (Wig 1990). Special transcultural syndromes, such as *koroh*, *latah*, and *dhat*, play a subordinate role, but should nevertheless be included in international classifications in appropriate places. The dualism concerning body and soul, characteristic of western psychiatry

until the present, is absent from many traditional ways of thinking. Thus the transition from ayurvedic medicine or from the medicine of traditional healers in Africa, for example, to modern, western medicine occurs across a conceptual gap that may be difficult to bridge. Nonetheless, ICD-10 fulfills many of the diagnostic needs of Third World psychiatry (Wig 1990).

3 Principles of Current Diagnostic Classification

The 1960s and 1970s were marked both by attacks on psychiatric diagnostic concepts, emanating from psychoanalysis and, above all, from antipsychiatry, and by a growing awareness of the need for unambiguous diagnostic criteria, particularly because of the increasing importance of psychopharmacologic research (Kendell 1975; Saß 1987).

In the United States, a reaction to the dominant psychoanalytic current of the 1950s and 1960s led to a reconsideration of Kraepelin's diagnostic system, termed neo-kraepelinianism (Klerman 1990). The Feighner Criteria (Feighner et al. 1972) and, later, the Research Diagnostic Criteria (RDC; Spitzer et al. 1975) were both developed for scientific purposes and served as forerunners of the more comprehensive modern systems of classification, starting with DSM-III.

The development of psychiatric classification from the diagnostic schemes of individual, prominent psychiatrists toward a consensus of many experts on the national and international level (Kendler 1990) culminated in the two major current systems: that of the World Health Organization (WHO), the *International Classification of Diseases* (ICD-10), and the American national psychiatric classification, the *Diagnostic and Statistical Manual* of the American Psychiatric Association (DSM-IV). The development has thus also been toward a reduction in the number of major systems in use. Nonetheless, geographic and ethnic variations remain, and will likely persist, in the frequency of certain diseases and disorders as well as in the tendency to make use of certain diagnostic categories (Sartorius et al. 1990).

3.1 International Cause-of-Death and Disease Statistics

A uniform international system of diagnosis was sought for general medicine long before the WHO tried to provide a classification of diagnoses. At the First International Statistical Congress in Brussels, in 1863, William Farr and Marc D'Espine called for the adoption of a common international nomenclature of causes of death (Kramer 1988). Their system, based on five major groups of categories, had originated in 1855 and underwent three revisions by the end of the century. A fundamentally new version was introduced in 1893 by Jacques Bertillon, then head of the Statistics Bureau of the city of Paris (Kendell 1975). This classification distinguished between generalized and localized diseases. It was revised every 10 years thereafter by a commission comprising representatives of the International Institute of Statistics and of the Health Organization of the League of Nations. A listing of diseases, consisting of a combination of previous national and international listings, was added to the cause-of-death classification in 1938. These existing international listings were adopted after the Second World War by the WHO and were incorporated into the sixth edition of the *International Statistical Classification of Diseases, Injuries and Causes of Death* (WHO 1948). The psychiatric part of this classification was accepted in only a few countries, even though the increasingly frequent contact among psychiatrists from different countries made the need for international agreement increasingly apparent.

3.2 ICD-8 and ICD-9 and the Development of DSM-III and DSM-IV

The eighth edition of ICD-10, used from 1969 onward in numerous countries, including West Germany, was the first to contain a glossary (i.e., a collection of brief definitions) and made progress toward more exact descriptions of disease (WHO 1967; Degkwitz et al. 1971). The classification systems of this edition and the following ninth edition, which is currently still valid (WHO 1978; Degkwitz et al. 1980), were recognized as official by the Federal Government of West Germany, thus enabling the collection of nationwide statistics, and were introduced into clinical practice by the Bundesarbeitsgemeinschaft der Träger psychiatrischer Krankenhäuser (Federal Psychiatric Hospital Association). Many comparative studies were thus made possible on both the national and the international levels.

The official American diagnostic classification, DSM-II (APA 1968), was still largely in accord with ICD-8. However, both ICD-8 and ICD-9 had major weaknesses, including lack of multiaxiality, nonuniform classification of depression, and problems relating to the diagnosis of sexual disorders. The American psychiatrists therefore chose to pursue a different route than their WHO colleagues with the third edition (and, later, the revised third edition) of the *Diagnostic and Statistical Manual of Mental Disorders* (APA 1980,

1987). The most important difference was the so-called operationalization of diagnosis, with the aid of clearly defined criteria; this stood in contrast to ICD-9, which had only a glossary containing brief descriptions. DSM-III was widely accepted in practical use, and even more widely in research, within a few years. Many scientific publications now require the description of patient populations by the criteria of DSM-III, DSM-III-R, and the most current version at the time of writing, DSM-IV (APA 1994). This development put the WHO under considerable pressure to conform. While the WHO was still obliged by multiple international agreements to construct and propagate its own classification system (Strömgren 1994), it could not deviate much from the model of DSM-III, which had already been adopted into common use.

3.3 Operational Diagnosis

Operational diagnosis is based on the phenomenological characterization of disorders without regard to their etiology. The typical diagnostic features of each disorder are listed, including the intensity and exact duration of the symptoms. A diagnostic algorithm including required and optional criteria, such as psychopathological abnormalities, is used to make a diagnosis. In addition, inclusion and exclusion criteria must be fulfilled.

Operational diagnosis can be contrasted with typological diagnosis (Dilling 1994), which relies mainly on typical case descriptions, making only secondary use of characteristic cross-sectional symptoms and symptom course. A diagnosis is made based on maximal similarity to a typical case, the so-called prototype. The diagnostician thus has considerable freedom in determining which cases are sufficiently comparable to his or her internalized prototype case to merit being given the corresponding diagnosis.

Typological and operational diagnosis differ primarily with respect to the diagnostic process. Even operational diagnosis has prototypes; these are the ideal cases that fulfill all of the diagnostic criteria for a given disorder. The number of criteria fulfilled can be considered an index of the nearness of a given constellation of symptoms to the prototype (Maier and Philipp 1988). Operational diagnosis is not concerned with the etiology of disorders and thus does not obey the classical principle of nosology, according to which an etiology and a constellation of symptoms together constitute a disease entity. Because of the relative lack of attention to etiology in operational diagnosis, the diagnostic categories of ICD-10 are deliberately referred to as disorders, not diseases.

3.4 Preparatory Steps Taken by the World Health Organization Toward the Introduction of ICD-10

In 1982, the WHO and the United States Alcohol and Drug Abuse and Mental Health Administration (ADAMHA) held a conference in Copenhagen to address the diagnosis and classification of mental disorders and alcohol and drug problems. This conference was based on extensive preparatory work (WHO 1981; Research Report 1983; Table 1). In 1984, the WHO organized expert sessions in Jakarta and in Geneva. These meetings led to a preliminary classification scheme for the psychiatric chapter of ICD-10. The individual sections were produced by various groups of mostly English-speaking experts and were provided with clinical descriptions and diagnostic guidelines. The first English version was submitted to the World Psychiatric Association (WPA) (Mezzich and von Cranach 1988), the national psychatric societies, and individual experts for comment and critical review (Dilling and Dittmann 1990).

The WHO received numerous suggestions for improvement, some of which were incorporated into further drafts. The so-called *Blue Book* underwent a series of revisions and was finally published in 1992 as *Clinical Descriptions and Diagnostic Guidelines*. In parallel with the work of the WHO, translations were prepared in Spanish, French, Arabic, German, Chinese, and many other languages; in 1997, the text was available in 22 languages and in preparation in a further nine. The German edition appeared in 1991 (Dilling et al. 1991). Ten so-called WHO Reference and Training Centres in Classification, Diagnosis and Assessment of Mental and Behavioural Disorders were established worldwide to develop the psychiatric section of ICD-10 by means of translations, field studies initiated by the WHO, and their own investigations (Sartorius 1995). The center responsible for the German-speaking countries is located in the Department of Psychiatry of the Medical University of Lübeck, Germany (Dilling et al. 1994b).

4 International Classification of Diseases (ICD-10)

4.1 Structure

Psychiatric classification is part the general medical classification of ICD-10 (WHO 1992a; DIMDI 1995/1996). Many more diagnoses are included in ICD-10

Table 1. Timetable of the development of psychiatric diagnosis from ICD-8 to ICD-10

Year	Classification system	Comments
1967	ICD-8	
1978	ICD-9	
1980	DSM-III	
1982		WHO/ADAMHA conference, Copenhagen
1984	ICD-10 Chap. V (F): first preliminary draft of classification	WHO conferences in Jakarta and Geneva
1986	ICD-10 Chap. V (F): Draft (0)	WPA consultation
1987	ICD-10 Chap. V (F): Draft I	Field study of the Clinical Descriptions and Diagnostic Guidelines
	DSM-III-R	
1989	ICD-10 Chap. V (F): Draft III	Beginning of the study on the Research Criteria
		Revision conference, Geneva
1990	ICD-10 Chap. V (F): Draft IV	
1991/92	Publication of the ICD-10 Guidelines	
1993	Publication of the ICD-10 Research Criteria	ICD-10 becomes the official WHO classification
1994	DSM-IV	

ADAMHA, Alcohol and Drug Abuse and Mental Health Administration; WHO, World Health Organization; WPA, World Psychiatric Association.

than in ICD-9 because of the need for refined diagnosis in many specialized areas. An alphanumeric system is used in which a capital letter designates one of a total of 21 different chapters. Psychiatric diseases are designated hierarchically by the letter F (Chap. V), followed by a number for the major diagnostic group, a decimal point, and a further number for the subordinate diagnostic group. A designation may include three or four digits. There are thus 1000 possible diagnoses for psychiatric disorders (F00.0–F99.9), of which approximately one third are now in use. This system allows the addition of new diagnoses in the future without the need for major changes in the classification. In contrast, both ICD-8 and ICD-9 had room for only 300 possible psychiatric diagnoses.

A fifth or sixth digit may be added to provide more precise documentation of the course of illness or other characteristics. Certain nonspecific symptoms or special circumstances, such as suicide, self-injury, or certain psychosocial conditions, are classified in other chapters (Chaps. X, Y, and Z). Somatic comorbidities are classified in the corresponding chapters, e.g., respiratory diseases in Chap. J (X). Psychiatric disorders occupy a special position in ICD-10, because they are the only disorders for which definitions and inclusion and exclusion criteria are provided; in all other areas, the diagnoses are merely named, without further explanation.

4.2 Organization of Chapter V (F)

The WHO intended Chap. F of ICD-10 to serve not just as a classification scheme for statistical purposes, but also, depending on its users, as a clinical manual, a textbook of diagnosis, and a research tool. A "family of documents" for different uses thus came into being:

- Various versions of the classification
  - Brief glossary
  - Clinical diagnostic guidelines
  - Research criteria
  - Multiaxial system (MAS)
  - Classification of mental disorders in primary health care (PHC) in child and adolescent psychiatry
  - Classification of mental disorders in PHC in adult psychiatry
  - Fascicles for special areas (e.g., mental retardation, neuroses, personality disorders)
- Cross-reference tables
- Teaching and learning materials (lexica, multilingual dictionaries of ICD-10 terminology, specialized texts, teaching overhead transparencies, adaptations, computer versions)
- Instruments for diagnostic assessment (Schedule for Assessment in Neuropsychiatry, SCAN; Composite

International Diagnostic Interview, CIDI; International Personality Disorder Examination, IPDE; Disability Assessment Schedule, DAS; International Symptom Checklist, ISCL; International Diagnostic Checklists, IDCL)

The concise version of ICD-10, Chap. V (F) is part of the system of ICD-10 diagnoses (WHO 1992a; DIMDI 1995/1996). The appended glossary provides brief explanatory descriptions of each disorder, which make psychiatric terminology accessible to many people in the health sector who may lack familiarity with it, such as statisticians, administrators, and insurance personnel.

The central portion of this work consists of the *Clinical Descriptions and Diagnostic Guidelines*, or *Blue Book*, whose approximately 350 pages contain extensive descriptions of all diagnoses and their clinical operationalization (WHO 1992b; Dilling et al. 1991, 1993).

Although the clinical descriptions are meant to be definitions of diagnostic entities with a discussion of their most important characteristics, and the diagnostic guidelines are meant to be listings of features in connection with temporal criteria and rules for inclusion and exclusion, these two areas inevitably overlap. This version of Chap. V (F) is meant primarily for psychiatrists providing care in hospital wards and in the outpatient setting.

The *Diagnostic Criteria for Research* (DCR; the *Green Book*) are more rigorous than the guidelines, in accordance with the needs of research studies (WHO 1993a; Dilling et al. 1994a). The inclusion and exclusion criteria are more stringent, and the temporal limits are more precisely defined. This greater stringency is achieved at the cost of the loss of a fairly large group of cases to which definite diagnoses can no longer be assigned. This perspicuous book of some 150 pages, containing no descriptive definitions of the disorders, is not only of use to researchers, but also practical for psychiatrists in both hospital and outpatient settings.

A special version of ICD-10, the Primary Health Care (PHC) version, was prepared for primary care providers in view of the high incidence of mental disorders among the general population, e.g., the highly prevalent depressive and dependency disorders (WHO 1996; Müßigbrodt et al. 1996). A total of 24 syndromes were chosen for inclusion in the English version. Their most important symptoms are described, as are diagnostic criteria, differential diagnoses, treatment, methods of dealing with patients and their families, and criteria for referral to specialists.

There is a German version is particularly aimed at the general practitioner (Müßigbrodt et al. 1996). It goes significantly beyond the requirements of the WHO concerning primary health care (e.g., in the Third World). Help is provided for the encoding of three- and four-digit diagnoses, as this will soon be required by the German health insurance system.

4.3 Multiaxial System

An overview of the WHO multiaxial system (MAS) is shown below:

I Clinical diagnoses
  Ia Mental disorders according to Chap. V (F)
  Ib Underlying or concurrent physical illnesses, as covered in the somatic chapters of ICD-10
II Assessment of social functional disability attributable to either mental or physical disorders (coding on a five-point scale)

  Specific functional areas:

  IIa Self-care and coping with everyday life (bodily hygiene, clothing, nutrition, etc.)
  IIb Ability to function in an occupation (gainful employment, study, housework, etc.)
  IIc Family and household (interaction with spouse or other partner, parents, children, and other relatives)
  IId Ability to function in other social roles and activities (relationship to members of the community, participation in leisure and social activities)
  IIe Global functional disability (overall disability)
III Environmental factors (selected Z codes)
  1. Negative life experiences in childhood
  2. Upbringing and education
  3. Primary relation group, including family
  4. Social environment
  5. Living accommodations and financial situation
  6. Occupational activity and unemployment
  7. Environmental stresses
  8. Psychosocial or legal problems
  9. Diseases or disabilities in the family
  10. Conduct of life, coping

As far back as the first half of the twentieth century, attempts were made to enlarge the excessively narrow scope of the diagnostic process by introducing a multiplicity of variables. The multidimensional diagnostic system of Kretschmer (1919) and, later, the multiaxial system of Essen-Möller (1973) were of this type. The multiaxial diagnostic system of Rutter et al. (1975) has been used in child and adolescent psychiatry for many years; it provides classification according to clinical syndrome, possible developmental delay, intelligence level, somatic

illnesses, and psychosocial stresses (Remschmidt and Schmidt 1996). Numerous proposals have been made for the introduction of multidimensional criteria into adolescent psychiatry (Mezzich 1988). A number of these were selected for inclusion in the multiaxial system of ICD-10. Unfortunately, there was a large interval between the completion of Chap. V (F) and the development of the MAS, with the result that the additional diagnostic axes have only seldom been used so far. DSM-III and DSM-IV share this problem with ICD-10. DSM makes frequent use of axis V, or global assessment of functional level (GAF), but relatively little of axis IV, psychosocial and environmental problems, which corresponds to axis III of ICD-10. Axes II and III of DSM-IV are included under axis I of ICD-10 under comorbidities. Thus personality disorders and somatic illnesses are not assigned to separate axes.

To simplify the assessment of axis II (disability), the WHO has developed a brief instrument, the Short Disability Assessment Schedule (WHO DAS-S). This may help in the assessment of the sequelae of axis I disorders (Janca et al. 1996).

In connection with the axis of social functional disability, the International Classification of Impairments, Disabilities and Handicaps (ICIDH) deserves to be mentioned (WHO 1980; Matthesius 1995). This classification was created by the WHO almost 20 years ago for the entire area of rehabilitation medicine, far beyond the borders of psychiatry. It is currently being revised and restructured by the WHO, with the participation of many centers (Dilling and Siebel 1995).

4.4 Further Texts on Chapter V (F)

Alongside these versions of and additions to ICD-10, a number of ancillary diagnostic works and specially covered areas deserve to be mentioned.

The successive replacement of ICD-8 by ICD-9 and ICD-10 created a partial lack of continuity of diagnostic categories, a problem which had to be overcome to enable various kinds of clinical and research work to be continued. Although many disorders are still designated by the same or similar names, the introduction of operational diagnosis meant a fundamental change in the system. A basis for statistical comparisons is fairly easy to create for disorders such as catatonic schizophrenia or obsessive-compulsive neurosis, but can be very difficult in other cases, e.g., the reconsideration of "neurotic depression" under "dysthymia" or the comparison of older diagnoses with newly proposed entities such as panic disorder and somatization disorder. Thus the cross-reference tables of the WHO (Freyberger et al. 1993a,b) should not be taken as a mechanical system of translation from one system to the other, because the recasting of diagnoses can only be handled on a case-by-case basis. These tables are to be used as an aid in this process (see also Chaps. 3, 4, this volume).

The WHO has also produced lexica of the psychopathological and other terminology of ICD-9 (WHO 1985), the terminology of ICD-10 (WHO 1994a), and terms relating to alcoholism and drug dependency (WHO 1994b). A further lexicon of transcultural terms is in preparation (Sartorius 1995).

Casebooks have been published in English and in German to give the users of ICD-10 a basis for clinical comparisons and to provide case material for introductory courses. The 100 cases contained in the English casebook are systematically organized to cover the entire field of Chap. V (F) (Üstün et al. 1996). The approximately 50 cases contained in the German text (Freyberger and Dilling 1993) follow no particular organizational principle and reflect the individual contributions of their authors, whose names are signed to the cases.

The WHO has issued numerous overhead transparencies for use in introductory courses, training seminars, and continuing education. These materials highlight various aspects of ICD-10, and some of them have been translated into other languages. A comparable collection of German-language transparencies on the research criteria has been prepared (Dilling et al. 1999).

The psychiatric and neurological adaptations of ICD-10 may be used as aids to coding. The neurological adaptation (Kessler and Freyberger 1996) contains all diagnostic codes of importance to neurologists, i.e., not only neurologic diagnoses, but also a number of psychiatric diagnoses and diagnoses in a series of special areas. The projected psychiatric adaptation (ICD-10 PA) will include diagnoses from the fields of psychiatry, neurology, and internal medicine and from Chaps. X, Y, and Z.

The parallel development of operational diagnostic systems and of computer technology has enabled a collaboration between the two areas (Andrews et al. 1994). A German-language ICD-10 tutorial is available in hypertext form and may be used for many purposes, particularly didactic ones (Malchow et al. 1995). Further texts and links to various texts will appear in the near future.

4.5 Operationalized Psychodynamic Diagnosis

In the Federal Republic of Germany, a working group of specialists in psychosomatic medicine, with the collaboration of several psychiatrists, developed a

multiaxial operational system for psychodynamic diagnosis (OPD) (Arbeitskreis OPD 1996). In addition to the ICD-10 diagnoses, the five axes of "illness experience," "treatment expectation," "relationship," "conflict," and "structure" are considered. This system is potentially very useful in the determination of indications for psychotherapy and in the assessment of the clinical course. An English translation is being prepared.

4.6 Diagnostic Instruments

Diagnostic instruments with an operational orientation have been developed to aid in the diagnosis of mental disorders according to either the ICD-10 or the DSM system.

A group of experts from 14 countries, led by J.K. Wing, developed the Schedule for Assessment in Neuropsychiatry (SCAN), a structured interview for clinical use (WHO 1994d). SCAN is comparable to the tenth edition of the Present State Examination (PSE) (Wing et al. 1974). It consists of a semistandardized interview, a glossary with symptom definitions, an Item Group Checklist, and a history sheet and takes 60–90 min to perform. The center for SCAN-based diagnosis in Germany is the Zentralinstitut für Seelische Gesundheit (Central Institute of Mental Health) in Mannheim.

The Composite International Diagnostic Interview (CIDI) was developed on the basis of an earlier interview, the Diagnostic Interview Schedule (DIS), and is now available in several languages (WHO 1993b; Wittchen and Semler 1991). CIDI can be performed by lay interviewers after a relatively short training period of a few days. Unlike SCAN, which relies on the judgment of the interviewer, the CIDI is a fully standardized interview in which the responses of the interviewee constitute the entirety of the data. The interview takes approximately 1 h. The center for CIDI-based diagnosis in Germany is the Max Planck Institute for Psychiatry in Munich.

The International Personality Disorder Examination (IPDE) was developed by the WHO for the diagnosis of personality disorders (Loranger 1996; Loranger et al. 1994). It is intended principally for use by experienced clinicians.

An International Symptom Checklist (ISCL) was developed and tested by the WHO (WHO 1994c; Janca et al. 1993) for the assessment of the severity, course, and duration of symptoms. This instrument has also been published in German under the title *ICD-10-Checklisten* (Hiller et al. 1995). The Symptom Checklist (SCL) is a screening procedure; after it is used, more precise ICD-10 diagnoses can be given with the aid of 32 International Diagnostic Checklists (IDCL). A further checklist has been developed especially for personality disorders (Bronisch et al. 1995).

Meanwhile, a separate German-language working group developed an ICD-10 checklist corresponding to the Diagnostic Guidelines; this checklist contains 750 criteria divided among 14 feature groups and was validated in eight centers by use in 858 patients. The validating study investigated the frequency, sensitivity, specificity, and predictive value of various features in ICD-10 disorders as well as the suitability of the diagnoses (Dittmann et al. 1992).

A further diagnostic instrument is the Structured Interview for the Diagnosis of Dementia in Alzheimer's Disease, Vascular Dementia, and Dementias in Other Diseases According to DSM-III-R, DSM-IV and ICD-10 (SIDAM) (Zaudig and Hiller 1996).

4.7 Structure and Subdivisions of Chapter V (F)

At first glance, the structure of Chap. V appears to follow the familiar sequence of ICD-8 and ICD-9. The classification begins with mental disorders of organic origin, proceeds through disorders due to the use of psychoactive substances, schizophrenic psychotic disorders, affective disorders, psychogenic disorders, and personality disorders, and concludes with mental retardation and disorders from the realm of child and adolescent psychiatry. However, a closer look reveals that the traditional division of diagnoses into the two major areas of psychoses (ICD-9: 290–299) and neuroses (ICD-9: 300–310) has been abandoned. Diagnostic terms are now used predominantly in a phenomenological, descriptive sense. According to the authors of ICD-10, a single mental disorder may have both psychotic and nonpsychotic manifestations, if we take "psychosis" to mean the appearance of productive symptoms. It was originally planned to leave the term "neurosis" out of ICD-10 entirely, as it had been used in too many different contexts and is based on theories of intrapsychic causation that are no longer generally accepted. The later decision to retain the term "neurotic disorders" in ICD-10 was a concession to traditional usage and does not imply any assumption concerning etiology.

The individual sections of the chapter are subdivided hierarchically, i.e., the descriptions of major diagnostic terms apply also to the three- and four-digit diagnostic categories that follow. As in the DSM, mental illnesses or diseases are no longer spoken of, and the term "disorder" is used throughout, with the exception of a few diseases in F0.

4.8 Particular Aspects of Individual Sections

4.8.1 F0 – Organic, Including Symptomatic, Mental Disorders

F0 includes all disorders of demonstrably organic etiology, regardless of whether they have psychotic or nonpsychotic symptoms. The scope of the term "dementia" has been considerably widened in accordance with the American usage of DSM, although a minimal duration of symptoms of 6 months is required. The diagnosis "delirium" is also less specific than before and no longer requires the presence of perceptual abnormalities.

4.8.2 F1 – Disorders Due to Psychoactive Substance Use

The consideration of mental and behavioral disorders due to the use of psychoactive substances in F1 is an improvement over their previous treatment in two separate places in the section in ICD-9. In F1, the third digit of the diagnosis code designates the causative substance or substance class, while the fourth and (sometimes) fifth digits designate the type of disorder. Distinctions are drawn between acute intoxication, harmful use, dependency syndrome, withdrawal syndrome, psychotic conditions, alcohol- and drug-induced amnesic syndromes, and alcohol- and drug-induced residual conditions. Thus each code designates not only the psychopathological syndrome, but also the responsible substance class. On the other hand, the simultaneous diagnosis of dependency and acute intoxication requires the assignment of two diagnostic codes.

4.8.3 F2 – Schizophrenia, Schizotypal and Delusional Disorders

The schizophrenias, acute psychotic disorders, and schizoaffective, schizotypal, and delusional disorders appear in F2. New entities include undifferentiated schizophrenia, post-schizophrenic depression, and schizotypal disorder. The presence of typical symptoms for at least 1 month is a prerequisite for the diagnosis of schizophrenia. This is in contrast to DSM-IV, which requires the presence of symptoms in the 6 months preceding the time of diagnosis, with at least 1 month of florid psychotic manifestations. Schizoaffective disorders and acute psychoses of brief duration arising within a period of 2 weeks, or even abruptly within 2 days, are presented in particular detail. This emphasis on the diagnosis of acute psychoses is a reflection of the concerns of psychiatrists from the Third World, where acute psychoses of brief duration are quite common and usually carry a good prognosis.

4.8.4 F3 – Mood (Affective) Disorders

The presentation of the affective disorders in F3 has undergone particularly extensive changes. The distinction between endogenous and neurotic depressions has been abandoned. The previously quite common category of "neurotic depression" (ICD-9: 300.4) no longer appears in the system, and its role has been taken over primarily by dysthymia, which, however, is said to be present only if the symptoms have persisted for at least 2 years. Regretfully, manic disorder with recurrent episodes is now absent, while single manic episodes still receive a diagnostic code. Particular emphasis is laid on the determination of the severity of depressive disorders; these are classified as mild, moderate, or severe. The overall subdivision and the introduction of a grading of severity are both analogous to features of DSM-IV, although some nuances of the latter are missing, such as the concept of major depression, which corresponds to the moderate and severe depressive episodes of ICD-10.

4.8.5 F4 – Neurotic, Stress-Related, and Somatoform Disorders

As mentioned above, the occurrence of the term "neurosis" in this section is merely a conventional usage, rather than an indication of acceptance of earlier etiologic theories of neurosis. The individual disorders are highly subdivided. For example, there are seven diagnostic subcategories of dissociative disorders, some of which are quite rare. On the other hand, the term "hysteria" has been definitively abandoned. Stress-induced disorders are classified according to their duration and severity as acute stress reaction, post-traumatic stress disorder, and adjustment disorder. The somatoform disorders appear for the first time in this classification, including somatization disorder, hypochondriacal and somatoform autonomic disorder, and, finally, the somatoform pain disorders. The diagnosis of neurasthenia, closely related to the somatoform disorders, is used with variable frequency.

4.8.6 F5 – Behavioral Syndromes Associated with Physiological Disturbances and Physical Factors

These elaborate enumerations occupy considerable space, with extensive and detailed descriptions. The sexual disorders, which were considered together in ICD-9, are found in two separate sections in ICD-10;

some are listed under physiological disturbances (F52), while others are listed in F6 under the heading "disorders of personality and behaviour," including disorders of gender identity (F64) and sexual preference (F65) as well as disorders of sexual development and orientation (F66). This revealing separation results in a better integration of the various sexual disorders into the context of the larger categories of disorders to which they belong.

4.8.7 F6 – Disorders of Adult Personality and Behavior

Cyclothymic personality disorder is conspicuously absent from the list of personality disorders in F6, appearing instead as "cyclothymia" in the chapter on affective disorders. Schizotypal disorder, too, might have been chosen for inclusion in F6, but was not. As in DSM-IV, the listing of personality disorders includes emotional instability of the borderline type, a diagnosis given very often (too often) in clinical practice. Artificial disorders, i.e., disorders generated or simulated by patients without any discernible purpose, appear here as a new entity. Accentuated personality traits are not included in the classification, although this was originally planned. The absence of narcissistic personality disorder is frequently decried, although this, like passive-aggressive personality disorder, can be found in the appendix to the research criteria.

The inclusion in this chapter of lasting personality changes after extreme stress, such as torture or incarceration in a concentration camp, is of great importance. German medicolegal practitioners often doubted or denied the existence of this category in the years, and even decades, after the end of the Second World War.

4.8.8 F7 – Mental Retardation

As in ICD-9, the section on mental retardation (F7) distinguishes between mild, moderate, severe, and extremely severe forms.

4.8.9 F8 – Disorders of Psychological Development/F9 – Behavioral and Emotional Disorders with Onset Usually Occurring in Childhood and Adolescence

The developmental disorders and the behavioral and emotional disorders with onset usually occurring in childhood and adolescence (F9) are treated much more extensively than in ICD-9. If possible, all disorders beginning in childhood and adolescence are to be given the diagnostic codes of the preceding sections (F0–F6); F8 and F9 contain only those special disorders that either do not occur in adults or typically begin in childhood.

5 Empirical Research Relating to ICD-10

The initial version of ICD-10, Chap. V, was based predominantly on diagnostic concepts emerging out of clinical practice, which then needed to be tested for suitability, reliability, and above all validity. Studies for these purposes were initiated primarily by the WHO and described in numerous publications. In 1987, the WHO initiated an international field study concerning the diagnostic guidelines, in which 112 institutions from 39 countries participated (Sartorius et al. 1993). A total of 711 clinicians performed 15,302 evaluations. In the German-speaking countries (the Federal Republic of Germany, Austria, and Switzerland), 134 diagnosticians from ten institutions for adult psychiatry and seven diagnosticians from two institutions for child and adolescent psychiatry participated (Dilling et al. 1990), and 2058 evaluations of joint case conferences and written cases were performed. The interrater reliability was highly variable for different diagnoses, reaching an overall value of $\kappa = 0.51$ for all cases. The Department of Psychiatry of the Medical University of Lübeck was responsible for coordinating the study in the German-speaking countries. In the wake of this study, a number of changes in ICD-10, Chap. V, were proposed to the WHO, some of which were incorporated into the final version.

The research criteria were the subject of a further study initiated by the WHO. A total of 151 centers in 32 countries participated (Sartorius et al. 1995), and 942 interviewers performed 11,491 evaluations. In most sections, the interrater reliability of the research criteria was found to be significantly higher than that of the clinical guidelines; in all sections other than F6 (personality disorders), the interrater reliability lay between $\kappa = 0.8$ and 1.0.

In the German-speaking countries, 451 raters from 34 centers participated in this study (Freyberger et al. 1996). A total of 2228 evaluations of 39 videotaped cases were performed. Here, too, there was a high interrater reliability ($\kappa = 0.86$) for three-digit diagnoses, although the value was lower than in the international study. There may be several reasons for this, e.g., the variable independence of raters who may evaluate patients, or videotapes, together as a working group. The suitability of the diagnoses and the degree of difficulty of assigning them were judged by the raters as favorable.

A multicenter study was carried out in the German-speaking countries to assess the symptoms and criteria included in the checklists underlying ICD-10 diagnosis (Dittmann et al. 1992). The practicality, quality, and validity of the clinical diagnostic guidelines were investigated.

The WHO further initiated a study of multiaxiality, in which ten cases were presented to numerous centers around the world for evaluation. Various studies of interrater reliability and validity were also carried out, including a study in the German-speaking countries involving the evaluation of typical cases on videotape (Michels et al. 1996).

A study was performed at the Zentralinstitut für seelische Gesundheit in Mannheim, in collaboration with the Departments of Psychiatry of the Universities of Munich and Mainz, to assess the reliability of ICD-10 diagnoses by means of video recordings. At the Department of Psychiatry of the University of Mainz, the DSM-III and ICD-10 classifications of psychotic disorders were compared in a study of clinical course (Maier and Philipp 1990).

The PHC version was the subject of a comprehensive international study. In the German-speaking portion of this study, the diagnostic categories were tested among groups of general medical practitioners, social workers, nurses, medical students, etc., for practicability and reliability (Kleinschmidt et al. 1995).

6 Diagnostic and Statistical Manual of Mental Disorders (DSM-III and DSM-IV)

The *Diagnostic and Statistical Manual of Mental Disorders* was developed in North America because of the perceived need for operational diagnosis, which was not yet a feature of the WHO system. DSM-III appeared in 1980 (APA 1980); its revision, DSM-III-R, in 1987 (APA 1987,Wittchen et al. 1989); and DSM-IV in 1994 (APA 1994; Saß et al. 1996).

With the introduction of DSM-III came the application of explicit, operationally defined diagnostic criteria, a multiaxial descriptive system and a descriptive approach intended to preserve maximum neutrality with regard to etiologic assumptions. In the 1980s, the two versions of DSM were the subject of intense scientific study, many corrections were suggested, and, finally, a systematic, consensus-based revision was carried out, taking account of the world literature. The WHO was also involved in this process; representatives of the APA and the WHO held joint meetings before the completion of DSM-IV. Agreement was reached in some areas, while differences remained in others.

7 Comparison of ICD-10 and DSM-IV

The overall difference between ICD-10 and DSM-IV is considerably less than that between ICD-9 and ICD-10. American diagnosticians were involved in the development of ICD-10 from its inception and exerted a strong influence on its content. Nevertheless, despite the convergence of these two major systems, a thorough congruence has not yet been achieved. The development of DSM-IV is discussed in great detail in the introduction, as well as the appendix, of its German edition. The German DSM-IV editors consider ICD-10 and DSM-IV to represent different dialects of the same language (Saß et al. 1996). Although they do not minimize the areas of divergence, these editors approvingly cite Thangavelu and Martin (1995) as follows: "The course of development of these two systems, and their emphasis on the operationalization of diagnoses in research and in inpatient and ambulatory care, has brought the world's psychiatrists closer together than ever before" (cited from Saß et al. 1996).

The structure of DSM-IV corresponds in broad outline to that of ICD-10, except that disorders occurring in infancy, childhood, and adolescence are listed before, rather than after, the organic mental disorders; these are listed under the section heading "delirium, dementia, amnestic and other cognitive disorders." This renaming was a consequence of the consideration that many other mental disorders also have bodily causes, so that restricting the use of the term "organic" to these disorders alone appears unjustified.

There are further differences in the diagnosis of individual disorders. In DSM-IV, as already mentioned, symptoms of schizophrenia are required to have been observable for at least 6 months before this disorder can be diagnosed, while ICD-10 requires only 1 month. ICD-10 includes conversion disorders among the dissociative disorders, while DSM-IV considers them separately. The eating disorders are defined differently in the two classifications. Finally, unlike ICD-10, DSM-IV exists in only one version, which makes its application less ambiguous, because no conflict can arise between the criteria of two different versions, such as ICD-10 Guidelines and Research Criteria. In many cases, however, and for general practitioners in particular, the absence of graded sets of criteria makes DSM-IV more difficult to apply.

The difference with respect to multiaxiality has already been mentioned; ICD-10 puts all medical diagnoses together on a single axis. In contrast, the multiaxial classification of DSM-IV contains five axes:

axis I, mental disorders; axis II, personality disorders and mental retardation; axis III, medical disease factors, i.e., somatic diagnoses; axis IV, psychosocial and environmental problems; and axis V, global assessment of functional level (GAF). Combining axis I and axis II results in a fairly close duplication of the multiaxial system of ICD-10.

The international and German-language editions of DSM-IV are oriented to the ICD-10 codes. In the United States, the existing coding system cannot be replaced until approximately the year 2000 because of technical and logistical considerations; at that time, ICD-10 can be introduced in its entirety, i.e., for all medical disciplines, including psychiatry. The differences between the American and other coding systems are thus limited at present to Chap. V (F). DSM-IV is much more comprehensive than Chap. V (F), in that it includes discussions of related findings such as laboratory tests as well as data on prevalence, clinical course, familial incidence, and differential diagnosis. DSM-IV thus takes on the character of a textbook rather than that of a diagnostic manual (although it contains no discussion of treatment).

8 Final Observations

8.1 Advantages of International Classification

What, then, are the advantages of international psychiatric classification? Uniform diagnosis allows the international standardization of treatment, as has been shown in recent years by a number of studies performed around the world. Not only are multicenter psychopharmacologic studies required, but also evaluative studies of psychotherapy and studies of the effectiveness of interventions involving social therapy. The use of standardized and structured interviews that enable diagnosis according to ICD-10 or DSM-IV has become well established; scientific studies will have to be based henceforth on this kind of diagnostic technique.

Cross-cultural comparative psychiatry is aided by a uniform classification that enables epidemiologic studies to be performed with identical instruments in different countries and different cultures, which can then provide data for valid clinical and epidemiological comparisons. One advantage of ICD-10 over its regional American counterpart, DSM-IV, is its more thorough consideration of European needs and, above all, the needs of the Third World. International and interregional comparisons of diagnosis-based administrative data would be of the utmost interest.

8.2 Risks and Disadvantages

The international operational diagnostic classification has risks and disadvantages in addition to its obvious advantages (Jablensky 1991). Diagnosticians must always remain aware that the psychiatric disorders listed in ICD-10 are conventional and not scientifically well founded disease entities. Further changes will undoubtedly be made in the coming decades, and a certain flexibility is required in the definitions of these disorders. Despite a high interrater reliability, most of the disorders in ICD-10 have been insufficiently tested for validity, and many of them may be redefined in the future on the basis of different characteristics than at present.

In the field of operational diagnosis, there is a strong compulsion to define diagnostic categories and to furnish the criteria that distinguish them, so that the individual disorder entities may be separated into groups according to their common syndrome characteristics. Both of the current diagnostic classifications are categorical in this sense and have little hint of dimensionality, except in a few peripheral areas, such as the personality disorders. The somatic medical categorical systems are based on etiology, but this is not possible for the majority of mental disorders, so that we are forced to work with conventional definitions for many disorders, i.e., with constructs whose long-term stability is uncertain. Clearly, while these constructs are acceptable in terms of their interrater reliability, stronger evidence is needed for their validity.

The traditional diversity of clinical schools and local diagnostic customs cannot be maintained into the future. Even if the WHO encourages the preservation of distinct psychiatric traditions, the worldwide standardization of diagnostic classification will make this impossible in the long run, much as local ethnic traditions and dialects inexorably die out as the world's cultures come closer together. Nonetheless, one may hope that sensitivity and openness toward local traditions in psychiatry will not be entirely lost, so that these can continue to serve as points of departure for new creative impulses.

The "language-conditioning effect" of any diagnostic system must also be borne in mind. In the current diagnostic systems, formulations have been sought that will no longer offend or insult the affected persons; thus the "asocial psychopath" of yesteryear now suffers from a "dissocial personality disorder," and "sexual perversions" are now referred to as "disorders of sexual preference." A danger exists that the presence of certain conditions, such as pyromania and kleptomania, in ICD-10 will automatically convert

all individuals with these characteristics into psychiatric patients. This would amount to a dangerous reification of what was intended to be merely a construct in ICD-10, applying only to a restricted group of people. Other conditions have been removed from the classification, such as homosexuality, on the ground that homosexuality ought to have the same social and juridical status as heterosexuality; a certain "political correctness effect" can be discerned here. Nevertheless, if psychiatric symptoms are connected to homosexuality as well as to heterosexuality, this can be coded.

A further danger of diagnostic classifications laid down along operational lines is that newer and perhaps better systems will not be allowed to develop, because scientific publications will require the use of the officially recognized systems. The same applies to research grants, scholarships, and so on.

The greatest danger is one inherent in any codified classification – that of unrestricted application by the social security and health insurance systems. Control mechanisms may be devised that operate to the patient's disadvantage; in this situation, the treating psychiatrist has a duty to prevent negative consequences to the patient. For example, the assigned diagnostic code may be used by health insurance companies to preset the allowed duration of the patient's stay in the hospital. Treating clinicians must firmly oppose this procedure, which fails to take account of the patient's individual circumstances, including the course of the disease in the individual case. In both the economic and the forensic spheres of the health care system, the danger exists that our diagnostic conventions, which may well represent erroneous notions, will be mistaken for established scientific facts and will thereby be granted immunity to further criticism.

Yet a further danger of these diagnostic schemes lies in their possible oversimplified use; diagnosticians may be content to assign a typological label to the patient's illness, as in the past, and the use of the stated criteria may turn out to be more of a pretense than a reality (Arolt and Dilling 1994). Most of the diagnoses listed in ICD-10 – and there are 50 codes just for various types of depression, for example – have the inherent potential of being turned into globalized "disorders" that will play a role equivalent to that of the previous global "disease patterns" and fail to be differentiated on the basis of the criteria required by ICD-10. This would amount to a reductionistic distortion of the diagnostic system. Indeed, the preliminary findings of a questionnaire we distributed, with the support of the WHO, regarding the frequency of various diagnoses in psychiatric inpatient wards and ambulatory services reveal a lack of appreciation and application of the differentiating power of the new classification. A small number of diagnoses were found to be used especially frequently; in the Federal Republic of Germany, 40% of initial diagnoses are in one of only three categories – alcoholism, depression, and adjustment disorder (Müßigbrodt et al. 1999).

While scientific papers that do not apply operational diagnostic systems run the risk of being rejected by prestigious journals, and the awarding of support for research is increasingly linked to the use of such systems, the situation in clinical practice appears markedly different. The new diagnostic concepts are indeed used by many clinicians to describe the patient's abnormalities, but the planning and delivery of treatment frequently appear to be based on other concepts. In some special areas, e.g., the psychogenic disorders, and for certain special applications, there is a need for increased differentiation and the construction of new diagnostic modules.

Thus, despite the introduction of ICD-10 around the world, operational diagnosis remains far from being generally accepted, particularly in ambulatory care. There are many practical difficulties, such as that of introducing new software, but there are also deeper sources of resistance. Many neurologists and psychiatrists are uneasy with the dissolution of deeply rooted traditional modes of thought, such as the triadic system, with their own lack of detailed knowledge of current diagnosis, and with being required to use a new code, possibly under outside control (Arolt 1994). Consequently, there is a need not merely for occasional introductory lectures on the new diagnostic system, but for systematic training, including introductory and advanced seminars and group discussions of case material, if a uniform, high standard of diagnosis is to be achieved. All of the modern media techniques and methods of information transfer should be applied. The acceptance or nonacceptance of operational diagnosis will ultimately depend on whether it improves the indications for treatment and therefore its results. In this respect, many sections of ICD-10, such as that concerning affective disorders, have a long road ahead.

8.3 Future Development

Both the international classification of mental disorders and the North American classification, beyond their global aspects, have led to a large number of developments in special areas, new diagnostic instruments, and various national and international versions and subclassifications. A far-reaching system of descriptive diagnosis has become established that no longer takes account of certain traditional models in psychiatry and psychotherapy, such as endogenous disorders or the concept of neurosis.

The postulation of the axes of "illness experience," "treatment expectation," "relationship," "conflict," and "structure" by the Task Force for Arbeitskreis OPD (Task Force on OPD) indicates that the operational method of the two major classifications has extended its influence to fields that initially resisted exact diagnosis, even if disagreement remains regarding content. As Hoffmann stated, "Our intention was to reduce the psychoanalytic arbitrariness of the diagnostic process, and to set down accepted and communicable standards" (Arbeitskreis OPD 1996).

The foregoing example shows one way in which future perspectives may open up for the emulation and furtherance of the WHO classification. Other possibilities include a behavior-theoretic classification of neurotic disorders and the current reworking of the ICIDH.

A series of detailed special classifications will thus be produced in the context of Chap. V of ICD-10, in which special disorder areas will benefit from a closer look, and the multiaxiality of the present system will be further elaborated. For example, the unsatisfactory axis III of ICD-10 might be replaced by a more comprehensive psychosocial diagnostic system.

Of the two major classification systems now in use for scientific diagnosis in psychiatry, ICD-10 will no doubt be the more used in future for routine statistical purposes. An eventual merging of the two systems into a single classification, with a number of different versions, would be desirable. A dichotomous use of ICD-10 in clinical practice and DSM-IV in research would be disadvantageous to both sides.

An especially important future version will be concerned with psychiatric disorders in general practice, where the diagnostic process necessarily differs from that of the specialist. Although severe psychiatric disturbances requiring specialized care have occupied the center of attention hitherto, the need for adequate treatment of mental disorders is now strongly felt in nonpsychiatric practice as well. The provision of adequate diagnostic aids should be a common concern of the two systems of classification.

Finally, even when all of the diagnostic rules are strictly followed, some cases will prove resistant to operational diagnosis. The diagnostician must then ignore the official criteria and make an individual judgment, as in the days before these systems were introduced.

Even though the diagnostic process has moved a good distance away from the intuitive typological view of diseases and the patient, the physician still must not forget to consider the totality of the patient's illness experience and his or her individuality. Etiology, diagnosis, and therapy ought to stand in a logical relation to each other, and, despite the current tendency toward description, nosology may someday come back into the foreground. The next few years may bring progress in the clarification of etiologic aspects of mental disorders, particularly when attention is focused on smaller disease entities that may come closest to the underlying substrate. These might include bipolar affective disorders, seasonal depression, and individual types of schizophrenia with a strong tendency to occur in families, such as periodic catatonia of the Kleist-Leonhard type (Leonhard 1986). Thus, for both psychotic and nonpsychotic disorders, the further development of the concept of disease and the overcoming of the currently espoused atheoretic approach to diagnosis may be regarded as important challenges for the future.

According to Sartorius (1988), classification is a way of seeing the world. We live in a world of increasingly rapid change, and we may thus confidently expect that diagnosis and classification will change more rapidly in the coming century than in the one now reaching its end. The shifting view of the world, and of psychiatry, through the eyes of the diagnostician is bound to yield many surprises.

International Psychiatric Classification: ICD-10 and DSM-IV

... ein Diagnosenschema ... hat daher nur einen stets vorläufigen Ordnungswert. Sie [eine solche Einteilung] ist eine Fiktion, die ihre Aufgabe erfüllt, wenn sie die zur Zeit relativ richtigste ist.
JASPERS (1973)

1 Background and Development

Classification is a systematic arrangement of the world as a result of a human ability to create systems in a multitude of otherwise chaotic entities in order to comprehend and master the surrounding world, an ability that probably corresponds to the structure of the human neural network. In psychiatry, classification is as old as history itself, from the Hippocratic school onwards. In the course of the last century, psychiatric classification has become increasingly refined but also subdivided among various schools and traditions, ending up with a number of different major national classifications, such as the French, German, Russian and Anglo-Saxon classifications and, outside Europe, the American, Chinese, Indonesian and Japanese ones. Moreover, within psychiatry, separate groups used to produce their own classification, e.g., for childhood mental disorders. In the years after the Second World War, with the re-establishment of international communication on psychiatric research, the need for a common classification became apparent (Stengel 1959). One of the goals of the Mental Health Division of the World Health Organization was to develop such a classification, and a committee of expert consultants prepared the psychiatric chapter of the eighth revision of the *International Classification of Diseases*, ICD-8 (World Health Organization 1965), which was followed by a *Glossary of Mental Disorders and Guide to Their Classification* a few years later (World Health Organization 1974). The glossary provided prototypical descriptions of the major diagnostic categories and indications of inclusion terms. The categories were arranged in a continuous code number system from 0 to 999, each with a fourth-character decimal subdivision into ten subcategories. Main psychiatric categories were distributed among the numbers 290–315. Several countries changed from their national classification to ICD-8, but overall use worldwide was still rather limited. The next revision, ICD-9, appeared in 1975 (World Health Organization 1975), followed by a glossary in 1978 (World Health Organization 1978). The psychiatric chapter was enlarged within the same code numbers 290–315 by a number of subcategories, particularly for child psychiatry disorders, but otherwise the changes in categorization and glossary descriptions were minor (Kramer et al. 1979). ICD-9 became more widely used, but a number of countries continued using ICD-8 because they did not find the changes sufficiently significant to justify the costs and inconvenience of replacing ICD-8 with ICD-9.

In the late 1960s and early 1970s, the U.S–U.K. diagnostic study demonstrated the lack of comparability between the psychiatric classifications in the two countries, using the Present State Examination for comparable registration of psychopathology (Cooper et al. 1972). As a consequence, more accurate and reliable diagnostic criteria were provided for research (Feighner et al. 1972; Spitzer et al. 1977). They were well accepted internationally and inspired a major revision of the U.S. national psychiatric classification, the *Diagnostic and Statistical Manual*, 3rd revision (DSM-III; American Psychiatric Association 1980). The revision was radical, implementing a change from more or less aetiologically defined, broadly described categories (American Psychiatric Association 1968) to purely descriptive, non-aetiological, criteria-based diagnostic categories based on empirical evidence for use in clinical practice and research. In spite of some shortcomings, revised in 1987 (DSM-III-R; American Psychiatric Association 1987), the DSM-III classifications (DSM-III and DSM-III-R) became a major success and were soon taken up outside the United States as well, primarily in research but in some countries also to define the content of the ICD-9 categories to which the DSM-III categories were linked. The DSM-III system seemed to meet a worldwide need for comparable diagnostics and common classification. In this way, psychiatric research and clinical practice was improved, increasing the identity and status of psychiatry as a medical discipline.

2 WHO ICD-10 Revision Principles

DSM-III also had a major impact on the ICD-10 revision of the psychiatric classification, which began in the early 1980s. The WHO-coordinated revision was based on a major and complex collaborative effort including groups of expert consultants, national psychiatric societies and the World Psychiatric Association (Sartorius 1991, 1993). The main obligation was to provide a major revision promoting a worldwide common language in psychiatric classification. The revision therefore had to follow certain principles (Sartorius 1988, 1995; Jablensky 1988; Cooper 1988).

It had to be comprehensive, including the majority of categories used in the various national classifications, particularly taking into consideration special categories seen in the developing countries which did not easily fit in with the previous classifications. The heading was changed from mental disorders to also include behavioural disorders. In this way, the total number of categories and subcategories was increased from about 300 to more than 1000, facilitated by an overall change from the numeric coding to an alpha-

numeric system based on codes with a single letter followed by two numbers at a three-character level (A00–Z99). Further detail is then provided by means of a decimal numeric subdivision at a four- or five-character level (World Health Organization 1992a). The fifth chapter of ICD-10, containing mental and behavioural disorders, received the letter F, followed by two numbers: F00–F99 for the main categories at the three-character level with decimals for subcategories (Fxx.xx), allowing a total of $10^4 = 10{,}000$ subdivisions at the five-character level. The system provides a possibility for future revisions to enlarge or change within wide frames with only minor changes in computer registration. The neutral term "disorder" was used throughout the classification to avoid problems inherent in the use of terms such as "disease", "illness" or "abnormality". To be included in the psychiatric classification, a "disorder" had to be clinically significant and defined by a recognizable set of symptoms or pattern of behaviour associated with distress or interference with daily-life personal functioning, avoiding inclusion of social deviance or conflict as such.

To provide a meaningful classification, diagnostic categories have to be mutually exclusive without substantial overlapping or ambiguity. Consequently, the categories had to be defined by clear and precise boundaries by operational criteria. They were presented by the WHO Mental Health Division in two major publications: *Clinical Descriptions and Diagnostic Guidelines*, with the criteria presented as diagnostic guidelines for flexible clinical use (World Health Organization 1992b), and *Diagnostic Criteria for Research*, with criteria presented in the same way as in the DSM-III system (World Health Organization 1993a). The guidelines and the research criteria were almost completely identical, with the exception of a few categories in which the research criteria had to be made more precise to ensure mutually exclusive categorization. Thus ICD-10 has no border areas or borderline states. The borders are sharp lines, and a disorder will be either on the one or the other side of the line. The criteria were, as far as possible, operationally defined, relying heavily on the glossary definitions of the Present State Examination symptom items.

Worldwide acceptability was a third principle the revision of the classification had to follow. This implied an atheoretical descriptive approach and the avoidance of social criteria. The national classifications were based on aetiological assumptions according to various traditions or schools, these in turn being based on different aetiological theories which were mutually incompatible. An atheoretical approach therefore requires a non-aetiological classification for most of the diagnostic categories, with the exception of those with a proven aetiology, e.g., the so-called organic disorders, which can be attributed to brain damage and dysfunction caused by an independently diagnosable cerebral or systemic physical disease or disorder. This implies that disorders caused by alcohol or other psychoactive substances also are "organic". Use of the term "organic" does not imply that conditions elsewhere in the classification are "non-organic" in the sense of having no cerebral substrate. The other group of disorders for which an aetiology has been universally accepted are the stress-related disorders with evidence of psychological causation, either in the form of exceptional mental stress or of more ordinary psychosocial stressors or life events. Otherwise, the non-aetiological approach has been strictly followed throughout, also in the choice of nomenclature or terms. The previous concepts of "psychosis" and "neurosis" have been abandoned and the terms deleted because of the aetiological implications. Only the adjective forms "psychotic" and "neurotic" have been retained as convenient descriptive terms. "Psychotic" is now purely descriptive, defined by the presence of "psychotic" symptoms such as hallucinations or delusions or a limited number of other severe abnormalities such as disorganized speech, catatonic behaviour and extreme psychomotor excitement or stupor, but with no implications of loss of sense of reality or lack of insight. "Neurotic" is used in the meaning "non-psychotic" and mainly as a descriptive term for anxiety, obsessive–compulsive and dissociative symptoms or disorders. These descriptive approaches are fully in line with the DSM-III classification.

Social criteria have been avoided almost completely in order to make the ICD-10 classification applicable and thus acceptable in the various cultures all over the world. Major areas of social functioning such as work or interpersonal relations differ substantially between the various cultures to a degree that makes it impossible to obtain universally applicable criteria in these areas. Only basic personal daily-life functioning such as basic self-care, which is universal to all cultures, may be applied, and this is already included in the definition of a "disorder". The avoidance of social criteria is one of the major principal differences between ICD-10 and the DSM-III system, which applies social criteria including occupation and personal relationships throughout. In ICD-10, social criteria only appear as an exception in a few categories such as "Simple Schizophrenia" and unavoidably in "Dyssocial Personality Disorder and Childhood Conduct Disorder".

In ICD-10, the ordering of the diagnostic categories follows the traditional division between (a) disorders with onset specific to childhood or adolescence but which may, however, persist into adulthood and (b) "adult" mental and behavioural disorders without

onset specific to childhood. The latter may occur in childhood as well, but most often appear in adult life. For adult disorders, the order of categories follows a hierarchical principle. The "organic" disorders, including the substance use disorders, are placed at the top of the hierarchy because they may imitate all other kinds of disorders; exclusion criteria for organic aetiology are thus required. In the hierarchical order, they are followed by schizophrenia and disorders descriptively related to schizophrenia, which again may imitate the disorders at a lower level in the hierarchy and therefore also have to be ruled out in the lower-level diagnoses. These are followed by mood or affective disorders, which, however, in some cases compete with the schizophrenia level as to hierarchical preference. The next disorders are neurotic, stress-related and somatoform disorders, behavioural syndromes associated with physiological disturbances and physical factors and, finally, disorders of adult personality and behaviour. This means that, if there is a simultaneous course of a depressive episode and an anxiety disorder, for example, the diagnosis of the depressive episode will take precedence and incorporate the anxiety disorder as part of the depressive episode. To some extent, this principle precludes the registration of co-morbidity. This is another major principal difference from the DSM system, which encourages the diagnosis of co-morbidity.

Last but not least, the ICD-10 revision needed to be based on demonstrated reliability and was designed be fairly easy to use in the daily clinic. This was tested by WHO-coordinated worldwide field trials of the pre-final drafts of the *Clinical Description and Diagnostic Guidelines* and the *Diagnostic Criteria for Research* (Sartorius et al. 1993, 1995). Categories with low reliability were deleted (e.g., "hazardous alcohol use" and "accentuated personality" traits) or re-defined (e.g., "specific personality disorders"). The final draft prepared for the complete ICD-10 was presented for and approved by the World Health General Assembly in 1989 to come into effect as of 1 January 1993.

The centres that coordinated the field trials continued their participation as WHO ICD-10 reference centres for the introduction and training in the use of ICD-10; these centres also serve as members of the WHO ICD-10 Advisory Committee.

3 DSM-IV Revision

Following DSM-III-R, the American Psychiatric Association began the preparation of another revision for the DSM-IV. A task force and its work groups conducted a three-stage empirical process that included the following: (a) comprehensive and systematic reviews of the published literature, (b) re-analysis of the previously collected data and (c) extensive field trials focused on specific issues. The revision followed the tradition embodied in DSM-III and DSM-III-R, and changes were introduced only if based on substantial evidence from literature reviews, data analyses and field trials results. A special effort to ensure compatibility with ICD-10 included mutual meetings between the task force and the WHO ICD-10 Expert Committee and between work group members from both systems. This led to an approximation of definitions and diagnostic criteria in a number of categories, but some of the major principal differences remained, such as the avoidance of social criteria and the hierarchical order of categories with restriction of co-morbidity in ICD-10. The DSM-IV revision was to serve as a national classification system in the United States, which allowed a more evidence-directed approach and the application of social criteria; in contrast, the WHO ICD-10 classification had to be the result of a universal worldwide consensus that not only required an evidence-based approach but also had to take diplomatic aspects into consideration. DSM-IV was finalized and introduced in 1994 (American Psychiatric Association 1994). Because of difficulties with the registration and insurance systems, the code numbers still follow the ICD-9 clinical modification system (ICD-9 CM), but will eventually change to the alphanumeric system of ICD-10 (American Psychiatric Association 1995). The similarities between the two systems are substantial, and for moderate and severe cases within the various diagnostic categories the correspondence is almost complete. The differences appear mainly in the mild to moderate cases because of differences in the definitions of various diagnostic categories affecting the diagnostic thresholds. The differences due to the ICD-10 lack of social criteria and restricted use of co-morbidity are also most prominent in these areas. This is particularly relevant for psychiatric research, because variation in diagnostic thresholds may create quite different diagnostic samples of corresponding categories for which the resulting evidence will not be comparable.

4 Differences Between the ICD-10 and DSM-IV Classifications

The presentation of the diagnostic categories differs substantially between the two systems. Disorders usually first diagnosed in infancy, childhood or adolescence are presented first in DSM-IV, whereas ICD-10 has placed them as the last part of the classification

with the main group code numbers F7–F9. Organic disorders and substance-related disorders are presented in DSM-IV in a new and unconventional way contrary to the hierarchical principle of ICD-10. Delirium, dementia and amnestic disorders are presented as main groups, as are substance dependence, abuse, intoxication and withdrawal. Other organic mental disorders are presented in the various syndrome sections under the headings "syndrome disorder due to a general medical condition" and "substance induced syndrome disorder". Otherwise, DSM-IV follows almost the same order of presentation as ICD-10. DSM-IV has an additional group of "other conditions that may be a focus of clinical attention", including a number of disorders or factors covered by categories outside Chap. V (F) of ICD-10.

4.1 Organic Disorders

Dementia (F00–F03), amnesic syndrome (F04) and delirium (F05) tend to be more narrowly defined in ICD-10 than in DSM-IV. For delirium, ICD-10 requires specific impairment of immediate recall and recent memory with relatively intact remote memory, psychomotor disturbances and disturbed sleep. ICD-10 differentiates between delirium not superimposed or superimposed on dementia and other delirium, including cases with mixed origin. Delirium may further be associated with substance use intoxication or withdrawal. DSM-IV differentiates between delirium due to a general medical condition, substance-induced delirium and delirium due to multiple aetiologies.

For dementia, the ICD-10 criteria requires a minimum duration of 6 months and an additional decline in emotional control, motivation or social behaviour. Both systems require a decline in memory and other cognitive abilities, which are more extensively presented in DSM-IV, also including aphasia, apraxia and agnosia. They both differentiate between dementia in Alzheimer's disease, vascular dementia and dementia in other neurological diseases affecting the brain, to which DSM-IV also adds dementia due to other general medical conditions, substance-induced persisting dementia and dementia due to multiple aetiologies.

In ICD-10, organic amnesic syndrome (referred to as amnestic disorder in DSM-IV) requires an additional defect of recent memory together with a reduced ability to recall past experiences; moreover, it requires that immediate recall is preserved in order to make a clear distinction from delirium. ICD-10 differentiates between amnesic syndrome not induced by alcohol and other psychoactive substances (F04) and amnesic syndrome due to psychoactive substance use (F1x.6). DSM-IV differentiates between amnestic disorder due to a general medical condition and substance-induced persistent amnestic disorder.

The following two ICD-10 subsections – F06 (other mental disorders due to brain damage and dysfunction and to physical disease) and F07 (personality and behavioural disorders due to brain disease, damage and dysfunction) – are also found in DSM-IV under the specific syndrome due to "a general medical disorder". ICD-10 includes a new category, F06.7 (mild cognitive disorder), which has no equivalent in DSM-IV except that it has been appended in the subsection of "criteria sets and axes provided for further study" in appendix B, under the heading "mild neurocognitive disorder". The same applies to post-concussional syndrome (F07.2), whereas post-encephalitic syndrome may be covered by DSM-IV in "cognitive disorder not otherwise specified".

For substance dependence, the diagnostic criteria are quite similar in the two systems. ICD-10 requires a strong desire or sense of compulsion to take a substance (craving), whereas DSM-IV considers this implicit and does not have a specific criterion for "craving". ICD-10 requires three symptoms simultaneously for at least 1 month or repeatedly within a 12-month period, whereas DSM-IV requires clinically significant impairment or distress manifested by three or more symptoms occurring at any time in the same 12-month period.

For harmful use (referred to in DSM-IV as substance abuse), the differences appear to be substantial. ICD-10 requires clear evidence of physical or psychological harm due to a pattern of use that has persisted for at least 1 month or has occurred repeatedly within a 12-month period. DSM-IV requires clinical and significant impairment or distress manifested by one or more of the following symptoms occurring within a 12-month period: (a) failure to fulfil major role obligations at work, school or home, (b) recurrent substance use in physically hazardous situations, (c) recurrent substance-related legal problems and/or (d) continuous substance use despite social or interpersonal problems. Here, the principal avoidance of social criteria in ICD-10 becomes apparent and seems to make the criteria for the two systems completely incompatible. The ICD-10 formulation, however, has been made flexible so that psychological harm can include "impaired judgement or dysfunctional behaviour, which may lead to disability or have adverse consequences for interpersonal relationships". Thus the DSM-IV social criteria may be interpreted as expressions of impaired judgement or dysfunctional behaviour, i.e., psychological harm, thus also meeting the ICD-10 criteria.

Substance intoxication and withdrawal broadly follow the same criteria, except for the DSM-IV requirement of "clinically significant distress or impairment",

which is implicit in the ICD-10 definition of a disorder. Both systems provide detailed substance-specific symptoms for intoxication and withdrawal, which are broadly equivalent, with the exception that ICD-10 includes phencyclidine use under F19 ("multiple drug use and use of other psychoactive substances").
